$$c(T_k) \coloneqq (1-\mu)c(T_{k_l}) + \mu\, c(T_{k_r}) \quad \text{with} \quad \mu \coloneqq \frac{k - k_l}{k_r - k_l}. \tag{1}$$

Since the phantom tree T_k was originally constructed by a linear interpolation of two real trees, this redefinition of the cost can only decrease its cost. See also [15] for a more detailed discussion. Hence, the phantom tree T_k remains a good k-tree. We denote the set $\mathcal{T}$ with the adjusted costs of the phantom trees by $\mathcal{T}'$. We analyze the approximation guarantee of the tour π_{ALG} obtained by running the concatenating algorithm on input $\mathcal{T}'$. In this section, we prove the following lemma.

▶ **Lemma 7.** *If all trees in $\mathcal{T}'$ were real trees, the tour π_{ALG} obtained from the concatenating algorithm with input $\mathcal{T}'$ is a feasible solution for the discounted graph search problem with approximation guarantee $\varrho_1(\alpha)$.*

For the remainder of this section, we denote by P^* the shortest 0–n-path in H computed in Step 2 of the concatenating algorithm on input $\mathcal{T}'$. Since each vertex $i \in V_H$ corresponds to a unique tree $T_i \in \mathcal{T}'$, we often refer to the vertices on P^* as the chosen trees. Furthermore, we extend the procedure of Step 3 to an arbitrary 0–n-path $P = (n_0, n_1, \dots, n_{l'})$ in H. More precisely, we introduce a randomized variant of Step 3 that runs as follows. We start with the empty sequence $\pi_P = (\cdot)$. For each phase $j = 1, \dots, l'$, we construct the tour $\pi(T_{n_j})$ according to Proposition 5. Then we pick a traversal direction (forward or backward) of the tour $\pi(T_{n_j})$ uniformly at random and set $\pi_P \leftarrow \pi_P + \pi(T_{n_j})$.

We proceed to analyze the sequence π_{ALG}. First, observe that P^* contains vertex n. Thus, the corresponding good n-tree T_n is traversed and appended to π_{ALG} in Step 3. This ensures that the returned tour π_{ALG} is a feasible solution to the discounted graph search problem with finite total α-latency, i.e., π_{ALG} visits all vertices. It remains to analyze the approximation factor obtained by π_{ALG}. To this end, we first show that for any given 0–n-path P in H, the expected total α-latency $\mathbb{E}[C_\alpha(\pi_P)]$ of π_P is at most the length $\ell(P)$ of P in H. Next, we use a probabilistic argument to prove the existence of a 0–n-path in H whose length is at most $\varrho_1(\alpha)$ times the total α-latency of an optimal tour. Finally, we explain how these two results imply that the concatenating algorithm on input $\mathcal{T}'$ indeed computes a tour with an approximation ratio of $\varrho_1(\alpha)$.

In that direction, we introduce the function ψ_P such that $\psi_P(k)$ gives an upper bound on the latency of the k-th distinct vertex in $V \setminus \{s\}$ visited by the tour constructed from path P in H. More formally, for a fixed 0–n-path $P = (n_0, n_1, \dots, n_l)$ in H, the function $\psi_P : [n]_0 \to \mathbb{R}_{\geq 0}$ is defined by

$$\psi_P(k) \coloneqq \begin{cases} 0 & \text{if } k = 0 \\ c(T_{n_j}) + (1+\alpha)\sum_{i=0}^{j-1} c(T_{n_i}) & \text{if } n_{j-1} < k \leq n_j, \text{for some } j \in \{1, \dots, l\}. \end{cases}$$

This definition is well-defined as $n_0 = 0$ and $n_l = n$. We obtain the following lemma. Its proof can be found in the full version of the paper.

▶ **Lemma 8.** *Let π_P be the randomized tour obtained from a 0–n-path P in H and let $v \in V$ be the k-th distinct vertex of $V \setminus \{s\}$ in π_P for some $k \in [n]_0$. Then we have $\mathbb{E}[C_{\alpha,v}(\pi_P)] \leq \psi_P(k)$.*

For a fixed 0–n-path P in H, Lemma 8 yields $\mathbb{E}[C_\alpha(\pi_P)] = \sum_{v \in V} \mathbb{E}[C_{\alpha,v}(\pi_P)] \leq \sum_{k=0}^{n} \psi_P(k)$. Recall that in Step 3 of the concatenating algorithm, we pick the traversal direction of each subtour such that $\sum_{v \in V_j} C_{\alpha,v}(\pi_{\text{ALG}} + \pi_{\min})$ is minimized, where $V_j \coloneqq V_{n_j} \setminus \left(\bigcup_{i=1}^{j-1} V_{n_i}\right)$. Hence, for the tour π_{ALG} we obtain the deterministic bound

$$C_\alpha(\pi_{\text{ALG}}) \leq \sum_{v \in V} C_{\alpha,v}(\pi_{P^*}) \leq \sum_{k=0}^{n} \psi_{P^*}(k). \tag{2}$$

Next, we use the following identity, which expresses the length of a path P in H in terms of ψ_P. Its proof can be found in the full version of the paper.

▶ **Lemma 9.** *For a 0–n-path P in H we have $\sum_{k=0}^{n} \psi_P(k) = \ell(P)$.*

The following lemma is the technically most challenging part of the analysis, as it compares the length of a 0–n-path P in H against the total α-latency of the optimal solution. The proof uses similar ideas as in [15] and [22]. We consider a randomized sequence of good k-trees with exponentially increasing costs where $\gamma \in (1, \infty)$ is a factor determining the rate of the exponential growth. Then the expected length of that path can be bounded by a constant factor times the optimal total α-latency. A probabilistic argument then yields that this bound is also attained by the shortest 0–n-path P^* in H. Specifically, we obtain the following bound. Its proof can be found in the full version of the paper.

▶ **Lemma 10.** *Let $\pi^* \in \Pi$ be an optimal solution for the discounted graph search problem. Then there exists a 0–n-path P in H such that $\ell(P) \leq 2\frac{\gamma+\alpha}{(1+\alpha)\ln\gamma} C_\alpha(\pi^*)$ for any $\gamma \in (1, \infty)$.*

Lemma 10 yields an approximation ratio parametrized in $\gamma \in (1, \infty)$. To obtain the smallest approximation ratio possible, we optimize over γ. To this end, we denote by $W : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ the Lambert-W function that assigns $x \geq 0$ the unique value $w \geq 0$ such that $we^w = x$. The proof of the following result can be found in the full version of the paper.

▶ **Lemma 11.** *For $\gamma \in (1, \infty)$, let h be defined as $h(\gamma) \coloneqq 2\frac{\gamma+\alpha}{(1+\alpha)\ln(\gamma)}$. Then h is minimized for $\gamma^* = e^{1+W(\alpha/e)}$. In particular, we have $\varrho_1(\alpha) = h(\gamma^*)$.*

Combining all previous results yields the proof for Lemma 7; this proof can be found in the full version of the paper.

We have shown so far that the concatenating algorithm with input $\mathcal{T}'$ (the set of trees guaranteed by Lemma 6 with adjusted costs for phantom trees) computes a solution to the discounted graph search problem with approximation guarantee $\varrho_1(\alpha)$. However, we obtained this result only under the assumption that all trees were real trees, i.e., that they could be transformed into tours. It remains to show that we can obtain the same approximation guarantee when using only real trees as input to the concatenating algorithm. The issue with phantom trees as input arises only if phantom trees lie on the shortest 0–n-path P^* computed by the concatenating algorithm, since these trees are the ones traversed to obtain the final tour π_{ALG}. As a first step towards proving Theorem 2, we thus show that whenever the shortest 0–n-path P^* on input $\mathcal{T}'$ contains a phantom tree, there exists another 0–n-path with the same length that visits only real trees. The proof of the lemma follows the argument of [4, 15] and can be found in the full version of the paper.

▶ **Lemma 12.** *Let H be the auxiliary graph constructed by the concatenating algorithm on input $\mathcal{T}'$. Then there exists a shortest 0–n-path P in H that does not visit any vertex whose corresponding tree is a phantom tree.*

By Lemma 12, applying the concatenating algorithm to the set $\mathcal{R} \subseteq \mathcal{T}$ of real trees in $\mathcal{T}$ ensures that the algorithm is well-defined while maintaining an approximation guarantee of $\varrho_1(\alpha)$. We can now prove Theorem 2; the proof can be found in the full version of the paper.

4 Algorithms for the p-Norm of α-Latencies

We now turn to the case of arbitrary $p \geq 1$. The case $p = 1$ was treated in the previous section, where the linearity of the objective allowed us to use an auxiliary graph whose edge lengths directly represent the additional latency caused by adding a tree. For $p > 1$, this linearity is lost, and the same construction no longer applies directly.

At a high level, we would still like to use sequences of trees of geometrically increasing cost. However, two difficulties arise. First, as pointed out by Garg [19], it is not possible, for every $k \in [n]$, to use the primal–dual algorithm to obtain a k-MST with cost no more than the optimum k-stroll. In particular, this issue occurs for those values of k for which the primal–dual procedure does not directly compute a k-MST. Second, when $p > 1$, the objective is nonlinear in the vertices' α-latencies. Thus, an analogue of the auxiliary-graph cost from the previous section has to keep track not only of how many vertices have already been visited, but also of the accumulated cost of the trees used so far.

We subdivide this section into two parts. First, we present a randomized algorithm based on a geometric scaling argument. Then, we show how to derandomize it using a time-expanded auxiliary graph; the resulting running time is pseudo-polynomial in the edge costs.

4.1 A Randomized Algorithm

To avoid the difficulties with the auxiliary-graph construction for the moment, we first give a randomized algorithm with the desired approximation guarantee.

▶ **Theorem 3.** *For every $p \geq 1$, there is a polynomial-time randomized algorithm for the discounted graph search problem with approximation factor*

$$\varrho_p(\alpha) = \min_{\gamma > 1} \left\{ \frac{2(1+\alpha)}{\gamma - 1} \left[\frac{\gamma^{2p} - \gamma^p}{p \ln \gamma} \right]^{1/p} \right\}.$$

The approximation ratio given in the above theorem is depicted in Section 1.1. It ranges from 2e for $\alpha = 0$ and $p = 1$ to a limiting value of 16 for $\alpha = 1$ as $p \to \infty$. Note that the value 2e matches the bound for $\alpha = 0$ and $p = 1$ from the previous section.

Instead of computing a *good* k-tree, we use Garg's 2-approximation [19] to compute a 2-approximate k-MST for every $k \in [n]$. Recall that such a tree contains s and visits k additional vertices. Let these trees be denoted by $T_1, T_2, \ldots, T_n$.

We next define a randomized sequence of trees, similar to the construction in the previous section. Fix some $\gamma > 1$, which will be optimized later. Let $b = \gamma^U$, where U is drawn uniformly at random from $[0, 1]$. For all relevant values of r, define $n_r = \max\{k \in [n]_0 : c(T_k) \leq 2b\gamma^r\}$. Here, $c(T_k)$ denotes only the total length of the tree and, in particular, does not depend on p.

Let $P = (n_0, n_1, \ldots, n_l)$ be the sequence of values obtained by the above procedure, where $n_0 = 0$. As in the previous section, we concatenate the sequence of trees induced by P to obtain a tour, which we denote by π_P. We also define a function ψ_P such that $\psi_P(k)$ gives an upper bound on the α-latency of the k-th distinct vertex in $V \setminus \{s\}$ visited by π_P. Formally, the function $\psi_P : [n]_0 \to \mathbb{R}_{\geq 0}$ is defined by

$$\psi_P(k) \coloneqq \begin{cases} 0 & \text{if } k = 0, \\ (1+\alpha) \sum_{i=0}^{j} c(T_{n_i}) & \text{if } n_{j-1} < k \leq n_j, \text{for some } j \in \{1, \ldots, l\}. \end{cases}$$

We obtain the following lemma.

▶ **Lemma 13.** *Let π_P be the randomized tour obtained from P, and let $v \in V$ be the k-th distinct vertex of $V \setminus \{s\}$ in π_P, for some $k \in [n]_0$. Then $C_{\alpha,v}(\pi_P) \leq \psi_P(k)$.*

Proof. This follows directly from the definition of ψ_P. In the worst case, all trees are nested and vertex k is visited at the very end of the last tree containing it. Moreover, the cost of the tour induced by tree T_{n_i} is bounded by $(1+\alpha)c(T_{n_i})$. ◀

Lemma 13 and the randomized sequence of trees imply Theorem 3.

Proof of Theorem 3. Let π^* be an optimal tour for the p-norm α-latency objective. Let v_i^* be the i-th vertex visited by π^*. Then

$$\mathrm{OPT} = \left(\sum_{i \in [n]} \left(C_{\alpha, v_i^*}(\pi^*) \right)^p \right)^{1/p}.$$

Fix some arbitrary $i \in [n]$. Let r be such that $C_{\alpha, v_i^*}(\pi^*) = d\gamma^r$ for some $d \in [1, \gamma)$. We consider two cases.

First case: $d \le b$. In this case, there is a tree T_{n_r} with cost at most $2b\gamma^r$ and $n_r \ge i$. Hence,

$$\psi_P(i) \le (1+\alpha) \sum_{k=1}^{r} c(T_{n_k}) \le (1+\alpha) \sum_{k=1}^{r} 2b\gamma^k < (1+\alpha) \sum_{k=-\infty}^{r} 2b\gamma^k = (1+\alpha) 2b\gamma^r \frac{\gamma}{\gamma - 1}.$$

Second case: $d > b$. In this case, the same argument applied to the next threshold gives

$$\psi_P(i) \le (1+\alpha) \sum_{k=1}^{r+1} c(T_{n_k}) \le (1+\alpha) \sum_{k=1}^{r+1} 2b\gamma^k < (1+\alpha) \sum_{k=-\infty}^{r+1} 2b\gamma^k = (1+\alpha) 2b\gamma^{r+1} \frac{\gamma}{\gamma - 1}.$$

Since U is chosen uniformly at random in $[0, 1]$ and $b = \gamma^U$, we can average over the two cases and obtain

$$\mathbb{E}_U[\psi_P(i)^p] \le \int_{\log_\gamma d}^{1} \left((1+\alpha) 2b\gamma^r \frac{\gamma}{\gamma - 1} \right)^p \mathrm{d}U + \int_{0}^{\log_\gamma d} \left((1+\alpha) 2b\gamma^{r+1} \frac{\gamma}{\gamma - 1} \right)^p \mathrm{d}U.$$

We now compute the right-hand side. Let $a \coloneqq \log_\gamma d$. Since $b = \gamma^U$, we have

$$\begin{aligned}
&\int_{\log_\gamma d}^{1} \left((1+\alpha) 2b\gamma^r \frac{\gamma}{\gamma - 1} \right)^p \mathrm{d}U + \int_{0}^{\log_\gamma d} \left((1+\alpha) 2b\gamma^{r+1} \frac{\gamma}{\gamma - 1} \right)^p \mathrm{d}U \\
&= \left((1+\alpha) 2 \frac{\gamma}{\gamma - 1} \right)^p \left[\gamma^{rp} \int_a^1 \gamma^{pU} \, \mathrm{d}U + \gamma^{(r+1)p} \int_0^a \gamma^{pU} \, \mathrm{d}U \right].
\end{aligned}$$

Using

$$\int \gamma^{pU} \, \mathrm{d}U = \frac{\gamma^{pU}}{p \ln \gamma},$$

we obtain

$$\begin{aligned}
&\left((1+\alpha) 2 \frac{\gamma}{\gamma - 1} \right)^p \left[\gamma^{rp} \int_a^1 \gamma^{pU} \, \mathrm{d}U + \gamma^{(r+1)p} \int_0^a \gamma^{pU} \, \mathrm{d}U \right] \\
&= \left((1+\alpha) 2 \frac{\gamma}{\gamma - 1} \right)^p \frac{\gamma^{rp}(\gamma^p - \gamma^{pa}) + \gamma^{(r+1)p}(\gamma^{pa} - 1)}{p \ln \gamma}.
\end{aligned}$$

Since $a = \log_\gamma d$, we have $\gamma^{pa} = d^p$. Hence,

$$\begin{aligned}
\mathbb{E}_U[\psi_P(i)^p] &\le \left((1+\alpha) 2 \frac{\gamma}{\gamma - 1} \right)^p \frac{\gamma^{rp}(\gamma^p - d^p) + \gamma^{(r+1)p}(d^p - 1)}{p \ln \gamma} \\
&= \left((1+\alpha) 2 \frac{\gamma}{\gamma - 1} \right)^p \frac{d^p \gamma^{rp}(\gamma^p - 1)}{p \ln \gamma} \\
&= (1+\alpha)^p \frac{2^p}{p \ln \gamma} \left[\left(\frac{d\gamma^{r+2}}{\gamma - 1} \right)^p - \left(\frac{d\gamma^{r+1}}{\gamma - 1} \right)^p \right].
\end{aligned}$$

The contribution of v_i^* to the optimum is

$$\left(C_{\alpha,v_i^*}(\pi^*)\right)^p = (d\gamma^r)^p.$$

Therefore, the previous bound implies

$$\frac{\mathbb{E}_U[\psi_P(i)^p]}{(d\gamma^r)^p} \leq (1+\alpha)^p \frac{2^p}{p\ln\gamma}\left[\left(\frac{\gamma^2}{\gamma-1}\right)^p - \left(\frac{\gamma}{\gamma-1}\right)^p\right] = (1+\alpha)^p \frac{2^p}{p\ln\gamma}\cdot\frac{\gamma^{2p}-\gamma^p}{(\gamma-1)^p} =: \eta. \tag{3}$$

In particular, since $C_{\alpha,v_i^*}(\pi^*) = d\gamma^r$, we have

$$\mathbb{E}_U[\psi_P(i)^p] \leq \eta \cdot \left(C_{\alpha,v_i^*}(\pi^*)\right)^p. \tag{4}$$

We now use this bound to compare the expected p-norm α-latency of the randomized tour with the optimum. By the definition of ψ_P, for every realization of U we have

$$C_{\alpha,v_i^*}(\pi_P) \leq \psi_P(i) \qquad \text{for all } i \in [n].$$

Hence,

$$\mathbb{E}_U\left[\left(\sum_{i\in[n]} C_{\alpha,v_i^*}(\pi_P)^p\right)^{1/p}\right] \leq \mathbb{E}_U\left[\left(\sum_{i\in[n]} \psi_P(i)^p\right)^{1/p}\right].$$

We next use Jensen's inequality. Recall that if f is concave and X is a nonnegative random variable, then

$$\mathbb{E}[f(X)] \leq f(\mathbb{E}[X]).$$

In our setting, we apply this with

$$f(x) = x^{1/p} \qquad \text{and} \qquad X = \sum_{i\in[n]} \psi_P(i)^p.$$

Since $p \geq 1$, the function $f(x) = x^{1/p}$ is concave on $\mathbb{R}_{\geq 0}$. Moreover, $X \geq 0$ for every realization of the random choice of U. Therefore, Jensen's inequality gives

$$\mathbb{E}_U\left[\left(\sum_{i\in[n]} \psi_P(i)^p\right)^{1/p}\right] \leq \left(\mathbb{E}_U\left[\sum_{i\in[n]} \psi_P(i)^p\right]\right)^{1/p} = \left(\sum_{i\in[n]} \mathbb{E}_U[\psi_P(i)^p]\right)^{1/p}.$$

Using (4), we obtain

$$\begin{aligned}
\mathbb{E}_U\left[\left(\sum_{i\in[n]} C_{\alpha,v_i^*}(\pi_P)^p\right)^{1/p}\right] &\leq \left(\sum_{i\in[n]} \eta\cdot\left(C_{\alpha,v_i^*}(\pi^*)\right)^p\right)^{1/p} \\
&= \eta^{1/p}\left(\sum_{i\in[n]} \left(C_{\alpha,v_i^*}(\pi^*)\right)^p\right)^{1/p} \\
&= \eta^{1/p}\cdot \mathrm{OPT}.
\end{aligned}$$

It remains to simplify $\eta^{1/p}$. By (3),

$$\begin{aligned}\eta^{1/p} &= (1+\alpha)\left[\frac{2^p}{p\ln\gamma}\cdot\frac{\gamma^{2p}-\gamma^p}{(\gamma-1)^p}\right]^{1/p}\\ &= (1+\alpha)\frac{2}{(p\ln\gamma)^{1/p}}\cdot\frac{(\gamma^{2p}-\gamma^p)^{1/p}}{\gamma-1}\\ &= (1+\alpha)\frac{2}{\gamma-1}\left[\frac{\gamma^{2p}-\gamma^p}{p\ln\gamma}\right]^{1/p}.\end{aligned}$$

Thus, for every fixed $\gamma > 1$, the randomized algorithm has expected approximation factor

$$(1+\alpha)\frac{2}{\gamma-1}\left[\frac{\gamma^{2p}-\gamma^p}{p\ln\gamma}\right]^{1/p}.$$

Optimizing over $\gamma > 1$ gives the claimed bound. ◀

4.2 Derandomization via a Time-Expanded Auxiliary Graph

We now describe how to derandomize the randomized algorithm from the previous subsection. The idea is similar to the derandomization used for the case $p = 1$: we construct an auxiliary graph and compare the length of a shortest path in this graph to the expected length of a suitable randomized path.

For $p = 1$, the auxiliary graph only needs to keep track of how many vertices have already been visited. For $p > 1$, however, the objective is nonlinear in the latencies. Thus, the additional cost of traversing a tree depends not only on the number of vertices visited so far, but also on the latency accumulated so far. We therefore use a two-dimensional auxiliary graph. One dimension keeps track of the number of vertices that have already been visited, and the other dimension keeps track of the total cost of the trees traversed so far.

▶ **Theorem 4.** *For every $p \geq 1$, there is a deterministic pseudo-polynomial-time algorithm for the discounted graph search problem with approximation factor $\varrho_p(\alpha)$ defined in Theorem 3. Moreover, if the tree costs are integral and polynomially bounded, then the algorithm runs in polynomial time.*

Let $T_1, \ldots, T_n$ be the 2-approximate k-MST trees used in the previous subsection, and let $c(T_k)$ denote the cost of tree T_k. We set T_0 to be the trivial tree containing only s, with $c(T_0) = 0$. Let

$$Z \coloneqq \left\{\sum_{k\in S} c(T_k) : S \subseteq [n]\right\}.$$

Thus, Z is the set of all values that can occur as the accumulated cost of a set of traversed trees.

We construct a directed auxiliary graph $H = (V_H, A_H)$ as follows: The vertex set is $V_H = \big([n]_0 \times Z\big) \cup \{\omega\}$, where ω is an additional terminal vertex. A vertex (i, z) represents the state in which i vertices of $V \setminus \{s\}$ have already been visited, and the total cost of the trees traversed so far is z. For every $i, j \in [n]_0$ with $i < j$ and every $z, z' \in Z$ with $z' = z + c(T_j)$, we add the directed edge $\big((i, z), (j, z')\big)$. The length of this edge is defined as

$$\ell_{(i,z),(j,z')} \coloneqq (n-i)\left(\big((1+\alpha)z'\big)^p - \big((1+\alpha)z\big)^p\right). \tag{5}$$

Finally, for every $z \in Z$, we add an edge $((n, z), \omega)$ of length zero. The algorithm computes a shortest path from $(0, 0)$ to ω in H. Let $P^* = \big((n_0, z_0), (n_1, z_1), \ldots, (n_l, z_l), \omega\big)$ be such a shortest path, where $n_0 = 0$, $z_0 = 0$, and $n_l = n$. The algorithm then concatenates the trees $T_{n_1}, T_{n_2}, \ldots, T_{n_l}$ in this order, using the tree-to-tour conversion from Proposition 5. We denote the resulting tour by π_{ALG}. We first relate the length of a path in H to the p-norm α-latency of the corresponding concatenated tour.

▶ **Lemma 14.** *Let $P = \big((n_0, z_0), (n_1, z_1), \ldots, (n_l, z_l), \omega\big)$ be any $(0, 0)$–ω path in H, where $n_0 = 0$, $z_0 = 0$, and $n_l = n$. Let π_P be the tour obtained by concatenating the trees $T_{n_1}, \ldots, T_{n_l}$. Then $\big(\sum_{v \in V} C_{\alpha,v}(\pi_P)^p\big)^{1/p} \leq \ell(P)^{1/p}$.*

Proof. For $h \in \{1, \ldots, l\}$, the transition from (n_{h-1}, z_{h-1}) to (n_h, z_h) corresponds to traversing tree T_{n_h}, and by construction

$$z_h = z_{h-1} + c(T_{n_h}).$$

After this traversal, the accumulated cost of the traversed trees is z_h. By the tree-to-tour conversion, the α-latency of every vertex that is first covered by T_{n_h} is at most

$$(1 + \alpha) z_h.$$

Hence, if $n_{h-1} < k \leq n_h$, then the k-th distinct vertex visited by π_P has α-latency at most $(1 + \alpha) z_h$.

Define

$$\psi_P(k) \coloneqq (1 + \alpha) z_h \qquad \text{if } n_{h-1} < k \leq n_h.$$

Then

$$C_{\alpha, v_k}(\pi_P) \leq \psi_P(k)$$

for the k-th distinct vertex v_k of $V \setminus \{s\}$ visited by π_P. Therefore,

$$\sum_{v \in V} C_{\alpha,v}(\pi_P)^p \leq \sum_{k=1}^{n} \psi_P(k)^p.$$

It remains to observe that the right-hand side is exactly the length of P. Indeed, using the definition of the edge lengths in (5), we get

$$\begin{aligned}
\ell(P) &= \sum_{h=1}^{l} (n - n_{h-1}) \left(\big((1 + \alpha) z_h\big)^p - \big((1 + \alpha) z_{h-1}\big)^p \right) \\
&= \sum_{h=1}^{l} (n_h - n_{h-1}) \big((1 + \alpha) z_h\big)^p \\
&= \sum_{k=1}^{n} \psi_P(k)^p.
\end{aligned}$$

The second equality follows by telescoping. Thus,

$$\sum_{v \in V} C_{\alpha,v}(\pi_P)^p \leq \ell(P),$$

which proves the claim. ◀

We next show that the auxiliary graph contains a path whose length is bounded by the same expression that appeared in the randomized analysis. For fixed $\gamma > 1$, define

$$\eta_\gamma \coloneqq (1+\alpha)^p \frac{2^p}{p \ln \gamma} \cdot \frac{\gamma^{2p} - \gamma^p}{(\gamma - 1)^p}.$$

▶ **Lemma 15.** *Let π^* be an optimal tour for the p-norm α-latency objective. Then, for every fixed $\gamma > 1$, there exists a $(0,0)$–ω path P in H such that*

$$\ell(P) \le \eta_\gamma \sum_{i \in [n]} \big(C_{\alpha, v_i^*}(\pi^*)\big)^p.$$

Proof. We use the randomized construction from the previous subsection. For a random choice of $U \in [0,1]$, let $P(U)$ be the corresponding sequence of trees. After removing consecutive repetitions, this sequence defines a path in the auxiliary graph H. Indeed, the first coordinate records the number of vertices covered, while the second coordinate records the accumulated cost of the selected trees.

By the definition of the auxiliary graph and the calculation in the proof of Lemma 14, we have

$$\ell(P(U)) = \sum_{i \in [n]} \psi_{P(U)}(i)^p.$$

From the randomized analysis, for every $i \in [n]$ we have

$$\mathbb{E}_U[\psi_{P(U)}(i)^p] \le \eta_\gamma \big(C_{\alpha, v_i^*}(\pi^*)\big)^p.$$

Taking the sum over all $i \in [n]$ and using linearity of expectation gives

$$\mathbb{E}_U[\ell(P(U))] = \mathbb{E}_U\left[\sum_{i \in [n]} \psi_{P(U)}(i)^p\right] = \sum_{i \in [n]} \mathbb{E}_U[\psi_{P(U)}(i)^p] \le \eta_\gamma \sum_{i \in [n]} \big(C_{\alpha, v_i^*}(\pi^*)\big)^p.$$

Therefore, there exists at least one realization of U such that

$$\ell(P(U)) \le \eta_\gamma \sum_{i \in [n]} \big(C_{\alpha, v_i^*}(\pi^*)\big)^p.$$

This proves the lemma. ◀

Using the above lemmas and analyzing the size of the time-expanded auxiliary graph, we prove Theorem 4.

Proof of Theorem 4. Let P^* be a shortest $(0,0)$–ω path in H, and let π_{ALG} be the tour obtained by concatenating the trees along P^*. By Lemma 14,

$$\left(\sum_{v \in V} C_{\alpha, v}(\pi_{\mathrm{ALG}})^p\right)^{1/p} \le \ell(P^*)^{1/p}.$$

Since P^* is a shortest path, for every $\gamma > 1$ and for the path P whose existence is guaranteed by Lemma 15, we have

$$\ell(P^*) \le \ell(P).$$

Thus,

$$\ell(P^*) \le \eta_\gamma \sum_{i\in[n]} \left(C_{\alpha,v_i^*}(\pi^*)\right)^p = \eta_\gamma \cdot \mathrm{OPT}^p.$$

Taking p-th roots gives

$$\left(\sum_{v\in V} C_{\alpha,v}(\pi_{\mathrm{ALG}})^p\right)^{1/p} \le \eta_\gamma^{1/p} \cdot \mathrm{OPT}.$$

Finally,

$$\eta_\gamma^{1/p} = (1+\alpha)\frac{2}{\gamma-1}\left[\frac{\gamma^{2p}-\gamma^p}{p\ln\gamma}\right]^{1/p}.$$

Since this holds for every $\gamma > 1$, we may minimize over $\gamma > 1$, which gives the claimed approximation factor.

It remains to discuss the running time. Let

$$N_H := |V_H| + |A_H|$$

denote the size of the auxiliary graph. All edge lengths in H are nonnegative, and hence a shortest $(0,0)$–ω path can be computed with Dijkstra's algorithm in time

$$O(N_H \log N_H).$$

In general, the set Z may be exponentially large, since it consists of all subset sums of the tree costs. Thus, the algorithm is pseudo-polynomial. If the tree costs are integral and polynomially bounded, then $|Z|$ is polynomially bounded as well. In this case, N_H is polynomially bounded, and the algorithm runs in polynomial time. ◀

5 Discussion

We studied the discounted graph search problem, a two-parameter framework that contains pathwise search, expanding search, TSP-type objectives, and MST-type objectives as special or limiting cases. The first parameter, $\alpha \in [0,1]$, determines how repeated traversals of edges are charged, while the second parameter, $p \ge 1$, determines how the individual vertex latencies are aggregated. For $p = 1$, we obtain a polynomial-time approximation algorithm whose guarantee interpolates between the currently best-known approximation ratios for expanding search and pathwise search. For general $p \ge 1$, we obtain a randomized constant-factor approximation and a deterministic pseudo-polynomial-time algorithm with the same approximation guarantee.

We stated and analyzed the problem for a uniform discount factor α. The results for $p = 1$ also extend to the case where every edge e has its own discount factor $\alpha_e \in [0,1]$. In this setting, the first traversal of edge e costs c_e, while every further traversal costs $\alpha_e c_e$. Let $\alpha_{\min} := \min_{e\in E} \alpha_e$ and $\alpha_{\max} := \max_{e\in E} \alpha_e$. Then the analysis yields the approximation guarantee

$$\varrho_1(\alpha) := \begin{cases} 2\mathrm{e} & \text{if } \alpha_{\max} = \alpha_{\min} = 0, \\ 2\dfrac{\alpha_{\max}}{(1+\alpha_{\min})W(\alpha_{\max}/\mathrm{e})} & \text{otherwise.} \end{cases}$$

The reason is that the analysis uses the largest possible discount factor when comparing the cost of trees to paths, while the conversion of trees into tours benefits from the smallest discount factor. Thus, the same proof goes through with α replaced by $\alpha_{\max}$ in the former part of the analysis and by $\alpha_{\min}$ in the latter.

A similar generalization is possible when the cost of an edge depends on how often it has already been used. Suppose that for each edge e we are given a sequence $c_e^{(1)}, c_e^{(2)}, c_e^{(3)}, \ldots$ such that the k-th traversal of edge e costs $c_e^{(k)}$. If these sequences are non-increasing, i.e., $c_e^{(k)} \geq c_e^{(k+1)}$ for all $e \in E$ and $k \in \mathbb{N}$, then our analysis can again be extended. Define $\alpha_{\min} := \min_{e \in E} c_e^{(2)}/c_e^{(1)}$ and $\alpha_{\max} := \max_{e \in E} c_e^{(2)}/c_e^{(1)}$. Then the same approximation guarantee as above follows. Indeed, in the comparison to the optimum, it is sufficient to consider paths in which each edge is used at most twice. On the other hand, the algorithm may use edges more often, and for non-increasing traversal costs, every traversal after the second one can only become cheaper. Thus, replacing all costs $c_e^{(k)}$ for $k \geq 2$ by $c_e^{(2)}$ can only make the algorithm more expensive, while preserving the relevant comparison to the optimum.

By contrast, for arbitrary non-decreasing traversal-cost sequences, one cannot hope for a constant-factor approximation in full generality. For example, suppose that $c_e^{(1)} = 0$ and $c_e^{(k)} = 1$ for all $k \geq 2$ for every edge $e \in E$. Then there is a traversal with total latency zero if and only if the graph has a Hamiltonian path starting at s. Otherwise, every feasible traversal must repeat some edge and hence has positive latency. Since deciding the existence of such a Hamiltonian path is NP-complete, no constant-factor approximation can exist in this setting unless P = NP. It would be interesting to understand which structural assumptions on the sequences $c_e^{(1)}, c_e^{(2)}, c_e^{(3)}, \ldots$ still allow constant-factor approximations.

Finally, for the case $p > 1$, one can also compare our bounds to algorithms for the limiting case $p = \infty$. For any nonnegative latency vector $x \in \mathbb{R}^n_{\geq 0}$, we have $\|x\|_\infty \leq \|x\|_p \leq n^{1/p}\|x\|_\infty$. Thus, any β-approximation for the maximum-latency objective immediately gives a $\beta n^{1/p}$-approximation for the p-norm objective. At the endpoint $\alpha = 1$, the maximum-latency objective corresponds to a TSP-path-type problem, while at the endpoint $\alpha = 0$ it corresponds to the MST problem. Therefore, for large values of p, one can use approximation algorithms for these limiting problems to obtain alternative approximation guarantees. In particular, once $p = \Omega(\log n)$, the factor $n^{1/p}$ becomes constant. For even larger values of p, this factor approaches 1, and the guarantee approaches that of the corresponding maximum-latency approximation algorithm. This gives better bounds for sufficiently large p in regimes where the limiting TSP- or MST-type objective can be approximated more accurately than the general bound obtained from the randomized geometric construction.

Abstract

We describe an $\widetilde{\Omega}(1/d^4)$-improvement over threshold rounding schemes for a broad class of Boolean MAX 2-CSP instances in which every variable appears in at most d constraints. In the case of MAX 2-SAT, we improve the ratio further and obtain an $(\beta_\star + \widetilde{\Omega}(1/d^2))$-factor approximation algorithm for bounded-degree MAX 2-SAT instances, where $\beta_\star$ is the UGC-optimal approximation ratio for MAX 2-SAT achieved by the LLZ algorithm [20]. Our result generalizes an $(\alpha_{GW} + \widetilde{\Omega}(1/d^2))$-factor approximation algorithm for MAX CUT on graphs with degrees bounded by d, due to Hsieh and Kothari [15]. Together with the state-of-the-art approximability results for MAX DI-CUT and MAX 2-AND [7], our result suggests that similar improvements exist for bounded-degree instances of these problems as well.

1 Introduction

Maximum Constraint Satisfaction Problems (MAX CSPs) are a fundamental class of combinatorial problems that are studied extensively in theoretical computer science. The design of approximation algorithms for MAX CSPs has been a central topic of research that has seen substantial progress in the past decades. Some of the main highlights include the design of approximation algorithms for MAX CSPs [21] and the development of a framework for hardness reductions to study the limits of approximation for CSPs [17, 18]. These developments have culminated in surprisingly tight characterizations of the optimal approximation factor of every MAX CSP [23], under the Unique Games Conjecture (UGC) [16].

In this work, we aim to explore the approximability of MAX CSPs for structurally simpler instances, namely, when the instances are *sparse*. Specifically, we explore the question of whether one can improve on the optimal approximation guarantee of a MAX CSP when the degree of the underlying constraint graph is bounded. Formally, we are interested in the following:

Given a MAX CSP problem P, suppose its optimal approximation factor is α_P. Then, if the degree of the instance is bounded by some constant d, can we efficiently achieve $\alpha_P + \epsilon_d$ approximation, where the improvement ϵ_d depends on the degree d?

The above question has been studied for various specific MAX CSPs in the literature [6, 13, 9, 4, 5, 15]. Arguably, one of the most interesting lines of work among these involves the approximability of MAX CUT in this setting. It was first studied by Feige, Karpinski, and Langberg [9], who showed that the MAX CUT problem on graphs with maximum degree d admits an efficient approximation guarantee of $\alpha_{GW} + \Omega(1/d^4)$, where $\alpha_{GW} \approx 0.87856$ denotes the optimal approximation factor for MAX CUT under the UGC [12, 19]. This was then improved by Florén [11] up to an $\alpha_{GW} + \Omega(1/d^3)$ factor, and by Hsieh and Kothari [15] to a factor of $\alpha_{GW} + \widetilde{\Omega}(1/d^2)$. Another notable work in this context is that of [5], who showed that one can bypass the approximation resistance of MAX k-LIN and other related problems in bounded-degree instances.

Unfortunately, generalizing this phenomenon beyond the specific examples mentioned above has been challenging. In particular, such results are not known even for well-studied friends of the MAX CUT problem, such as MAX 2-SAT and MAX 2-AND. One of the main difficulties in obtaining similar guarantees for general MAX CSPs has been the following: most of the aforementioned improvements in the bounded-degree setting implicitly rely on tight structural characterizations of the hardest-to-round, i.e., integrality gap, instances of the problem[1]. Such explicit characterizations are known only for a handful of examples (e.g., MAX CUT [10], MAX k-LIN [14], MAX 2-SAT [20, 8]), and even the question of tightly characterizing the gap instances for every Boolean 2-CSP is a long-standing open question.

To get around this bottleneck, we instead consider improving the approximation guarantee of a family of algorithms in the degree-bounded setting. Specifically, we consider the family of $\mathcal{THRESH}^-$-rounding scheme-based algorithms described informally below[2]:

SDP + $\mathcal{THRESH}^-$-Rounding Algorithm

1. Solve the canonical semi-definite programming (SDP) relaxation for the MAX CSP.
2. Round the SDP solution using the $\mathcal{THRESH}^-$ family of rounding functions.

Figure 1 The $\mathcal{THRESH}^-$-based Approximation Framework.

The above framework was first introduced by Lewin, Livnat, and Zwick [20], and it vastly generalizes the hyperplane rounding-based algorithm of Goemans and Williamson [12]. This algorithmic framework has been used successfully for obtaining optimal and near-optimal guarantees for a wide variety of MAX CSPs such as MAX 2-SAT [20, 8], MAX 2-AND [7], MAX BISECTION [3], and several other related problems. Furthermore, Austrin showed that under a certain positivity condition, the above framework is optimal for approximating Boolean MAX 2-CSPs assuming UGC [2]. Guided by these considerations, we are therefore motivated to ask – *Can we improve on the approximation guarantee of the $\mathcal{THRESH}^-$-based algorithm, when the degree of the input instance is bounded?* – which is the main question explored by this work.

[1] We elaborate the connection between integrality gaps and improvements in the bounded-degree setting in Section 1.2.

[2] We refer the reader to Section 2 for a more formal description of the SDP relaxation and the $\mathcal{THRESH}^-$ rounding scheme.

1.1 Our Results

In this work, we make progress on the above questions and give improved approximation guarantees for bounded-degree Boolean MAX 2-CSP instances which satisfy a natural "reasonable" condition. The formal definition of the reasonable condition is a bit technical, and we instead attempt to give an informal description of it. Let $\mathcal{P}$ denote a set of Boolean predicates, and let MAX CSP($\mathcal{P}$) denote the MAX CSP problem where the predicates corresponding to the constraints belong to $\mathcal{P}$. Then loosely speaking, we say that the MAX CSP($\mathcal{P}$) problem is reasonable if for any hardest-to-round instance[3] of MAX CSP($\mathcal{P}$), the local geometric arrangement of the vector solution in the neighborhood of any vertex satisfies certain "general position" conditions. In particular, these conditions ensure that certain pairwise moments involving labels of variables in the neighborhood are non-constant under the rounding distribution (see Lemma 22). We refer the reader to Definitions 6 and 20 for a formal description of this condition.

We now state our main result, which gives improved approximation guarantees for reasonable CSPs.

▶ **Theorem 1** (Informal version of Theorem 23). *Suppose $\mathcal{P}$ is a set of Boolean binary predicates such that the MAX CSP($\mathcal{P}$) problem is reasonable. Let $\beta_{\mathcal{P}}$ denote the approximation factor achieved by the algorithm in Figure 1 for MAX CSP($\mathcal{P}$). Let I be an instance of MAX CSP($\mathcal{P}$) such that every variable appears in at most d constraints. Then, there exists an algorithm that achieves an approximation factor of $\beta_{\mathcal{P}} + \widetilde{\Omega}(d^{-4})$ on I, where the constant hidden in $\widetilde{\Omega}$ only depends on $\mathcal{P}$.*

While the above theorem by itself just implies improvement on the approximation guarantee of $\mathcal{THRESH}^{-}$-based algorithms, it has stronger implications for MAX CSPs that satisfy certain additional properties. As mentioned above, Austrin [2] showed that if $\mathcal{P}$ satisfies the positivity condition, then the algorithm from Figure 1 obtains the optimal approximation guarantee assuming UGC. Therefore, for MAX CSP($\mathcal{P}$) problems that satisfy the reasonable and positivity conditions, the above theorem actually implies improvement on the optimal approximation guarantee in the bounded-degree setting.

Furthermore, by leveraging the structural insights from the recent work [8], we are able to derive a sharper version of the above theorem for the MAX 2-SAT problem. We formally state this result in the next theorem.

▶ **Theorem 2.** *Let I be an instance of MAX 2-SAT such that every variable appears in at most d constraints. Then there is an efficient algorithm that can return a $\beta_\star + \Omega(d^{-2}\log^{-1}(d))$-approximation to I, where $\beta_\star \approx 0.9401$ is the optimal approximation guarantee for the MAX 2-SAT problem.*

We point out a couple of interesting features of the above theorem. Firstly, observe that the above theorem does not mention the "reasonable" condition. This is because the structural results from [8] directly imply that the hardest-to-round instances of MAX 2-SAT naturally satisfy the reasonable condition, and hence we are able to apply our framework to obtain an unconditional improvement for degree-bounded MAX 2-SAT instances. Furthermore, by using the specific structure of the 2-SAT predicate, we are able to improve the additive gain in the approximation factor from $\widetilde{\Omega}(d^{-4})$ to $\widetilde{\Omega}(d^{-2})$.

[3] An instance I of MAX CSP($\mathcal{P}$) is said to be hardest-to-round if the algorithm from Figure 1 achieves its worst approximation guarantee in I.

1.2 On Integrality Gaps and Bounded-degree CSPs

We close out this section by highlighting the connection between hard-to-round instances and improved approximation for bounded-degree CSPs. Most of the previous works in this setting adopt the approach of improving the performance of a base algorithm via a greedy post-processing step that relies on certain anti-concentration properties of the objective function at local neighborhoods (similar to Lemma 18). In particular, such an approach has to be capable of interpolating between the following extremal scenarios:

- For instances that are far from being an integrality gap, the base algorithm by itself is capable of yielding improved approximation guarantees,
- And for instances that are close to being an integrality gap, the post-processing procedure should be able to leverage the bounded-degree structure of the instance to improve on the worst-case approximation guarantee.

Now, note that under this framework, it stands to reason that the greedy post-processing needs to be more effective for instances that are closer to being an integrality gap, whereas it may be less useful for easier instances – e.g., for instances which are perfectly solvable by the base algorithm, the procedure cannot improve the quality of the solution output by the base algorithm any further. Therefore, the analysis of the post-processing step necessarily requires a structural understanding of the hardest instances for the base algorithm. For example, for the MAX CUT problem, the analyses of algorithms in [9, 11, 15] use the well-known characterization that the edges that are hardest to round by hyperplane rounding are those for which the inner product of the corresponding SDP vectors is equal to a certain critical value.

We conclude by noting that while it might be possible to obtain improvements without explicitly characterizing the hardest instances, such a result will require algorithms that go beyond the above two-phase approach.

1.3 Organization of the Paper

The rest of the paper is organized as follows. In Section 2, we formally define MAX CSP, the Basic SDP relaxation, the $\mathcal{THRESH}^-$ rounding family, and related concepts. In Section 3, we present our algorithm and define some algorithmic quantities. In Section 4, we analyze the algorithm in the case of MAX 2-SAT, proving Theorem 2. In Section 5, we analyze our algorithm for general Boolean MAX 2-CSPs, where we state and prove the formal version of Theorem 1. Finally, we state in Appendix A certain variance lower bounds needed in the analysis, whose proofs we defer to the full version of the paper.

2 Preliminaries

For $n \in \mathbb{N}$, let $[n] \coloneqq \{1, 2, \ldots, n\}$. Let Φ, φ be the c.d.f. and p.d.f. of a standard Gaussian variable. Given an event A, we use $\mathbf{1}\{A\}$ to denote the indicator random variable for A. We use `true`, `false` for the truth values of a Boolean variable. We may also represent the truth values using $\{0, 1\}$ or $\{-1, 1\}$: in the former case 1 stands for `true` and 0 stands for `false`, while in the latter case -1 stands for `true` and 1 stands for `false`.

2.1 MAX CSP and the Basic SDP Relaxation

▶ **Definition 3.** *Let $\mathcal{P}$ be a set of Boolean predicates. An instance $I = (V, \mathcal{C}, w)$ of* MAX CSP($\mathcal{P}$) *is defined by*

- *A finite set V of variables.*

- *A finite set $\mathcal{C}$ of constraints where each constraint $C \in \mathcal{C}$ is obtained by applying some predicate P to some variables from V. We use $C = (P, i_1, i_2, \ldots, i_k)$ to denote a constraint C obtained by applying some k-ary predicate P to variables $i_1, i_2, \ldots, i_k$.*
- *A weight function $w : \mathcal{C} \to \mathbb{R}^{\geq 0}$.*

Given an assignment $A : V \to \{-1, 1\}$, we say that a constraint C is satisfied if the corresponding predicate evaluates to 1, and we use $\mathrm{Val}(I, A)$ to denote the total weight of constraints satisfied by A. The objective is to find an assignment A that maximizes $\mathrm{Val}(I, A)$.

For simplicity, we will assume without loss of generality that $\sum_{C \in \mathcal{C}} w(C) = 1$. This can always be achieved by renormalizing, which does not meaningfully change the problem. In this case we may also think of $\mathcal{C}$ as a distribution over constraints, with probabilities specified by w. We will also assume $V = [n]$ for some $n \in \mathbb{N}$.

In this paper we only consider the special case of MAX 2-CSP, namely the case where every Boolean predicate in $\mathcal{P}$ is of arity 2. For convenience, we encode truth assignments for variables using $\{-1, 1\}$, while predicates take values in $\{0, 1\}$, and thus each predicate has the form $P : \{-1, 1\}^2 \to \{0, 1\}$. Given a MAX 2-CSP instance $I = (V, \mathcal{C}, w)$, we can formulate its *Basic SDP relaxation* [23] as follows (cf. [8]).

$$
\begin{aligned}
\text{maximize} \quad & \sum_{C=(P,i,j)\in\mathcal{C}} w(C) \cdot \left(\hat{P}_\varnothing + \hat{P}_i \mathbf{v}_0 \cdot \mathbf{v}_i + \hat{P}_j \mathbf{v}_0 \cdot \mathbf{v}_j + \hat{P}_{i,j} \mathbf{v}_i \cdot \mathbf{v}_j \right) \\
\text{subject to} \quad & \forall i \in \{0, 1, 2, \ldots, n\} \,, \qquad \mathbf{v}_i \cdot \mathbf{v}_i = 1 \,, \\
& \forall C = (P, i, j) \in \mathcal{C} \,, \qquad \begin{aligned} (\mathbf{v}_0 - \mathbf{v}_i) \cdot (\mathbf{v}_0 - \mathbf{v}_j) &\geq 0 \,, \\ (\mathbf{v}_0 + \mathbf{v}_i) \cdot (\mathbf{v}_0 - \mathbf{v}_j) &\geq 0 \,, \\ (\mathbf{v}_0 - \mathbf{v}_i) \cdot (\mathbf{v}_0 + \mathbf{v}_j) &\geq 0 \,, \\ (\mathbf{v}_0 + \mathbf{v}_i) \cdot (\mathbf{v}_0 + \mathbf{v}_j) &\geq 0 \,. \end{aligned}
\end{aligned}
$$

Here $\hat{P}_\varnothing, \hat{P}_i, \hat{P}_j, \hat{P}_{i,j} \in \mathbb{R}$ are the *Fourier coefficients* of P, namely, we have

$$P(x_i, x_j) = \hat{P}_\varnothing + \hat{P}_i x_i + \hat{P}_j x_j + \hat{P}_{i,j} x_i x_j.$$

for every $x_i, x_j \in \{-1, 1\}$ (See [22] for more on Fourier analysis of Boolean functions). The constraints in (2.1) are often referred to as *triangle inequalities*. In fact, we may in addition impose triangle inequalities on all triples of vectors:

$$
\forall i, j, k \in \{0, 1, \ldots, n\} \,, \qquad \begin{aligned} (\mathbf{v}_i - \mathbf{v}_j) \cdot (\mathbf{v}_i - \mathbf{v}_k) &\geq 0 \,, \\ (\mathbf{v}_i + \mathbf{v}_j) \cdot (\mathbf{v}_i - \mathbf{v}_k) &\geq 0 \,, \\ (\mathbf{v}_i - \mathbf{v}_j) \cdot (\mathbf{v}_i + \mathbf{v}_k) &\geq 0 \,, \\ (\mathbf{v}_i + \mathbf{v}_j) \cdot (\mathbf{v}_i + \mathbf{v}_k) &\geq 0 \,. \end{aligned}
$$

▶ **Definition 4.** *We say that unit vectors $\mathbf{v}_0, \mathbf{v}_1, \ldots, \mathbf{v}_n$ are an SDP solution for some MAX 2-CSP instance over the variable set $[n]$, if they satisfy (2.1). We say that they satisfy all triangle inequalities if they further satisfy (2.1). For $i, j \in [n]$, we write*

$$b_i = \mathbf{v}_0 \cdot \mathbf{v}_i \qquad \text{and} \qquad b_{ij} = \mathbf{v}_i \cdot \mathbf{v}_j.$$

We will often need to take projections for an SDP solution. For $i \in [n]$ and $S \subseteq \{0\} \cup [n]$, we use $\mathbf{v}_i^{\perp\{S\}}$ to denote the (renormalized) component in $\mathbf{v}_i$ that is orthogonal to $\mathrm{span}\{\mathbf{v}_j \mid j \in S\}$. In particular, $\mathbf{v}_i^{\perp\{0\}} = \frac{\mathbf{v}_i - b_i \mathbf{v}_0}{\sqrt{1-b_i^2}}$ is the (renormalized) component in $\mathbf{v}_i$ that is orthogonal to $\mathbf{v}_0$ (in the case $|b_i| = 1$, we may define $\mathbf{v}_i^{\perp\{0\}}$ to be any unit vector that is orthogonal to all other vectors in the SDP solution, but this case won't show up in our paper). We will write $\mathbf{v}_i^\perp$ for $\mathbf{v}_i^{\perp\{0\}}$ to avoid clutter.

2.2 Configurations

To analyze SDP-based approximation algorithms, it is sometimes more convenient to work with the inner products between vectors in an SDP solution rather than the vectors themselves. This leads to the following definition.

▶ **Definition 5.** *A* configuration *is a tuple of the form (b_i, b_j, b_{ij}, P) where P is a Boolean predicate of arity 2, and $b_i, b_j, b_{ij} \in [-1, 1]$ are real numbers such that*

$$-1 + |b_i + b_j| \leq b_{ij} \leq 1 - |b_i - b_j|.$$

We say that a tuple (b_i, b_j, b_{ij}) is valid *if it satisfies (5). Given a configuration $\theta = (b_i, b_j, b_{ij}, P)$, we define $\rho(\theta) = \frac{b_{ij} - b_i b_j}{\sqrt{(1-b_i^2)(1-b_j^2)}}$ if $\sqrt{(1-b_i^2)(1-b_j^2)} \neq 0$ and $\rho(\theta) = 0$ otherwise.*

It can be easily verified that the inequality (5) corresponds exactly to the triangle inequalities in (2.1), and therefore a tuple (b_i, b_j, b_{ij}) is valid if and only if it can be obtained as inner products between $\mathbf{v}_0, \mathbf{v}_i, \mathbf{v}_j$ from an SDP solution. In this case, $\rho(\theta)$ is exactly the inner product between $\mathbf{v}_i^\perp$ and $\mathbf{v}_j^\perp$.

▶ **Definition 6.** *Given a MAX 2-CSP instance $I = (V, \mathcal{C}, w)$ and an SDP solution $\mathbf{v}_0, \cdots, \mathbf{v}_n$, we say that a distribution $\mathcal{D}$ of configurations* represents *the SDP solution if it is obtained as follows:*

- *Sample a constraint $C = (P, i, j) \sim \mathcal{C}$ from the instance.*
- *Return the configuration $\theta = (b_i, b_j, b_{ij}, P)$.*

We may also say that θ as defined above represents the constraint C.

Now we define *completeness*, which corresponds to the value of the Basic SDP relaxation.

▶ **Definition 7** (Completeness)**.** *Given a configuration $\theta = (b_i, b_j, b_{ij}, P)$, we define its* completeness *to be*

$$\mathsf{Completeness}(\theta) = \hat{P}_\varnothing + \hat{P}_i b_i + \hat{P}_j b_j + \hat{P}_{i,j} b_{ij}.$$

For a distribution $\mathcal{D}$ over configurations, we define $\mathsf{Completeness}(\mathcal{D}) = \mathbb{E}_{\theta \sim \mathcal{D}}[\mathsf{Completeness}(\theta)]$.

By construction, if a distribution $\mathcal{D}$ represents some SDP solution, then its completeness corresponds exactly to the SDP objective value achieved by that SDP solution.

2.3 The $\mathcal{THRESH}^-$ Rounding Family

The $\mathcal{THRESH}^-$ rounding family, introduced in [20], is a powerful family of rounding algorithms for Boolean MAX 2-CSPs. A rounding algorithm from the $\mathcal{THRESH}^-$ rounding family is specified by a *threshold function* $f : [-1, 1] \to \mathbb{R}$. Given an SDP solution $\mathbf{v}_0, \mathbf{v}_1, \ldots, \mathbf{v}_n$, it computes the projection $\mathbf{v}_i^\perp = \frac{\mathbf{v}_i - b_i \mathbf{v}_0}{\sqrt{1-b_i^2}}$ for every $i \in [n]$, samples a standard Gaussian vector $\mathbf{r}$, and sets the variable i to be `true` if $\mathbf{r} \cdot \mathbf{v}_i^\perp \geq f(b_i)$ and `false` otherwise.

We now define *soundness*, which corresponds to the probability that a configuration (or more precisely, any constraint represented by the configuration) is satisfied using a $\mathcal{THRESH}^-$ rounding algorithm.

▶ **Definition 8** (Soundness). *Let $f : [-1, 1] \to \mathbb{R}$ be a threshold function. Given a configuration $\theta = (b_i, b_j, b_{ij}, P)$, let (g_i, g_j) be a pair of standard Gaussian random variables with correlation $\rho(\theta)$, and define*

$$X_i = \begin{cases} -1, & \text{if } g_i \geq f(b_i), \\ 1, & \text{otherwise,} \end{cases} \qquad X_j = \begin{cases} -1, & \text{if } g_j \geq f(b_j), \\ 1, & \text{otherwise,} \end{cases}$$

Then, the soundness *of θ with respect to f is defined to be*

$$\mathsf{Soundness}_f(\theta) = \Pr[P(X_i, X_j) = \texttt{true}].$$

For a distribution $\mathcal{D}$ over configurations, we define $\mathsf{Soundness}_f(\mathcal{D}) = \mathbb{E}_{\theta \sim \mathcal{D}}[\mathsf{Soundness}_f(\theta)]$.

By construction, if a distribution $\mathcal{D}$ represents some SDP solution, then its soundness with respect to f corresponds to the expected satisfied fraction if we use $\mathcal{THRESH}^-$ with f to round that SDP solution.

3 Description of the Algorithm

We now state our main algorithm. It is adapted from the bounded-degree MAX CUT algorithm due to [15]. The quantities $W_{i,1}, W_{i,0}$, and $W_{i,*}$ will be defined momentarily after the algorithm.

Algorithm 1 Algorithm for Bounded-Degree Boolean MAX 2-CSP.

1: **Input:** Boolean MAX 2-CSP instance $I = (V, \mathcal{C}, w)$ with variable set $V = [n]$, parameter $\epsilon > 0$, and an SDP solution $\{\mathbf{v}_i \mid i \in V \cup \{0\}\}$.
2: **Output:** an assignment $A : V \to \{\texttt{true}, \texttt{false}\}$.
3: Choose a standard Gaussian vector $\mathbf{r}$.
4: **for** $i \in V$ **do**
5: Compute $b_i = \mathbf{v}_0 \cdot \mathbf{v}_i$ and $\mathbf{v}_i^\perp = \frac{\mathbf{v}_i - b_i \mathbf{v}_0}{\sqrt{1-b_i^2}}$.
6: Set $A'(i) = \texttt{true}$ if $\mathbf{r} \cdot \mathbf{v}_i^\perp \geq f(b_i)$ and $\texttt{false}$ otherwise.
7: Set $A(i) = A'(i)$ if $\left|\mathbf{r} \cdot \mathbf{v}_i^\perp - f(b_i)\right| \geq \epsilon$ and $*$ otherwise.
8: **for** $i \in V$ **do**
9: **if** $A(i) = *$ **then**
10: Set $A(i) = \begin{cases} \texttt{true} & \text{if } W_{i,1} > W_{i,0} + W_{i,*}, \\ \texttt{false} & \text{if } W_{i,0} > W_{i,1} + W_{i,*}, \\ A'(i) & \text{otherwise.} \end{cases}$
11: **return** A

Informally, the algorithm first computes an assignment A' using $\mathcal{THRESH}^-$ with the threshold function f. It then greedily flips any variable which lies approximately on the boundary of the $\mathcal{THRESH}^-$ rounding algorithm (more specifically, $\left|\mathbf{r} \cdot \mathbf{v}_i^\perp - f(b_i)\right| < \epsilon$) if there is some *local gain*, which we define below.

For every variable i, let $\mathcal{C}_i \subseteq \mathcal{C}$ be the set of constraints that involve i. We define the following subsets of $\mathcal{C}_i$ with respect to the (partial) assignment A before executing the for-loop at Line 8:

$$\begin{aligned}
\mathcal{C}_{i,*} &= \{C \in \mathcal{C}_i \mid \text{the other variable in } C \text{ is unassigned}\} \\
\mathcal{C}_{i,\mathtt{sat}} &= \{C \in \mathcal{C}_i \setminus \mathcal{C}_{i,*} \mid C \text{ is satisfied regardless of the truth value of } i\} \\
\mathcal{C}_{i,\mathtt{unsat}} &= \{C \in \mathcal{C}_i \setminus \mathcal{C}_{i,*} \mid C \text{ is unsatisfied regardless of the truth value of } i\} \\
\mathcal{C}_{i,1} &= \{C \in \mathcal{C}_i \setminus \mathcal{C}_{i,*} \mid C \text{ is satisfied if } i \text{ is } \mathtt{true} \text{ and unsatisfied if } i \text{ is } \mathtt{false}\} \\
\mathcal{C}_{i,0} &= \{C \in \mathcal{C}_i \setminus \mathcal{C}_{i,*} \mid C \text{ is satisfied if } i \text{ is } \mathtt{false} \text{ and unsatisfied if } i \text{ is } \mathtt{true}\}.
\end{aligned}$$

We use $W_{i,*}, W_{i,\mathtt{sat}}, W_{i,\mathtt{unsat}}, W_{i,1}, W_{i,0}$ to denote the total weights of clauses in these subsets, and we define

$$W_i \coloneqq \sum_{C \in \mathcal{C}_i} w(C) = W_{i,*} + W_{i,\mathtt{sat}} + W_{i,\mathtt{unsat}} + W_{i,1} + W_{i,0}$$

to be the total weight of constraints which contain i. We would like to understand how the for-loop starting at Line 8 affects the constraints in these subsets. By definition, constraints in $\mathcal{C}_{i,\mathtt{sat}}$ and $\mathcal{C}_{i,\mathtt{unsat}}$ won't be affected by the truth value for i since they are already fixed, and therefore they (as well as the weights $W_{i,\mathtt{sat}}, W_{i,\mathtt{unsat}}$) won't play a role in our analysis. The only constraints whose status can be affected in the for-loop are the ones in $\mathcal{C}_{i,*}, \mathcal{C}_{i,0}$ and $\mathcal{C}_{i,1}$. If we set i to be $\mathtt{true}$, then we satisfy every constraint in $\mathcal{C}_{i,1}$, possibly some constraints in $\mathcal{C}_{i,*}$, and certainly none in $\mathcal{C}_{i,0}$. Similarly, if we set i to be $\mathtt{false}$, then we satisfy every constraint in $\mathcal{C}_{i,0}$, possibly some constraints in $\mathcal{C}_{i,*}$, and certainly none in $\mathcal{C}_{i,1}$. It follows that if we flip i from $\mathtt{true}$ to $\mathtt{false}$, then the total weight of satisfied constraints changes by $W_{i,0} - W_{i,1} - p \cdot W_{i,*}$, for some $p \in [-1, 1]$. If we have $W_{i,0} - W_{i,1} - W_{i,*} > 0$, then this change is guaranteed to be positive. In particular, this means when $W_{i,0} - W_{i,1} - W_{i,*} > 0$ and $A'(i) = \mathtt{true}$, we obtain an improvement over A' by setting $A(i) = \mathtt{false}$. Analogously, when $W_{i,1} - W_{i,0} - W_{i,*} > 0$ and $A'(i) = \mathtt{false}$, we also obtain an improvement over A' by setting $A(i) = \mathtt{true}$. This motivates the formal definition of *local gains* as follows:

▶ **Definition 9.** *We define the local gain Δ_i of the variable i to be*

$$\begin{aligned}
\Delta_i = (W_{i,0} - W_{i,1} - W_{i,*})_+ \cdot \mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i), f(b_i) + \epsilon)\} \\
+ (W_{i,1} - W_{i,0} - W_{i,*})_+ \cdot \mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i) - \epsilon, f(b_i))\}.
\end{aligned}$$

Here $(z)_+$ is defined to be z if $z \geq 0$ and 0 if $z < 0$.

Note that there is tension over the choice of ϵ, which controls how many vertices we potentially flip in the for-loop: on one hand we would like to flip more vertices in order to get more local gain, on the other hand we would like $W_{i,*}$ to be small, for otherwise it may overwhelm the difference between $W_{i,0}$ and $W_{i,1}$ and we won't get any local gain at all.

The following lemma formalizes the motivation for local gains.

▶ **Lemma 10.** *Let $\mathcal{D}$ be the distribution of configurations that represents the SDP solution in the input to Algorithm 1. Then, we have $\mathbb{E}[\mathrm{Val}(I, A)] \geq \mathsf{Soundness}_f(\mathcal{D}) + \sum_{i \in V} \mathbb{E}[\Delta_i]$.*

Proof. Observe that for any $i \in V$, we have $A'(i) = A(i)$ unless

- $W_{i,1} > W_{i,0} + W_{i,*}$ and $\mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i) - \epsilon, f(b_i))$, or
- $W_{i,0} > W_{i,1} + W_{i,*}$ and $\mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i), f(b_i) + \epsilon)$.

In these two cases, we flip the value of variable i and the weight of satisfied constraints increases by at least Δ_i. So we have

$$\mathrm{Val}(I, A) - \mathrm{Val}(I, A') \geq \sum_{i \in V} \Delta_i.$$

The lemma follows by taking expectation and observing that $\mathbb{E}[\mathrm{Val}(I, A')] = \mathsf{Soundness}_f(\mathcal{D})$. ◀

4 Analysis for MAX 2-SAT

We first analyze Algorithm 1 in the case of MAX 2-SAT. Let $\mathcal{P}_{2SAT} = \{x \vee y, \overline{x} \vee y, \overline{x} \vee \overline{y}\}$, then MAX 2-SAT is exactly MAX CSP($\mathcal{P}_{2SAT}$). We start by stating some known results for MAX 2-SAT. For $\beta \in [0,1]$, define the threshold function $f_\beta : [-1,1] \to \mathbb{R}$ by

$$f_\beta(t) = \Phi^{-1}\left(\frac{1+\beta t}{2}\right),$$

where Φ^{-1} is the inverse CDF for a standard Gaussian variable. Observe that f_β is odd for any $\beta \in [0,1]$, in the sense that $f_\beta(-t) = -f_\beta(t)$ for every $t \in [-1,1]$.

▶ **Theorem 11** ([20, 1, 8]). *There exists some constant $\beta_\star \approx 0.94016567$ such that for any MAX 2-SAT configuration θ,*

$$\mathsf{Soundness}_{f_{\beta_\star}}(\theta) - \beta_* \cdot \mathsf{Completeness}(\theta) \geq 0.$$

Consequently, the $\mathcal{THRESH}^-$ algorithm with the $f = f_{\beta_\star}$ achieves a $\beta_\star$-approximation for MAX 2-SAT. On the other hand, assuming the Unique Games Conjecture, for any $\epsilon > 0$ it is NP-hard to approximate MAX 2-SAT within a factor of $\beta_\star + \epsilon$.

By inspecting the proofs in [8] we in fact have the following slightly stronger statement:

▶ **Theorem 12** ([8]). *Given a valid triple (b_i, b_j, b_{ij}), define*

$$g(b_i, b_j, b_{ij}) = \mathsf{Soundness}_{f_{\beta_\star}}(\theta) - \beta_* \cdot \mathsf{Completeness}(\theta),$$

where $\theta = (b_i, b_j, b_{ij}, x \vee y)$. Then g has exactly two minimizers

$$g(b_\star, b_\star, -1+2b_\star) = g(-b_\star, -b_\star, -1+2b_\star) = 0$$

where $b_\star \approx 0.162478$. Furthermore, there exists $c > 0$ such that for any valid tuple (b_i, b_j, b_{ij}),

$$\begin{aligned} &g(b_i, b_j, b_{ij}) \\ &\geq c \cdot \left(\min\left(\|(b_i, b_j, b_{ij}) - (b_\star, b_\star, -1+2b_\star)\|, \|(b_i, b_j, b_{ij}) - (-b_\star, -b_\star, -1+2b_\star)\|\right)\right)^2. \end{aligned}$$

Let $\theta = (b_i, b_j, b_{ij}, P)$ be a MAX 2-SAT configuration (i.e., $P \in \mathcal{P}_{2SAT}$) and $\delta > 0$. We say that θ is δ-critical, if one of the following holds:

- $P = x \vee y$ or $P = \overline{x} \vee \overline{y}$, and

$$\min\left(\|(b_i, b_j, b_{ij}) - (b_\star, b_\star, -1+2b_\star)\|, \|(b_i, b_j, b_{ij}) - (-b_\star, -b_\star, -1+2b_\star)\|\right) \leq \delta.$$

- $P = \overline{x} \vee y$ and

$$\min\left(\|(b_i, b_j, b_{ij}) - (b_\star, -b_\star, 1-2b_\star)\|, \|(b_i, b_j, b_{ij}) - (-b_\star, b_\star, 1-2b_\star)\|\right) \leq \delta.$$

Theorem 12 shows that for non-critical configurations we may hope for a better-than-$\beta_\star$ approximation.

▶ **Lemma 13.** *Let θ be a MAX 2-SAT configuration θ that is not δ-critical. Then*

$$\mathsf{Soundness}_{f_{\beta_\star}}(\theta) - \beta_\star \cdot \mathsf{Completeness}(\theta) = \Omega(\delta^2).$$

Proof. Follows directly from Theorem 12. ◀

On the other hand, for δ-critical configurations with sufficiently small $\delta > 0$, we may use Algorithm 1 to obtain an improvement if the instance is bounded degree.

▶ **Theorem 14.** *There exists some constant $\delta > 0$ such that the following holds. Let $I = (V, \mathcal{C}, w)$ be an instance of MAX 2-SAT such that every variable appears in at most d constraints. Let $\mathcal{D}$ be a distribution of configurations representing some SDP solution $\{\mathbf{v}_i \mid i \in V \cup \{0\}\}$ for I such that $b_i \geq 0$ for every variable i, and every $\theta \in \mathrm{supp}(\mathcal{D})$ is δ-critical. Then, for $f = f_{\beta_\star}$ and $\epsilon = d^{-1}\log^{-1} d$, Algorithm 1 returns an assignment A such that $\mathbb{E}[\mathrm{Val}(I, A)] = \mathsf{Soundness}_f(\mathcal{D}) + \Omega(d^{-2}\log^{-1}(d))$.*

We remark that the assumption that $b_i \geq 0$ for every variable i is for convenience only. The proof of Theorem 14 is deferred to Section 4.1. Combining Lemma 13 and Theorem 14 we obtain the following theorem:

▶ **Theorem 15** (Restatement of Theorem 2)**.** *Let I be an instance of MAX 2-SAT such that every variable appears in at most d constraints. Let $\mathcal{D}$ be a distribution of configurations representing an SDP solution for I. Then, for $f = f_{\beta_\star}$, we can find an assignment A such that*

$$\mathrm{Val}(I, A) \geq \beta_\star \cdot \mathsf{Completeness}(\mathcal{D}) + \Omega(d^{-2}\log^{-1}(d)).$$

Proof. Let $\delta > 0$ be chosen as in Theorem 14 and $\eta = cd^{-2}\log^{-1}(d)$ for some small constant $c > 0$. If there are at least η-fraction (in the weighted sense) of configurations in $\mathcal{D}$ that are not δ-critical, then in this case by Lemma 13 we have that the $\mathcal{THRESH}^-$ algorithm with the $f = f_{\beta_\star}$ already achieves $\mathsf{Soundness}_f(\mathcal{D}) \geq \beta_\star \cdot \mathsf{Completeness}(\mathcal{D}) + \Omega(\eta) = \beta_\star \cdot \mathsf{Completeness}(\mathcal{D}) + \Omega(d^{-2}\log^{-1}(d))$.

Now assume at least $(1-\eta)$-fraction of the configurations are δ-critical, then we may ignore the constraints corresponding to configurations that are not δ-critical and form a new instance I' and a new distribution of configurations $\mathcal{D}'$ supported only on δ-critical configurations by renormalizing the weights. Applying Theorem 14 to I' and $\mathcal{D}'$ (after possibly flipping variables and SDP vectors so that $b_i \geq 0$ for every i), we obtain an assignment achieving a satisfying fraction of at least

$$\begin{aligned}
&(1-\eta)\cdot\big(\mathsf{Soundness}_f(\mathcal{D}') + \Omega(d^{-2}\log^{-1}(d))\big)\\
\geq\ &(1-\eta)\cdot\big(\beta_\star\cdot\mathsf{Completeness}(\mathcal{D}') + \Omega(d^{-2}\log^{-1}(d))\big)\\
\geq\ &(1-\eta)\cdot\big(\beta_\star\cdot(\mathsf{Completeness}(\mathcal{D}) - \eta) + \Omega(d^{-2}\log^{-1}(d))\big)\\
=\ &\beta_\star\cdot\mathsf{Completeness}(\mathcal{D}) + \Omega(d^{-2}\log^{-1}(d)) - \eta\cdot O(1)\\
=\ &\beta_\star\cdot\mathsf{Completeness}(\mathcal{D}) + \Omega(d^{-2}\log^{-1}(d)).
\end{aligned}$$

◀

4.1 Analyzing a Local Neighborhood

In this subsection we aim to prove Theorem 14. Since we assume $b_i \geq 0$ for every variable i, our δ-critical configurations (b_i, b_j, b_{ij}, P) must all satisfy that $\|(b_i, b_j, b_{ij}) - (b_\star, b_\star, -1+2b_\star)\| \leq \delta$ and P is either $x \vee y$ or $\overline{x} \vee \overline{y}$, if we take δ to be sufficiently small.

To prove Theorem 14, we first state and prove a few lemmas on the algorithmic quantities $W_{i,0}, W_{i,1}, W_{i,*}, \Delta_i$ in the neighborhood of i defined in Section 3. To avoid ambiguity, we use A_* to denote the (partial) assignment A before the execution of the for-loop at Line 8. The overall idea is to show that conditioned on i being unassigned, $W_{i,0} - W_{i,1}$ must have a large variance, leading to a nontrivial local gain.

▶ **Lemma 16.** *For every i and $t \in (f(b_i) - \epsilon, f(b_i) + \epsilon)$, we have*

$$\mathbb{E}[|W_{i,0} - W_{i,1}| \mid \mathbf{r} \cdot \mathbf{v}_i^{\perp} = t] = W_i \cdot \Omega(d^{-1}),$$

where the constant in Ω can be chosen independently from t.

Proof. Let $\mathcal{C}_i^+ \subseteq \mathcal{C}_i$ be the set of constraints involving i that are defined using the predicate $x \vee y$, and $\mathcal{C}_i^- \subseteq \mathcal{C}_i$ be the set of those defined using $\overline{x} \vee \overline{y}$. For $C \in \mathcal{C}_i$, let j_C be the variable other than i involved in C. For every $C \in \mathcal{C}_i^+$, we have

$$C \in \begin{cases} \mathcal{C}_{i,\mathtt{sat}} & \text{if } A_*(j_C) = \mathtt{true}, \\ \mathcal{C}_{i,1} & \text{if } A_*(j_C) = \mathtt{false}, \\ \mathcal{C}_{i,*} & \text{if } A_*(j_C) = *. \end{cases}$$

Similarly, for every $C \in \mathcal{C}_i^-$, we have

$$C \in \begin{cases} \mathcal{C}_{i,\mathtt{sat}} & \text{if } A_*(j_C) = \mathtt{false}, \\ \mathcal{C}_{i,0} & \text{if } A_*(j_C) = \mathtt{true}, \\ \mathcal{C}_{i,*} & \text{if } A_*(j_C) = *. \end{cases}$$

So we have

$$W_{i,0} - W_{i,1} = \sum_{C \in \mathcal{C}_i^+} w(C)\mathbf{1}\{A_*(j_C) = \mathtt{true}\} - \sum_{C \in \mathcal{C}_i^-} w(C)\mathbf{1}\{A_*(j_C) = \mathtt{false}\}.$$

Given a configuration $\theta = (b_i, b_j, b_{ij}, P)$, we have $A_*(j) = \mathtt{true}$ if and only if $\mathbf{r} \cdot \mathbf{v}_j^{\perp} \geq f(b_j) + \epsilon$, or equivalently $\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}} \geq \frac{-\rho(\theta)\mathbf{r}\cdot\mathbf{v}_i^{\perp} + f(b_j) + \epsilon}{\sqrt{1-\rho(\theta)^2}}$. Similarly $A_*(j) = \mathtt{false}$ if and only if $\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}} \leq \frac{-\rho(\theta)\mathbf{r}\cdot\mathbf{v}_i^{\perp} + f(b_j) - \epsilon}{\sqrt{1-\rho(\theta)^2}}$. Since $\mathbf{r} \cdot \mathbf{v}_i^{\perp} \in (f(b_i) - \epsilon, f(b_i) + \epsilon)$ and θ is δ-critical, we have $\| \frac{-\rho(\theta)\mathbf{r}\cdot\mathbf{v}_i^{\perp} + f(b_j) \pm \epsilon}{\sqrt{1-\rho(\theta)^2}} - s \| = O(\epsilon + \delta)$, where

$$s \coloneqq \frac{-\rho_\star f(b_\star) + f(b_\star)}{\sqrt{1-\rho_\star^2}} = f(b_\star) \cdot \frac{1-\rho_\star}{\sqrt{1-\rho_\star^2}} = f(b_\star) \cdot \sqrt{\frac{1-\rho_\star}{1+\rho_\star}}$$

and $\rho_\star = \frac{-1+2b_\star - b_\star^2}{1-b_\star^2} = -\frac{1-b_\star}{1+b_\star}$. By plugging in the value of $b_\star$ and $\beta_\star$, we get $s \approx 0.4779$. So we may rewrite

$$\begin{aligned} & W_{i,0} - W_{i,1} \\ &= \sum_{C \in \mathcal{C}_i^+} w(C)\mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_{j_C}^{\perp\{0,i\}} \geq s \pm O(\epsilon + \delta)\} - \sum_{C \in \mathcal{C}_i^-} w(C)\mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_{j_C}^{\perp\{0,i\}} \leq s \pm O(\epsilon + \delta)\} \\ &= \sum_{C \in \mathcal{C}_i} w(C)\mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_{j_C}^{\perp\{0,i\}} \geq s \pm O(\epsilon + \delta)\} - \sum_{C \in \mathcal{C}_i^-} w(C). \end{aligned}$$

In the last step we used the fact that for a continuous random variable X we have $\mathbf{1}\{X \leq s\} = 1 - \mathbf{1}\{X \geq s\}$. In the above calculations, the terms $O(\epsilon + \delta)$ may be different depending on C but we may choose them small enough so that they are all less than $s/2$. Note that $\sum_{C \in \mathcal{C}_i^-} w(C)$ is a constant which does not affect the variance. So, we can apply Lemma 26 and obtain

$$\mathrm{Var}[W_{i,0} - W_{i,1} \mid \mathbf{r} \cdot \mathbf{v}_i^{\perp} = t] = W_i^2 \cdot \Omega(d^{-1}).$$

It follows that

$$\begin{aligned}\mathbb{E}[|W_{i,0} - W_{i,1}| \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp} = t] &\geq \frac{1}{W_i}\cdot\mathbb{E}[(W_{i,0}-W_{i,1})^2 \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}=t]\\ &\geq \frac{1}{W_i}\cdot\mathrm{Var}[W_{i,0}-W_{i,1}\mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}=t]\\ &= W_i\cdot\Omega(d^{-1}).\end{aligned}$$

◀

▶ **Lemma 17.** *For every i and $t \in (f(b_i)-\epsilon, f(b_i)+\epsilon)$ we have $\mathbb{E}\left[W_{i,*} \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}=t\right] = \Theta(\epsilon\cdot W_i)$ where the constant in Θ can be chosen independently from t.*

Proof. Consider a constraint $C \in \mathcal{C}_i$ involving i and some other variable j, represented by the configuration $\theta = (b_i, b_j, b_{ij}, P)$. As computed in the proof of Lemma 16, we have that j is unassigned if and only if

$$\frac{-\rho(\theta)\mathbf{r}\cdot\mathbf{v}_i^{\perp} + f(b_j) - \epsilon}{\sqrt{1-\rho(\theta)^2}} < \mathbf{r}\cdot\mathbf{v}_j^{\perp\{0,i\}} < \frac{-\rho(\theta)\mathbf{r}\cdot\mathbf{v}_i^{\perp} + f(b_j) + \epsilon}{\sqrt{1-\rho(\theta)^2}}.$$

This is an interval of length $\Theta(\epsilon)$. It follows that

$$\mathbb{E}\left[\mathbf{1}\{C\in\mathcal{C}_{i,*}\} \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}=t\right] = \Theta(\epsilon),$$

and therefore

$$\mathbb{E}\left[W_{i,*} \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}=t\right] = \mathbb{E}\left[\sum_{C\in\mathcal{C}} w(C)\mathbf{1}\{C\in\mathcal{C}_{i,*}\} \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}=t\right] = \Theta(\epsilon\cdot W_i).$$

◀

▶ **Lemma 18** (Local gains)**.** *Choose $\epsilon = cd^{-1}\log^{-1}(d)$ for some sufficiently small constant $c>0$. Then, for every variable i, we have $\mathbb{E}[\Delta_i \mid A_*(i)=*] = W_i\cdot\Omega(d^{-1})$.*

Proof. It is sufficient to show that

$$\mathbb{E}[\Delta_i \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}=t] = W_i\cdot\Omega(d^{-1})$$

either for every $t\in(f(b_i)-\epsilon, f(b_i))$ or for every $t\in(f(b_i), f(b_i)+\epsilon)$.

From the definition

$$\begin{aligned}\Delta_i = (W_{i,0}-W_{i,1}-W_{i,*})_+ &\cdot \mathbf{1}\{\mathbf{r}\cdot\mathbf{v}_i^{\perp}\in(f(b_i), f(b_i)+\epsilon)\}\\ + (W_{i,1}-W_{i,0}-W_{i,*})_+ &\cdot \mathbf{1}\{\mathbf{r}\cdot\mathbf{v}_i^{\perp}\in(f(b_i)-\epsilon, f(b_i))\}\end{aligned}$$

we have

$$\begin{aligned}&\mathbb{E}[\Delta_i \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}\in(f(b_i), f(b_i)+\epsilon)]\\ &= \mathbb{E}\left[(W_{i,0}-W_{i,1}-W_{i,*})_+ \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}\in(f(b_i), f(b_i)+\epsilon)\right]\\ &\geq \mathbb{E}\left[(W_{i,0}-W_{i,1})_+ - W_{i,*} \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}\in(f(b_i), f(b_i)+\epsilon)\right]\\ &= \mathbb{E}\left[\frac{|W_{i,0}-W_{i,1}| + (W_{i,0}-W_{i,1})}{2} - W_{i,*} \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}\in(f(b_i), f(b_i)+\epsilon)\right],\end{aligned}$$

and similarly

$$\begin{aligned}&\mathbb{E}[\Delta_i \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}\in(f(b_i)-\epsilon, f(b_i))]\\ &\geq \mathbb{E}\left[\frac{|W_{i,1}-W_{i,0}| + (W_{i,1}-W_{i,0})}{2} - W_{i,*} \mid \mathbf{r}\cdot\mathbf{v}_i^{\perp}\in(f(b_i)-\epsilon, f(b_i))\right].\end{aligned}$$

Assume that $\mathbb{E}[W_{i,0} - W_{i,1} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i), f(b_i) + \epsilon)] \geq -W_i/(d\sqrt{\log d})$. Then by Lemma 16 and Lemma 17 we have

$$\begin{aligned}
&\mathbb{E}\left[\frac{|W_{i,0} - W_{i,1}| + (W_{i,0} - W_{i,1})}{2} - W_{i,*} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i), f(b_i) + \epsilon)\right] \\
&\geq W_i \cdot \left(\Omega(d^{-1}) - d^{-1}\log^{-1/2}(d) - O(d^{-1}\log^{-1}(d))\right) \\
&= W_i \cdot \Omega(d^{-1}).
\end{aligned}$$

Otherwise, we have $\mathbb{E}[W_{i,0} - W_{i,1} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i), f(b_i) + \epsilon)] < -W_i/(d\sqrt{\log d})$, or equivalently $\mathbb{E}[W_{i,1} - W_{i,0} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i), f(b_i) + \epsilon)] > W_i/(d\sqrt{\log d})$. Observe that by Equation (4.1) the function $\mathbb{E}[W_{i,1} - W_{i,0} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp = t]$ is $O(W_i)$-Lipschitz in t, so we have

$$\mathbb{E}[W_{i,1} - W_{i,0} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i) - \epsilon, f(b_i))] > W_i/(d\sqrt{\log d}) - \epsilon \cdot O(W_i) = W_i \cdot \Omega(d^{-1}\log^{-1/2}(d)).$$

It follows that

$$\begin{aligned}
&\mathbb{E}\left[\frac{|W_{i,1} - W_{i,0}| + (W_{i,1} - W_{i,0})}{2} - W_{i,*} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i) - \epsilon, f(b_i))\right] \\
&\geq W_i \cdot \left(\Omega(d^{-1}) + \Omega(d^{-1}\log^{-1/2}(d)) - O(d^{-1}\log^{-1}(d))\right) \\
&= W_i \cdot \Omega(d^{-1}).
\end{aligned}$$

Thus, we conclude that $\mathbb{E}[\Delta_i \mid A_*(i) = *] = W_i \cdot \Omega(d^{-1})$. ◀

We are now ready to prove Theorem 14.

Proof of Theorem 14. By Lemma 10, we have

$$\begin{aligned}
\mathbb{E}[\mathrm{Val}(I, A)] &\geq \mathsf{Soundness}_f(\mathcal{D}) + \sum_{i \in V} \mathbb{E}[\Delta_i] \\
&\geq \mathsf{Soundness}_f(\mathcal{D}) + \sum_{i \in V} \mathbb{E}[\Delta_i \mid A_*(i) = *] \cdot \Pr[A_*(i) = *] \\
&\geq \mathsf{Soundness}_f(\mathcal{D}) + \sum_{i \in V} W_i \cdot \Omega(d^{-1}) \cdot \Omega(\epsilon) \\
&\geq \mathsf{Soundness}_f(\mathcal{D}) + \Omega(d^{-2}\log^{-1} d).
\end{aligned}$$

Here we used the assumption that $\sum_{i \in V} W_i = 2$ (since total weight is 1 and each constraint is counted twice) and Lemma 18. ◀

5 Analysis for General Boolean MAX 2-CSPs

In this section we analyze general Boolean MAX 2-CSPs. To this end we need the distribution of configurations to be *reasonable* as introduced below.

▶ **Definition 19.** *We say that two predicates $P_1, P_2 : \{-1,1\}^2 \to \{0,1\}$ are* aligned *if there exist $\sigma_1, \sigma_2 \in \{-1,1\}$ and $s \in \{0,1\}$ such that*

$$P_1(-1, \sigma_1) = P_2(-\sigma_2, \sigma_1\sigma_2) = s \quad \text{and} \quad P_1(1, \sigma_1) = P_2(\sigma_2, \sigma_1\sigma_2) = 1 - s.$$

We say that they are anti-aligned *if there exist $\sigma_1, \sigma_2 \in \{-1,1\}$ and $s \in \{0,1\}$ such that*

$$P_1(-1, \sigma_1) = P_2(\sigma_2, \sigma_1\sigma_2) = s \quad \text{and} \quad P_1(1, \sigma_1) = P_2(-\sigma_2, \sigma_1\sigma_2) = 1 - s.$$

Informally, if we look at two constraints with one variable in common, then they are aligned if there is a way to fix the other variables to induce the same unary preference on the shared variable, and they are anti-aligned if they induce opposite unary preferences.

▶ **Definition 20.** *We say that a distribution of configurations $\mathcal{D}$ representing some SDP solution is* reasonable *if the following conditions hold:*

- *For every $\theta = (b_i, b_j, b_{ij}, P) \in \mathrm{supp}(\mathcal{D})$, we have $|b_i|, |b_j| \le 0.4$ and $|b_{ij}| \in [0.5, 0.9]$.*
- *If $\theta_1 = (b_i, b_j, b_{ij}, P_1), \theta_2 = (b_i, b_k, b_{ik}, P_2) \in \mathrm{supp}(\mathcal{D})$ represent some constraints (P_1, i, j) and (P_2, i, k), then $\rho(\theta_1)\rho(\theta_2) \ge 0$ if P_1 and P_2 are aligned and $\rho(\theta_1)\rho(\theta_2) \le 0$ if P_1 and P_2 are anti-aligned.*

▶ Remark 21. The conditions for reasonableness may seem somewhat arbitrary. Indeed, the constants are chosen only for convenience: with these values we are able to prove bounds on the covariances as in Lemma 22. That said, it may be verified that the hardest (optimal under UGC) distributions for MAX CUT and MAX 2-SAT are both reasonable. Furthermore, the known (numerically) hardest distributions (though not known to be optimal) for MAX 2-AND and MAX DI-CUT due to [7] are also reasonable.

The main benefit of reasonableness is the following bound on covariances in a local neighborhood. The proof of this lemma is deferred to the end of this section.

▶ **Lemma 22.** *Let $\mathcal{D}$ be a reasonable distribution of configurations representing some SDP solution $\{\mathbf{v}_i \mid i \in \{0\} \cup [n]\}$ which satisfies all triangle inequalities. Let $\theta_1 = (b_i, b_j, b_{ij}, P_1), \theta_2 = (b_i, b_k, b_{ik}, P_2) \in \mathrm{supp}(\mathcal{D})$ be two configurations representing some constraints (P_1, i, j) and (P_2, i, k). If P_1 and P_2 are aligned, then $\mathbf{v}_j^{\perp\{0,i\}} \cdot \mathbf{v}_k^{\perp\{0,i\}} \ge -5/6$. If P_1 and P_2 are anti-aligned, then $\mathbf{v}_j^{\perp\{0,i\}} \cdot \mathbf{v}_k^{\perp\{0,i\}} \le 5/6$.*

Under the reasonableness condition, we prove the following theorem.

▶ **Theorem 23.** *Let $\mathcal{P}$ be a set of Boolean predicates of arity 2 such that every $P \in \mathcal{P}$ depends on both coordinates. Let $d \in \mathbb{N}$, and $B > 0$. Let I be an instance of* MAX CSP($\mathcal{P}$) *such that every variable appears in at most d constraints. Let $\mathcal{D}$ be a reasonable distribution of configurations corresponding to an SDP solution satisfying all triangle inequalities. Then, for some $\epsilon = \Theta(d^{-2}\log^{-2}(d))$ and any $f : [-1, 1] \to [-B, B]$, Algorithm 1 returns an assignment to I that satisfies at least $\mathsf{Soundness}_f(\mathcal{D}) + \Omega(d^{-4}\log^{-7/2} d)$ fraction of constraints, where the constant inside the Ω notation depends only on $\mathcal{P}$ and B.*

We will implicitly assume the assumptions in Theorem 23 in our analysis for the remainder of the section. We use A_* to denote the (partial) assignment A before the execution of the for-loop at Line 8. The overall idea is similar to Theorem 14: we show that $W_{i,0} - W_{i,1}$ has a large variance which overwhelms the expected value of $W_{i,*}$, and therefore at least one of the two terms in Δ_i will have a nontrivial contribution. The variance lower bound for $W_{i,0} - W_{i,1}$ is shown in the following lemma.

▶ **Lemma 24.** *There exist $c, \epsilon_0 > 0$ (depending only on the configurations and the threshold function f) such that for any $\epsilon < \epsilon_0$, $i \in V$ and any $t \in (f(b_i) - \epsilon, f(b_i) + \epsilon)$, we have*

$$\mathbb{E}[|W_{i,0} - W_{i,1}| \mid \mathbf{r} \cdot \mathbf{v}_i^{\perp} = t] \ge \frac{c \cdot W_i}{d^2 \log^{3/2} d}.$$

Proof. We have

$$W_{i,0} - W_{i,1} = \sum_{C \in \mathcal{C}_i} w(C) \left(\mathbf{1}\{C \in \mathcal{C}_{i,0}\} - \mathbf{1}\{C \in \mathcal{C}_{i,1}\}\right).$$

Let $C \in \mathcal{C}_i$ be a constraint on i and some other variable j, represented by the configuration $\theta = (b_i, b_j, b_{ij}, P)$. Observe that since by assumption P depends on both variables, the indicator functions $\mathbf{1}\{C \in \mathcal{C}_{i,0}\}$ and $\mathbf{1}\{C \in \mathcal{C}_{i,1}\}$ are two distinct functions among the three functions $\mathbf{1}\{A_*(j) = \texttt{true}\}$, $\mathbf{1}\{A_*(j) = \texttt{false}\}$, and 0 (as a constant function). Conditioned on $\mathbf{r} \cdot \mathbf{v}_i^{\perp} = t$, we may write the first two indicators as $\mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}} \geq s_j\}$, $\mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}} \leq s'_j\}$, where s_j, s'_j are some thresholds whose absolute values are bounded due to our reasonableness assumption (the expressions for these thresholds are the same as those in (4.1)). By using the fact that $\mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}} \leq s'_j\} = 1 - \mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}} \geq s'_j\}$, we may therefore rewrite (5) as

$$W_{i,0} - W_{i,1} = \sum_{j \in J_1} w_j \mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}} \geq s_j\} - \sum_{j \in J_2} w_j \mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}} \geq s'_j\} + c$$

where J_1, J_2 are some (multi-)sets of variables and c is some constant. We also have $\sum_{j \in J_1} w_j + \sum_{j \in J_2} w_j \in [W_i, 2W_i]$ since each constraint contributes either 1 or 2 nonzero indicator functions.

Now we aim to bound the inner products between the $\mathbf{v}_j^{\perp\{0,i\}}$ vectors, which are equivalently the covariances between the standard Gaussian variables $\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}}$. Take another constraint C' involving i and some third variable k, represented by $\theta' = (b_i, b_k, b_{ik}, P')$. Then P and P' are aligned if there exist $s \in \{0,1\}$ and $\mathtt{s} \in \{\texttt{true}, \texttt{false}\}$ such that

$$\mathbf{1}\{C \in \mathcal{C}_{i,s}\} = \mathbf{1}\{A_*(j) = \mathtt{s}\} \quad \text{and} \quad \mathbf{1}\{C' \in \mathcal{C}_{i,s}\} = \mathbf{1}\{A_*(k) = \mathtt{s}\},$$

or

$$\mathbf{1}\{C \in \mathcal{C}_{i,s}\} = \mathbf{1}\{A_*(j) = \mathtt{s}\} \quad \text{and} \quad \mathbf{1}\{C' \in \mathcal{C}_{i,1-s}\} = \mathbf{1}\{A_*(k) = \texttt{not } \mathtt{s}\},$$

where we used $\texttt{not } \mathtt{s}$ to mean the truth value other than $\mathtt{s}$. These are exactly the cases where we get both $j, k \in J_1$ or $j, k \in J_2$. By Lemma 22, we have $\mathbf{v}_j^{\perp\{0,i\}} \cdot \mathbf{v}_k^{\perp\{0,i\}} \geq -5/6$ if P and P' are aligned. On the other hand, P and P' are anti-aligned if there exist $s \in \{0,1\}$ and $\mathtt{s} \in \{\texttt{true}, \texttt{false}\}$ such that

$$\mathbf{1}\{C \in \mathcal{C}_{i,s}\} = \mathbf{1}\{A_*(j) = \mathtt{s}\} \quad \text{and} \quad \mathbf{1}\{C' \in \mathcal{C}_{i,s}\} = \mathbf{1}\{A_*(k) = \texttt{not } \mathtt{s}\},$$

or

$$\mathbf{1}\{C \in \mathcal{C}_{i,s}\} = \mathbf{1}\{A_*(j) = \mathtt{s}\} \quad \text{and} \quad \mathbf{1}\{C' \in \mathcal{C}_{i,1-s}\} = \mathbf{1}\{A_*(k) = \mathtt{s}\}.$$

These are exactly the cases where one of $\{j, k\}$ is in J_1 and the other is in J_2. Again by Lemma 22, we have $\mathbf{v}_j^{\perp\{0,i\}} \cdot \left(-\mathbf{v}_k^{\perp\{0,i\}}\right) \geq -5/6$ if P and P' are anti-aligned.

Hence, by rewriting

$$\begin{aligned} W_{i,0} - W_{i,1} &= \sum_{j \in J_1} w_j \mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}} \geq s_j\} - \sum_{j \in J_2} w_j \mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}} \geq s'_j\} + c \\ &= \sum_{j \in J_1} w_j \mathbf{1}\{\mathbf{r} \cdot \mathbf{v}_j^{\perp\{0,i\}} \geq s_j\} + \sum_{j \in J_2} w_j \mathbf{1}\{\mathbf{r} \cdot (-\mathbf{v}_j^{\perp\{0,i\}}) \geq -s'_j\} - \sum_{j \in J_2} w_j + c, \end{aligned}$$

we obtain an expression which is the weighted sum of indicators of the form $\mathbf{1}\{g_j \geq s''_j\}$ (plus some constant) where g_j's are correlated standard Gaussians and the covariances between them are all at least $-5/6$. We can therefore apply Lemma 28, which gives us

$$\mathrm{Var}[W_{i,0} - W_{i,1} \mid \mathbf{r} \cdot \mathbf{v}_i^{\perp} = t] \geq \Omega\left(\frac{W_i^2}{d^2 \log^{3/2} d}\right).$$

Since $|W_{i,0} - W_{i,1}| \le W_i$, we have

$$\mathbb{E}[|W_{i,0} - W_{i,1}| \mid \mathbf{r} \cdot \mathbf{v}_i^\perp = t] \ge \frac{1}{W_i}\,\mathbb{E}[(W_{i,0} - W_{i,1})^2 \mid \mathbf{r} \cdot \mathbf{v}_i^\perp = t] \ge \Omega\left(\frac{W_i}{d^2 \log^{3/2} d}\right). \quad \blacktriangleleft$$

▶ **Lemma 25** (Local gains). *Choose $\epsilon = cd^{-2}\log^{-2}(d)$ for some sufficiently small constant $c > 0$. Then, for every variable i, we have $\mathbb{E}[\Delta_i \mid A_*(i) = *] = W_i \cdot \Omega(d^{-2}\log^{-3/2}(d))$.*

Proof. As in the proof of Lemma 18, it is sufficient to show that

$$\mathbb{E}[\Delta_i \mid \mathbf{r} \cdot \mathbf{v}_i^\perp = t] = W_i \cdot \Omega(d^{-2}\log^{-3/2}(d))$$

either for every $t \in (f(b_i) - \epsilon, f(b_i))$ or for every $t \in (f(b_i), f(b_i) + \epsilon)$.

As in Lemma 17, we have $\mathbb{E}\left[W_{i,*} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp = t\right] = \Theta(\epsilon \cdot W_i)$. Assume that $\mathbb{E}[W_{i,0} - W_{i,1} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i), f(b_i) + \epsilon)] \ge -W_i \cdot d^{-2} \cdot \log^{-2}(d)$. Then by Lemma 24 we have

$$\begin{aligned}
&\mathbb{E}[\Delta_i \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i), f(b_i) + \epsilon)] \\
&\ge \mathbb{E}\left[\frac{|W_{i,0} - W_{i,1}| + (W_{i,0} - W_{i,1})}{2} - W_{i,*} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i), f(b_i) + \epsilon)\right] \\
&\ge W_i \cdot \Big(\Omega(d^{-2}\log^{-3/2}(d)) - d^{-2}\log^{-2}(d) - O(d^{-2}\log^{-2}(d))\Big) \\
&= W_i \cdot \Omega(d^{-2}\log^{-3/2}(d)).
\end{aligned}$$

Otherwise, we have $\mathbb{E}[W_{i,0} - W_{i,1} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i), f(b_i) + \epsilon)] < -W_i \cdot d^{-2} \cdot \log^{-2}(d)$, or equivalently $\mathbb{E}[W_{i,1} - W_{i,0} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i), f(b_i) + \epsilon)] > W_i \cdot d^{-2} \cdot \log^{-2}(d)$. Since the function $\mathbb{E}[W_{i,1} - W_{i,0} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp = t]$ is $O(W_i)$-Lipschitz in t, we have

$$\mathbb{E}[W_{i,1} - W_{i,0} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i) - \epsilon, f(b_i))] > W_i \cdot d^{-2}\log^{-2}(d) - \epsilon \cdot O(W_i) \ge -W_i \cdot O(d^{-2}\log^{-2}(d)).$$

It follows that

$$\begin{aligned}
&\mathbb{E}[\Delta_i \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i) - \epsilon, f(b_i))] \\
&\ge \mathbb{E}\left[\frac{|W_{i,1} - W_{i,0}| + (W_{i,1} - W_{i,0})}{2} - W_{i,*} \mid \mathbf{r} \cdot \mathbf{v}_i^\perp \in (f(b_i) - \epsilon, f(b_i))\right] \\
&\ge W_i \cdot \Big(\Omega(d^{-2}\log^{-3/2}(d)) - O(d^{-2}\log^{-2}(d)) - O(d^{-2}\log^{-2}(d))\Big) \\
&= W_i \cdot \Omega(d^{-2}\log^{-3/2}(d)).
\end{aligned}$$

Thus, we conclude $\mathbb{E}[\Delta_i \mid A_*(i) = *] = W_i \cdot \Omega(d^{-2}\log^{-3/2}(d))$. $\blacktriangleleft$

Proof of Theorem 23. Follows similarly as in the proof of Theorem 14. By Lemma 10, we have

$$\begin{aligned}
\mathbb{E}[\mathrm{Val}(I, A)] &\ge \mathsf{Soundness}_f(\mathcal{D}) + \sum_{i \in V} \mathbb{E}[\Delta_i] \\
&\ge \mathsf{Soundness}_f(\mathcal{D}) + \sum_{i \in V} \mathbb{E}[\Delta_i \mid A_*(i) = *] \cdot \Pr[A_*(i) = *] \\
&\ge \mathsf{Soundness}_f(\mathcal{D}) + \sum_{i \in V} W_i \cdot \Omega(d^{-2}\log^{-3/2}(d)) \cdot \Omega(\epsilon) \\
&\ge \mathsf{Soundness}_f(\mathcal{D}) + \Omega(d^{-4}\log^{-7/2} d).
\end{aligned}$$

$\blacktriangleleft$

5.1 Proof of Lemma 22

We only prove the case where P_1 and P_2 are aligned since the anti-aligned case can be reduced to the aligned case by negating the variable k as well as $\mathbf{v}_k$. Assume that P_1 and P_2 are aligned. Then, since $\mathcal{D}$ is reasonable, we have $\rho(\theta_1)\rho(\theta_2) \geq 0$, $|b_i|, |b_j|, |b_k| \leq 0.4$ and $|b_{ij}|, |b_{ik}| \geq 0.5$. This implies that $|b_{ij}| \geq |b_i||b_j|$, and therefore b_{ij} and $\rho(\theta_1) = \frac{b_{ij}-b_ib_j}{\sqrt{(1-b_i^2)(1-b_j^2)}}$ have the same sign. We may then by possibly negating $\mathbf{v}_i$ assume that $b_{ij}, b_{ik}, \rho(\theta_1), \rho(\theta_2) \geq 0$.

For $\ell \in \{j,k\}$, let $\mathbf{u}_\ell^{\perp\{0,i\}}$ be the component of $\mathbf{v}_\ell$ parallel to $\mathbf{v}_\ell^{\perp\{0,i\}}$, so we have

$$\mathbf{u}_\ell^{\perp\{0,i\}} = \sqrt{1-b_\ell^2}\mathbf{v}_\ell^\perp - \frac{b_{i\ell}-b_ib_\ell}{\sqrt{1-b_i^2}}\mathbf{v}_i^\perp.$$

It follows that

$$\|\mathbf{u}_\ell^{\perp\{0,i\}}\|^2 = 1 - b_\ell^2 - \frac{(b_{i\ell}-b_ib_\ell)^2}{1-b_i^2}$$

for $\ell \in \{j,k\}$, and

$$\mathbf{u}_j^{\perp\{0,i\}} \cdot \mathbf{u}_k^{\perp\{0,i\}} = (b_{jk}-b_jb_k) - \frac{(b_{ij}-b_ib_j)(b_{ik}-b_ib_k)}{1-b_i^2}.$$

For $\sigma \in \{-1,1\}$ and $\ell \in \{j,k\}$, let us define

$$p_\sigma = \frac{1+\sigma b_i}{2}, \quad \text{and} \quad q_{\sigma,\ell} = \frac{1+\sigma b_i - \sigma b_\ell - b_{i\ell}}{2(1+\sigma b_i)}.$$ [4]

By the triangle inequalities, we have $1 - b_i + b_\ell - b_{i\ell} \geq 0$, so $b_\ell \geq -1 + b_i + b_{i\ell} \geq -0.5 + b_i$. Since $|b_\ell| \leq 0.4$, we have $b_\ell \geq \max(-0.4, -0.5+b_i)$. So we have

$$q_{+1,\ell} = \frac{1+b_i-b_\ell-b_{i\ell}}{2(1+b_i)} \leq \frac{1+b_i-\max(-0.4,-0.5+b_i)-0.5}{2(1+b_i)}.$$

When $b_i \geq 0.1$, the right hand side above is $\frac{1}{2(1+b_i)} \leq \frac{5}{11}$. When $b_i \leq 0.1$, the right hand side above is $\frac{0.9+b_i}{2(1+b_i)} = \frac{1}{2} - \frac{0.1}{2(1+b_i)} \leq \frac{5}{11}$. So in either case we obtain $q_{+1,\ell} \leq \frac{5}{11}$. Similarly, for $q_{-1,\ell}$ we use the triangle inequality $1+b_i-b_\ell-b_{i\ell} \geq 0$, from which we deduce $b_\ell \leq \min(0.4, 0.5+b_i)$, and therefore

$$q_{-1,\ell} = \frac{1-b_i+b_\ell-b_{i\ell}}{2(1-b_i)} \leq \frac{1-b_i+\min(0.4,0.5+b_i)-0.5}{2(1-b_i)}.$$

When $b_i \leq -0.1$, the right hand side above is $\frac{1}{2(1-b_i)} \leq \frac{5}{11}$. When $b_i \geq -0.1$, the right hand side above is $\frac{0.9-b_i}{2(1-b_i)} = \frac{1}{2} - \frac{0.1}{2(1-b_i)} \leq \frac{5}{11}$. So in either case we obtain $q_{-1,\ell} \leq \frac{5}{11}$.

Now let's relate the quantities $p_\sigma, q_{\sigma,\ell}$ to the SDP vectors. We have

$$\begin{aligned}
\sum_{\sigma\in\{-1,1\}} p_\sigma q_{\sigma,\ell}(1-q_{\sigma,\ell}) &= \sum_{\sigma\in\{-1,1\}} \frac{1+\sigma b_i}{2} \cdot \frac{(1+\sigma b_i)^2 - (\sigma b_\ell + b_{i\ell})^2}{4(1+\sigma b_i)^2} \\
&= \frac{1}{4}\left(1 - \frac{(b_\ell+b_{i\ell})^2}{2(1+b_i)} - \frac{(b_\ell-b_{i\ell})^2}{2(1-b_i)}\right) \\
&= \frac{1}{4}\|\mathbf{u}_\ell^{\perp\{0,i\}}\|^2,
\end{aligned}$$

as well as

$$\begin{aligned}
&\sum_{\sigma\in\{-1,1\}} p_\sigma q_{\sigma,j} q_{\sigma,k} \\
&= \sum_{\sigma\in\{-1,1\}} \frac{(1+\sigma b_i - \sigma b_j - b_{ij})(1+\sigma b_i - \sigma b_k - b_{ik})}{8(1+\sigma b_i)} \\
&= \sum_{\sigma\in\{-1,1\}} \frac{1}{4}\left(\frac{1+\sigma b_i - (\sigma b_j + b_{ij} + \sigma b_k + b_{ik})}{2} + \frac{(b_j+\sigma b_{ij})(b_k+\sigma b_{ik})}{2(1+\sigma b_i)}\right) \\
&= \frac{1}{4}\left(1 - b_{ij} - b_{ik} + \frac{(b_j+b_{ij})(b_k+b_{ik})}{2(1+b_i)} + \frac{(b_j-b_{ij})(b_k-b_{ik})}{2(1-b_i)}\right) \\
&= \frac{1}{4}\left(1 - b_{ij} - b_{ik} + b_j b_k + \frac{(b_{ij}-b_i b_j)(b_{ik}-b_i b_k)}{1-b_i^2}\right) \\
&= \frac{1}{4}\left(1 - b_{ij} - b_{ik} + b_{jk} - \mathbf{u}_j^{\perp\{0,i\}} \cdot \mathbf{u}_k^{\perp\{0,i\}}\right) \\
&\geq -\frac{1}{4}\mathbf{u}_j^{\perp\{0,i\}} \cdot \mathbf{u}_k^{\perp\{0,i\}}.
\end{aligned}$$

Here the last inequality is due to the triangle inequalities.

Observe that since $q_{\sigma,\ell} \leq \alpha$ where $\alpha = \frac{5}{11}$ for every $\sigma \in \{-1,1\}, \ell \in \{j,k\}$, we have

$$q_{\sigma,j} q_{\sigma,k} \leq \frac{\alpha}{1-\alpha}\sqrt{q_{\sigma,j}(1-q_{\sigma,j}) q_{\sigma,k}(1-q_{\sigma,k})}$$

and therefore

$$\begin{aligned}
&\sum_{\sigma\in\{-1,1\}} p_\sigma q_{\sigma,j} q_{\sigma,k} \\
&\leq \frac{\alpha}{1-\alpha} \cdot \sum_{\sigma\in\{-1,1\}} p_\sigma \sqrt{q_{\sigma,j}(1-q_{\sigma,j}) q_{\sigma,k}(1-q_{\sigma,k})} \\
&\leq \frac{\alpha}{1-\alpha} \cdot \sqrt{\left(\sum_{\sigma\in\{-1,1\}} p_\sigma q_{\sigma,j}(1-q_{\sigma,j})\right)} \sqrt{\left(\sum_{\sigma\in\{-1,1\}} p_\sigma q_{\sigma,k}(1-q_{\sigma,k})\right)},
\end{aligned}$$

where the last inequality is due to Cauchy-Schwarz. Thus, we have

$$\begin{aligned}
&\mathbf{u}_j^{\perp\{0,i\}} \cdot \mathbf{u}_k^{\perp\{0,i\}} \\
&\geq -4 \sum_{\sigma\in\{-1,1\}} p_\sigma q_{\sigma,j} q_{\sigma,k} \\
&\geq -4 \cdot \frac{\alpha}{1-\alpha} \cdot \sqrt{\left(\sum_{\sigma\in\{-1,1\}} p_\sigma q_{\sigma,j}(1-q_{\sigma,j})\right)} \sqrt{\left(\sum_{\sigma\in\{-1,1\}} p_\sigma q_{\sigma,k}(1-q_{\sigma,k})\right)} \\
&= -\frac{\alpha}{1-\alpha} \cdot \|\mathbf{u}_j^{\perp\{0,i\}}\| \|\mathbf{u}_k^{\perp\{0,i\}}\|
\end{aligned}$$

By shifting the factors, we obtain

$$\mathbf{v}_j^{\perp\{0,i\}} \cdot \mathbf{v}_k^{\perp\{0,i\}} = \frac{\mathbf{u}_j^{\perp\{0,i\}} \cdot \mathbf{u}_k^{\perp\{0,i\}}}{\|\mathbf{u}_j^{\perp\{0,i\}}\| \|\mathbf{u}_k^{\perp\{0,i\}}\|} \geq -\frac{\alpha}{1-\alpha} = -\frac{5}{6}.$$

This completes the proof.

A Variance of Sums of Gaussian Threshold Indicator Functions

In this appendix, we study the variance of functions of the form

$$\sum_{i=1}^{d} w_i \mathbf{1}\{g_i \geq s_i\},$$

where $(g_1, \ldots, g_d)$ is a centered Gaussian vector with unit variances, $s_1, \ldots, s_d \in \mathbb{R}$ are some thresholds for the Gaussians, and $w_1, \ldots, w_d \geq 0$ are some nonzero weights. We state a few different versions with different assumptions on the covariance structure or on the thresholds. They will be used to show that there is sufficient variance in a local neighborhood of a bounded-degree MAX 2-CSP instance for an algorithm to exploit, generalizing Lemma 7 from [15] which served a similar purpose for MAX CUT. Due to the page limit, we defer the proofs in this section to the full version of the paper.

In the first version, there is no assumption on the covariance structure but the thresholds are assumed to be close to some nonzero real number.

▶ **Lemma 26.** *Let $(g_1, \ldots, g_d)$ be a centered Gaussian vector with unit variances. Let $s \in \mathbb{R}$ be nonzero, $\delta = |s|/2$, $s_1, \ldots, s_d \in (s - \delta, s + \delta)$, and $w_1, \ldots, w_d \in \mathbb{R}^{\geq 0}$, then we have*

$$\operatorname{Var}\left[\sum_{i=1}^{d} w_i \cdot \mathbf{1}\{g_i \geq s_i\}\right] = \left(\sum_{i=1}^{d} w_i\right)^2 \cdot \Omega(d^{-1}),$$

where the constant inside Ω depends only on s.

In the second version we assume that the covariances are somewhat bounded away from 1 in absolute value, and that the thresholds are also absolutely bounded.

▶ **Lemma 27.** *Fix some constants $B > 0$. Let $(g_1, \ldots, g_d)$ be a centered Gaussian vector with unit variances and pairwise covariances in $\left[-1 + \frac{1}{d^2 \log^2 d}, 1 - \frac{1}{d^2 \log^2 d}\right]$. Let $s_1, \ldots, s_d \in [-B, B]$ and $w_1, \ldots, w_d \in \mathbb{R}^{\geq 0}$, then we have*

$$\operatorname{Var}\left[\sum_{i=1}^{d} w_i \cdot \mathbf{1}\{g_i \geq s_i\}\right] = \left(\sum_{i=1}^{d} w_i\right)^2 \cdot \Omega(d^{-2} \log^{-3/2} d),$$

where the constant inside Ω depends only on B.

In the last version, we assume that the covariances are bounded away from -1 by a constant, and again the thresholds are bounded in absolute value.

▶ **Lemma 28.** *Fix some constants $\eta, B > 0$. Let $(g_1, \ldots, g_d)$ be a centered Gaussian vector with unit variances and pairwise covariances at least $-1 + \eta$. Let $s_1, \ldots, s_d \in [-B, B]$ and $w_1, \ldots, w_d \in \mathbb{R}^{\geq 0}$, then we have*

$$\operatorname{Var}\left[\sum_{i=1}^{d} w_i \cdot \mathbf{1}\{g_i \geq s_i\}\right] = \left(\sum_{i=1}^{d} w_i\right)^2 \cdot \Omega(d^{-2} \log^{-3/2} d),$$

where the constant inside Ω depends only on η and B.

Incremental Consistent k-Center Clustering

Mara Grilnberger
Department of Computer Science, University of Salzburg, Austria

Antonis Skarlatos
Department of Computer Science, University of Warwick, Coventry, UK

Abstract

In the incremental consistent k-center clustering problem, we are given a sequence of adversarial point insertions and aim to maintain a k-center solution with small approximation ratio and small recourse. In this work, we explore the following question: what is the best approximation ratio of a polynomial-time algorithm with a worst-case recourse of 1? Our result improves upon the 6-approximation algorithm of Forster and Skarlatos [SODA '25], which itself improved over the 8-approximation algorithm of Charikar, Chekuri, Feder, and Motwani [STOC '97]. Moreover, we show that any incremental k-center algorithm that achieves an approximation ratio strictly less than $\sqrt{2}$ requires a worst-case recourse of k.

1 Introduction

Clustering is a fundamental problem in data analysis and classification. One of the most classical k-clustering problems is the k-center problem, which has been studied in various settings [15, 9, 2]. Given a metric space $(\mathcal{X}, \text{dist})$, a set of points $P \subseteq \mathcal{X}$ with $|P| = n$, and an integer $k \leq n$, the goal of the k-center problem is to output a subset $S \subseteq P$ of at most k points, called *centers*, such that the maximum distance from every point in P to its closest center is minimized. The k-center problem admits polynomial-time 2-approximation algorithms [16, 12], and it is known to be NP-hard to approximate the k-center objective within a factor of $(2 - \epsilon)$ for any constant $\epsilon > 0$ [17].

In the *fully dynamic* setting, the adversary can insert and delete points. In the *partially dynamic* setting, only one type of adversarial update – either insertions or deletions – is allowed. For example, in the *incremental* setting, the set of centers S is maintained under adversarial point insertions into P. The k-clustering problems in the dynamic setting with recourse have attracted a lot of attention [7, 19, 10, 11, 6, 5, 14].

Worst-case recourse

The *worst-case recourse* is the number of replacements made to the set of centers after any adversarial point update. In general, worst-case guarantees are crucial in real-time systems, and extensive research efforts have focused on achieving them [8, 3, 20, 4, 1, 14, 13]. From a theoretical perspective, minimizing worst-case recourse is a fundamental combinatorial problem, as it captures how smoothly solutions adapt in response to adversarial updates. From a practical standpoint, consider a scenario where the centers are used for an expensive task, and any modification to the solution introduces latency. Amortized recourse guarantees may still allow occasional long delays, whereas worst-case recourse guarantees ensure that no significant delays occur at any step.

To understand the limitations of recourse, an interesting direction is to study the best approximation ratio achievable by a polynomial-time algorithm with optimal recourse bounds. Fully dynamic algorithms with small recourse tend to have large approximation ratios. Hence, it is natural to study the incremental setting when the recourse is optimal – namely, a worst-case recourse of 1.

1.1 Upper Bounds

The area of research focusing on optimizing the recourse is commonly referred to as *consistent clustering*, a concept introduced by Lattanzi and Vassilvitskii [19]. In the incremental consistent setting, the "doubling algorithm" of Charikar, Chekuri, Feder, and Motwani [7] achieves an 8-approximation; their incremental algorithm maintains k clusters and only permits merging two clusters. The same work also presents a 6-approximation algorithm that requires solving the NP-hard clique partition problem as a subroutine. More recently, Forster and Skarlatos [11] obtained a 6-approximation algorithm in the incremental setting with a worst-case recourse of 1 and a worst-case update time of $O(k^2)$.[1] To compare their incremental algorithm with the "doubling algorithm", the authors in [11] showed that a slightly modified version of the latter [7] admits a worst-case recourse of 1 as well. In this direction, we improve upon prior work by reducing the approximation ratio to $3+\sqrt{5} \approx 5.23$.

▶ **Theorem 1.** *There is a deterministic incremental algorithm for the k-center clustering problem that, given a point set P in a metric space subject to point insertions and an integer $k \geq 1$, maintains a subset of points $S \subseteq P$ with $|S| = k$ such that:*

- *The set S is a $(3+\sqrt{5})$-approximate k-center solution.*
- *The worst-case recourse is at most 1.*
- *The worst-case update time is $O(k^2)$.*

Interestingly, our improved approximation ratio beats even the randomized algorithm of [7], which yields a $2e \approx 5.43$ approximation. As a result, our deterministic algorithm improves on a longstanding bound from more than 25 years ago. To obtain this improvement, motivated by the idea of [11] to combine the two standard static k-center algorithms – Gonzalez's algorithm and the Hochbaum–Shmoys algorithm [16] – we introduce new ideas and provide a more fine-grained and sophisticated analysis of the approximation ratio.

[1] The main result of [11] is, however, their fully dynamic algorithm.

1.2 Lower Bounds

Another interesting direction is to find the best approximation ratio for some fixed worst-case recourse bound. While there are results giving lower bounds on amortized recourse [19], namely a lower bound of $\Omega(\frac{k \log n}{n})$ changes, nothing is known about lower bounds for worst-case recourse. We initiate this line of work by proving the following theorem for the partially dynamic setting.

▶ **Theorem 2.** *Consider a point set P in a metric space subject to point insertions, an integer $k \geq 1$, and an approximation factor $\alpha \in [1, \sqrt{2})$. Then any partially dynamic α-approximate k-center algorithm has a worst-case recourse of k.*

Recently, Kozma [18] investigates the *nested* setting, where the k-center solution has to be built center by center, giving a good solution at each step (where the number of centers is at most k). While this differs from the incremental setting that we consider, two of the presented lower bounds transfer to "our" incremental setting, where we allow adversarial point insertions. This is because the adversary can add $k-1$ points to their examples that are at a distance "infinity" from all other points, leaving less centers for the original points at each insertion. Once the number of centers on the original points becomes small enough, by their arguments, the same bounds follow. As a result, the actual lower bound for an approximation factor is at least $2\cos\left(\frac{\pi}{7}\right)$ (see Section 2.2 in [18]).

2 Preliminaries

Consider a point set P in a metric space $(\mathcal{X}, \mathrm{dist})$ with $|P| = n$. We omit the notation $(\mathcal{X}, \mathrm{dist})$ when the context is clear. For each point $p \in P$ and each subset $S \subseteq P$, the *distance* from p to S is equal to $\mathrm{dist}(p, S) \coloneqq \min_{q \in S} \mathrm{dist}(p, q)$.

▶ **Definition 3** (k-center clustering problem)**.** *Given a point set P in a metric space and an integer $k \geq 1$, the goal of the k-center clustering problem is to output a subset $S \subseteq P$ of at most k points such that the value $\max_{p \in P} \mathrm{dist}(p, S)$ is minimized.*

The points in S are referred to as *centers*, and the (k-center) *cost* of S is equal to $\mathrm{cost}(S) \coloneqq \max_{p \in P} \mathrm{dist}(p, S)$. The *optimal* k-center cost is denoted by $R^* \coloneqq \min_{|S| \leq k} \mathrm{cost}(S)$. In the *improper* k-center clustering problem, the k-center solution S is allowed to include points from the metric space that are not contained in the point set P.

▶ **Definition 4** (improper k-center clustering problem)**.** *Given a point set P in a metric space $(\mathcal{X}, \mathrm{dist})$ and an integer $k \geq 1$, the goal of the improper k-center clustering problem is to output a subset $S \subseteq \mathcal{X}$ of at most k points such that the value $\max_{p \in P} \mathrm{dist}(p, S)$ is minimized.*

The improper k-center clustering problem is defined for the following technical reason. The optimal k-center cost $\hat{R}^*$ of the improper version is non-decreasing under adversarial point insertions, whereas the optimal k-center cost R^* of Definition 3 may decrease after an adversarial point insertion. Moreover, by definition it holds that $\hat{R}^* \leq R^*$. Therefore, we can upper bound the cost of our k-center solution with respect to the monotonic $\hat{R}^*$, which in turn is upper bounded by the desired optimal k-center cost R^*.

In the *incremental* setting, the set of centers S is maintained under adversarial point insertions into P. The *worst-case recourse* is the number of replacements made to the set of centers after any adversarial point insertion. Note that deterministic dynamic algorithms work against an adaptive adversary.

3 Technical Overview

3.1 Incremental Algorithm

Our incremental k-center algorithm is given an incremental point set P that is subject to adversarial point insertions. The algorithm unfolds in *phases*, where each phase can last for multiple adversarial point insertions. During a phase the radius r remains unchanged, and when the subsequent phase begins the radius r is increased by at least a factor of $\alpha > 1$.

Each center is labeled as either *leader* or *regular*. Each point is assigned to its responsible center, and the corresponding distance provides an upper bound on the cost of the k-center solution. A leader center is responsible for points within distance $\alpha r + \beta r$, while a regular center (at the beginning of a phase) is responsible for points within distance βr. Whenever the radius r is increased, some centers become regular. For the updated radius r, every point lies within distance βr from its nearest center. Therefore, the parameters α and β should satisfy $\alpha r + \beta r = \alpha\beta r$, which means that $\alpha + \beta = \alpha\beta$.

Gonzalez Operation

At the beginning of each phase, the centers are ordered using Gonzalez's algorithm [12], which iteratively selects the point farthest from the previously chosen centers as the next center. Any center within distance αr of another center with a lower index is labeled as regular, and the rest are labeled as leaders.

3.1.1 Approximation Ratio Within a Phase

At the last adversarial point insertion of a phase, all pairwise distances between centers are greater than $\alpha^i \cdot r$, all centers are leaders, and the newly inserted point is at a distance greater than $\alpha^i \cdot r$ from every center, where $i \geq 1$ is an integer. The radius r is then increased to at least $\alpha^i \cdot r$, which implies that $r \leq 2\hat{R}^* \leq 2R^*$ for the increased radius r. As new points are inserted by the adversary, the *primary goal* during a phase is to adjust the centers so that the minimum pairwise distance between them is at least αr. The leader centers remain fixed, while the regular centers are allowed to *move* in order to achieve the primary goal. Whenever a regular center c moves, it becomes a leader center and the incremental algorithm ensures that the distance between c and all other centers is greater than βr. Furthermore, the algorithm ensures that c is at a distance greater than αr from any other leader center. Once the primary goal is fulfilled, the phase ends and the subsequent phase begins.

Subphases

Notice that when a regular center moves, some points may lose their assigned center. In turn, another center c becomes responsible for these points, potentially increasing the distance from c to points assigned to it. This center c might also move as a result of another adversarial point insertion, causing a chain of changes in which some points are repeatedly reassigned to different centers. Since these adjustments affect the approximation ratio, for the purpose of analyzing the approximation ratio, we divide each phase into two subphases.

The first subphase is active while the pairwise distances of centers are at least r. The second subphase begins when the minimum distance between two centers becomes greater than βr. Since the incremental algorithm ensures that the distance between a center that moves and all other centers is greater than βr, the minimum distance between any two centers stays greater than βr until the end of the phase.

First subphase. During the first subphase, the pairwise distances of centers are at least r, which implies that $r \leq 2R^*$. Moreover during the first subphase, the minimum distance between two centers involves only centers that have not moved. In turn due to the Gonzalez Operation, the old position in the metric space of every *replaced* center is within distance $2R^*$ from its closest center. As a result, all points are within distance $\max(2R^* + \beta r, \alpha r)$ from their closest center.

Second subphase. During the second subphase, the pairwise distances of centers are greater than βr, which implies that $\beta r \leq 2R^*$. Since every regular center is within distance αr from a leader center, the old position in the metric space of every *replaced* center is within distance αr from its closest center. As a result, all points are within distance $\alpha r + \beta r$ from their nearest center. Observe that as $\beta r \leq 2R^*$, we have $\alpha r \leq 2R^* \cdot \frac{\alpha}{\beta}$. Consequently, it follows that all points are within distance $2R^* \cdot (\frac{\alpha}{\beta} + 1)$ from their closest center.
Finally, the values for the parameters α and β that satisfy the requirements (i.e., $1 \leq \beta < \alpha$ and $\alpha + \beta \leq \alpha\beta$) and minimize the approximation ratio are $\alpha = \frac{3+\sqrt{5}}{2}$ and $\beta = \frac{1+\sqrt{5}}{2}$. The resulting approximation ratio of the incremental algorithm is $3 + \sqrt{5}$.

4 Incremental Consistent k-Center Clustering

In the incremental setting, the point set P undergoes point insertions sent by the adaptive adversary. Our goal is to develop an incremental algorithm for the k-center clustering problem with small approximation ratio, low update time, and worst-case recourse of 1. In this section, we develop a deterministic incremental algorithm whose guarantees are demonstrated in Theorem 1. Recall that R^* denotes the current optimal k-center cost of the given instance.

▶ **Theorem 1.** *There is a deterministic incremental algorithm for the k-center clustering problem that, given a point set P in a metric space subject to point insertions and an integer $k \geq 1$, maintains a subset of points $S \subseteq P$ with $|S| = k$ such that:*

- *The set S is a $(3 + \sqrt{5})$-approximate k-center solution.*
- *The worst-case recourse is at most 1.*
- *The worst-case update time is $O(k^2)$.*

State of the incremental algorithm

Our incremental algorithm maintains an ordered set $S = \{c_1, \ldots, c_k\}$ of k centers, a *radius* r, and the minimum pairwise distance between centers $minDistS := \min_{x,y \in S,\, x \neq y} \mathrm{dist}(x, y)$. Each center is labeled as either *regular* or *leader*, and we denote by S_{reg} and S_{ldr} the sets of regular and leader centers respectively. Two parameters α and β are used in the algorithm satisfying $1 \leq \beta < \alpha$ and $\alpha + \beta \leq \alpha\beta$; the specific values of these parameters are $\alpha = \frac{3+\sqrt{5}}{2}$ and $\beta = \frac{1+\sqrt{5}}{2}$ (i.e., β is the golden ratio).

Invariants for the approximation ratio

The following four invariants are satisfied throughout the incremental algorithm. By enforcing Invariant 1 and Invariant 2, we deduce that $r \leq 2R^*$. Using Invariant 3 and a more fine-grained version of Invariant 4, we prove that the approximation ratio is $3 + \sqrt{5}$. These invariants are responsible solely for the approximation ratio, so our aim is to satisfy them with a worst-case recourse of 1.

Invariant 1: $|S| = k$.

Invariant 2: There is a point $p_S \in P \setminus S$ such that the pairwise distances of points in $S \cup \{p_S\}$ are at least r.

Invariant 3: For every regular center $c_1 \in S_{\text{reg}}$, there is a leader center $c_2 \in S_{\text{ldr}}$ such that $\text{dist}(c_1, c_2) \leq \alpha r$.

Invariant 4: Every point $p \in P$ is within distance $\alpha r + \beta r$ from its closest center in S.

4.1 Incremental Algorithm

We begin by describing the Gonzalez Operation, which is central to the incremental algorithm and induces an ordering of the centers. Next, we present the preprocessing phase of the incremental algorithm, and then explain how the algorithm handles adversarial point insertions. A pseudocode of the incremental algorithm is provided in Algorithm 1. Recall that α and β satisfy $1 \leq \beta < \alpha$ and $\alpha + \beta \leq \alpha\beta$.

Gonzalez Operation

During the Gonzalez Operation, the algorithm sets c_1 to be an arbitrary point from S and labels it as a leader. In each subsequent iteration $i \geq 2$, the algorithm sets c_i to be a point from $S \setminus \{c_1, \ldots, c_{i-1}\}$ that is farthest from the already assigned centers $\{c_1, \ldots, c_{i-1}\}$. If c_i is within distance αr from a leader, it is labeled as regular; otherwise, c_i is labeled as a leader. Observe that this procedure results in an index $j \in [1, k]$ such that $S_{\text{ldr}} = \{c_1, \ldots, c_j\}$ and $S_{\text{reg}} = \{c_{j+1}, \ldots, c_k\}$.

4.1.1 Preprocessing Phase

The preprocessing phase is similar to that of the incremental algorithm in [11]. It utilizes the following method by Hochbaum and Shmoys [16] that repeatedly computes a *distance-r independent set*.

▶ **Definition 5** (Distance-r Independent Set)**.** *Given a point set P in a metric space and a parameter $r > 0$, a distance-r independent set $S \subseteq P$ is a subset of points such that $\min_{p,q \in S} \text{dist}(p, q) > r$.*

▶ **Lemma 6** ([16])**.** *Consider a k-center instance (P, k), where P is a point set in a metric space, and let D be the sorted set of pairwise distances among points in P. By applying binary search on the set D and calling a maximal distance-r independent set algorithm $\mathcal{A}$ at each iteration, we can find a 2-approximate solution for the k-center instance. The running time of this algorithm is $O(\mathcal{T}_{\mathcal{A}} \cdot \log |P|)$, where $\mathcal{T}_{\mathcal{A}}$ is the running time of $\mathcal{A}$.*

In the preprocessing phase, we run the method of Lemma 6 to obtain a 2-approximate solution S. Let $r \coloneqq \max_{p \in P} \text{dist}(p, S)$ be the radius of S. The next task is to ensure that all four invariants are satisfied. To achieve this, the following steps are executed while $|S| < k$:

- If there is a point at a distance of at least r from S, then it is added to S.
- Otherwise, r is updated to $\frac{r}{\beta}$.

Once $|S| = k$, the radius r is repeatedly divided by β until there is a point $p \in P \setminus S$ such that $\text{dist}(p, S) \geq r$. Then the Gonzalez Operation is run, which assigns indices to the centers so that each subsequent center is the farthest from the previously selected centers. Additionally, the Gonzalez Operation assigns labels such that there is an index j for which all centers with index at most j are leaders, and all centers with index greater than j are regular.

Note that the point set P may initially contain at most k points. In this special case, the preprocessing phase continues while $|P| \leq k$, and all points in P become centers. Some invariants might be violated in this special case, but this is not an issue as every point is a center. Once $|P| = k + 1$, the computation of the set S and the radius r is performed as described before. Notice that the worst-case recourse is 1, since all points except one belong to S after the computation. Finally, the Gonzalez Operation is executed to determine the sets S_{reg} and S_{ldr}.

Analysis of the preprocessing phase

In this paragraph, we show that all four invariants are satisfied after the preprocessing phase. At the end of the preprocessing phase, we have $|S| = k$ and so Invariant 1 is satisfied. By the choice of S and r given by the method in Lemma 6 and of the preprocessing phase, there is a point $p_S \in P \setminus S$ such that the pairwise distances of points in $S \cup \{p_S\}$ are at least r, as required for Invariant 2. The validity of Invariant 3 follows by the construction of the Gonzalez Operation. Regarding Invariant 4, observe that the radius r is divided by β only when there is no point $p \in P \setminus S$ with $\text{dist}(p, S) \geq r$. Consequently, no point lies at a distance of at least βr from the k-center solution S. Since $1 \leq \beta < \alpha$, for all points $p \in P$ it holds that $\text{dist}(p, S) < \beta r \leq \alpha r + \beta r$. Therefore, once the preprocessing phase has ended, all four invariants hold. Furthermore, the set S is a 2-approximate k-center solution because we run the method of Lemma 6, and adding more points to S can only reduce its approximation ratio.

4.1.2 Adversarial Point Insertion

When the adversary inserts a new point p^+ into the point set P (i.e., $P \coloneqq P \cup \{p^+\}$), the incremental algorithm proceeds as follows. If the new point p^+ is within distance βr from a regular center or within distance αr from a leader center, then the algorithm does nothing. Otherwise, the new point p^+ is at distance greater than βr from all centers and at distance greater than αr from all leader centers. In this scenario, the incremental algorithm continues based on whether the minimum pairwise distance between centers is at most αr.

Case 1: If $\mathit{minDistS} \leq \alpha r$, let c_i be the center that satisfies the following three conditions:
- $\text{dist}(c_i, S \setminus \{c_i\}) = \mathit{minDistS}$.
- c_i is a regular center.
- i is the largest possible index in $S = \{c_1, \ldots, c_k\}$.

The algorithm then replaces c_i in the set of centers S with the new point p^+, and sets $c_i \coloneqq p^+$.[2] Hence, the new point p^+ becomes the i-th center of the ordered set S. Finally, the algorithm labels $c_i = p^+$ as a leader.

Case 2: Otherwise if $\mathit{minDistS} > \alpha r$, let j be the smallest power such that:

$$\min\left(\text{dist}(p^+, S), \mathit{minDistS}\right) \leq \alpha^j r.$$

The algorithm then increases the radius r to $\alpha^{j-1} r$ and invokes the previously described Gonzalez Operation. Once the Gonzalez Operation finishes, the incremental algorithm repeats the initial steps for p^+ (see Line 33 in Algorithm 1), and notice that the algorithm either does nothing or proceeds as in Case 1.

[2] Note that c_i is a variable referring to a point in P. Hence, when we say "replace c_i in S with p^+", we mean replace the value of c_i in S with p^+. Following that, the value of c_i is updated to p^+.

Algorithm 1 Incremental Consistent k-Center.

▷ Let $S = \{c_1, \ldots, c_k\}$ be the ordered set of k centers
▷ Let r be the radius
▷ Let $minDistS \coloneqq \min_{x,y \in S,\, x \neq y} \mathrm{dist}(x, y)$
▷ The algorithm has global access to all its variables and data structures

function GonzalezOp()
  Let c_1 be an arbitrary center in S
  $j \leftarrow 1$
  for $i \in \{2, \ldots, k\}$ **do**
    $c_i \leftarrow \mathrm{argmax}_{c \in S \setminus \{c_1, \ldots, c_{i-1}\}} \mathrm{dist}(c, \{c_1, \ldots, c_{i-1}\})$
    if $\mathrm{dist}(c_i, \{c_1, \ldots, c_{i-1}\}) > \alpha r$ **then**
      $j \leftarrow i$
    end if
  end for
  $S \leftarrow \{c_1, \ldots, c_k\}$ ▷ Recall that S is an ordered set
  $S_{\mathrm{ldr}} \leftarrow \{c_1, \ldots, c_j\}$
  $S_{\mathrm{reg}} \leftarrow \{c_{j+1}, \ldots, c_k\}$
end function

function InsertPoint(p^+)
  Insert p^+ into P (if $p^+ \notin P$)
  if $\mathrm{dist}(p^+, S_{\mathrm{reg}}) \leq \beta r$ **or** $\mathrm{dist}(p^+, S_{\mathrm{ldr}}) \leq \alpha r$ **then**
    exit from InsertPoint()
  end if
  if $minDistS \leq \alpha r$ **then** ▷ case C1
    Find $c_i \in S_{\mathrm{reg}}$ that minimizes $\mathrm{dist}(c_i, S \setminus \{c_i\})$ and i is the largest possible index in $S = \{c_1, \ldots, c_k\}$
    Remove c_i from S and S_{reg}
    Add p^+ to S and S_{ldr}
    $c_i \leftarrow p^+$
  else ▷ case C2
    Find the smallest power $j+1$ such that $\min\left(\mathrm{dist}(p^+, S), minDistS\right) \leq \alpha^{j+1} r$
    $r \leftarrow \alpha^j r$
    ▷ New phase begins
    GonzalezOp()
    InsertPoint(p^+)
  end if
end function

4.2 Analysis of the Incremental Algorithm

In this section, we prove Theorem 1 by analyzing the incremental Algorithm 1. We denote by $S^{(\mathrm{old})}$ and $r^{(\mathrm{old})}$ the set of centers and the radius before the adversarial point insertion; the set of centers and the radius after the incremental algorithm processes the adversarial point insertion are denoted by S and r. Hence throughout the analysis, we use (old) as a superscript for the states before the adversarial point insertion, and omit the (old) superscript for the states after the incremental algorithm processes the adversarial point insertion. Recall that α and β satisfy $1 \leq \beta < \alpha$ and $\alpha + \beta \leq \alpha\beta$.

A contiguous block of executions of `InsertPoint()` during which the radius remains unchanged is called a *phase* of Algorithm 1. A phase ends when, upon an adversarial point insertion, the radius increases (i.e., r is updated to at least $\alpha r^{(\mathrm{old})}$); the next phase then begins with the next invocation of `InsertPoint()`.

▶ **Definition 7** (phase of the incremental algorithm). *A new phase begins after the invocation of `InsertPoint()` whenever the radius r has increased (i.e., $r > r^{(old)}$).*

4.2.1 Proof of Invariant 3 and Auxiliary Results

▶ **Lemma 8.** *After an adversarial point insertion, for every regular center $c_1 \in S_{reg}$ there is a leader center $c_2 \in S_{ldr}$ such that* $\text{dist}(c_1, c_2) \leq \alpha r$ *(i.e., Invariant 3 is satisfied).*

Proof. Notice that immediately after an execution of the Gonzalez Operation, a center is regular if and only if it is within distance αr from a leader center. Hence, it suffices to analyze independently each sequence of adversarial point insertions between two consecutive executions of the Gonzalez Operation. The proof proceeds by induction on the adversarial point insertions within a single such sequence. The base case is the beginning of such a sequence, where the statement holds due to the Gonzalez Operation. Whenever a recursive call to `InsertPoint`() after the Gonzalez Operation changes the solution S, the same argument as in the induction step of Case 1 applies.

For the induction step, consider an adversarial point insertion p^+. Observe that the incremental Algorithm 1 could not have proceeded with Case 2, as otherwise the Gonzalez Operation would be invoked, signaling the end of the current sequence. During Case 1, a regular center becomes a leader (see Lines 25 and 26 in Algorithm 1). Hence by the induction hypothesis, for every regular center c_1 there is a leader center c_2 such that $\text{dist}(c_1, c_2) \leq \alpha r^{(\text{old})}$. Since in Case 1 the radius does not increase, we have $r = r^{(\text{old})}$, and thus the claim follows. ◀

The following lemma shows that during Case 2 of the incremental Algorithm 1 (in which the Gonzalez Operation is executed), a new phase begins (i.e., the radius increases).

▶ **Lemma 9.** *After an adversarial point insertion, a new phase begins if and only if the Gonzalez Operation is executed.*

Proof. By the construction of the incremental Algorithm 1, the Gonzalez Operation is invoked only during Case 2. Since during Case 1 the radius remains unchanged, it suffices to prove that during Case 2 a new phase always begins. Let p^+ be the new adversarially inserted point. By construction, the incremental algorithm proceeds with Case 2 if and only if $\text{dist}(p^+, S_{\text{reg}}^{(\text{old})}) > \beta r^{(\text{old})}$, $\text{dist}(p^+, S_{\text{ldr}}^{(\text{old})}) > \alpha r^{(\text{old})}$ and $minDistS^{(\text{old})} > \alpha r^{(\text{old})}$.

Because $minDistS^{(\text{old})} > \alpha r^{(\text{old})}$, no two centers are within distance $\alpha r^{(\text{old})}$. Based on Lemma 8 (Invariant 3), every regular center is within distance $\alpha r^{(\text{old})}$ from a leader center, and thus it holds that $S_{\text{reg}}^{(\text{old})} = \emptyset$. Since $S^{(\text{old})} = S_{\text{ldr}}^{(\text{old})} \cup S_{\text{reg}}^{(\text{old})}$, it follows that $\text{dist}(p^+, S^{(\text{old})}) = \text{dist}(p^+, S_{\text{ldr}}^{(\text{old})}) > \alpha r^{(\text{old})}$. Therefore, it holds that $\min\left(\text{dist}(p^+, S^{(\text{old})}), minDistS^{(\text{old})}\right) > \alpha r^{(\text{old})}$, which implies that the power $j+1$ in Line 29 of Algorithm 1 is at least 2. As a result, the radius increases by at least a factor of α in Line 30 (i.e., $r \geq \alpha r^{(\text{old})}$). Since $\alpha > 1$, a new phase begins according to Definition 7, and thus the claim follows. ◀

The next two observations establish the correctness of Line 24 in Algorithm 1, which involves identifying a proper regular center to be sacrificed.

▶ **Observation 10.** *After an adversarial point insertion, for every two leader centers $c_1, c_2 \in S_{ldr}$ it holds that* $\text{dist}(c_1, c_2) > \alpha r$.

Proof. Notice that immediately after an execution of the Gonzalez Operation, any two leader centers are at distance greater than αr. Hence, it suffices to analyze each phase independently according to Lemma 9. The proof proceeds by induction on the adversarial point insertions within a single phase. The base case is the beginning of the phase, where the Gonzalez Operation is executed, after which `InsertPoint`() is called recursively. Since the

statement holds immediately after the Gonzalez Operation, the argument for the recursive call of `InsertPoint`() is identical to the induction step, where $S^{(\text{old})}$ corresponds to the set of centers immediately after the Gonzalez Operation.

For the induction step, consider an adversarial point insertion p^+. Observe that the set of leader centers S_{ldr} changes only if $\text{dist}(p^+, S_{\text{ldr}}^{(\text{old})}) > \alpha r^{(\text{old})}$. Moreover, the incremental Algorithm 1 must have proceeded with Case 1, as otherwise the next phase begins according to Lemma 9. During Case 1, a center c becomes a leader (i.e., c is added to S_{ldr}) only in Line 26 where $c = p^+$, and also $r = r^{(\text{old})}$. Therefore, together with the induction hypothesis, any two leader centers are at distance greater than αr within a single phase. ◀

The next observation indicates that whenever the incremental Algorithm 1 proceeds with Case 1, a regular center is successfully found to be replaced in the set of centers. This implies the correctness of Line 24 in Algorithm 1.

▶ **Observation 11.** *During Case 1 of the incremental Algorithm 1, there is a regular center* $c_i \in S_{reg}^{(old)}$ *such that* $\text{dist}(c_i, S^{(old)} \setminus \{c_i\}) = \mathit{minDistS}^{(old)}$.

Proof. Suppose towards a contradiction that $\mathit{minDistS}^{(\text{old})} \leq \alpha r^{(\text{old})}$ but for all regular centers $c \in S_{\text{reg}}^{(\text{old})}$ we have $\text{dist}(c, S^{(\text{old})} \setminus \{c\}) > \mathit{minDistS}^{(\text{old})}$. Since $S_{\text{ldr}}^{(\text{old})}$ and $S_{\text{reg}}^{(\text{old})}$ partition $S^{(\text{old})}$, there must be two leader centers $c_1, c_2 \in S_{\text{ldr}}^{(\text{old})}$ such that $\text{dist}(c_1, c_2) = \mathit{minDistS}^{(\text{old})} \leq \alpha r^{(\text{old})}$. However, this yields a contradiction based on Observation 10, and thus the claim follows. ◀

4.2.2 Worst-Case Update Time

Observe that the incremental Algorithm 1 in Case 2 recursively calls `InsertPoint`(p^+). The next lemma shows that there is at most one recursive call.

▶ **Lemma 12.** *The recursion depth of* `InsertPoint`() *is at most two.*

Proof. When Line 33 in Algorithm 1 is executed, then either $\alpha r \geq \text{dist}(p^+, S^{(\text{old})})$ or $\alpha r \geq \mathit{minDistS}^{(\text{old})}$, where r is the updated radius. Observe that $S^{(\text{old})}$ is the set of centers after the Gonzalez Operation in Line 32 and $\mathit{minDistS}^{(\text{old})}$ is the corresponding minimum pairwise distance among centers in $S^{(\text{old})}$. Consider the two cases separately after the recursive call to `InsertPoint`() in Line 33:

- Assume that $\mathit{minDistS}^{(\text{old})} \leq \alpha r$. In this case, the incremental algorithm either does nothing due to Line 20, or it proceeds with Case 1, in which no further recursive calls to `InsertPoint`() occur.
- Otherwise, assume that $\mathit{minDistS}^{(\text{old})} > \alpha r$ and $\text{dist}(p^+, S^{(\text{old})}) \leq \alpha r$. Let $S_{\text{ldr}}^{(\text{interm})}$ denote the set of leader centers after the execution of the Gonzalez Operation with the updated radius r. By the construction of the Gonzalez Operation, it holds that $S_{\text{ldr}}^{(\text{interm})} = S^{(\text{old})}$. In turn, this implies that $\text{dist}(p^+, S_{\text{ldr}}^{(\text{interm})}) = \text{dist}(p^+, S^{(\text{old})}) \leq \alpha r$. Hence, the condition of the if-statement in Line 20 is true, and the incremental algorithm terminates.

Consequently, there is at most one recursive call to `InsertPoint`(), and so the recursion depth of `InsertPoint`() is at most two. ◀

Therefore, the update time is dominated by the Gonzalez Operation that runs Gonzalez's algorithm [12] on the set S, which is of size k by Lemma 14 (Invariant 1).

▶ **Corollary 13.** *The worst-case update time of the incremental Algorithm 1 is* $O(k^2)$.

4.2.3 Proofs of Invariant 1 and Invariant 2

▶ **Lemma 14.** *After an adversarial point insertion, the size of S is k (i.e., Invariant 1 is satisfied). Moreover, the worst-case recourse is* 1.

Proof. In the preprocessing phase, the incremental algorithm constructs a solution S of k centers. During an adversarial point insertion, the set of centers S is altered only when the algorithm proceeds with Case 1. In this case, exactly one point is removed from S and the new adversarially inserted point is added to S (see Lines 25 and 26 in Algorithm 1). As a consequence, we have $|S| = k$ after every adversarial point insertion.

Notice that Case 1 occurs at most once per adversarial point insertion (see also Lemma 12). Thus, the set of centers changes by at most one point per adversarial update. ◀

The following lemma can be credited to Hochbaum and Shmoys [16], who presented a reduction from the k-center clustering problem to a variant of the maximal independent set problem. We denote by R^* the optimal k-center cost of Definition 3 and by $\hat{R}^*$ the optimal improper k-center cost of Definition 4.

▶ **Lemma 15** ([16])**.** *Consider a k-center instance (P, k), and let $S \subseteq P$ be a subset of points with $|S| \geq k+1$ such that for every pair of distinct points $p, q \in S$, we have $\mathrm{dist}(p, q) \geq r$. Then it holds that $r \leq 2\hat{R}^*$.*

Proof. Let S^* be an optimal improper k-center solution. Since the size of S^* is at most k, by the pigeonhole principle there exists a center $c^* \in S^*$ and two distinct points $p, q \in S$ such that $\mathrm{dist}(p, c^*) \leq \hat{R}^*$ and $\mathrm{dist}(q, c^*) \leq \hat{R}^*$. By the triangle inequality, we have $\mathrm{dist}(p, c^*) + \mathrm{dist}(q, c^*) \geq \mathrm{dist}(p, q) \geq r$. Hence, without loss of generality we can assume that $\mathrm{dist}(p, c^*) \geq \frac{r}{2}$. Since $\mathrm{dist}(p, c^*) \leq \hat{R}^*$, it follows that $\hat{R}^* \geq \frac{r}{2}$, as needed. ◀

▶ **Observation 16.** *Consider a k-center instance (P, k). Then it holds that $\hat{R}^* \leq R^*$.*

Proof. Observe that every k-center solution $S \subseteq P$ with $|S| \leq k$ is also a feasible solution with the same cost for the improper k-center clustering problem. Hence, comparing the respective optimal k-center solutions, it follows that $\hat{R}^* \leq R^*$. ◀

▶ **Lemma 17.** *After an adversarial point insertion, there is a point $p_S \in P \setminus S$ such that the pairwise distances of points in $S \cup \{p_S\}$ are at least r (i.e., Invariant 2 is satisfied). Moreover, the value of the radius r is at most $2\hat{R}^* \leq 2R^*$.*

Proof. The proof is by induction on the adversarial point insertions. The base case is immediately after the preprocessing phase, where Invariant 2 is satisfied. For the induction step, consider an adversarial point insertion p^+, and let P be the updated point set including p^+. If $\mathrm{dist}(p^+, S_{\mathrm{reg}}^{(\mathrm{old})}) \leq \beta r$ or $\mathrm{dist}(p^+, S_{\mathrm{ldr}}^{(\mathrm{old})}) \leq \alpha r$, then neither the set of centers nor the radius is modified (i.e., $S = S^{(\mathrm{old})}$ and $r = r^{(\mathrm{old})}$). By the induction hypothesis, there is a point $p_S \in (P \setminus \{p^+\}) \setminus S^{(\mathrm{old})}$ such that the pairwise distances of points in $S^{(\mathrm{old})} \cup \{p_S\}$ are at least $r^{(\mathrm{old})}$. Since $S = S^{(\mathrm{old})}$ and $r = r^{(\mathrm{old})}$ in this scenario, there is a point $p_S \in P \setminus S$ such that the pairwise distances of points in $S \cup \{p_S\}$ are at least r, as needed. Otherwise the incremental algorithm proceeds either with Case 1 or Case 2:

- Assume that the incremental algorithm proceeds with Case 1. In this case, it holds that $\mathrm{dist}(p^+, S^{(\mathrm{old})}) > \beta r^{(\mathrm{old})} \geq r^{(\mathrm{old})}$, as $\beta \geq 1$. By the construction of the algorithm, we have $S = (S^{(\mathrm{old})} \setminus \{c\}) \cup \{p^+\}$ for some $c \in S^{(\mathrm{old})}$ and the radius remains unchanged (i.e., $r = r^{(\mathrm{old})}$). By the induction hypothesis, the pairwise distances of points in $S^{(\mathrm{old})}$ are at least $r^{(\mathrm{old})} = r$. Thus by setting $p_S \coloneqq c$ and since $\mathrm{dist}(p^+, S^{(\mathrm{old})}) > r$, we infer that there is a point $p_S \in P \setminus S$ such that the pairwise distances of points in $S \cup \{p_S\}$ are at least r, as required.

- Assume that the incremental algorithm proceeds with Case 2. In this case, the radius r is updated to $\alpha^j r^{(\text{old})}$, where j is the largest power such that $\mathit{minDistS}^{(\text{old})} > \alpha^j r^{(\text{old})}$ and $\text{dist}(p^+, S^{(\text{old})}) > \alpha^j r^{(\text{old})}$. Since $S = S^{(\text{old})}$ at that moment, Invariant 2 holds after the radius r is assigned in Line 30 of Algorithm 1. Next, the incremental algorithm continues recursively with `InsertPoint`(p^+), where $r = \alpha^j r^{(\text{old})}$. Let $S_{\text{reg}}^{(\text{interm})}$ and $S_{\text{ldr}}^{(\text{interm})}$ denote the sets of regular and leader centers immediately after the execution of the Gonzalez Operation.
  - If $\text{dist}(p^+, S_{\text{reg}}^{(\text{interm})}) \leq \beta r$ or $\text{dist}(p^+, S_{\text{ldr}}^{(\text{interm})}) \leq \alpha r$, then the set of centers does not change (i.e., $S = S^{(\text{old})}$) and so Invariant 2 remains satisfied.
  - Otherwise, we have $S = (S^{(\text{old})} \setminus \{c\}) \cup \{p^+\}$ for some $c \in S^{(\text{old})}$. Thus by setting again $p_S \coloneqq c$ and since $\text{dist}(p^+, S^{(\text{old})}) > r$, we deduce that Invariant 2 remains satisfied. In other words, there is a point $p_S \in P \setminus S$ such that the pairwise distances of points in $S \cup \{p_S\}$ are at least r, as required.

Upper bound on r

By construction, the maintained k-center solution S is a subset of the point set P. Since Invariant 2 and Invariant 1 (see Lemma 14) are satisfied, there are $k+1$ points in P whose pairwise distances are at least r. Thus by Lemma 15 and Observation 16, it follows that $r \leq 2\hat{R}^* \leq 2R^*$. ◀

4.2.4 Approximation Ratio

In this subsection, we analyze the approximation ratio of our incremental algorithm, using a more fine-grained version of Invariant 4. The set S_{init} denotes the ordered set of centers at the beginning of the current phase; according to Lemma 9, the set S_{init} is the result after the last execution of the Gonzalez Operation. Observe that the set S_{init} may differ from the current set of centers $S^{(\text{old})}$ just before the incremental algorithm processes an adversarial point insertion. We note that S_{init} is an auxiliary set used in the following lemma.

▶ **Lemma 18.** *After an adversarial point insertion, for every point $p \in P$ it holds that either*

$$\text{dist}(p, S_{init}) \leq \beta r \quad \textit{or} \quad \text{dist}(p, S_{ldr}) \leq \alpha r.$$

Proof. The proof is by induction on the adversarial points insertions. The base case is immediately after the preprocessing phase, where $S_{\text{init}} = S$ and every point $p \in P$ is within distance βr from a center. For the induction step, consider an adversarial point insertion p^+, and let P be the updated point set including p^+. Since $S_{\text{reg}} \subseteq S_{\text{init}}$ at the beginning of each phase, and no new centers are added to S_{reg} during a phase, it follows that $S_{\text{reg}} \subseteq S_{\text{init}}$ throughout the algorithm.

In the scenario where $\text{dist}(p^+, S_{\text{reg}}^{(\text{old})}) \leq \beta r^{(\text{old})}$ or $\text{dist}(p^+, S_{\text{ldr}}^{(\text{old})}) \leq \alpha r^{(\text{old})}$, it holds that $\text{dist}(p^+, S_{\text{init}}) \leq \text{dist}(p^+, S_{\text{reg}}^{(\text{old})})$, $S_{\text{init}} = S_{\text{init}}^{(\text{old})}$, $r = r^{(\text{old})}$, $S_{\text{reg}} = S_{\text{reg}}^{(\text{old})}$, and $S_{\text{ldr}} = S_{\text{ldr}}^{(\text{old})}$, and so together with the induction hypothesis the correctness of the statement follows. Otherwise, the incremental algorithm proceeds either with Case 1 or Case 2:

- Assume that $\mathit{minDistS}^{(\text{old})} \leq \alpha r^{(\text{old})}$ (Case 1). Let $c_i \in S_{\text{reg}}^{(\text{old})}$ and $c_j \in S^{(\text{old})}$ such that $\text{dist}(c_i, c_j) = \mathit{minDistS}^{(\text{old})}$ and i is the largest possible index. Based on Observation 11, such centers c_i and c_j must exist. The algorithm replaces c_i in the set of centers with p^+ and labels p^+ as a leader. Since $S_{\text{reg}}^{(\text{old})} \subseteq S_{\text{init}}$, the old regular center c_i belongs to S_{init}. Hence, as in Case 1 we have $r = r^{(\text{old})}$ and $S_{\text{init}} = S_{\text{init}}^{(\text{old})}$, for all points in $P \setminus \{p^+\}$ the claim holds by the induction hypothesis. Additionally, for the inserted point p^+ we have $\text{dist}(p^+, S_{\text{ldr}}) = 0 \leq \alpha r$, as needed.

- Assume that $\mathit{minDistS}^{(\text{old})} > \alpha r^{(\text{old})}$ (Case 2); the incremental algorithm continues recursively with $\texttt{InsertPoint}(p^+)$ in Line 33. According to Lemma 9, a new phases begins which means that $r \geq \alpha r^{(\text{old})}$. For the updated radius r, the inserted point p^+ becomes a center if and only if (i) $\text{dist}(p^+, S_{\text{reg}}^{(\text{old})}) > \beta r$, (ii) $\text{dist}(p^+, S_{\text{ldr}}^{(\text{old})}) > \alpha r$, and (iii) $\mathit{minDistS}^{(\text{old})} \leq \alpha r$. First, we consider the newly inserted point p^+. If p^+ becomes a center during Case 1, then the claim holds for p^+. Otherwise based on Lemma 12, the algorithm does not continue with Case 2 again. Consequently, it holds that either $\text{dist}(p^+, S_{\text{reg}}) \leq \beta r$ or $\text{dist}(p^+, S_{\text{ldr}}) \leq \alpha r$, and since $S_{\text{reg}} \subseteq S_{\text{init}}$ the claim follows for p^+. It remains to consider the remaining points in $P \setminus \{p^+\}$. Since a new phase begins during Case 2, we have $r \geq \alpha r^{(\text{old})}$ and the set S_{init} changes. Let $S_{\text{init}}^{(\text{new})}$ be the set of centers after the Gonzalez Operation is invoked (i.e., $S_{\text{init}}^{(\text{new})} = S^{(\text{old})}$). Based on Lemma 8 (Invariant 3) and the fact that $\mathit{minDistS}^{(\text{old})} > \alpha r^{(\text{old})}$, we can infer that $S_{\text{ldr}}^{(\text{old})} = S^{(\text{old})}$, which means that $S_{\text{ldr}}^{(\text{old})} = S^{(\text{old})} = S_{\text{init}}^{(\text{new})}$. For an arbitrary point $q \in P \setminus \{p^+\}$, by the induction hypothesis either $\text{dist}(q, S_{\text{init}}^{(\text{old})}) \leq \beta r^{(\text{old})}$ or $\text{dist}(q, S_{\text{ldr}}^{(\text{old})}) \leq \alpha r^{(\text{old})}$; we analyze the two cases separately:
  - Consider a point $q \in P \setminus \{p^+\}$ such that $\text{dist}(q, S^{(\text{old})}) \leq \alpha r^{(\text{old})}$. Then as $\beta \geq 1$, it holds that:

    $$\text{dist}(q, S_{\text{init}}^{(\text{new})}) \leq \alpha r^{(\text{old})} \leq r \leq \beta r.$$

  - Consider a point $q \in P \setminus \{p^+\}$ such that $\text{dist}(q, S_{\text{init}}^{(\text{old})}) \leq \beta r^{(\text{old})}$ and $\text{dist}(q, S^{(\text{old})}) > \alpha r^{(\text{old})}$. Observe that leader centers are never removed from the set of centers during a (fixed) phase and that the distance from q to the set of centers increased during the (previous) phase. Hence, the closest center $c_q \in S_{\text{init}}^{(\text{old})}$ to q that was removed from the set of centers was a regular center (when the radius was $r^{(\text{old})}$). By Lemma 8 (Invariant 3), there must be another leader center $c \in S_{\text{ldr}}^{(\text{old})}$ such that $\text{dist}(c_q, c) \leq \alpha r^{(\text{old})}$. By the triangle inequality and since $\alpha + \beta \leq \alpha\beta$, we obtain that:

    $$\text{dist}(q, S_{\text{init}}^{(\text{new})}) \leq \alpha r^{(\text{old})} + \beta r^{(\text{old})} \leq \alpha\beta r^{(\text{old})} \leq \beta r.$$

  Since the algorithm is currently in Case 2, based on Lemma 12, the next recursive call of $\texttt{InsertPoint}(p^+)$ does not enter Case 2 again. This implies that the radius is no longer modified by this adversarial point insertion and the set S_{init} remains unchanged. If the solution changes due to Case 1 of the recursive $\texttt{InsertPoint}(p^+)$, the claim follows using the same arguments as before. ◀

To analyze the approximation ratio, we split every phase into two *subphases* and analyze each subphase separately; the subphases are defined as follows.

▶ **Definition 19** (subphases of a phase)**.** *During a phase of the incremental algorithm, the first subphase ends when the minimum pairwise distance between centers is greater than βr; the second subphase then begins.*

▶ **Observation 20.** *During a phase of the incremental algorithm, any $c \in S \setminus S_{init}$ that becomes a center after the beginning of the phase is at a distance greater than βr from all other centers until the end of the phase.*

Proof. According to Lemma 9, whenever the Gonzalez Operation is invoked during Case 2 of the incremental Algorithm 1, a new phase begins. Hence, it suffices to analyze only Case 1 of the incremental Algorithm 1. The proof is by induction on the adversarial point insertions within a single phase. The base case is at the beginning of the phase, where $S = S_{\text{init}}$ and

the statement trivially holds. For the induction step, consider an adversarial point insertion p^+. The set of centers is modified only in Case 1, which occurs only when the if-statement in Line 20 is false. This implies that for the new center p^+ (see Line 26 in Algorithm 1), it holds that $\text{dist}(p^+, S_{\text{reg}}^{(\text{old})}) > \beta r$ and $\text{dist}(p^+, S_{\text{ldr}}^{(\text{old})}) > \alpha r$, since $r = r^{(\text{old})}$ during a phase. In turn, it holds that $\text{dist}(p^+, S^{(\text{old})}) = \text{dist}(p^+, S_{\text{reg}}^{(\text{old})} \cup S_{\text{ldr}}^{(\text{old})}) > \beta r$. For any other center $c \in S^{(\text{old})} \setminus S_{\text{init}}$, the statement holds by the induction hypothesis, as $r = r^{(\text{old})}$. ◀

Hence, during the first subphase, the value *minDistS* is defined by two centers in $S \cap S_{\text{init}}$. From the start of the second subphase onward, *minDistS* exceeds βr until the end of the phase. This is because Observation 20 applies for any new center that is added until the end of the phase. Let $S_i \coloneqq \{c_j \in S_{\text{init}} \mid j \leq i\}$ denote the ordered subset of S_{init} up to center c_i, for any $1 \leq i \leq k$.

▶ **Lemma 21.** *Consider a fixed phase of the incremental algorithm. After an adversarial point insertion during the first subphase, assume that the incremental algorithm removes the i-th center c_i from the set of centers. Then the distance* $\text{dist}(c_i, S_{i-1})$ *equals the minimum pairwise distance between centers at that moment.*

Proof. Based on Observation 20 and Definition 19, the minimum pairwise distance between centers is attained between two centers in S_{init}. By the construction of the Gonzalez Operation, all leader centers have smaller index than regular centers in S_{init}. Since i is the largest such index in Line 24 of Algorithm 1 (during Case 1), it holds that $\text{dist}(c_i, S_{i-1}) \leq \text{dist}(c_i, S^{(\text{old})} \setminus \{c_i\})$, where c_i refers to the old location determined in Line 24. Based on Observation 11, we have $\text{dist}(c_i, S^{(\text{old})} \setminus \{c_i\}) = \mathit{minDistS}^{(\text{old})}$. Thus at the moment that c_i is removed from the set of centers, the minimum pairwise distance between centers is attained between c_i and S_{i-1}. ◀

▶ **Lemma 22.** *Consider a fixed phase of the incremental algorithm. After an adversarial point insertion during the first subphase, assume that the incremental algorithm removes the i-th center c_i from the set of centers. Then it holds that $S_{i-1} \subseteq S^{(old)}$ and $S_{i-1} \subseteq S$.*

Proof. After an adversarial insertion of a point p^+, the center c_i is replaced by p^+ in the set of centers (i.e., $S = (S^{(\text{old})} \setminus \{c_i\}) \cup \{p^+\}$). Since $p^+ \notin S_{i-1}$, it suffices to show that $S_{i-1} \subseteq S$. Suppose to the contrary that there is an adversarial point insertion such that c_i (referring to the old location) is removed from the set of centers and $S_{i-1} \not\subseteq S$, and consider the first such adversarial point insertion. Let c_j be the center (referring to the old location) with the smallest index j in S_{init} which has been removed from the set of centers in a previous adversarial point insertion (i.e., $c_j \in S_i \setminus S$ with the smallest possible index j). By the minimality of the counter-example, it holds that $S_{j-1} \subseteq S$ and $j < i$, which implies that c_i does not belong to S_{j-1}. By the construction of the Gonzalez Operation, we have $\text{dist}(c_i, S_{j-1}) \leq \text{dist}(c_j, S_{j-1})$.

Let τ be the moment when c_j was removed from the set of centers. Since the phase is fixed, the τ-th adversarial point insertion occurs during the same first subphase. Based on Lemma 21, the minimum pairwise distance in Line 24 of Algorithm 1 (during Case 1) at time τ is achieved between c_j and S_{j-1}. However, as $\text{dist}(c_i, S_{j-1}) \leq \text{dist}(c_j, S_{j-1})$ at the τ-th adversarial point insertion, the minimum pairwise distance between centers at time τ could also be achieved with c_i. Since $i > j$, the incremental algorithm should have replaced c_i before replacing c_j, which leads to a contradiction. ◀

Recall that the optimal k-center cost of Definition 3 is denoted by R^*, and the optimal improper k-center cost of Definition 4 is denoted by $\hat{R}^*$.

▶ **Observation 23.** *Consider a k-center instance (P, k) subject to adversarial point insertions. Then $\hat{R}^*$ is non-decreasing at all times.*

Proof. Consider an optimal improper k-center solution $\hat{S}_1^*$ before the adversarial point insertion, where $\text{cost}^{(\text{old})}(\hat{S}_1^*) = (\hat{R}^*)^{(\text{old})}$. Suppose to the contrary that after an adversarial point insertion, the optimal improper k-center cost decreases (i.e., $\hat{R}^* < (\hat{R}^*)^{(\text{old})}$). Under adversarial point insertions, the cost of $\hat{S}_1^*$ is non-decreasing (i.e., $\text{cost}^{(\text{old})}(\hat{S}_1^*) \leq \text{cost}(\hat{S}_1^*)$). Thus, there must be another optimal k-center solution $\hat{S}_2^*$ after the adversarial point insertion, where $\text{cost}(\hat{S}_2^*) = \hat{R}^*$.

Since $\hat{S}_2^*$ is a subset of the metric space and $|\hat{S}_2^*| \leq k$, the set $\hat{S}_2^*$ is also a feasible improper k-center solution before the adversarial point insertion. The cost of $\hat{S}_2^*$ is non-decreasing under adversarial point insertions, and so $\text{cost}^{(\text{old})}(\hat{S}_2^*) \leq \text{cost}(\hat{S}_2^*)$. Combining all these together, it follows that $\text{cost}^{(\text{old})}(\hat{S}_2^*) \leq \text{cost}(\hat{S}_2^*) = \hat{R}^* < (\hat{R}^*)^{(\text{old})}$, contradicting the fact that $\hat{S}_1^*$ was an optimal improper k-center solution before the adversarial point insertion. Therefore, the optimal improper k-center cost cannot decrease when a new point is inserted by the adversary. ◀

▶ **Lemma 24.** *Let $\alpha := \frac{3+\sqrt{5}}{2}$ and $\beta := \frac{1+\sqrt{5}}{2}$. After an adversarial point insertion, for every point $p \in P$ it holds that:*

$$\text{dist}(p, S) \;\leq\; (3+\sqrt{5})\hat{R}^* \;\leq\; (3+\sqrt{5})R^*.$$

Proof. Based on Lemma 18, every point $p \in P$ is either within distance βr from the set S_{init} or within distance αr from a leader center in S_{ldr}. In the latter case, by Lemma 17 we have $r \leq 2\hat{R}^* \leq 2R^*$, and as $S_{\text{ldr}} \subseteq S$ it follows that $\text{dist}(p, S) \leq \alpha r \leq 2\alpha\hat{R}^* = (3+\sqrt{5})\hat{R}^* \leq (3+\sqrt{5})R^*$, as needed. Since $\beta < \alpha$, the same conclusion holds for any point $p \in P$ satisfying $\text{dist}(p, c) \leq \beta r$ for some center $c \in S_{\text{init}} \cap S_{\text{reg}}$. Notice that when a new phase begins then $S_{\text{init}} = S_{\text{reg}} \cup S_{\text{ldr}}$, implying the correctness of the statement by Lemma 18 together with the fact that $r \leq 2\hat{R}^* \leq 2R^*$. Hence, it remains to analyze points $p \in P$ such that $\text{dist}(p, S_{\text{ldr}}) > \alpha r$ and $\text{dist}(p, S_{\text{init}}) = \text{dist}(p, q) \leq \beta r$ for some $q \in S_{\text{init}} \setminus S$ during a fixed phase. Namely, the point q has been replaced as a center during this phase.

The proof is by induction on the adversarial point insertions within a single phase. The base case is at the beginning of the phase, where $S_{\text{init}} = S$ and the statement holds as explained earlier. For the induction step, consider an adversarial point insertion p^+, and let P be the updated point set including p^+. In the scenario where $\text{dist}(p^+, S_{\text{reg}}^{(\text{old})}) \leq \beta r^{(\text{old})}$ or $\text{dist}(p^+, S_{\text{ldr}}^{(\text{old})}) \leq \alpha r^{(\text{old})}$, neither the set of centers nor the radius is modified (i.e., $S = S^{(\text{old})}$ and $r = r^{(\text{old})}$). Thus the statement holds by the induction hypothesis combined with Observation 23 and Observation 16. Otherwise it holds that $\text{dist}(p^+, S^{(\text{old})}) > \beta r^{(\text{old})}$, and the incremental algorithm continues either with Case 1 or Case 2. According to Lemma 9, during Case 2 of the incremental Algorithm 1, a new phase begins. Therefore, we only need to consider adversarial point insertions for which the incremental algorithm proceeds with Case 1 in the current phase.

For clarity regarding the reset of c_i in Line 27 of Algorithm 1, let $c_i^{(\text{old})}$ denote the old center (referring to the old location) determined in Line 24. Since the radius does not increase in Case 1, we have $r = r^{(\text{old})}$. Observe that the newly inserted point p^+ becomes a leader in Line 26 of Algorithm 1, and by construction we have $S_{\text{reg}} = S_{\text{reg}}^{(\text{old})} \setminus \{c_i^{(\text{old})}\}$ and $S_{\text{ldr}} = S_{\text{ldr}}^{(\text{old})} \cup \{p^+\}$ (i.e., $S = (S^{(\text{old})} \setminus \{c_i^{(\text{old})}\}) \cup \{p^+\}$). This implies that for all points whose nearest center in $S^{(\text{old})}$ is not $c_i^{(\text{old})}$, the claim follows by the induction hypothesis combined with Observation 23 and Observation 16. Hence, it suffices to consider points $p \in P^{(\text{old})}$ whose nearest center in $S^{(\text{old})}$ is the point $c_i^{(\text{old})}$. For a fixed such point $p \in P^{(\text{old})}$,

let $q \in S_{\text{init}}$ be its nearest center at the beginning of the current phase. Recall that for a point $p \in P$, its closest point q in S_{init} may not belong to the set of centers before or after the adversarial update (i.e., S_{init} can differ from $S^{(\text{old})}$ and S). There are two cases to analyze depending on which subphase of the incremental Algorithm 1 is active:

The first subphase is active. Let i be the index determined in Line 24 of Algorithm 1. Since the first subphase is active (see Definition 19), it holds that $\text{dist}(c_i^{(\text{old})}, S^{(\text{old})} \setminus \{c_i^{(\text{old})}\}) = \mathit{minDistS}^{(\text{old})} \leq \beta r$, which implies that $\text{dist}(c_i^{(\text{old})}, S^{(\text{old})} \setminus \{c_i^{(\text{old})}\}) < \text{dist}(p^+, S^{(\text{old})})$. Since the distance between $c_i^{(\text{old})}$ and $S^{(\text{old})} \setminus \{c_i^{(\text{old})}\}$ is the minimum over all pairwise distances of points in $S^{(\text{old})}$, the pairwise distances of points in $S^{(\text{old})} \cup \{p^+\}$ are at least $\text{dist}(c_i^{(\text{old})}, S^{(\text{old})} \setminus \{c_i^{(\text{old})}\})$. Based on Lemma 14 we have $|S^{(\text{old})} \cup \{p^+\}| = k+1$, and observe that $S^{(\text{old})} \cup \{p^+\} \subseteq P$. As a consequence, by Lemma 15 it holds that $\text{dist}(c_i^{(\text{old})}, S^{(\text{old})} \setminus \{c_i^{(\text{old})}\}) \leq 2\hat{R}^*$.

Observe that if $q = c_i^{(\text{old})}$ then by the triangle inequality and by Observation 16, we have $\text{dist}(p, S) \leq \beta r + \text{dist}(q, S) \leq \beta r + 2\hat{R}^* \leq (1+\beta)2\hat{R}^* = (3+\sqrt{5})\hat{R}^* \leq (3+\sqrt{5})R^*$, as needed for p. Otherwise $q \notin S^{(\text{old})}$ and based on Lemma 22, we can infer that $q \notin S_{i-1}$. Due to the order induced by the Gonzalez Operation, we have $\text{dist}(q, S_{i-1}) \leq \text{dist}(c_i^{(\text{old})}, S_{i-1})$. Again by Lemma 22, it follows that $\text{dist}(q, S) \leq \text{dist}(q, S_{i-1})$, and so $\text{dist}(q, S) \leq \text{dist}(c_i^{(\text{old})}, S_{i-1})$. Based on Lemma 21 (note that i is the largest such index in Line 24), it holds that $\text{dist}(c_i^{(\text{old})}, S_{i-1}) \leq \text{dist}(c_i^{(\text{old})}, S^{(\text{old})} \setminus \{c_i^{(\text{old})}\})$. Combining these inequalities, we conclude that $\text{dist}(q, S) \leq \text{dist}(c_i^{(\text{old})}, S^{(\text{old})} \setminus \{c_i^{(\text{old})}\})$. Since we previously showed that $\text{dist}(c_i^{(\text{old})}, S^{(\text{old})} \setminus \{c_i^{(\text{old})}\}) \leq 2\hat{R}^*$, we deduce that $\text{dist}(q, S) \leq 2\hat{R}^*$. As a result, by the triangle inequality it follows that $\text{dist}(p, S) \leq 2\hat{R}^* + \beta r$. By Lemma 17 we have $r \leq 2\hat{R}^* \leq 2R^*$, and thus $\text{dist}(p, S) \leq (3+\sqrt{5})\hat{R}^* \leq (3+\sqrt{5})R^*$, as required for p.

The second subphase is active. At any moment during the second subphase, the minimum pairwise distance between centers is greater than $\beta r^{(\text{old})}$ (i.e., $\mathit{minDistS}^{(\text{old})} > \beta r^{(\text{old})}$). As $r = r^{(\text{old})}$ we have $\text{dist}(p^+, S^{(\text{old})}) > \beta r$, which means that the pairwise distances of points in $S^{(\text{old})} \cup \{p^+\}$ are at least βr. According to Lemma 14 we have $|S^{(\text{old})} \cup \{p^+\}| = k+1$, and thus by Lemma 15 it holds that $\beta r \leq 2\hat{R}^*$. Note that the point q belongs to S_{init} but is no longer a center (i.e., q was already replaced by another point in the set of centers during this phase). By the construction of the incremental Algorithm 1, only regular centers are removed from the set of centers. In turn, according to Lemma 8 (Invariant 3) and since the radius remains unchanged during a fixed phase, there is a leader center within distance αr from the point q. Therefore, by the triangle inequality and as $r \leq \frac{2\hat{R}^*}{\beta}$ and $\hat{R}^* \leq R^*$, it follows that $\text{dist}(p, S) \leq \alpha r + \beta r \leq \frac{\alpha}{\beta} 2\hat{R}^* + 2\hat{R}^* = (\frac{\alpha}{\beta} + 1)2\hat{R}^* = (3+\sqrt{5})\hat{R}^* \leq (3+\sqrt{5})R^*$, as required for p. ◀

Proof of Theorem 1. The proof follows by Lemmas 14 and 24 and Corollary 13. ◀

5 Lower Bound on Worst-Case Recourse

In this section, we show a lower bound on the worst-case recourse. In the following, we give the proof for the incremental setting. For the decremental setting, this proof can be "reversed", starting with p^+ as part of the original point set. Then, the adversary deletes that point and the original setting of the following proof needs to be restored, requiring k centers to be moved.

▶ **Theorem 2.** *Consider a point set P in a metric space subject to point insertions, an integer $k \geq 1$, and an approximation factor $\alpha \in [1, \sqrt{2})$. Then any partially dynamic α-approximate k-center algorithm has a worst-case recourse of k.*

Proof. Consider the following k-center instance containing $3k-2$ points $p_1, p_2, \ldots, p_{3k-2}$ such that:

- $\text{dist}(p_1, p_2) = \text{dist}(p_2, p_3) = d'$,
- $\text{dist}(p_{i-1}, p_i) = 2d'$, for all $i \geq 4$ with $i \equiv 1 \pmod 3$,
- $\text{dist}(p_{i-1}, p_i) = d$, for all $i \geq 5$ with $i \not\equiv 1 \pmod 3$, and
- $\text{dist}(p_1, p_i) = \text{dist}(p_1, p_{i-1}) + \text{dist}(p_{i-1}, p_i)$ for all i,

where d and d' satisfy $\max(\frac{2}{3}, \frac{\alpha}{2})d < d' < \frac{d}{\alpha}$.

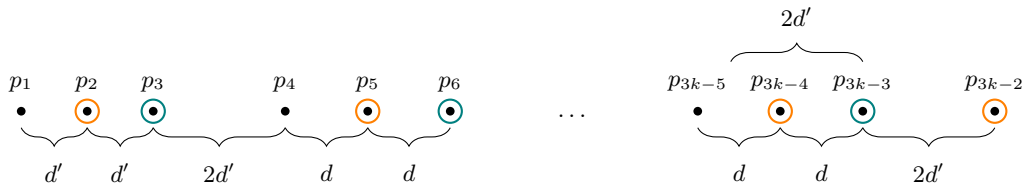

Figure 1 The k-center instance given to an α-approximation algorithm before the adversarial insertion of the point p^+. The orange circles mark the α-approximate placement of the k centers. The teal circles mark the α-approximate placement of $k-1$ centers.

First, we show that there is a unique α-approximate k-center solution. This k-center solution consists of the $k-1$ points p_i with $i \equiv 2 \pmod 3$ and the last point at p_{3k-2} (see Figure 1); the k-center cost of this solution is d. Regarding the uniqueness, each triple p_i, p_{i+1}, p_{i+2} (for every $1 \leq i \leq 3k-5$ with $i \equiv 1 \pmod 3$) and the point p_{3k-2} must contain a center, as otherwise the cost would be at least $2d'$. Moreover, each such center must be placed at the middle point of each triple, as otherwise the cost would be at least $2d'$ (for the leftmost triple) or at least $\min(2d, 2d') = 2d'$ (for any other triple). A strict lower bound on $2d'$ is:

$$2d' > 2\frac{\alpha}{2}d > \alpha d,$$

and thus placing a center at the middle point of each triple and a center at p_{3k-2} is the only possible α-approximate k-center solution.

Assume now that the adversary inserts a point p^+ at a distance greater than $2\alpha d$ from any other point $p_1, p_2, \ldots, p_{3k-2}$. We show that there is a unique α-approximate k-center solution whose cost is $2d'$. To obtain such a solution, one center has to move to p^+, as otherwise the cost would be at least $2\alpha d > \alpha \cdot 2d'$. Hence, we have $k-1$ centers remaining to cover the original $3k-2$ points. To obtain this unique k-center solution, the center from p_{3k-2} is moved to p^+ and all the remaining centers are shifted to the right; namely the $k-1$ remaining centers are placed at p_i where $i \equiv 0 \pmod 3$ (see points marked in teal in Figure 1). The cost of this solution is $2d'$ because $2d < 3d'$ and thus $d < 2d'$; the leftmost point in each triple (except the leftmost one) is covered by the center in the left neighboring triple.

We now show that no other placement of $k-1$ centers among the old points can achieve a cost smaller or equal to $\alpha \cdot 2d'$. Leaving a triple without a center would lead to a cost of at least:

$$\min(4d', 2d' + d) > 2d > \alpha \cdot 2d'.$$

Hence, for any α-approximate solution each triple has to have exactly one center. Suppose to the contrary that in the triple p_i, p_{i+1}, p_{i+2} for some $i \equiv 1 \pmod 3$ the center is not at p_{i+2}. If it is the rightmost triple ($i = 3k-5$), the cost of the solution is at least $2d' + d > 3d' > \alpha \cdot 2d'$.

Otherwise, consider the largest i with $i \equiv 1 \pmod 3$ such that the center for the triple p_i, p_{i+1}, p_{i+2} is not at p_{i+2}. If $i \neq 1$, the cost would be at least $\min(d + 2d', 2d) = 2d > 2\alpha d'$. If $i = 1$, the cost would be at least $\min(3d', 2d) = 2d > 2\alpha d'$.

After the adversarial insertion of p^+, the unique α-approximate solution is given by the set of centers $\{p_i \mid 3 \leq i \leq 3k-3, i \equiv 0 \pmod 3\} \cup \{p^+\}$. As a consequence, the recourse of the solution before and after the adversarial point insertion is k, concluding the proof. ◀

Abstract

The geometric median problem asks to find a point in $\mathbb{R}^d$ that minimizes the sum of Euclidean distances to an input set. It is a classical problem in computational geometry and appears as a subroutine in numerous optimization tasks, many of which require the solution to satisfy additional structural constraints. A common approach to reduce the input size is to construct a coreset, which is a small weighted subset that faithfully represents the input for a specific optimization problem. Strong coresets preserve the cost of every candidate solution but require linear time to construct; weak coresets admit sublinear construction, in fact by uniform sampling, but only preserve near-optimal solutions, which is insufficient when the solution is constrained. To address this, we focus instead on the recently introduced intermediate notion of a *stable coreset*, which simultaneously handles all constrained variants. Currently, there is a large gap between the known sample sizes for stable and weak coresets.

Our main result is that a uniform sample of size $O(\epsilon^{-2} \log \frac{1}{\epsilon})$ is a stable $(\epsilon, O(\epsilon))$-coreset for the geometric median, with high constant probability, and this bound is tight up to the logarithmic factor. Our analysis adapts recent machinery of Carmel and Krauthgamer (ICLR 2026) for constructing stable coresets, which incurs an $O(\log d)$ factor. We show an iterative argument that progressively reduces the sample size, and eliminates this dependence on the dimension d. At a high level, this approach resembles the technique of iterative size reduction, which is applicable for strong coresets but not for weak coresets.

1 Introduction

Clustering is a basic tool for understanding large collections of data, with applications throughout machine learning, statistics, and optimization. The core idea is to partition the data points into sets (called clusters) that share common characteristics, and a classical formulation is center-based clustering, where each cluster is represented by a single point. One of the most fundamental problems in this family is the *geometric median*, which asks for a point that minimizes the sum of distances to all the input points. Despite its

apparent simplicity, the geometric median exhibits strong robustness properties and has broad applications, from robust statistics to facility location and machine learning. To define this problem formally, we view it as a special case of the *k-median problem*, where the input is a point set P in a metric space $(\mathcal{X}, \mathrm{dist})$, and the goal is to find a set $C \subseteq \mathcal{X}$ of k centers that minimize the objective

$$\mathrm{cost}(C, P) := \sum_{p \in P} \min_{c \in C} \mathrm{dist}(p, c).$$

The *geometric median problem* (also called the *Fermat-Weber problem*) is the case $k = 1$ in the widely studied setting of Euclidean spaces, i.e., $\mathcal{X} = \mathbb{R}^d$ and $\mathrm{dist}(x, y) = \|x - y\|_2$. Our main result addresses the geometric median problem, however the broader context is often useful, e.g., our proof connects this problem to 1-median in ℓ_1 spaces.

As datasets grow in size, data reduction techniques have become essential, as they enable algorithms to operate on small summaries rather than on the entire dataset. A coreset formalizes this idea by providing a small instance of the same problem, where solving the problem on the coreset immediately provides similar guarantees for the original dataset. Coresets usually offer a tunable tradeoff between size and quality, the latter measured as an approximation factor. A *strong ϵ-coreset* for k-median is a weighted subset $Q \subseteq P$ such that for every set of k centers $C \subset \mathbb{R}^d$, the cost is approximately preserved, namely,

$$\mathrm{cost}(C, Q) \in (1 \pm \epsilon) \cdot \mathrm{cost}(C, P). \tag{1}$$

Strong coresets for the classical k-median problem in Euclidean space, alongside numerous variants, have been studied extensively over the past two decades, see Section 1.3 for more details.

Many modern applications involve massive datasets, for which even linear-time processing might be prohibitive. Yet, constructing a strong coreset inherently requires reading each data point, which takes at least linear time $\Omega(nd)$, regardless of the coreset's size.[1] Therefore, to open the door for sublinear-time algorithms, one natural relaxation is the notion of a *weak coreset*. A weighted subset $Q \subseteq P$ is called a weak (ϵ, η)-coreset if every near-optimal solution for Q is also a near-optimal solution for P, namely, for every set of k centers $C \subset \mathbb{R}^d$,

$$\text{if } \mathrm{cost}(C, Q) \le (1+\epsilon) \cdot \min_{|C'|=k} \mathrm{cost}(C', Q), \text{ then } \mathrm{cost}(C, P) \le (1+\eta) \cdot \min_{|C'|=k} \mathrm{cost}(C', P). \tag{2}$$

It is worth noting that most constructions achieve $\eta = O(\epsilon)$, but covering the entire literature requires two separate parameters. Weak coresets can be constructed via uniform sampling, a method widely adopted in practice, often without theoretical guarantees, and naturally suited to streaming and distributed settings. See Table 1 for known bounds and references.

Despite its appeal, the weak coreset notion has a fundamental limitation: A strong coreset has guarantees for *every* candidate solution, but a weak coreset provides guarantees only for candidates that are near-optimal (on the coreset). This might be a severe limitation when the solutions of interest are constrained to a subset $\mathcal{X}' \subset \mathcal{X}$ (because an optimal solution in $\mathcal{X}'$ need not be optimal also in $\mathcal{X}$), and such constraints indeed arise from structural requirements or downstream tasks, as we discuss further below.

[1] Consider an instance P with a single extremely distant point. A strong coreset must include this point, which requires scanning the entire instance.

Table 1 Sublinear-time constructions of coresets for the geometric median problem. In all of them, the sample complexity equals the (listed) coreset size; in fact, the coreset is simply the sample, except when marked by †, in which the sample is post-processed. Strong coresets are not listed as they require at least linear time.

Coreset type	Coreset size	Reference
weak $(0, \epsilon)$	$\widetilde{O}(\epsilon^{-2}d)$	[1, 45]
	$\widetilde{O}(\epsilon^{-4})$	[25]
weak $(\epsilon, O(\epsilon))$	$\widetilde{O}(\epsilon^{-4})$ †	[21]
	$\widetilde{O}(\epsilon^{-3})$	[33]
	$\widetilde{O}(\epsilon^{-2})$	[53]
stable $(\epsilon, O(\epsilon))$	$\widetilde{O}(\epsilon^{-2}\log d)$	[13]
	$\widetilde{O}(\epsilon^{-2})$	Theorem 1.1

The notion of a *stable coreset*, recently introduced by [13], is intermediate between the strong and weak coreset notions and addresses this issue, by preserving the relative quality of *all pairs* of candidate solutions. Formally, a weighted subset $Q \subseteq P$ is called a stable (ϵ, η)-coreset if for every pair of candidates $C, C' \subset \mathbb{R}^d$,

$$\text{if } \operatorname{cost}(C, Q) \le (1+\epsilon)\cdot \operatorname{cost}(C', Q), \text{ then } \operatorname{cost}(C, P) \le (1+\eta)\cdot \operatorname{cost}(C', P). \tag{3}$$

Crucially, since this guarantee holds simultaneously for all pairs of candidates, the same stable coreset can be reused across multiple constraints and downstream tasks, and its construction does not require a priori knowledge of the constraints.

The geometric median problem is used as a subroutine in numerous optimization tasks, and many of them require the solution to satisfy additional constraints, which essentially restrict it to a predetermined subset $\mathcal{X}' \subset \mathcal{X} = \mathbb{R}^d$. For instance, the solution may be required to lie in a low-dimensional linear subspace, or more generally on an algebraic variety, or to have a sparse coordinate structure (e.g., $\|c\|_0 \le \alpha$).

We illustrate this with three concrete examples. First, in kernel-based methods, the input points are all images of a feature map φ and also the solution must be an image of φ [44, 47]; in this case, $\mathcal{X}'$ is simply the image set of φ. Second, the *discrete* geometric median problem requires the solution to be one of the input points in P [46, 30, 24]; in this case $\mathcal{X}' = P$ is discrete. Third, the *ultrametric* 1-*median* problem, in which the input distances form an ultrametric and the solution is a median terminal node, admits a $(1+\epsilon)$-approximation in $\widetilde{O}(\epsilon^{-3})$ time [14]. Since finite ultrametrics embed isometrically into ℓ_2 [51], this is a special case of constrained ℓ_2 1-median.

In all these cases where we seek an optimal or near-optimal solution in $\mathcal{X}'$, a weak coreset provides no guarantees, while a stable coreset is applicable, in fact simultaneously for all possible restrictions $\mathcal{X}'$.

1.1 Our Results

A long line of work has progressively refined the size of weak coresets (see Table 1), however these results and techniques do not extend (at least not directly) to stable coresets, for which the known bound falls behind and even depends on the dimension d. Our main result is a stable coreset for geometric median that is constructed via uniform sampling (with no post-processing) and has near-optimal size and query complexity. In our result, a uniform sample is one drawn without replacement.

▶ **Theorem 1.1.** *Let $\epsilon \in (0, 1/4)$ and let $P \subset \mathbb{R}^d$ be finite. Then a uniform sample of size $O(\epsilon^{-2} \log \frac{1}{\epsilon})$ from P is a stable $(\epsilon, 17\epsilon)$-coreset for 1-median in ℓ_2^d with probability at least $4/5$.*

This result improves over the stable coreset of [13], which is also via uniform sampling and has size $\widetilde{O}(\epsilon^{-2} \log d)$. Our bound completely eliminates the dependence on the dimension. Technically, their main result is for ℓ_1 metrics, and the Euclidean case follows by Dvoretzky's theorem [29, 49]. Previously, a similar coreset size $\widetilde{O}(\epsilon^{-2})$, also via uniform sampling, was known only for weak coreset [53], which is strictly less powerful. Technically, it is obtained as a corollary of a result for multiple ℓ_p regression, whose proof leverages ℓ_p Lewis weight sampling. In contrast, our proof refines the framework for stable coresets recently developed by [13], and employs an iterative argument to progressively reduce the sample size, see Section 1.2.

The dependence on ϵ in our bound is near-tight, as an $\Omega(\epsilon^{-2})$ lower bound follows from more general results of [16, 48]. For completeness, we provide a short self-contained proof in Appendix A .

▶ Remark 1.2. We consider only the case $k = 1$ in order to obtain clean theoretical guarantees. It is well-known that sublinear algorithms face a major challenge when $k > 1$, because small clusters can be missed by sublinear methods. Prior work by [33] (see also references therein) has formalized this issue through a *balancedness parameter* $\beta \in (0, 1]$, which measures the smallest cluster size in an optimal solution, modifying the coreset definition to consider only β-balanced clusterings of the coreset.

1.2 Technical Overview

We now overview the proof of our main result, Theorem 1.1. Our starting point is a result of [13, Corollary D.2], which establishes that a uniform sample of size $O(\epsilon^{-2} \log(d/\epsilon))$ is a stable $(\epsilon, O(\epsilon))$-coreset for 1-median in ℓ_2^d with high constant probability. Their proof exploits the fact that ℓ_2^d embeds into $\ell_1^{O(d)}$, by Dvoretzky's theorem, and applies their analysis for the 1-median problem in ℓ_1. We make a simple observation, that a folklore terminal embedding (Theorem 2.3) reduces the problem to the case where $d \le n$, and therefore a uniform sample Q of size $O(\epsilon^{-2} \log(n/\epsilon))$ suffices for such a coreset, regardless of the ambient dimension d of our dataset P.

Building on this simple observation, our high-level idea is to apply iterative size reduction, a technique introduced by [9] for strong coresets, hence we need to adapt it to stable coresets. Suppose we have a uniform sample $Q \subset P$ of size $\widetilde{O}(\epsilon^{-2} \log n)$, and then we pick from it a uniform sample $R \subseteq Q$ of size $\widetilde{O}(\epsilon^{-2} \log |Q|) = \widetilde{O}(\epsilon^{-2} \log \log n)$. By our preceding discussion, with constant high probability, Q is a stable coreset of P, and also R is a stable coreset of Q. Now if coresets can be composed (i.e., a coreset of a coreset is a coreset), which is indeed the case for strong coresets, then R is also a coreset of our initial dataset P. The crux is to apply this argument iteratively until the size of the sample no longer decreases, and by solving $|Q| \le \epsilon^{-2} \log(|Q|/\epsilon)$ we can easily see that the final sample size is $\widetilde{O}(\epsilon^{-2})$. Importantly, while this analysis goes through cumbersome iterations, the algorithm is simple: A uniform sample R from Q, which itself is a uniform sample from P, amounts to a uniform sample R taken directly from P. Therefore, the final coreset is just a uniform sample of size $\widetilde{O}(\epsilon^{-2})$ from the input P.

Unfortunately, the above strategy has considerable gaps. One issue is that each iteration might fail with a constant probability, which is too large because the number of iterations is typically $O(\log^* n)$. One can decrease this probability by tuning parameters differently

(standard amplification by majority over repetitions would deviate from uniform sampling), but the final coreset size will depend on n, missing our intended goal. Another issue is that the errors accumulate over the iterations. Prior work [9, 21, 37] addressed this by setting a different approximation parameter ϵ_i for each iteration i. Typically, one starts with a small value, say $\epsilon_1 = 1/\log n$, and increases it exponentially fast until some final value ϵ_{final}, which determines the final coreset size. For strong coresets, the accumulated error is $\prod_i(1+\epsilon_i) \le 1 + \sum_i O(\epsilon_i) \le 1 + O(\epsilon_{\text{final}})$, however for stable coresets the errors compound completely differently. Suppose that each iteration yields a stable $(\epsilon, 2\epsilon)$-coreset, then we must set $\epsilon_{i+1} = \epsilon_i/2 = \epsilon_1/2^i$, which results overall in a stable $(\epsilon_{\text{final}}, \epsilon_1)$-coreset. As the number of iterations grows with n, albeit slowly like $O(\log^* n)$, this guarantee is rather poor and certainly misses our intended goal.

Since iterative size reduction cannot be applied in a black-box manner, we need to implement the iterations in a more specialized manner. We identify that (a slight adaptation of) a notion called *Relative Cost-Difference Approximation* (RCDA), that was introduced by [13], avoids the core issue in the scheme above. Informally, the RCDA notion asserts that the difference in costs between any two candidate centers is approximately the same when measured on the sample versus on the full dataset. We compose this RCDA notion over the iterations, which requires some technical adaptations. It also introduces some error terms and failure probabilities, and tracking these carefully over the iterations is somewhat intricate. Our main technical lemma (Lemma 4.2) shows that the final sample is an RCDA for P, which, in turn, implies that it forms a stable coreset.

1.3 Related Work

Strong coresets, which are often simply referred to as coresets, have been extensively studied for the k-median and k-means problems in Euclidean metrics. After a long line of works, which includes [31, 15, 28, 52, 39, 9, 22], the current state-of-the-art constructions for k-median and k-means match the known lower bound of $\Omega(k\epsilon^{-2})$, up to polylogarithmic factors [20, 37]. For the ℓ_1 metric, a coreset of size $\text{poly}(k/\epsilon)$ follows from [40] by going through ℓ_2-squared. The case of $k = 1$ has received special attention. In low-dimensional Euclidean spaces [32] obtain a strong coreset of size $\widetilde{O}(\sqrt{d}/\epsilon)$, which was subsequently improved by [2] to $\widetilde{O}(\epsilon^{-d/(d+1)})$ for any constant dimension d.

Many coreset variants of the k-median and k-means problems have been studied as well. Closest to our work is the line of weak coresets for 1-median in Euclidean spaces, where the construction can be performed in sublinear time; see Table 1 for a detailed comparison of previous results. Additionally, coresets have been studied for other variants of the geometric median problem and the more general k-median problem in Euclidean metrics, including capacitated k-median [7, 36], fair clustering [50, 35, 18], robust clustering [34, 41, 27], fuzzy clustering [6], ordered weighted clustering [8], and time-series clustering [38].

Another closely related problem is the 1-center, also known as the minimum enclosing ball problem. Strong coresets for this problem in Euclidean metrics require exponential dependence on the dimension [3]. Weak coresets, in contrast, were studied by [11, 10], who show a tight size bound of $\lceil 1/\epsilon \rceil$. For the ℓ_1 metric, [12] studied both strong and weak coresets, and showed that the coreset size must depend on the dimension.

Lastly, a separate line of work studies sublinear approximation algorithms for the geometric median (or the related 1-means objective), rather than constructing a coreset [19, 5].

2 Preliminaries

In the 1-median problem on the metric space $\ell_q^d = (\mathbb{R}^d, \|\cdot\|_q)$, we are given a set $P \subset \mathbb{R}^d$ and the goal is to find a point $x \in \mathbb{R}^d$ that minimizes the sum of distances to P, that is, to minimize the cost function

$$\mathrm{cost}_q(x, P) = \frac{1}{|P|} \sum_{p \in P} \|x - p\|_q .$$

We denote by μ^P an optimal solution to the median problem on P, $\mu^P = \mathrm{argmin}_{x \in \mathbb{R}^d} \mathrm{cost}_q(x, P)$.

In this paper, we focus on the 1-median problem in the Euclidean metric, that is, $q = 2$. Throughout our analysis, we leverage metric embeddings to translate results between ℓ_2 and ℓ_1.

The following theorem is a classical consequence of Gordon's refinement of Dvoretzky's theorem [29, 49].

▶ **Theorem 2.1** (Dvoretzky's theorem). *For every $\gamma \in (0, 1)$ and natural number d, there exists a linear map $f : \mathbb{R}^d \to \mathbb{R}^m$ with $m = O(\gamma^{-2} d)$ such that*

$$\forall x \in \mathbb{R}^d, \qquad \|f(x)\|_1 \in (1 \pm \gamma) \|x\|_2 .$$

Given such embedding f, it immediately follows that the cost function is also preserved up to $1 \pm \gamma$. For a set $P \subset \mathbb{R}^d$, we denote by $f(P) = \{f(p) : p \in P\}$ the image of P under f.

▶ **Corollary 2.2.** *Let $f : \mathbb{R}^d \to \mathbb{R}^m$ be as in Theorem 2.1 with parameter γ and let $P \subset \mathbb{R}^d$. Then*

$$\forall x \in \mathbb{R}^d, \qquad \mathrm{cost}_1(f(x), f(P)) \in (1 \pm \gamma) \mathrm{cost}_2(x, P).$$

We will need the following folklore isometric terminal embedding in ℓ_2. Although variants of it appear in [26, 39], we include a proof for completeness.

▶ **Theorem 2.3** (Folklore). *Let $P \subset \mathbb{R}^d$ of size n. Then there exists an isometric terminal embedding $f : \mathbb{R}^d \to \mathbb{R}^n$, that is, for all $x \in \mathbb{R}^d$ and $p \in P$, $\|f(x) - f(p)\|_2 = \|x - p\|_2$.*

Proof. Let $P = \{p_1, \ldots, p_n\} \subset \mathbb{R}^d$ be a terminal set. By shifting the points, we can assume w.l.o.g. that p_n lies at the origin. Consider the $(n-1)$-dimensional subspace V spanned by the vectors $p_1, \ldots, p_{n-1}$. As every d-dimensional subspace of ℓ_2 is isometric to $\mathbb{R}^d$, we can also assume w.l.o.g. that $V = \mathbb{R}^{n-1}$. Let $\Pi : \mathbb{R}^d \to V$ be the orthogonal projection map onto V and define the terminal embedding $f : \mathbb{R}^d \to V \times \mathbb{R} = \mathbb{R}^n$ by $f(z) = (\Pi(z), \|\Pi(z) - z\|_2)$. Using the Pythagorean theorem, we conclude that for every $p \in P \subset V$ and $x \in \mathbb{R}^d$

$$\begin{aligned} \|f(p) - f(x)\|_2^2 &= \|\Pi(p) - \Pi(x)\|_2^2 + (\|\Pi(x) - x\|_2 - 0)^2 \\ &= \|p - \Pi(x)\|_2^2 + \|\Pi(x) - x\|_2^2 = \|p - x\|_2^2. \end{aligned}$$

◀

3 RCDA in ℓ_2 via Dimension Reduction

The RCDA property was formulated in [13]. Here we introduce a slightly modified definition.

▶ **Definition 3.1** (Relative Cost-Difference Approximation). *We say that $Q \subseteq P$ is an ϵ-RCDA$_q$ of P if*

$$\forall x, y \in \mathbb{R}^d, \quad \Big| \big[\mathrm{cost}_q(x, P) - \mathrm{cost}_q(y, P)\big] - \big[\mathrm{cost}_q(x, Q) - \mathrm{cost}_q(y, Q)\big] \Big| \leq \epsilon \cdot (\mathrm{cost}_q(x, P) + \mathrm{cost}_q(y, P)). \tag{4}$$

We will denote the left-hand side by $\mathrm{RCDA}_q(x, y, Q, P)$ *for brevity.*

Our definition differs from that in [13] in that (4) quantifies over all pairs $x, y \in \mathbb{R}^d$, whereas the original property was defined with respect to x and the median μ^P. Specifically, the original definition required

$$\forall x \in \mathbb{R}^d, \qquad \mathrm{RCDA}_q(x, \mu^P, Q, P) \le \epsilon \, \mathrm{cost}_q(x, P). \tag{5}$$

However, the two definitions are essentially equivalent. Indeed, if for every $x \in \mathbb{R}^d$, $\mathrm{RCDA}_q(x, \mu^P, Q, P) \le \epsilon \cdot \mathrm{cost}_q(x, P)$, then for every $x, y \in \mathbb{R}^d$,

$$\mathrm{RCDA}_q(x, y, Q, P) \le \mathrm{RCDA}_q(x, \mu^P, Q, P) + \mathrm{RCDA}_q(\mu^P, y, Q, P) \le \epsilon \cdot (\mathrm{cost}_q(x, P) + \mathrm{cost}_q(y, P)),$$

where the first inequality follows from the triangle inequality. Conversely, if for every $x, y \in \mathbb{R}^d$, we have $\mathrm{RCDA}_q(x, y, Q, P) \le \epsilon \cdot (\mathrm{cost}_q(x, P) + \mathrm{cost}_q(y, P))$, then for every $x \in X$,

$$\mathrm{RCDA}_q(x, \mu^P, Q, P) \le \epsilon \cdot (\mathrm{cost}_q(x, P) + \mathrm{cost}_q(\mu^P, P)) \le 2\epsilon \cdot \mathrm{cost}_q(x, P).$$

The main technical result from [13] establishes the RCDA property for a uniform sample in ℓ_1^d.

▶ **Lemma 3.2** (Lemma 4.6 in [13]). *Let $\epsilon \in (0, 1)$ and let $P \subset \mathbb{R}^d$ of size n. Then a uniform sample $Q \subseteq P$ of size $O(\epsilon^{-2} \log \frac{d}{\delta})$ is an ϵ-RCDA$_1$ of P in ℓ_1^d with probability at least $1 - \delta$.*

▶ Remark 3.3. While [13] does not explicitly state whether the uniform sample is taken with or without replacement, their result holds in both cases. The only step in their proof that depends on the sampling scheme is a theorem from [42] on ϵ-approximations, which applies equally to sampling with and without replacement [23].

A direct consequence of the RCDA property, is a uniform bound over all costs.

▶ **Proposition 3.4.** *Let $\epsilon \in (0, 1/2)$ and $\alpha \ge 1$. If Q is an ϵ-RCDA$_q$ of P and $\mathrm{cost}_q(\mu^P, Q) \le \alpha \, \mathrm{cost}_q(\mu^P, P)$, then,*

$$\forall x \in \mathbb{R}^d, \qquad \mathrm{cost}_q(x, Q) \le 2\alpha \, \mathrm{cost}_q(x, P).$$

Proof. By Definition 3.1, we have $\mathrm{RCDA}_q(x, \mu^P, Q, P) \le \epsilon \cdot (\mathrm{cost}_q(x, P) + \mathrm{cost}_q(\mu^P, P))$. Therefore:

$$\begin{aligned}
\mathrm{cost}_q(x, Q) &\le \mathrm{cost}_q(x, P) + \mathrm{cost}_q(\mu^P, Q) - \mathrm{cost}_q(\mu^P, P) + \epsilon(\mathrm{cost}_q(x, P) + \mathrm{cost}_q(\mu^P, P)) \\
&\le (1 + \epsilon) \, \mathrm{cost}_q(x, P) + (\alpha - 1 + \epsilon) \, \mathrm{cost}_q(\mu^P, P) \\
&\le (1 + \epsilon) \, \mathrm{cost}_q(x, P) + (\alpha - 1 + \epsilon) \, \mathrm{cost}_q(x, P) && (\mu^P \text{ is optimal}) \\
&= (\alpha + 2\epsilon) \, \mathrm{cost}_q(x, P) \le 2\alpha \, \mathrm{cost}_q(x, P). && (2\epsilon \le 1 \le \alpha)
\end{aligned}$$

◀

We now establish that uniform sampling yields RCDA in ℓ_2^d by reducing to the ℓ_1 case.

▶ **Lemma 3.5.** *Let $\epsilon \in (0, 1)$, $\alpha \ge 1$, and let $P \subset \mathbb{R}^d$ of size n. Then, with probability at least $1 - 1/\alpha - \delta$, a uniform sample $Q \subseteq P$ of size $O(\epsilon^{-2} \log \frac{\alpha \cdot n}{\epsilon \cdot \delta})$ satisfies:*

1. *Q is an ϵ-RCDA$_2$ of P in ℓ_2^d, and,*
2. *For every $x \in \mathbb{R}^d$, $\mathrm{cost}_2(x, Q) \le 3\alpha \, \mathrm{cost}_2(x, P)$.*

Proof. By Theorem 2.3, we may assume without loss of generality that $d = n$.

Let $\gamma = \frac{\epsilon}{10\alpha}$. By Theorem 2.1, there exists $m = O(\alpha^2 \epsilon^{-2} n)$ and a linear map $f : \mathbb{R}^d \to \mathbb{R}^m$ such that for all $x \in \mathbb{R}^d$, $\|f(x)\|_1 \in (1 \pm \gamma) \|x\|_2$.

By Lemma 3.2, a uniform sample $Q \subseteq P$ of size $O(\epsilon^{-2} \log \frac{m}{\delta}) = O(\epsilon^{-2} \log \frac{\alpha n}{\epsilon\delta})$ is a $\frac{\epsilon}{2}$-RCDA$_1$ of $f(P)$ in ℓ_1^m with probability at least $1-\delta$. That is,

$$\forall x, y \in \mathbb{R}^d, \qquad \mathrm{RCDA}_1(f(x), f(y), f(Q), f(P)) \\ \leq \frac{\epsilon}{2}(\mathrm{cost}_1(f(x), f(P)) + \mathrm{cost}_1(f(y), f(P))). \tag{6}$$

Let μ^P be the optimal median of P in ℓ_2^d. Since $\mathbb{E}_Q[\mathrm{cost}_1(f(\mu^P), f(Q))] = \mathrm{cost}_1(f(\mu^P), f(P))$, by Markov's inequality, with probability at least $1 - 1/\alpha$,

$$\mathrm{cost}_1(f(\mu^P), f(Q)) \leq \alpha \, \mathrm{cost}_1(f(\mu^P), f(P)). \tag{7}$$

In this event, by Proposition 3.4 applied in ℓ_1^m (noting $\epsilon/2 < 1/2$),

$$\forall x \in \mathbb{R}^d, \qquad \mathrm{cost}_1(f(x), f(Q)) \leq 2\alpha \, \mathrm{cost}_1(f(x), f(P)). \tag{8}$$

Using Corollary 2.2, for all $x \in \mathbb{R}^d$,

$$\begin{aligned}\mathrm{cost}_2(x, Q) &\leq (1+\gamma)\,\mathrm{cost}_1(f(x), f(Q)) \leq (1+\gamma) \cdot 2\alpha \, \mathrm{cost}_1(f(x), f(P)) \\ &\leq \frac{2\alpha(1+\gamma)}{1-\gamma}\,\mathrm{cost}_2(x, P) \leq 3\alpha \, \mathrm{cost}_2(x, P),\end{aligned}$$

where the last inequality uses $\gamma = \epsilon/(10\alpha) \leq 1/10$, establishing property (2).

To show property (1), let $x, y \in \mathbb{R}^d$. Again using Corollary 2.2 applied to each of the four cost terms and the triangle inequality:

$$\begin{aligned}\mathrm{RCDA}_2(x, y, Q, P) \leq \mathrm{RCDA}_1(f(x), f(y), f(Q), f(P)) + \gamma(&\mathrm{cost}_1(f(x), f(P)) + \mathrm{cost}_1(f(y), f(P)) \\ &+ \mathrm{cost}_1(f(x), f(Q)) + \mathrm{cost}_1(f(y), f(Q)))\end{aligned}$$

By the union bound (6) and (8) holds with probability at least $1 - 1/\alpha - \delta$. We get:

$$\begin{aligned}\mathrm{RCDA}_2(x, y, Q, P) &\leq \frac{\epsilon}{2}(\mathrm{cost}_1(f(x), f(P)) + \mathrm{cost}_1(f(y), f(P))) \\ &\quad + \gamma(2\alpha+1)(\mathrm{cost}_1(f(x), f(P)) + \mathrm{cost}_1(f(y), f(P))) \\ &\leq \frac{1}{1-\gamma}\left(\frac{\epsilon}{2} + \gamma(2\alpha+1)\right)(\mathrm{cost}_2(x, P) + \mathrm{cost}_2(y, P)) \\ &\leq \frac{10}{9}\left(\frac{\epsilon}{2} + \frac{\epsilon(2\alpha+1)}{10\alpha}\right)(\mathrm{cost}_2(x, P) + \mathrm{cost}_2(y, P)) \\ &\leq \frac{10}{9}\left(\frac{\epsilon}{2} + \frac{3\epsilon}{10}\right)(\mathrm{cost}_2(x, P) + \mathrm{cost}_2(y, P)) \leq \epsilon(\mathrm{cost}_2(x, P) + \mathrm{cost}_2(y, P)). \blacktriangleleft\end{aligned}$$

4 Upper Bound (Proof of Theorem 1.1)

To apply the iterative size reduction technique, we first establish the following composition property for RCDA, which allows errors to be tracked across iterations.

▶ **Proposition 4.1.** *Let $Q'' \subseteq Q' \subseteq Q$ with $\epsilon, \epsilon' \in (0,1)$ and $\beta \geq 1$. Suppose Q' is an ϵ-RCDA$_q$ of Q and Q'' is an ϵ'-RCDA$_q$ of Q'. If for every $x \in \mathbb{R}^d$ we have $\mathrm{cost}_q(x, Q') \leq \beta \, \mathrm{cost}_q(x, Q)$, then, Q'' is an $(\epsilon + \epsilon'\beta)$-RCDA$_q$ of Q.*

Proof. For $x, y \in \mathbb{R}^d$, using the triangle inequality,

$$\begin{aligned}\mathrm{RCDA}_q(x, y, Q, Q'') &\leq \mathrm{RCDA}_q(x, y, Q, Q') + \mathrm{RCDA}_q(x, y, Q', Q'') \\ &\leq \epsilon(\mathrm{cost}_q(x, Q) + \mathrm{cost}_q(y, Q)) + \epsilon'(\mathrm{cost}_q(x, Q') + \mathrm{cost}_q(y, Q')) \\ &\leq (\epsilon + \epsilon'\beta)(\mathrm{cost}_q(x, Q) + \mathrm{cost}_q(y, Q)). \blacktriangleleft\end{aligned}$$

We are now ready to prove our main technical lemma. The proof involves balancing the errors with the guaranteed size reduction. To streamline the presentation, we use explicit constants and while we attempt to avoid huge constants, they are probably far from optimal.

▶ **Lemma 4.2.** *Let $\epsilon \in (0, \frac{1}{4})$ and let $P \subset \mathbb{R}^d$ of size n. Then, with probability at least $1 - \frac{1}{30}$, a uniform sample $Q \subseteq P$ of size $O(\epsilon^{-2} \log \frac{1}{\epsilon})$ is an ϵ-RCDA$_2$ of P in ℓ_2^d.*

Proof. By Theorem 2.3, we may assume $d = n$. Denote the i-th iterated logarithm (with base 2) by $\log^{(i)}$, i.e., $\log^{(i+1)} n = \log(\log^{(i)} n)$ where $\log^{(0)} n = n$. Let $t \geq 1$ be the smallest integer such that $\log^{(t-1)} n \leq 2048\epsilon^{-2} \log \epsilon^{-1}$; then it also satisfies $\log^{(t-1)} n > \log(2048\epsilon^{-2} \log \epsilon^{-1}) \geq 16$. For $i = 1, \ldots, t$, define

$$\epsilon_i = \frac{\epsilon}{1440(\log^{(i)} n)^{\frac{1}{2}}}, \qquad \alpha_i = 180(\log^{(i)} n)^{\frac{1}{4}}, \qquad \delta_i = 1/\alpha_i.$$

We construct $Q_t \subseteq Q_{t-1} \subseteq \cdots \subseteq Q_1 \subseteq Q_0 = P$, where each Q_{i+1} is obtained from Q_i by uniform sampling of size

$$O\left(\epsilon_{i+1}^{-2} \log\left(\frac{\alpha_{i+1} n_i}{\epsilon_{i+1}\delta_{i+1}}\right)\right)$$

with $n_i = |Q_i|$, as guaranteed by Lemma 3.5. We next prove the following claim.

▷ Claim 4.3. For every $i \in \{1, \ldots, t\}$, with probability at least $1 - 3\sum_{j=1}^{i} \delta_j$,

$$Q_i \text{ is an } \epsilon \sum_{j=1}^{i} \frac{1}{4(\log^{(j)} n)^{\frac{1}{4}}}\text{-RCDA}_2 \text{ of } P.$$

Proof. The proof proceeds by induction on $i \in \{1, \ldots, t\}$.

Base case. By Lemma 3.5 with parameters $\epsilon_1, \alpha_1, \delta_1$, it follows that Q_1 is an ϵ_1-RCDA$_2$ of P with probability at least $1 - 2\delta_1$. The base case holds as $\epsilon_1 = \epsilon/1440(\log^{(1)} n)^{\frac{1}{2}} \leq \epsilon/4(\log^{(1)} n)^{\frac{1}{4}}$.

Inductive step. Since Q_i is a uniform sample of P, by Markov's inequality, with probability at least $1 - 1/\alpha_{i+1}$,

$$\text{cost}_2(\mu^P, Q_i) \leq \alpha_{i+1} \text{cost}_2(\mu^P, P).$$

By Proposition 3.4, for every $x \in \mathbb{R}^d$, $\text{cost}_2(x, Q_i) \leq 2\alpha_{i+1} \text{cost}_2(x, P)$. Thus, applying Lemma 3.5 to sampling Q_{i+1} from Q_i gives that, with probability at least $1-2\delta_{i+1}$, Q_{i+1} is an ϵ_{i+1}-RCDA$_2$ of Q_i. As by the induction hypothesis, Q_i is an $\epsilon \sum_{j=1}^{i} \frac{1}{4(\log^{(j)} n)^{\frac{1}{4}}}$-RCDA$_2$ of P with probability at least $1-3\sum_{j=1}^{i} \delta_j$, both events hold with probability at least $1-3\sum_{j=1}^{i+1} \delta_j$ by a union bound. Assuming they both hold, we can now apply Proposition 4.1 and get,

$$Q_{i+1} \text{ is an } \left(\epsilon \sum_{j=1}^{i} \frac{1}{4(\log^{(j)} n)^{\frac{1}{4}}} + \epsilon_{i+1} \cdot 2\alpha_{i+1}\right)\text{-RCDA}_2 \text{ of } P.$$

Since $\epsilon_{i+1} \cdot 2\alpha_{i+1} = \frac{\epsilon}{1440(\log^{(i+1)} n)^{\frac{1}{2}}} \cdot 360(\log^{(i+1)})^{\frac{1}{4}} = \frac{\epsilon}{4(\log^{(i+1)} n)^{\frac{1}{4}}}$, we have,

$$\epsilon \sum_{j=1}^{i} \frac{1}{4(\log^{(j)} n)^{\frac{1}{4}}} + \epsilon_{i+1} \cdot 2\alpha_{i+1} \leq \epsilon \sum_{j=1}^{i+1} \frac{1}{4(\log^{(j)} n)^{\frac{1}{4}}},$$

concluding the induction step, and proving the claim. ◁

We proceed with the proof of Lemma 4.2. By choice of t, for $1 \le j \le t-2$, we have $(\log^{(j+1)} n)^{\frac{1}{4}} \le \frac{1}{8}(\log^{(j)} n)^{\frac{1}{4}}$ since $\log^{(j)} n \ge 2^{16}$. Thus,

$$\epsilon \sum_{j=1}^{t-1} \frac{1}{4(\log^{(j)} n)^{\frac{1}{4}}} \le \frac{\epsilon}{4(\log^{(t-1)} n)^{\frac{1}{4}}} \sum_{j=0}^{t-2} 8^{-j} \le \frac{2\epsilon}{7(\log^{(t-1)} n)^{\frac{1}{4}}},$$

where the last inequality uses the standard bound over a sum of a geometric series. Additionally, since $\log^{(t-1)} n \ge 16$,

$$\epsilon \sum_{j=1}^{t} \frac{1}{4(\log^{(j)} n)^{\frac{1}{4}}} \le \frac{2\epsilon}{7(\log^{(t-1)} n)^{\frac{1}{4}}} + \frac{\epsilon}{4(\log^{(t)} n)^{\frac{1}{4}}} \le \frac{\epsilon}{2},$$

and similarly,

$$3\sum_{j=1}^{t} \delta_j \le 3\sum_{j=1}^{t-1} \delta_j + 3\delta_t \le \frac{24}{7}\delta_{t-1} + 3\delta_t \le \frac{24}{7 \cdot 180(\log^{(t-1)} n)^{\frac{1}{4}}} + \frac{3}{180(\log^{(t)} n)^{\frac{1}{4}}} \le \frac{1}{105} + \frac{1}{60} \le \frac{3}{100},$$

where overall, we get that Q_t is ϵ-RCDA$_2$ of P with probability at least $1 - \frac{3}{100}$.

Sample size. It is easy to verify the invariant $n_i \le C\,\epsilon^{-2} \log \epsilon^{-1} (\log^{(i)} n)^2$ for all $i \in \{1, \ldots, t\}$, for a sufficiently large constant C. Thus, at iteration t, since $\log^{(t-1)} n = O(\epsilon^{-2} \log \epsilon^{-1})$, we have that $n_t = O(\epsilon^{-2} \log \epsilon^{-1} \cdot (\log(\epsilon^{-2} \log \epsilon^{-1}))^2) = O(\epsilon^{-2} \log^3 \frac{1}{\epsilon})$.

To further improve the sample size to $O(\epsilon^{-2} \log \frac{1}{\epsilon})$, we apply one additional iteration with constant parameters. Set $\epsilon_f = \frac{\epsilon}{4000}$, $\alpha_f = 1000$, and $\delta_f = 1/\alpha_f$, and uniformly sample $Q \subseteq Q_t$ of size

$$O\left(\epsilon_f^{-2} \log \frac{\alpha_f n_t}{\epsilon_f \delta_f}\right) = O(\epsilon^{-2} \log \frac{1}{\epsilon}),$$

where note that, since sampling is uniform at every step, Q is also a uniform sample of P.

Finally, by applying the same arguments as in the inductive step, we get that Q is an

$$\left(\frac{\epsilon}{2} + \epsilon_f \cdot 2\alpha_f\right)\text{-RCDA}_2 = \epsilon\text{-RCDA}_2$$

uniform sample of P of size $O(\epsilon^{-2} \log \frac{1}{\epsilon})$ with probability at least $1 - \frac{3}{100} - (2/\alpha_f + \delta_f) \ge 1 - \frac{1}{30}$. This concludes the proof of Lemma 4.2. ◀

We can now prove our main result, by plugging our notion of RCDA into the framework of [13].

▶ **Theorem 1.1.** *Let $\epsilon \in (0, 1/4)$ and let $P \subset \mathbb{R}^d$ be finite. Then a uniform sample of size $O(\epsilon^{-2} \log \frac{1}{\epsilon})$ from P is a stable $(\epsilon, 17\epsilon)$-coreset for 1-median in ℓ_2^d with probability at least $4/5$.*

Proof. By Lemma 4.2, a uniform sample Q of size $O(\epsilon^{-2} \log \epsilon^{-1})$ is $\frac{\epsilon}{2}$-RCDA$_2$ of P in ℓ_2^d with probability at least $29/30$. By Markov's inequality, with probability at least $5/6$, $\mathrm{cost}_2(\mu^P, Q) \le 6\,\mathrm{cost}_2(\mu^P, P)$. By the union bound, both events occur with probability at least $4/5$. Now, let $x, y \in \mathbb{R}^d$ such that $\mathrm{cost}_2(x, Q) \le (1+\epsilon)\,\mathrm{cost}_2(y, Q)$, then

$$\begin{aligned}
\operatorname{cost}_2(x,P) &\le \tfrac{\epsilon}{2}[\operatorname{cost}_2(x,P)+\operatorname{cost}_2(y,P)]+[\operatorname{cost}_2(x,Q)-\operatorname{cost}_2(y,Q)]+\operatorname{cost}_2(y,P) \\
&\qquad (Q \text{ is } \tfrac{\epsilon}{2}\text{-RCDA}_2 \text{ of } P) \\
&\le \tfrac{\epsilon}{2}\operatorname{cost}_2(x,P)+(1+\tfrac{\epsilon}{2})\operatorname{cost}_2(y,P)+\epsilon\operatorname{cost}_2(y,Q) \\
&\qquad (\operatorname{cost}_2(x,Q)\le(1+\epsilon)\operatorname{cost}_2(x,Q)) \\
&\le \tfrac{\epsilon}{2}\operatorname{cost}_2(x,P)+(1+\tfrac{\epsilon}{2}+12\epsilon)\operatorname{cost}_2(y,P) \\
&\qquad (\text{by Proposition 3.4, } \operatorname{cost}_2(y,Q)\le 12\operatorname{cost}_2(y,P)) \\
&\le (1+\epsilon)(1+12.5\epsilon)\operatorname{cost}_2(y,P)\le(1+17\epsilon)\operatorname{cost}_2(y,P).
\end{aligned}$$

This establishes that Q is a stable $(\epsilon, 17\epsilon)$-coreset of P. ◀

A Lower Bound

▶ **Theorem A.1.** *For every $\epsilon \in (0, 1/4)$ and every metric space $(\mathcal{X}, \mathrm{dist})$ containing at least two distinct points, there exists a finite point set $P \subseteq \mathcal{X}$, such that every algorithm producing a weak $(0, \epsilon)$-coreset (and in particular weak $(\epsilon/2, \epsilon)$-coreset) for 1-median with probability at least $4/5$, has query complexity $\Omega(\epsilon^{-2})$.*

Proof. Without loss of generality assume $\mathcal{X}$ contains two distinct points x, y of distance 1. For simplicity, assume $\epsilon/2$ divides n.

Consider two multisets P_0 and P_1. P_0 contains $n/2$ copies of x and $n/2$ copies of y, consequently, $\mathrm{cost}(x, P_0) = \mathrm{cost}(y, P_0) = 1/2$. P_1 contains $n(1-\epsilon)/2$ copies of x and $n(1+\epsilon)/2$ copies of y. For P_1, $\mathrm{cost}(x, P_1) = (1+\epsilon)/2$ and $\mathrm{cost}(y, P_1) = (1-\epsilon)/2$, so $\mathrm{cost}(x, P_1) > (1+2\epsilon)\,\mathrm{cost}(y, P_1)$.

Let Q be a multiset containing s copies of x and $m - s$ copies of y. Then $\mathrm{cost}(x, Q)/\,\mathrm{cost}(y, Q) = (m-s)/s$. If $s \geq m/2$, then $\mathrm{cost}(x, Q) \leq \mathrm{cost}(y, Q)$. Therefore, producing a weak coreset requires distinguishing whether Q was sampled from P_0 or P_1. As a weak $(0, \epsilon)$-coreset of P_1 must have y as an optimal solution. Under uniform sampling, $s \sim \mathrm{Binomial}(m, 1/2)$ for P_0 and $s \sim \mathrm{Binomial}(m, (1-\epsilon)/2)$ for P_1. By an information-theoretic lower bound, distinguishing between two binomial distributions whose biases differ by ϵ with constant probability requires $m = \Omega(\epsilon^{-2})$ samples [17, 43, 4]. ◀

Unbounded-Width CSPs Are Untestable in a Sublinear Number of Queries

Yumou Fei
Massachusetts Institute of Technology, Cambridge, MA, USA

Abstract

The bounded-degree query model, introduced by Goldreich and Ron (*Algorithmica, 2002*), is a standard framework in graph property testing and sublinear-time algorithms. Many properties studied in this model, such as bipartiteness and 3-colorability of graphs, can be expressed as satisfiability of constraint satisfaction problems (CSPs). We prove that for the entire class of *unbounded-width* CSPs, testing satisfiability requires $\Omega(n)$ queries in the bounded-degree model. This result unifies and generalizes several previous lower bounds. In particular, it applies to all CSPs that are known to be **NP**-hard to solve, including k-colorability of ℓ-uniform hypergraphs for any $k, \ell \geqslant 2$ with $(k, \ell) \neq (2, 2)$.

Our proof combines the techniques from Bogdanov, Obata, and Trevisan (*FOCS, 2002*), who established the first $\Omega(n)$ query lower bound for CSP testing in the bounded-degree model, with known results from universal algebra.

1 Introduction

Property testing is a class of algorithmic problems in which the algorithm is allowed to inspect only a small portion of the input. In exchange for this limited access, the goal is relaxed: instead of deciding whether the input exactly satisfies a given property, the tester must merely distinguish inputs that satisfy the property from those that are *far* from satisfying it, under an appropriate notion of distance.

In this paper, we consider the problem of testing satisfiability of constraint satisfaction problems (CSPs). We formally define CSPs as follows. First of all, every CSP considered in this paper is specified by a finite *template*.

▶ **Definition 1.** *A* relational structure *is a pair (D, Γ) where D is a finite set, and Γ is a finite collection of relations on D. Each relation $R \in \Gamma$ is a function $R : D^k \to \{0, 1\}$ for some positive integer k (called the* arity *of R). A fixed relational structure (D, Γ) is also referred to as a* CSP template*.*

As a running example, if we let $D = \{0, 1\}$ and take $\Gamma = \{\mathbb{1}_{\{10,01\}}\}$, where $\mathbb{1}_{\{10,01\}}(x, y) = 1$ if and only if $x \neq y$, then the template (D, Γ) could express the bipartiteness property of graphs, as we will soon explain.

Given a CSP template (D, Γ), we can collect all *instances* of the CSP into an infinite set $\mathrm{CSP}(\Gamma)$.

▶ **Definition 2.** *Given a CSP template (D, Γ), we define* $\mathrm{CSP}(\Gamma)$ *as the (infinite) collection of all* instances $I = (V, \mathcal{C})$*, where V is a finite set of* variables *and $\mathcal{C} = \{C_1, \ldots, C_m\}$ is a multi-set of* constraints *satisfying the following. Each constraint C_i is a pair $(\mathbf{v}, R)$, where $\mathbf{v} = (v_1, \ldots, v_k)$ is a tuple of distinct*[1] *variables from V, and $R : D^k \to \{0, 1\}$ is a relation from Γ. The variable set $\{v_1, \ldots, v_k\} \subseteq V$ is called the* scope *of C_i.*

Now an instance in $\mathrm{CSP}(\{\mathbb{1}_{\{10,01\}}\})$ can be viewed as a graph, with variables as vertices and constraints as edges. The graph is bipartite if and only if the CSP instance is "satisfiable," as defined in the following definition.

▶ **Definition 3.** *An* assignment *for an instance $I = (V, \mathcal{C}) \in \mathrm{CSP}(\Gamma)$ is a map $\tau : V \to D$. We say τ* satisfies *a constraint $((v_1, \ldots, v_k), R)$ if $R\big(\tau(v_1), \ldots, \tau(v_k)\big) = 1$. The* value *of an assignment τ, denoted by $\mathrm{val}_I(\tau)$, is the fraction of constraints in $\mathcal{C}$ satisfied by τ. Note that $\mathrm{val}_I(\tau) \in [0, 1]$. If $\mathrm{val}_I(\tau) = 1$, we say that τ* satisfies *the instance I, or τ is a* satisfying assignment *of I. The* value *of the instance I, denoted by val_I, is the maximum possible value any assignment may achieve.*

The CSP defined by the bipartiteness template $\big(\{0, 1\}, \{\mathbb{1}_{\{10,01\}}\}\big)$ will be denoted by 2COL. Similarly, the property of vertex 3-colorability in graphs can be expressed as a constraint satisfaction problem denoted by 3COL.

1.1 Testing CSP Satisfiability

We study the property testing of CSP satisfiability in the *bounded-degree query model*, defined in Definition 5 below. In this model, the input CSP instance has a fixed variable set, and the degree of each variable (i.e. the number of constraints involving the variable) in the instance is assumed to be uniformly bounded by a constant.

▶ **Definition 4.** *Let (D, Γ) be a CSP template and let V be a set of variables. We write $\mathrm{CSP}(\Gamma, V) \subseteq \mathrm{CSP}(\Gamma)$ for the collection of all $\mathrm{CSP}(\Gamma)$-instances whose variable set is V.*

▶ **Definition 5.** *Fix a CSP template (D, Γ). In the $\mathrm{BD}(d, n)$ model for testing satisfiability, the tester is given oracle access to a CSP instance $I = ([n], \mathcal{C}) \in \mathrm{CSP}(\Gamma, [n])$ with maximum degree at most d. The goal of an ε-tester, where $\varepsilon > 0$ is a fixed constant, is to achieve the following:*

1. *If I is satisfiable, the tester must accept I with probability at least $2/3$.*
2. *If at least εdn constraints must be removed from $\mathcal{C}$ to make I satisfiable, the tester must reject I with probability at least $2/3$.*

The tester accesses the instance I through oracle queries*: when the tester queries a variable $v \in [n]$, the oracle reveals an arbitrary one of the previously unseen constraints involving v, unless all constraints involving v have been revealed (in which case the oracle returns $\perp$).*

The bounded-degree query model was first introduced by [17], in the context of graph property testing. One of the earliest results in this model is that testing bipartiteness (i.e. testing satisfiability of 2COL instances) requires at least $\Omega(\sqrt{n})$ queries [17] (for some degree

[1] Some authors allow repetition of variables in a constraint. In our setting, one can also "artificially" allow repetitions by adding more relations to the relational structure. See the full version of this paper for details.

bound d and error $\varepsilon > 0$) and can be done with at most $\widetilde{O}(\sqrt{n})$ queries [16] (for any degree bound d and any error $\varepsilon > 0$). In contrast, Bogdanov, Obata, and Trevisan [6] showed that testing vertex 3-colorability requires $\Omega(n)$ queries.[2]

The study of testing CSP satisfiability in the bounded-degree model was already formally initiated in the early work of Bogdanov, Obata, and Trevisan [6], who showed that, beyond the specific case of 3COL, several other CSPs (such as 3SAT and 3LIN) require $\Omega(n)$ queries to test in this model. A more systematic investigation was later carried out by Yoshida [27], who proved that any CSP *robustly solved by BasicLP* (the basic linear program) has a satisfiability tester that makes a constant number of queries. Typical examples of such CSPs include 1SAT and 3HornSAT. For the satisfiability testing of any CSP that is not *solved by BasicLP*, [27] further showed that at least $\Omega(\sqrt{n})$ queries are necessary. Examples of such CSPs include 2SAT and 2COL.[3]

The main result of this paper strengthens this picture by proving that, among these BasicLP-unsolvable CSPs, the subclass of *unbounded-width* CSPs requires $\Omega(n)$ queries to test.

▶ **Theorem 6.** *For any CSP template (D, Γ) of unbounded width, there exist constants $\varepsilon \in (0, 1)$ and $d \in \mathbb{N}$ such that any ε-tester for satisfiability of $\mathrm{CSP}(\Gamma)$ instances in the $\mathrm{BD}(d, n)$ model must make $\Omega_{d,\varepsilon}(n)$ queries.*

The notion of bounded width (formally defined in Appendix A) originates from [12] and has been extensively studied in the universal-algebraic approach to CSPs. Bounded-width CSPs can be solved in polynomial time (see Proposition 15), so the class of unbounded-width CSPs includes all CSPs whose satisfiability is **NP**-hard to decide (unless $\mathbf{P} = \mathbf{NP}$, in which case all CSPs are trivially **NP**-hard). Consequently, Theorem 6 implies that all CSPs known to be **NP**-hard are also unconditionally (and maximally) hard to test in the bounded-degree model. This encompasses, for example, the property of k-colorability in ℓ-uniform hypergraphs for all $k, \ell \geqslant 2$ with $(k, \ell) \neq (2, 2)$ (see Remark A.5 of the full version). Our result thus unifies and extends several prior lower bounds from works such as [6, 28, 1].[4]

1.2 Discussion: Testing vs. Approximation

A property tester can be viewed as an algorithm that approximates the distance of an input to satisfying a property – albeit in a very coarse sense, as it only distinguishes zero distance from sufficiently large distance. Nevertheless, many property testers (for example, the constant-query tester of [27] for certain CSPs) operate by explicitly estimating this distance and checking whether it is close to zero. On the negative side, a hardness result for property testing (such as our Theorem 6) can often be interpreted as a hardness of approximation result. This connection to approximation algorithms was, in fact, one of the original motivations in [15], where graph property testing was first introduced.

In this subsection, we examine and discuss our main result Theorem 6 from the perspective of sublinear-time approximation algorithms.

---

[2] These seminal works, along with a large number of subsequent studies (such as [18, 5, 28, 29, 10], to name a few), also investigated a wide range of other graph properties within the bounded-degree model, many of which are not constraint satisfaction problems.

[3] Robust solvability by BasicLP is a stronger condition than solvability by BasicLP, so [27] left open the possibility of CSPs with superconstant but $o(\sqrt{n})$ query complexity. However, a recent unpublished note by Brady [7] proves that all CSPs solvable by BasicLP are also robustly solvable by it, thereby turning the result of [27] into a full dichotomy theorem.

[4] The recent work of [1] proves that testing k-colorability in k-uniform hypergraphs requires $\Omega(n)$ queries, for any $k \geqslant 3$.

1.2.1 MaxCSP Problems

A natural approximation problem associated with CSPs is that of estimating the value of a CSP instance (as defined in Definition 3).[5] This estimation task can be conveniently formulated in the following "gap version."

▶ **Definition 7.** *For a fixed CSP template (D, Γ), a completeness parameter $c \in (0, 1]$ and a soundness parameter $s \in [0, c)$, the problem $\mathsf{MaxCSP}(\Gamma)[c, s]$ is the promise problem where given an instance $I \in \mathrm{CSP}(\Gamma)$, the (randomized) algorithm should distinguish between the following two cases:*

1. *Yes case: if $\mathrm{val}_I \geqslant c$, then the algorithm should accept with probability at least $2/3$.*
2. *No case: if $\mathrm{val}_I \leqslant s$, then the algorithm should reject with probability at least $2/3$.*

The complexity of MaxCSP problems has been extensively studied in the context of polynomial-time algorithms, and a central question is to determine for which tuples (Γ, c, s) the problem $\mathsf{MaxCSP}(\Gamma)[c, s]$ can be solved in polynomial time. Notably, Raghavendra [24] almost[6] characterizes all such tuples, conditioned on the Unique Games Conjecture of [23].

1.2.2 MaxCSP vs. Satisfiability Testing

Whether property testing of CSP satisfiability has implications for MaxCSP problems depends on the notion of "distance to satisfiability" used by the property tester. In the d-bounded-degree model, having distance ε to satisfiability means that at least εdn constraints must be removed to make the instance satisfiable. In contrast, an instance with value $1 - \varepsilon$ in the MaxCSP sense requires removing at least an ε *fraction* of its constraints. Thus, testing CSP satisfiability in the bounded-degree model is analogous to solving $\mathsf{MaxCSP}(\Gamma)[1, 1 - \varepsilon]$, provided the CSP instance has $\Theta(n)$ constraints.

However, a CSP instance in the d-bounded-degree model $\mathrm{BD}(d, n)$ may have far fewer than $\Theta(n)$ constraints. In fact, if an instance contains only $O(1)$ constraints, it would be unreasonable to expect any sublinear-time algorithm to approximate its value, since with high probability the queried variables would not appear in any constraint. To address this, we introduce a modified model $\mathrm{BD}^*(d, \alpha, n)$, where $\alpha > 0$ is a fixed constant ensuring that all CSP instances considered contain at least αn constraints.

Under this refinement, Theorem 6 can be equivalently stated as follows:

▶ **Theorem 8.** *For any CSP template (D, Γ) of unbounded width, there exist constants $\varepsilon, \alpha \in (0, 1)$ and $d \in \mathbb{N}$ such that any algorithm for $\mathsf{MaxCSP}(\Gamma)[1, 1 - \varepsilon]$ in the $\mathrm{BD}^*(d, \alpha, n)$ model must make $\Omega(n)$ queries.*

It is easy to see that Theorem 8 implies Theorem 6. Due to the convenience provided by this rephrased version, in the rest of the paper we will work with Theorem 8 instead of Theorem 6.

---

[5] Ideally, an approximation algorithm would also produce an assignment achieving this value, i.e. one that satisfies as many constraints as possible. However, since we focus on sublinear-time algorithms in this paper, we cannot expect them to explicitly output a complete assignment.

[6] Except for the perfect-completeness case (i.e. the case $c = 1$), which remains a mystery.

1.2.3 Sublinear Time vs. Polynomial Time

As discussed in Section 1.2.2, because of the specific notion of "distance to satisfiability" used in the bounded-degree model, satisfiability testing in this setting most naturally corresponds to MaxCSP problems on instances with $\Theta(n)$ constraints. In contrast, the *dense graph model* (the more extensively studied model in graph property testing) uses another notion of distance, making it better aligned with MaxCSP problems on "dense" instances.

We argue that exactly due to this difference in instance regimes, the bounded-degree model provides a stronger connection to the study of polynomial-time algorithms for MaxCSPs, at least with respect to worst-case approximation ratios. First, MaxCSP problems on general instances can often be reduced to bounded-degree instances (see, e.g., [26]), so bounded-degree instances already capture much of the hardness in the problems. Second, MaxCSP problems tend to be easier on dense instances (see, e.g., [3]). Indeed, [2] shows that every CSP admits a constant-query satisfiability tester in the dense graph model. In contrast, in the bounded-degree model, satisfiability testing already exhibits a wide spectrum of complexities across CSP templates, with query complexity ranging from constant, to $\widetilde{\Theta}(\sqrt{n})$, up to $\Theta(n)$.

We next discuss some results about MaxCSP in the polynomial-time setting that are most relevant to this work.

In the context of polynomial-time algorithms, for certain CSP templates (D, Γ), the *perfect-completeness* problem $\mathsf{MaxCSP}(\Gamma)[1, 1-\varepsilon]$ can exhibit a markedly different level of complexity from the (potentially harder) *imperfect-completeness* problem $\mathsf{MaxCSP}(\Gamma)[1-\varepsilon', 1-\varepsilon]$, even when $\varepsilon' \to 0$ and ε is fixed. For example, in the case of $\mathsf{3LIN}$ (an unbounded-width CSP), the former problem admits a polynomial-time algorithm via Gaussian elimination, whereas the latter is **NP**-hard (due to [20]). More generally, Dalmau and Krokhin [11] proved that the imperfect-completeness problem is **NP**-hard for all unbounded-width CSP templates.

▶ **Theorem 9** ([11]). *For any CSP template (D, Γ) of unbounded width, there exists a constant $\varepsilon \in (0, 1)$ such that for every constant $\varepsilon' \in (0, \varepsilon)$, the problem $\mathsf{MaxCSP}(\Gamma)[1-\varepsilon', 1-\varepsilon]$ is* **NP***-hard.*

In terms of conclusions, our result is not directly comparable with Theorem 9, for multiple reasons. First, Theorem 9 is a hardness result for the imperfect completeness problem, while our Theorem 8 shows hardness for the (potentially easier) perfect completeness problem. Second, Theorem 9 is proved against polynomial-time algorithms, while Theorem 8 is against sublinear-query algorithms. Although **NP**-hardness is likely much stronger than a linear query lower bound, the latter does have the benefit of being unconditional. It is also not clear a priori whether some useful algorithms could have sublinear query complexity but super-polynomial time complexity, so **NP**-hardness usually does not immediately imply query lower bounds in sublinear-time models, even when assuming $\mathbf{P} \neq \mathbf{NP}$.

In terms of techniques, however, the proof of Theorem 8 runs in direct parallel to that of Theorem 9 in [11]. While [11] constructs a reduction from the **NP**-hardness of approximating $\mathsf{3LIN}$ instances (established by [20]), our proof of Theorem 8 builds an analogous reduction from the linear-query lower bound for $\mathsf{3LIN}$ instances (proved in [6]). Unlike in the **NP** setting, where a reduction need only run in polynomial time, our bounded-degree query setting requires addressing several additional subtleties. In particular, certain parts of the proof rely on a careful combination of techniques from both [6] and [11].

▶ Remark 10. The result of [11] (Theorem 9) was later shown to be tight by Barto and Kozik [4]. Specifically, they proved that for every CSP template (D, Γ) of bounded width and every constant $\varepsilon \in (0, 1)$, there exists a constant $\varepsilon' \in (0, \varepsilon)$ such that the problem

$\mathsf{MaxCSP}(\Gamma)[1-\varepsilon', 1-\varepsilon]$ belongs to $\mathbf{P}$. Together with the result of [11], this establishes that bounded width exactly characterizes the class of *robustly solvable* CSPs, as conjectured earlier by Guruswami and Zhou [19].

1.2.4 Sublinear Time vs. Sublinear Space

The past decades have seen a growing body of work on MaxCSP problems in *sublinear-space* algorithmic models (such as [21, 22, 9, 8, 25, 13], to name a few), particularly in the contexts of sketching and streaming algorithms. Recent studies [14, 13] reveal a phenomenological connection between the *multi-pass streaming* model and the bounded-degree query model: the class of MaxCSP problems that are easy in the bounded-degree model (admitting algorithms with constantly many queries) almost[7] coincides with those that are easy in the multi-pass streaming model (admitting algorithms with constantly many passes and polylogarithmic space). We view this connection as further motivation for studying MaxCSP and other approximation problems in the bounded-degree query model.

In light of this connection, a natural question arises: does the hardness result of Theorem 8 also extend to the multi-pass streaming model?

▶ **Question 11.** *Is it true that for every CSP template (D, Γ) of unbounded width, there exists a constant $\varepsilon > 0$ such that $\mathsf{MaxCSP}(\Gamma)[1, 1-\varepsilon]$ requires $\Omega(n)$ space in the multi-pass streaming model?*

We remark that, as discussed in [13], query lower bounds in sublinear time models are usually easier to establish than space lower bounds, and thus Theorem 8 can be seen as a preliminary step towards answering Question 11.

1.3 Open Problems

Perhaps the most obvious open problem left by this work is whether the result of Theorem 8 is tight, analogous to the case of Theorem 9 (see Remark 10).

▶ **Question 12.** *Do sublinear-query algorithms exist for satisfiability testing of all bounded-width CSPs?*

In their original work, Bogdanov, Obata and Trevisan [6] asked whether, given a CSP template (D, Γ), one can determine the optimal hardness gap ε for which $\mathsf{MaxCSP}(\Gamma)[1, 1-\varepsilon]$ requires $\Omega(n)$ queries. This question remains wide open (even for "simple" templates such as $\mathsf{3COL}$). Here, we pose the following more ambitious version.

▶ **Question 13.** *Determine the query complexity of $\mathsf{MaxCSP}(\Gamma)[c, s]$ in the bounded-degree model, for all predicate families Γ and parameters c and s.*

As discussed in Section 1.2.4, this question may also have strong relevance to sublinear-space computational models. Moreover, resolving Question 13 unconditionally (without assuming $\mathbf{P} \neq \mathbf{NP}$ or the Unique Games Conjecture) could possibly shed new light on the corresponding question for polynomial-time algorithms.

[7] Except for the perfect-completeness case, which remains a mystery for both models.

A Definition of Bounded Width

In this section, we provide the definition and basic properties of the "bounded width" notion for CSPs. The class of bounded-width CSP templates is defined by the correctness of an algorithm, which we call the width-(k, ℓ) algorithm, in deciding satisfiability of instances.

▶ **Definition 14** ([12]). *Let k, ℓ be integers such that $\ell \geqslant k \geqslant 1$. A CSP template (D, Γ) is said to have width (k, ℓ) if for all instances $I \in \mathrm{CSP}(\Gamma)$, Algorithm 1 correctly decides whether I is satisfiable. A template (D, Γ) is said to have bounded width if it has width (k, ℓ) for some integers k, ℓ; otherwise, we say (D, Γ) has unbounded width.*

Note that Algorithm 1 is always correct if it outputs `unsatisfiable`, so the only mistake is when the input instance is unsatisfiable but it outputs `satisfiable`. Also, since the running time of Algorithm 1 is clearly polynomial in $|V|$ and m, we immediately have the following property:

▶ **Proposition 15.** *For a CSP template (D, Γ), we let Γ-SAT be the problem of deciding satisfiability of instances from $\mathrm{CSP}(\Gamma)$. If (D, Γ) has bounded width, then Γ-SAT $\in \mathbf{P}$.*

Algorithm 1 Width-(k, ℓ) Algorithm.

Input : a CSP(Γ) instance $I = (V, (C_1, \ldots, C_m))$
Output : `satisfiable` or `unsatisfiable`

for *each subset* $U \subseteq V$ *of size* ℓ **do**
  Initialize a set of partial assignments $S_U \leftarrow D^U$
  for *each pair* (τ, i) *of partial assignment* $\tau \in D^U$ *and constraint index* $i \in [m]$ **do**
    if U *contains the scope of* C_i **and** τ *does not satisfy* C_i **then**
      $S_U \leftarrow S_U \setminus \{\tau\}$ `// remove inconsistencies with original constraints`

`// finish initialization; start main procedure`
repeat
  for *each pair of subsets* $U_1, U_2 \subseteq V$ *such that* $|U_1| = |U_2| = \ell$ **do**
    for *each (if any) subset* $W \subseteq U_1 \cap U_2$ *such that* $|W| = k$ **do**
      for *each* $\tau \in S_{U_1}$ **do**
        if $\tau_{|W} \neq \sigma_{|W}$ *for all* $\sigma \in S_{U_2}$ **then**
          $S_{U_1} \leftarrow S_{U_1} \setminus \{\tau\}$ `// remove inconsistencies in any` k `variables`
until *the sets* S_U *stop changing*
Output `unsatisfiable` if $S_U = \emptyset$ for some U; otherwise **output** `satisfiable`

Tight Simulation of a Distribution Using Conditional Samples

Tomer Adar
Technion – Israel Institute of Technology, Haifa, Israel

Abstract

We present an algorithm for simulating a distribution using prefix conditional samples (Adar, Fischer and Levi, 2024), as well as "prefix-compatible" conditional models such as the interval model (Cannone, Ron and Servedio, 2015) and the subcube model (CRS15, Bhattacharyya and Chakraborty, 2018). The sample complexity is $O(\log^2 N/\varepsilon^2)$ prefix conditional samples per query, which improves on the previously known $\tilde{O}(\log^3 N/\varepsilon^2)$ (Kumar, Meel and Pote, 2025). Moreover, our simulating distribution is $O(\varepsilon^2)$-close to the input distribution with respect to the Kullback-Leibler divergence, which is stricter than the usual guarantee of being $O(\varepsilon)$-close with respect to the total-variation distance.

We show that our algorithm is tight with respect to the highly-related task of estimation: every algorithm that is able to estimate the mass of individual elements within $(1 \pm \varepsilon)$-multiplicative error must make $\Omega(\log^2 N/\varepsilon^2)$ prefix conditional samples per element.

1 Introduction

Distribution testing, formally initiated by [4, 3], is a branch of property testing where the goal is distinguishing with high probability between distributions that have some property (for example, uniformity) and distributions that are far from any distribution with this property (for example, extremely biased distributions). "Farness" (or closeness) of distributions is usually determined by comparing the total-variation distance to a threshold parameter, usually denoted by ε.

The sampling model of distribution testing allows the algorithm to obtain a sequence of independent samples from its input distribution. One core result of distribution testing in the sampling model is uniformity testing over a domain of size N, at the cost of $\Theta(\sqrt{N}/\varepsilon^2)$ [15] samples. Other elementary properties, such as identity to an explicit distribution [3] and equivalence to an unknown distribution [11], require polynomial number of samples as well (but still sublinear).

The sampling model of distribution testing is ineffective for high-dimensional domains, such as the set of binary strings of length n, since it requires a polynomial number of samples in the domain size even for simple core properties, which is exponential in the dimension n. For obtaining sub-polynomial testing algorithms, we strengthen the model.

The conditional sampling model, independently introduced by [9] and [10], allows the algorithm to choose a set A and draw a sample from the input distribution when conditioned on belonging to A. Various works focus on restricted forms of the conditional sampling model, where only sets of a restricted form are eligible for conditioning. We recall a few of them.

Subcube conditions

The subcube conditional model defined by [5] (see further works: [7, 12, 1, 13]) is defined for distributions over product sets: the domain is Σ^n for some alphabet Σ, and the sets eligible for condition are the cartesian product of their projections on individual characters. More formally, a subcube condition is a set of the form $A = \prod_{i=1}^{n} A_i$ for $A_1, \ldots, A_n \subseteq \Sigma$. Conceptually, the subcube conditional model resembles the "SELECT ... WHERE"-form of SQL queries.

Prefix conditions

In this paper, we focus on prefix conditions [1] (implicitly in [13, 5, 10]). Prefix conditions are a restricted form of subcube conditions in which there exists some k for which $A_1, \ldots, A_{k-1}$ are all singletons and $A_k, \ldots, A_n = \Sigma$. Note that we can identify every condition set $\{a_1\} \times \cdots \times \{a_{i-1}\} \times \Omega^{n-|w|}$ with the prefix $w = a_1 \ldots a_{i-1}$ (of length $i-1$) itself.

Additional works define various condition models such as *pair conditions* [9] (the condition set must have two elements), *interval conditions* [9] ($A = \{a, \ldots, b\} \subseteq \{1, \ldots, N\}$) and *coordinate conditions* [6] (we fix all symbols of a string but one). For binary string domains ($\Omega = \{0,1\}^n$), prefix conditions can be seen as prefix-interval condition sets (through the encoding $x \in \{0,1\}^n \to 1 + \sum_{i=1}^{n} 2^{n-i} x_i$ [1]) and coordinate conditions can be seen as subcube-pair condition sets.

1.1 Estimation and simulation of a distribution

In the string model of property testing (for example [16, 17]), the algorithm can choose an index to query and reveal the bit in that index. In other words, it obtains certain (undoubted) information about its input. In contrast, in all sampling models, the access to the input is indirect: the algorithm only obtains "behavioral" information about its input.

There are two concepts of "bridging" between sampling and querying. The first is *estimation*: given an element $x \in \Omega$, the algorithm estimates $\mu(x)$ (with high probability) within a reasonable error range using samples. The second is *simulation*: the algorithm constructs an explicit distribution $\tilde{\mu}$, which is hopefully close to the input distribution μ, and then queries it instead of the input distribution. Since approximating an entire distribution is too expensive, we allow a lazy construction of $\tilde{\mu}$, starting with "$\tilde{\mu}$ can be any distribution over Ω" and then gradually adding details required to answer queries.

Estimation and simulation are highly related tasks. While estimation demands "bounded worst-case error (for most input elements)", simulation of a close distribution can be seen as a "bounded expected estimation error (over the choice of the input element)". However, they are not fully compatible with each other:

- Assume that we can estimate all probabilities with a small error. Estimations can be biased, and therefore, the estimated probability masses do not necessarily sum to 1. Moreover, even if they do, the specific implementation of the estimator might be unable to *sample* the distribution implied by the individual estimations.
- Assume that we can access a distribution $\tilde{\mu}$ which is close to μ with respect to some divergence measure. For common divergences such as the KL-divergence, it might be the case that most elements are poorly estimated, but the estimation errors cancel each other, which results in a relatively low divergence.

One algorithmic paradigm which is compatible with both estimation and simulation is the distribution tree[1], or "slice and dice". First, we define a tree of sets eligible for conditioning by the model, where the root holds the whole domain Ω and every non-leaf node has two children whose disjoint union is the set it holds. Whenever an estimation $\mu(x)$ is required, we estimate the conditional mass $\mu(\mathsf{CHILD}|\mathsf{PARENT})$ in all nodes in the path from the root to the leaf containing the singleton $\{x\}$. To obtain the estimation, we use the chain rule: if $\{x\} = A_k \subseteq A_{k-1} \subseteq \cdots A_1 \subseteq A_0 = \Omega$, then $\Pr_\mu[x] = \prod_{i=1}^{k} \Pr_\mu[A_i|A_{i-1}]$. The estimation algorithm uses $\tilde{\mu}(x) = \prod_{i=1}^{k} \mathrm{est}(\Pr_\mu[A_i|A_{i-1}])$.

In [13] there is an explicit "slice-and-dice" algorithm for the subcube conditional sampling model. The algorithm can estimate $\mu(x)$ within $(1 \pm \varepsilon)$-factor for every x, unless one or more of its marginals is too close to 0 or to 1. The overall mass of these xs is bounded by $O(\varepsilon)$, which implies that the simulating distribution is $O(\varepsilon)$-close to μ with respect to the total-variation distance. The cost for every query is $\tilde{O}(n^3/\varepsilon^2)$ subcube conditional samples.

In this work we reduce the cost of the "slice and dice" method to $O(n^2/\varepsilon^2)$ conditional samples per query and improve the accuracy of the simulating distribution to be $O(\varepsilon^2)$-close with respect to the Kullback-Leibler divergence. Note that by Pinsker's inequality (see Lemma 59) it is never worse than $O(\varepsilon)$-total-variation-close.

The KL-divergence has two advantages over the total-variation distance for intermediate analysis: its propagation over multiple dimensions is tight (compare the equality in Lemma 62 to the corresponding upper bound for total-variation distance, for example in [5]), and it provides a refined divergence bound of indicator estimations (see Lemma 31 vs. the well-known $O(1/\sqrt{m})$-bound for total-variation distance), allowing for propagating over a higher dimension subject to the constraint $\mathrm{KL} = O(\mathrm{poly}(\varepsilon))$. We provide our algorithm in the prefix conditional model, but it can be implemented in every conditional model that resembles the "slice and dice" behavior (see Section 3 for more details).

Since explicitly learning a whole distribution is inevitably expensive (as we would have to store information about every element in the domain), we prefer to use local learning. Instead of storing a whole distribution, we provide an oracle access to the learned object, and store only the information needed to describe the queried parts. When processing a query, we compute only the (missing) parts needed to respond.

Notations

We refer to a *learning algorithm* whose input is an oracle access to a distribution μ, also called the *simulated distribution*, and its output is an oracle access to an output distribution $\tilde{\mu}$, which is called the *simulating distribution* (of μ).

1.2 Usage example

The distance estimation algorithms of [13, 2] consist of two modules: first, an estimation procedure $x \to \mathrm{est}(\mu(x))$, which we call a *mass query*, and second, an unconditional sampling algorithm that obtains the approximated mass of its samples and uses them to estimate the distance between the input distributions. While the first module requires a different logic for implementation in various models, the second module is fixed and stated in the following proposition.

[1] Note that a specific *implementation* inspired by this paradigm is not necessarily compatible with both.

▶ **Proposition 1** ([2], implicit in [13]). *Consider the following oracle for accessing a distribution μ: the oracle draws $x \sim \mu$, and returns a pair of the form $(x, (1 \pm O(\varepsilon))\mu(x))$. There exists an algorithm whose input is such an oracle access to two distributions μ and τ that makes $O(1/\varepsilon^2)$ oracle calls to estimate $d_{\mathrm{TV}}(\mu, \tau)$ within a $\pm\varepsilon$-additive error with probability at least $2/3$.*

1.3 Our results

The main result of this paper is the following theorem.

▶ **Theorem 2** (Informal statement of Theorem 33). *For every sufficiently small $\varepsilon > 0$ and sufficiently large $n \geq 1$, there exists an algorithm for simulating an input distribution over $\{0,1\}^n$ using $O(n^2/\varepsilon^2)$ prefix conditional samples per mass query and $O(n^2/\varepsilon^2)$ prefix conditional samples for sampling the simulating distribution. Moreover, the expected KL-divergence of the simulating distribution from the input distribution is $O(\varepsilon^2)$.*

Additionally, we show that any estimation algorithm must make $\Omega(n^2/\varepsilon^2)$ prefix conditional samples per query. The exact meaning of an "estimation algorithm" is detailed in the formal statement of Theorem 49.

▶ **Theorem 3** (Informal statement of Theorem 49). *Every estimation algorithm must make at least $\Omega(n^2/\varepsilon^2)$ prefix conditional samples per query.*

In Section 4, we provide a technical overview and the proof roadmap.

2 Preliminaries

In this section we formally define the notation scheme of this paper, as well as a few definitions more specific for this work. See Appendix B for formal definition of widely used distribution notations (such as Bernoulli) and for formal statements of well known facts (such as asymptotic bounds for $\ln x$ and Pinsker's inequality).

2.1 Basic notations

▶ **Definition 4** (Conditional distribution). *Let μ be a distribution over Ω and let $A \subseteq \Omega$ be a set. The* conditional distribution $\mu|^A$ *is defined as the distribution where $\Pr[x] = \frac{\Pr_\mu[x]}{\Pr_\mu[A]}$ for every $x \in A$ and $\Pr[x] = 0$ for every $x \notin A$. If $\Pr_\mu[A] = 0$, then the conditional distribution $\mu|^A$ is undefined.*

▶ **Definition 5** (Projected distribution, restricted distribution). *Let μ be a distribution over $\Omega = \prod_{i=1}^k \Omega_i$. For a non-empty set $I \subseteq \{1, \ldots, k\}$, the* projected distribution μ_I *is defined as the distribution over $\prod_{i \in I} \Omega_i$ for which $\Pr[x] = \Pr_{z \sim \mu}[\forall i \in I : z_i = x_i]$ for every $x \in \prod_{i \in I} \Omega_i$. In other words, it is the distribution obtained by drawing a sample from μ and* restricting *it to the entries in I's indexes.*

The overloaded notation $\mu|_I^A$ is interpreted as $(\mu|^A)_I$. In other words, we first sample according to the condition A, and then restrict the result to I's entries.

▶ **Definition 6** (Product of distributions). *Let $\mu_1, \ldots, \mu_k$ be distributions over $\Omega_1, \ldots, \Omega_k$, respectively. The* product distribution $\mu = \prod_{i=1}^k \mu_i$ *is the distribution over $\Omega = \prod_{i=1}^k \Omega_i$ where, for every $(a_1, \ldots, a_k) \in \Omega$, $\mu((a_1, \ldots, a_k)) = \prod_{i=1}^n \mu_i(a_i)$.*

▶ **Definition 7** (Total-variation distance). *Let μ and τ be two distributions over a domain Ω. Their* total-variation divergence *is $d_{\mathrm{TV}}(\mu,\tau) = \frac{1}{2}\sum_{x\in\Omega}|\mu(x)-\tau(x)|$.*

▶ **Definition 8** (Kullback-Leibler divergence). *Let μ and τ be two distributions over a domain Ω. The* KL-divergence *of μ from τ is $D_{\mathrm{KL}}(\mu \parallel \tau) = \mathrm{E}_{x\sim\mu}[\log_2(\mu(x)/\tau(x))]$.*

For convenience, we abuse the notation to define KL-divergence of probabilities:

▶ **Definition 9** (KL-divergence of probabilities (overloaded notation)). *For $p,q\in[0,1]$, we use the notation $D_{\mathrm{KL}}(p,q) = D_{\mathrm{KL}}(\mathrm{Ber}(p) \parallel \mathrm{Ber}(q)) = p\log\frac{p}{q} + (1-p)\log\frac{1-p}{1-q}$.*

2.2 Distribution testing models

A testing algorithm must access its input using oracles. Below we define two oracles for distribution testing.

▶ **Definition 10** (The sampling oracle). *Given an unknown input distribution μ over a set Ω, a call to the oracle results in a sample $x\in\Omega$ that distributes according to μ, independently of past calls to the oracle.*

▶ **Definition 11** (The conditional sampling oracle). *Given an unknown input distribution μ over a set Ω, the input of the oracle is a non-empty explicit subset $A\subseteq\Omega$ and the output is a sample $x\in\Omega$ that distributes like $\mu|^A$. If the mass of A in μ is zero, then the behavior of the oracle is undefined (it is only guaranteed that $x\in A$ with probability 1).*

▶ **Definition 12** (Prefix condition sets). *Let $\Omega=\Sigma^n$ be a domain. A set A is a* prefix condition *if there exists a string $w\in\bigcup_{i=0}^{n}\Sigma^i$ for which $A=\prod_{i=1}^{|w|}\{w_i\}\times\Sigma^{n-|w|}$.*

2.3 Algorithmic notions

In this subsection we formally define the notions of estimation and simulation of distributions.

Estimation algorithm must be able to correctly estimate the mass of *most* elements within a given *multiplicative factor*.

▶ **Definition 13** ((ε,c)-estimation algorithm). *Consider an algorithm whose input is a pair (μ,x), where μ is a distribution and x is an element in the domain of μ. For given parameters $0<\varepsilon<1$ and $0<c<1$, such an algorithm is an* (ε,c)-estimation algorithm *if for every input distribution μ there exists a set G_μ for which $\mu(G_\mu)\geq 1-c$ such that, for every $x\in G_\mu$, with probability at least $2/3$, the output of the algorithm for the input (μ,x) is a number in the range $(1\pm\varepsilon)\mu(x)$.*

A simulation algorithm must be defined through an interaction interface rather than a one-time call. It consists of a one-time initialization and a sequence of allowed interactions, "sample" and "query". After each interaction, the internal state of the simulation can mutate (in particular, the simulation can track its interaction history).

▶ **Definition 14** (Distribution simulation interface). *For a domain Ω, the interface of a* distribution simulation *consists of three procedures:*

- *Initialization: the input is a distribution μ and any additional parameters.*
- *Query: the input is an element $x\in\Omega$, and the output is a number $p\in[0,1]$.*
- *Sample: the output is an element $x\in\Omega$ and a number $p\in[0,1]$.*

▶ **Definition 15** (Interaction notation). *We formalize the q-round interaction of the caller with the simulation algorithm (Definition 14) as:*

- *A* request *sequence* $(\text{init}(\mu); X_1, \ldots, X_q)$*, where* $X_i \in \Omega \cup \{\perp\}$ *represents a query request (if* $X_i \in \Omega$*) or a sample request (*$X_i = \perp$*).*
- *A* response *sequence* $((\hat{X}_i, \hat{P}_i))_{1 \le i \le q}$*, where* $\hat{X}_i$ *represents the sampled element (for a sample request) or the queried element* X_i *(for a query request), and* $\hat{P}_i$ *represents the p-output.*

The simulation interface lacks of constraints ensuring that the output "looks like a simulation", which we have to formalize separately. Ideally, an implementation of the simulation interface secretly chooses a distribution $\tilde{\mu}$ (which is hopefully a good representation of μ) at the initialization phase, and then responds to sample and query interactions by sampling and querying the chosen $\tilde{\mu}$.

▶ **Definition 16** (The secret-distribution constraint). *An algorithmic implementation $\mathcal{A}$ for the distribution simulation interface follows the* secret-distribution constraint *if for every input distribution μ there exists a distribution $\mathcal{A}_\mu$ over distributions such that the interaction can be seen as drawing a secret distribution $\tilde{\mu} \sim \mathcal{A}_\mu$ in the initialization phase and then responding to sample and query requests through $\tilde{\mu}$. More precisely, given the request sequence $(\text{init}(\mu); X_1, \ldots, X_q)$, the probability to obtain the response $((\hat{X}_1, \hat{P}_1), \ldots, (\hat{X}_q, \hat{P}_q))$ is exactly:*

$$\sum_{\tilde{\mu}:\bigwedge_{i=1}^{q}(\tilde{\mu}(\hat{X}_i)=\hat{P}_i)} \left(\Pr_{\mathcal{A}_\mu}[\tilde{\mu}] \times \prod_{i=1}^{q} \begin{cases} 1 & X_i = \hat{X}_i \text{ (query)} \\ \tilde{\mu}(\hat{X}_i) & X_i = \perp \text{ (sample)} \\ 0 & X_i \neq \hat{X}_i, \perp \text{ (violation)} \end{cases} \right)$$

▶ **Definition 17** ((D, δ)-simulation of a distribution). *For a given divergence measure D and a parameter δ, an algorithmic implementation $\mathcal{A}$ of the distribution simulation interface is a* (D, δ)-simulation *if:*

- *Simulation behavior: $\mathcal{A}$ follows the secret-distribution constraint.*
- *Closeness: for every μ, regarding the distribution $\mathcal{A}_\mu$ (over distributions) required by the secret-distribution constraint,* $\mathrm{E}_{\tilde{\mu} \sim \mathcal{A}_\mu}[D(\tilde{\mu}|\mu)] \le \delta$.

3 Simulating conditional samples using prefix conditions

In this section we provide a conceptual reduction from conditional models compatible with the distribution-tree paradigm, which we formally define below, to the prefix conditional model.

First, we define a *breakdown tree*, which is the underlying structure of a distribution tree.

▶ **Definition 18** (A breakdown tree). *Let Ω be a domain. A* breakdown tree *is the following combinatorial tree structure:*

- *All leaves have the same depth.*
- *Every node holds a subset of the domain.*
- *A leaf can hold either the empty set or a singleton.*
- *The root holds the domain set Ω.*
- *Every non-leaf node has two children, arbitrarily named "left" and "right".*
- *Every non-leaf node holds the disjoint union of the subsets held by its children.*

▶ **Observation 19.** *Let $\mathcal{T}$ be a breakdown tree over Ω. For every $x \in \Omega$, there exists a single leaf that holds the singleton $\{x\}$.*

A conditional sampling model is *compatible with the distribution-tree paradigm* if for every set Ω which is valid as a domain of distributions in this model, there exists a breakdown tree in which every subset associated with a node is a valid condition set in the model. It is immediate to see that the subcube conditional model, the interval conditional model and the prefix conditional model are compatible with the distribution-tree paradigm, whereas the pair conditional model[2] is not.

We extend the structure of a breakdown tree to define distribution trees.

▶ **Definition 20** (A distribution tree). *Let Ω be a domain. A* distribution tree *consists of a breakdown tree and additionally:*

- *Every edge holds a probability.*
- *For every non-leaf node, the sum of its (two) outgoing edges is* 1.
- *The probability of an edge from a node holding a non-empty set to a child holding the empty set is* 0.
- *The probability of an edge from a node holding the empty set to its left child is* 1.

▶ **Definition 21** (Representation). *A distribution tree $\mathcal{T}$ of height ℓ over Ω* represents *a distribution μ over Ω if, for every $x \in \Omega$, considering the tree path $\Omega = A_0 \supseteq A_1 \supseteq \cdots \supseteq A_{\ell-1} \supseteq A_\ell = \{x\}$ and the weights $p_1, \ldots, p_\ell$ associated with the edges $A_0 \to A_1, \ldots, A_{\ell-1} \to A_\ell$, it holds that $\mu(x) = \prod_{i=1}^{\ell} p_i$.*

▶ **Observation 22.** *Let $\mathcal{T}$ be a breakdown tree over a domain Ω. There exists a bijection between distribution trees with the same structure of $\mathcal{T}$ and distributions over Ω such that every tree represents the distribution it is mapped to. Moreover, the mapped tree can be computed directly by associating every edge $A \to B$ ($A \supseteq B$) with the probability $\Pr_{z\sim\mu}[z \in B | z \in A]$.*

Observe that, given a breakdown tree of edge-height ℓ for a conditional model over a domain Ω, every condition associated with a node can be seen as a prefix condition in $\{0,1\}^\ell$, where the encoding of elements $x \in \Omega$ into elements in $\{0,1\}^\ell$ corresponds to the sequence of left and right edges in the path from the root to x.

Therefore, every prefix conditional model algorithm can be directly executed in every conditional model that has a breakdown tree, where the n parameter (for prefix algorithms over $\{0,1\}^n$) is the edge-height of the breakdown tree.

4 Overview

4.1 The prefix conditional model

We re-define the notions of a breakdown tree and a distribution tree to specifically match the behavior of prefix conditions.

▶ **Definition 23** (Prefix domain). *For $n \geq 1$, let $\{0,1\}^{<n} = \bigcup_{i=0}^{n-1} \{0,1\}^i$ be the set of all true prefixes of strings in $\{0,1\}^n$.*

Observe that there is a natural bijection between strings in $\{0,1\}^{<n}$ and non-singleton prefix conditions in $\{0,1\}^n$: a string $w \in \{0,1\}^{<n}$ corresponds to the prefix condition set $\{w\} \times \{0,1\}^{n-|w|}$. Moreover, the prefix conditional model has exactly one breakdown tree: the tree in which the non-leaf nodes are the sets corresponding to binary strings of length strictly less than n, the leaf nodes are the elements of $\{0,1\}^n$, and the children of a non-leaf node w correspond to the prefixes $w0$ and $w1$.

[2] The pair conditional model is defined in [9]. Beside the whole domain, the valid condition sets are all sets with exactly two elements.

▶ **Definition 24** (Marginal tree). *Let $\Omega = \{0,1\}^n$. A marginal tree consists of the (unique) breakdown tree and a function $\{0,1\}^{<n} \to [0,1]$ representing the probabilities associated with the one-edges (the edges of the form $w \to w1$).*

▶ **Observation 25** (Representation). *Given the marginal function $f : \{0,1\}^{<n} \to [0,1]$, the marginal tree defines a distribution in which, for every $x \in \{0,1\}^n$,*

$$\Pr[x] = \prod_{i=1}^{n}(x_i f(x_{1,\ldots,i-1}) + (1-x_i)(1-f(x_{1,\ldots,i-1}))) = \prod_{i=1}^{n}\begin{cases} f(x_{1,\ldots,i-1}) & x_i = 1 \\ 1-f(x_{1,\ldots,i-1}) & x_i = 0 \end{cases}$$

We use the specific structure of the only breakdown tree in the prefix conditional model to introduce a notation for marginal probabilities.

▶ **Definition 26** (Overloaded notation for marginals). *The marginal function $f : \{0,1\}^{<n} \to [0,1]$ represents a single distribution μ over $\{0,1\}^n$. For a prefix w of length $i-1$, we use the notation $\mu(x_i = 1|x_{1,\ldots,i-1} = w)$, its short form $\mu(x_i = 1|w)$ and its shorter form $\mu(1|w)$, to denote $f(w)$. Analogously, $\mu(x_i = 0|x_{1,\ldots,i-1} = w)$, $\mu(x_i = 0|w)$ and $\mu(0|w)$ denote $1 - f(w)$.*

In both the upper bound and the lower bound analysis, we use the chain rule for distributions over strings.

To *query* the mass of $x \in \{0,1\}^n$ with respect to μ, we multiply its marginal probabilities:

$$\mu(x) = \prod_{i=1}^{n}\mu(x_i|x_{1,\ldots,i-1}) = \prod_{i=1}^{n}(x_i f(x_{1,\ldots,i-1}) + (1-x_i)(1-f(x_{1,\ldots,i-1})))$$

To *estimate* $\mu(x)$, we multiply the estimations of its marginals.

$$\mathrm{est}(\mu(x)) = \prod_{i=1}^{n}\mathrm{est}(\mu(x_i|x_{1,\ldots,i-1})) = \prod_{i=1}^{n}(x_i\mathrm{est}(f(x_{1,\ldots,i-1})) + (1-x_i)(1-\mathrm{est}(f(x_{1,\ldots,i-1}))))$$

Note that the estimations of the marginals can be fully independent.

In parts of our analysis we use a weaker form of the prefix conditional sampling oracle.

▶ **Definition 27** (The marginal prefix sampling oracle). *Let μ be a distribution over $\Omega = \{0,1\}^n$. The input of a* marginal prefix sampling oracle *is a prefix condition $\{w\} \times \{0,1\}^{n-|w|}$ (for some $w \in \{0,1\}^{<n}$, and its output is a single bit that distributes like $\mu|_{|w|+1}^{w\times\{0,1\}^{n-|w|}}$.*

In other words, a marginal prefix oracle call draws a prefix conditional sample and then ignores all but the first free bit of the sample.

We can convert any prefix conditional sampling (including an unconditional sampling, in which the condition corresponds to the empty prefix) to a (random) sequence of marginal prefix samples whose length is the same as the number of free bits. Let $X_1, \ldots, X_n$ be the random variables for which the result sample is the concatenation $x = X_1 \cdots X_n$. Let $w \in \{0,1\}^{<n}$ of length $k-1$ ($1 \le k \le n$) be the prefix to condition on. For $1 \le i \le k-1$, X_i is the fixed value w_i. For $k \le i \le n$, once $X_1, \ldots, X_{i-1}$ are determined, we can sample X_i as the first bit of a sample conditioned on the prefix $X_1 \cdots X_{i-1}$.

4.2 The upper bound (Section 5)

We show that we can estimate a single marginal probability using m samples such that the expected KL-divergence of the estimation from the true marginal probability is bounded by $1/m$. By the chain rule, if we estimated all $2^n - 1$ marginal probabilities independently,

then the expected KL-divergence of the result distribution from the input distribution would be bounded by n/m. We choose $m = n/\varepsilon^2$ to have an $O(\varepsilon^2)$-D_{KL}-close distribution in expectation at the cost of $O(n/\varepsilon^2)$ prefix samples per marginal estimation. Since the marginal estimations are fully independent, given an element x we can estimate only its n marginals at the cost of $O(n^2/\varepsilon^2)$ prefix samples.

4.3 The lower bound (Section 6, Appendix A)

Recall that the input for the algorithm is pair of (1) a distribution over $\Omega = \{0,1\}^n$ and (2) an element $x \in \Omega$, and the output should be a number in the range $(1 \pm \varepsilon)\mu(x)$ with probability $2/3$.

We first describe the construction. We define two internal parameters, $\delta = \sqrt{2}\varepsilon/\sqrt{n}$ and $r = 8/\sqrt{n}$. For every $w \in \{0,1\}^{<n}$ we draw $s_w \in \{+1,-1\}$ uniformly and independently. We define the two distributions μ and μ' through its marginals. For every $w \in \{0,1\}^n$, we define:

- $\mu(1|w) = \frac{1}{2}(1 + s_w\delta)$, so that $\Pr_\mu[x] = 2^{-n}\prod_{i=1}^{n}(1 + (-1)^{1-x_i}s_{x_{1,\ldots,i-1}}\delta)$.
- $\mu'(1|w) = \frac{1}{2}(1 - s_w r)$, so that $\Pr_{\mu'}[x] = 2^{-n}\prod_{i=1}^{n}(1 + (-1)^{x_i}s_{x_{1,\ldots,i-1}}r)$.

We define two distributions over inputs, based on the choice of s_w variables:

- D_{yes}: the input provided to the algorithm is (μ, x), where x is drawn uniformly.
- D_{no}: the input provided to the algorithm is (μ, x), where x is drawn according to μ'.

The construction guarantees different concentration ranges for $\mu(x)$, as stated in the following lemma.

▶ **Lemma 28** (See Lemma 38, 43, 44). *For every sufficiently large $n \geq N_0$ and sufficiently small $0 < \varepsilon \leq \varepsilon_0$ there exist p_L and p_H for which:*

- $(1+\varepsilon)p_L < (1-\varepsilon)p_H$.
- *If (μ, x) is drawn from D_{yes}, then $\mu(x) \geq p_H$ with probability at least $1 - e^{-7.95}$.*
- *If (μ, x) is drawn from D_{no}, then $\mu(x) \leq p_L$ with probability at least $e^{-7.38}$.*

To prove a lower bound, we recall the meaning of a good estimation algorithm:

- The set of "good" elements has mass $1 - O(\varepsilon)$ according to the input distribution.
- Given a "good" element x, the output is in the range $(1 \pm \varepsilon)\mu(x)$ with probability at least $\frac{2}{3}$.

Note that the success probability in second requirement can be strengthen to $1 - c$ (instead of $2/3$) at the cost of $O(\log(1/c))$, which is asymptotically ignorable when c is a constant.

Consider an estimation algorithm $\mathcal{A}$ that can estimate $\mu(x)$ within a $(1 \pm \varepsilon)$-factor with probability at least $1 - e^{-20}$, unless x belongs to a small set "bad" elements whose mass is bounded by e^{-20}. In this setting,

$$\begin{aligned} d_{\mathrm{TV}}(\mathcal{A}(D_{\mathrm{yes}}), \mathcal{A}(D_{\mathrm{no}})) &\geq \Pr[\mathcal{A}(D_{\mathrm{yes}}) \geq (1-\varepsilon)p_H] - \Pr[\mathcal{A}(D_{\mathrm{yes}}) \geq (1-\varepsilon)p_H] \\ &\geq (e^{-7.38} - e^{-7.95}) - 4e^{-20} \geq e^{-8.25} \end{aligned}$$

Therefore, if an algorithm makes too few queries to distinguish between D_{yes} and D_{no} with total-variation distance at least $e^{-8.25}$, then it cannot be a good estimation algorithm. It remains to describe the lower bound for distinguishing between D_{yes} and D_{no} using prefix queries.

Let I_x be the set of prefixes (elements in $\{0,1\}^{<n}$) that are not prefixes of x. When x is explicitly given as an input, $\mu(x)$ is fully determined by the random sequence $(s_{x_{1,\ldots,i-1}})_{1 \leq i \leq n}$, which may depend on the choice of x. Also, note that if x is drawn uniformly, then $\mu(x)$ is independent of the assignment of all s_ws for $w \in I_x$. We observe that this independence is preserved even if x is drawn from μ' (Lemma 36).

Based on this analysis, we can define a random sequence $p_i = \mu(x_{1,\ldots,i}|x_{1,\ldots,i-1})$ (for $1 \le i \le n$).

- For D_{yes}, $p_i = (1+\delta)/2$ with probability $1/2$ and otherwise $p_i = (1-\delta)/2$.
- For D_{no}, $p_i = (1+\delta)/2$ with probability $(1-r)/2$ and otherwise $p_i = (1-\delta)/2$.

Clearly, distinguishing between D_{yes} and D_{no} cannot be easier than distinguishing between the sequences $(p_1, \ldots, p_n)$ drawn from D_{yes} and from D_{no}.

To show a lower bound for distinguishing between the p_i-sequence inputs, we use the following model that has been introduced in [14]: the input is a sequence of n coins, and in every step, the algorithm can choose a coin and sample it. Alternatively, the input can be seen as a sequence of inaccessible probabilities $p_1, \ldots, p_n \in [0,1]$, and in every step, the algorithm can choose an index $1 \le i \le n$ and sample a single bit that distributes like $\text{Ber}(p_i)$.

We use the following reduction for simulating the coin model using the prefix sampling model. The input of the distinguishing task corresponds to the sequence of marginals of a given random element x (that is, $p_1, \ldots, p_n$). Every prefix conditional sample translates into $O(1)$ steps in the coin model in expectation (see Lemma 48).

We can use the following result regarding a closely related task to deduce an $\Omega(1/r^2\delta^2) = \Omega(n^2/\varepsilon^2)$ lower bound. However, we explicitly prove hardness in Appendix A for completeness.

▶ **Lemma 29** (Rephrase of Theorem 3 in [14]). *Assume that for every $1 \le i \le n$, $p_i \ge (1+\delta)/2$ or $p_i \le (1-\delta)/2$. In this setting, estimating the fraction of positively-biased ($p_i \ge (1+\delta)/2$) within a $\pm r$-additive error requires $\Omega(1/r^2\delta^2)$ samples.*

4.4 Parameter table

Different sections use different parameter constraints. The upper bound uses n and ε. The lower bound for the sequence-distinguishing task uses n, δ and r, whereas the lower bound for estimation uses n and ε and explicitly defines δ, r.

Section	n	ε	δ	r
5 Upper bound	$n \ge 1$	$\varepsilon > 0$	N/A	N/A
6 Lower bound	$n \ge 4.5 \cdot 10^{16}$	$0 < \varepsilon \le e^{-11}$	$\sqrt{2}\varepsilon/\sqrt{n}$	$8/\sqrt{n}$
A Sequence distinguishing	by context	N/A	$0 < \delta < 1/3$	$0 \le r < 1/12$

5 The simulation algorithm

In this section we describe our simulation algorithm in the prefix conditional sampling model for an input distribution μ over $\Omega = \{0,1\}^n$.

Before we introduce our algorithm, we describe the common method (which is compatible with [13]). For every $1 \le i \le n$ and every $w \in \{0,1\}^{i-1}$, we use $O(n^2 \log(n/\varepsilon)/\varepsilon^2)$ samples to estimate the marginal probability $\mu(x_i = 1|w)$ within a $\left(1 \pm \frac{\varepsilon}{\sqrt{n}}\right)$-multiplicative factor with probability at least $1 - O(\varepsilon/n)$ (unless it is too close to zero or one, and in this case we estimate it as zero or one with probability $1 - O(\varepsilon/n)$).

Along the path from the root to a given leaf there are n edges, but errors of different directions (overshooting and undershooting) mostly cancel each other. Hence, with high probability, the accumulated error (when multiplying all n errors) in the range is $\left(1 \pm \frac{\varepsilon}{\sqrt{n}}\right)^{\pm\Theta(\sqrt{n})} = 1 \pm O(\varepsilon)$. By the union bound, the probability to obtain good estimations in all edges is at least $1 - O(\varepsilon)$. Overall, all elements have their mass estimated within

$(1 \pm O(\varepsilon))$-multiplicative error, except for a set of elements whose expected mass is $O(\varepsilon)$ as well. This implies that the expected total-variation distance of μ and the simulating distribution is $O(\varepsilon)$. The cost of querying the simulating distribution is $O(n^3 \log(n/\varepsilon)/\varepsilon^2)$, since we have to query n edges at the cost of $O(n^2 \log(n/\varepsilon)/\varepsilon^2)$ prefix samples per edge.

Our simulation algorithm uses the chain rule for D_{KL} (Lemma 62). Similarly to [5, 1], repeatedly applying the chain rule results in a bitwise identity.

▶ **Lemma 30** (Repeated chain rule for D_{KL})**.** *Let μ and τ be two distributions over $\{0,1\}^n$. In this setting, $D_{\mathrm{KL}}(\mu \parallel \tau) = \sum_{i=1}^{n} \mathrm{E}_{w \sim \mu|_{1,\ldots,i-1}} \left[D_{\mathrm{KL}}\left(\mu|_i^{\{w\}\times\{0,1\}^{n-i}} \,\middle\|\, \tau|_i^{\{w\}\times\{0,1\}^{n-i}} \right) \right]$.*

While the total-variation distance of Bernoulli distributions is linear, Lemma 61 states that the KL-divergence has a χ^2-like behavior, which is sublinear in many cases.

The following lemma is the core of our algorithm. It states that the expected KL-divergence of an estimated probability mass is linear in the number of samples, rather than its square-root as in total-variation distance.

▶ **Lemma 31.** *Let $p \in [0,1]$ and $m \geq 1$. In this setting, $\mathrm{E}_{t \sim \mathrm{Bin}(m,p)} \left[D_{\mathrm{KL}}(\frac{t}{m}, p) \right] \leq \frac{1}{m}$.*

Proof. For $p = 0$ and $p = 1$, $\Pr[t = mp] = 1$, and hence $\mathrm{E}[D_{\mathrm{KL}}(\frac{t}{m}, p)] = 0 \leq \frac{1}{m}$. For the rest of the proof we assume that $0 < p < 1$. In particular, we can safely divide by p and by $1 - p$.

Let $\hat{p} = \frac{t}{m}$ and $\delta = \frac{\hat{p}}{p} - 1$ (so that $\hat{p} = (1+\delta)p$). By Lemma 61, $D_{\mathrm{KL}}(\hat{p}, p) \leq \frac{(\hat{p}-p)^2}{p(1-p)} = \frac{\delta^2 p}{1-p}$. Therefore,

$$\begin{aligned}
\mathop{\mathrm{E}}_{t}[D_{\mathrm{KL}}(t/m, p)] \leq \frac{p}{1-p} \cdot \mathop{\mathrm{E}}_{t}\left[\left(\frac{t/m}{p} - 1 \right)^2 \right] &= \frac{p}{(mp)^2(1-p)} \cdot \mathop{\mathrm{E}}_{t}\left[(t - \mathrm{E}[t])^2 \right] \\
&= \frac{1}{m^2 p(1-p)} \mathrm{Var}[t] \\
&= \frac{1}{m^2 p(1-p)} p(1-p)m = \frac{1}{m}
\end{aligned}$$

◀

We show two implementations of $(D_{\mathrm{KL}}, \delta)$-simulation. The first, shown in Algorithms 2, 3 and 4 as a conceptual introduction, is extremely inefficient, but it is quite easy to show its correctness as a learning algorithm. The second, in Algorithms 5, 7 and 8, is efficient, and we prove its correctness by coupling its behavior with the behavior of the first implementation.

Both implementations use a common procedure Estimate-edge (Algorithm 1) that estimates the probability mass of a single edge by drawing $m = \lceil n/\delta \rceil$ prefix conditional samples and averaging the first free bit.

The first implementation has the learn-then-read concept. We exhaustively build the distribution tree of a distribution $\tilde{\mu}$ simulating the input distribution μ, and then query $\tilde{\mu}$ at individual elements whenever needed.

The initialization procedure, Learn-distribution, estimates all right edges (of the form $w \to w1$) independently.

The query procedure Query-learned-distribution and the sample procedure Sample-learned-distribution just access the explicitly-written learned distribution $\tilde{\mu}$.

▶ **Lemma 32.** *The triplet (Learn-distribution, Query-learned-distribution, Sample-learned-distribution) is a $(D_{\mathrm{KL}}, \delta)$-simulation of its input distribution.*

The second implementation has the lazy-construction concept. Since the estimations of Algorithm 2 are independent, it suffices to evaluate an edge when it (or its sibling edge) lies on a path of a query for the first time.

The initialization procedure Initialize-simulation initializes an empty memorization object.

Algorithm 1: Procedure Estimate-edge$(n, \mu, \delta; w, b)$.

Input: μ is the distribution over $\Omega = \{0,1\}^n$.
Input: δ is the accuracy parameter.
Input: $w \to wb$ is the edge to estimate.
Output: An estimation of $\mu(b|w)$.

1. Let $m \leftarrow \lceil n/\delta \rceil$.
2. Draw $x_1, \ldots, x_m$ independently from μ, conditioned on $x_{1,\ldots,|w|} = w$.
3. Let k be the number of samples $x_1, \ldots, x_m$ in which the $|w|+1$st bit is b.
4. Return k/m.

Algorithm 2: Procedure Learn-distribution(n, μ, δ).

Input: μ is the distribution over $\Omega = \{0,1\}^n$ to simulate.
Input: δ is the accuracy parameter.
Output: The simulating distribution $\tilde{\mu}$.
Accuracy: $\mathrm{E}\left[D_{\mathrm{KL}}(\tilde{\mu} \parallel \mu)\right] \leq \delta$.

1. Initialize the marginal function $f : \{0,1\}^{<n} \to [0,1]$, with all entries initially undefined.
2. For $w \in \{0,1\}^{<n}$ in an arbitrary order:
   a. Run and write $f(w) \leftarrow$ Estimate-edge$(n, \mu, \delta; w, 1)$.
3. Let $\tilde{\mu}$ be the distribution represented by the marginal function f. (Def. 24, Obs. 25)
4. Return $\tilde{\mu}$.

Algorithm 3: Procedure Query-learned-distribution$(\tilde{\mu}, x)$.

Input: $\tilde{\mu}$ is the learned distribution returned by Learn-distribution.
Output: The probability mass of x according to $\tilde{\mu}$.

1. Return $\tilde{\mu}(x)$.

Algorithm 4: Procedure Sample-learned-distribution$(\tilde{\mu})$.

Input: $\tilde{\mu}$ is the learned distribution returned by Learn-distribution.
Output: A sample x drawn from the learned distribution, and its probability mass $\tilde{\mu}(x)$.

1. Draw x from $\tilde{\mu}$.
2. Return $(x, \tilde{\mu}(x))$.

Algorithm 5: Procedure Initialize-simulation(n, μ, δ).

Input: μ is the distribution over $\Omega = \{0,1\}^n$ to simulate.
Input: δ is the accuracy parameter.

1. Return $(n, \mu, \delta, hist)$, where $hist$ is an empty list.

The sample and query procedures internally call the Access-simulation-edge procedure for an edge-by-edge execution.

The Access-simulation-edge procedure allows a memorized estimation of an edge. If the requested edge has never been estimated, then the procedure estimates it using Estimate-edge and then memorizes the result for both that edge and its sibling edge.

Algorithm 6: Procedure Access-simulation-edge(sim, w, b).

Input: sim: the simulation object obtained by Initialize-simulation.
Input: $w \to wb$ is edge to access.
Side effects: The $hist$ component of sim may change.

1. Let $n, \mu, \delta, hist$ be the components of sim as a 4-tuple.
2. If $hist$ contains $((w, b), ans)$:
   a. Let $f \leftarrow ans$.
3. Else:
   a. Let $f \leftarrow$ Estimate-edge$(n, \mu, \delta; w, b)$.
   b. Add $((w, b), f)$, $((w, 1-b), 1-f)$ to $hist$.
4. Return f.

The query and sample procedures execute an edge-by-edge logic. The edges are estimated through Access-simulation-edge.

Algorithm 7: Procedure Query-simulation(sim, x).

Input: sim: the simulation object obtained by Initialize-simulation.
Output: The probability mass of x according to the secret distribution.
Side effects: The $hist$ component of sim may change.

1. Let $n, \mu, \delta, hist$ be the components of sim as a 4-tuple.
2. Set $p_x \leftarrow 1$.
3. For i from 1 to n:
   a. Let $f_{x,i} \leftarrow$ Access-simulation-edge$(sim, x_{1,\ldots,i-1}, x_i)$.
   b. Set $p_x \leftarrow p_x \cdot f_{x,i}$.
4. Return p_x.

Algorithm 8: Procedure Sample-simulation(sim).

Input: sim: the simulation object obtained by Initialize-simulation.
Output: A sample x drawn from the secret distribution, and its probability mass according to that distribution.
Side effects: The *hist* component of sim may change.

1. Let $n, \mu, \delta, hist$ be the components of sim as a 4-tuple.
2. Set $p \leftarrow 1$.
3. Set $x \leftarrow$ the empty word.
4. For i from 1 to n:
   a. Let $f_i \leftarrow$ Access-simulation-edge$(sim, x, 1)$.
   b. Draw $b_i \in \{0, 1\}$ according to $\mathrm{Ber}(f_i)$.
   c. Set $x \leftarrow xb_i$. Append b to the end of x.
   d. If $b_i = 1$:
      i. Set $p \leftarrow p \cdot f_i$.
   e. Else:
      i. Set $p \leftarrow p \cdot (1 - f_i)$.
5. Return (x, p).

▶ **Theorem 33.** *The triplet (Initialize-simulation, Query-simulation, Sample-simulation) has the exact behavior (with respect to the user) as the triplet (Learn-distribution, Query-learned-distribution, Sample-learned-distribution). In particular, it is a $(D_{\mathrm{KL}}, \delta)$-simulation of its input distribution.*

Proof. The interaction of Query-simulation and Sample-simulation with the simulation object is only done through Access-simulation-edge calls. Since in Algorithm 2 the edges are independent, the specific order of assigning their weight is irrelevant. Each call to Access-simulation-edge assigns a weight to two sibling edges, independently of other edges. Therefore, the sequential access to the constructed distribution tree through Access-simulation-edge is identically distributed as evaluating all edges in advance as in Learn-distribution followed by reading the preprocessed data. ◀

We improve on [13] by applying Theorem 33 to Proposition 1.

▶ **Corollary 34.** *Let μ and τ be two distributions over $\Omega = \{0, 1\}^n$. Estimating the total-variation distance of μ and τ up to a $\pm\varepsilon$-additive error with probability at least $2/3$ can be done using $O(n^2/\varepsilon^4)$ prefix conditional samples.*

Proof. We use Theorem 33 to simulate μ and τ using random distributions $\tilde{\mu}$ and $\tilde{\tau}$ such that $\mathrm{E}[D_{\mathrm{KL}}(\tilde{\mu} \parallel \mu)] < \frac{1}{36}\varepsilon^2$ and $\mathrm{E}[D_{\mathrm{KL}}(\tilde{\tau} \parallel \tau)] < \frac{1}{36}\varepsilon^2$. After we initialize the simulation at no sample cost, we run a $O(1/\varepsilon^2)$-test of Proposition 1 to estimate the total-variation distance between $\tilde{\mu}$ and $\tilde{\tau}$ within $\pm\frac{1}{3}\varepsilon$-additive error. Such a test appears in [13] (inlined in a bigger subroutine) and in [2] (explicitly).

The complexity of the test is $O(1/\varepsilon^2)$ samples of the simulating distributions, each costing $O(n^2/\varepsilon^2)$ prefix conditional samples of the input distributions.

By Markov's inequality, with probability at least $(7/8)^2$, both $D_{\mathrm{KL}}(\tilde{\mu} \parallel \mu)$ and $D_{\mathrm{KL}}(\tilde{\tau} \parallel \tau)$ are at most $\frac{2}{9}\varepsilon^2$, and in this case, $|d_{\mathrm{TV}}(\mu, \tau) - d_{\mathrm{TV}}(\tilde{\mu}, \tilde{\tau})| \le d_{\mathrm{TV}}(\tilde{\mu}, \mu) + d_{\mathrm{TV}}(\tilde{\tau}, \tau) \le 2 \cdot \frac{1}{3}\varepsilon$.

Hence, estimating $d_{\mathrm{TV}}(\tilde{\mu},\tilde{\tau})$ within $\pm\frac{1}{3}\varepsilon$-additive error suffices to deduce a $\pm\varepsilon$-additive error estimation of $d_{\mathrm{TV}}(\mu,\tau)$. If we use $O(1)$ trials to amplify the success probability of estimating $d_{\mathrm{TV}}(\tilde{\mu},\tilde{\tau})$ to 8/9, then the success probability is at least $(7/8)^2 \cdot (8/9) > 2/3$. ◀

In particular, estimating the total-variation distance between two distributions over binary strings using subcube conditional sampling requires $O(n^2/\varepsilon^4)$ samples, a polynomial gain over the previously best known distance estimation algorithm for subcube conditions (by [13]), whose complexity is $\tilde{O}(n^3/\varepsilon^5)$ subcube conditional samples.

6 Lower bound

We show that estimation of the probability mass of individual elements using prefix conditional samples cannot be more efficient than simulating the input distribution as a whole (through Algorithms 5, 7, 8 and Theorem 33). Recall that we can fully define a distribution by assigning weights to the edges of the breakdown tree implied by the prefix condition sets.

▶ **Definition 35** (The counter-estimation distributions over inputs). *Let $\Omega = \{0,1\}^n$ be the domain and $\delta = \sqrt{2}\varepsilon/\sqrt{n}$, $r = 8/\sqrt{n}$ be internal parameters. For every $w \in \{0,1\}^{<n}$, we draw $s_w \in \{+1,-1\}$ uniformly and independently. We define the input distribution μ, and an additional distribution μ', through their marginals. For every $w \in \{0,1\}^{<n}$, we define $\mu(x_{|w|+1} = 1|w) = \frac{1+s_w\delta}{2}$ and $\mu'(x_{|w|+1} = 1|w) = \frac{1-s_w r}{2}$. In D_{yes}, we draw x uniformly and then return the pair (μ,x). In D_{no}, we draw $x \sim \mu'$ and return the pair (μ,x).*

We insist that μ is the input distribution in both cases. We only use μ' for drawing x in D_{no}.

▶ **Lemma 36.** *For every $x \in \{0,1\}^n$, let I_x be the set of prefixes $w \in \{0,1\}^{<n}$ that are not prefixes of x. In both D_{yes} and in D_{no}, when conditioned on an explicitly given x, the random variables $\{s_w\}_{w\in I_x}$ are drawn uniformly and independently from $\{+1,-1\}$.*

6.1 Concentration gap

For $n \geq 2$, $\varepsilon > 0$, $\delta = \sqrt{2}\varepsilon/\sqrt{n}$ and $r = 8/\sqrt{n}$, we define the following notations.

▶ **Definition 37** (A few technical definitions).

$$k_H = \frac{1}{2}n - \sqrt{3}\sqrt{n} \qquad k_L = \frac{1}{2}n - \sqrt{6}\sqrt{n}$$
$$p_H = 2^{-n}(1+\delta)^{k_H}(1-\delta)^{n-k_H} \qquad p_L = 2^{-n}(1+\delta)^{k_L}(1-\delta)^{n-k_L}$$
$$H_\mu = \{x : \mu(x) \geq p_H\} \qquad L_\mu = \{x : \mu(x) \leq p_L\}$$

The following lemmas (38-44) are technical.

▶ **Lemma 38.** *For $n \geq 1$ and $\varepsilon < 1/150$, $(1-\varepsilon)p_H > (1+\varepsilon)p_L$.*

▶ **Lemma 39.** *With probability 1 over the choice of μ, μ is ε-close to the uniform distribution over $\{0,1\}^n$.*

▶ **Lemma 40.** *For $n \geq 2.2 \cdot 10^8$, with probability 1 over the choice of μ, $\mu(H_\mu) \geq 1 - e^{-8}$.*

▶ **Lemma 41.** *For $n \geq 4.5 \cdot 10^{16}$ and $\varepsilon < \frac{1}{2000}$, with probability 1 over the choice of μ, $\mu(L_\mu) > e^{-14.57}$.*

▶ **Lemma 42.** *For $n \geq 3 \cdot 10^{10}$ and $\varepsilon > 0$, with probability 1 over the choice of μ and μ', for every $x \in L_\mu$, $\mu'(x) \geq e^{7.19}\mu(x)$.*

▶ **Lemma 43.** *For $n \geq 4.5 \cdot 10^{16}$ and $\varepsilon \leq e^{-11}$, $\Pr_{(\mu,x)\sim D_{\mathrm{yes}}}[\mu(x) \geq p_H] \geq 1 - e^{-7.95}$.*

▶ **Lemma 44.** *For $n \geq 4.5 \cdot 10^{16}$ and $\varepsilon \leq e^{-11}$, $\Pr_{(\mu,x)\sim D_{\mathrm{no}}}[\mu(x) \leq p_L] \geq e^{-7.38}$.*

6.2 The lower bound theorem

▶ **Lemma 45.** *For $n \geq 4.5 \cdot 10^{16}$ and $\varepsilon \leq e^{-11}$, let $\mathcal{A}$ be an algorithm that uses prefix conditional samples and results in a real number such that for every distribution μ over $\Omega = \{0,1\}^n$ there exists a set $G_\mu \subseteq \Omega$ of mass $\Pr_\mu[G_\mu] > 1 - e^{-20}$ for which $\Pr[\mathcal{A}(\mu, x) \in (1 \pm \varepsilon)\mu(x)] > 1 - e^{-20}$ for every $x \in G_\mu$. In this setting, the total variation distance of the behaviors of the algorithm when given an input drawn from D_{yes} and from D_{no} is greater than $e^{-8.25}$.*

Note that, for estimation algorithms, having $\mu(G_\mu) = 1$ is infeasible, and general upper bound algorithms usually guarantee that $\mu(G_\mu) = 1 - O(\varepsilon)$. Here we show a lower bound for a much weaker demand, that allows for excluding a fixed weight of the elements.

Proof. Consider the distributions D_{yes} and D_{no} and the following algorithm: we use $\mathcal{A}$ to estimate $(1 \pm \varepsilon)\mu(x)$. If the result estimation is greater than $(1 - \varepsilon)p_H$ then we accept, and otherwise we reject. By Lemma 38, the ranges $(1 \pm \varepsilon)p_H$ and $(1 \pm \varepsilon)p_L$ are disjoint, and therefore, a $1 \pm \varepsilon$-multiplicative error suffices to distinguish between p_H and p_L.

Let B_{wrong} be the bad event "the estimation of $\mu(x)$ is outside the range $(1 \pm \varepsilon)\mu(x)$". The probability to reject an input (μ, x) drawn from D_{yes} is bounded by:

$$\begin{aligned}
\Pr[\text{REJECT}|D_{\text{yes}}] &\leq \Pr_{D_{\text{yes}}}[x \notin H_\mu \cap G_\mu] + \Pr[B_{\text{wrong}}|x \in G_\mu] \\
&\leq d_{\text{TV}}(\mathcal{U}, \mu) + (1 - \mu(H_\mu)) + (1 - \mu(G_\mu)) + e^{-20} \\
\text{[L 39, L 40]} &\leq \varepsilon + e^{-8} + e^{-20} + e^{-20}
\end{aligned}$$

By Lemma 41 and Lemma 42,

$$\mu'(L_\mu \cap G_\mu) \geq \min_{x \in L_\mu} \frac{\mu'(x)}{\mu(x)} \cdot (\mu(L_\mu) - (1 - \mu(G_\mu))) \geq e^{7.19} \cdot (e^{-14.57} - e^{-20}) \geq e^{-7.385}$$

The probability to reject an input (μ, x) drawn from D_{no} is at least:

$$\Pr[\text{REJECT}|D_{\text{no}}] \geq \Pr_{D_{\text{no}}}[x \in G_\mu \cap L_\mu] \cdot \Pr[\neg B_{\text{wrong}}|x \in G_\mu] \geq e^{-7.385} \cdot (1 - e^{-20}) \geq e^{-7.39}$$

Therefore, the distance in behaviors of the algorithms when running on D_{yes} and D_{no} is at least $e^{-7.39} - (\varepsilon + e^{-8} + e^{-20} + e^{-20}) > e^{-8.25}$ (for $\varepsilon \leq e^{-11}$). ◀

▶ **Lemma 46.** *For $n \geq 4.5 \cdot 10^{16}$ and $\varepsilon < e^{-11}$, let $\mathcal{A}$ be an algorithm that uses marginal prefix conditional samples and results in a real number such that for every distribution μ over $\Omega = \{0,1\}^n$ there exists a set $G_\mu \subseteq \Omega$ of mass $\Pr_\mu[G_\mu] > 1 - e^{-20}$ for which $\Pr[\mathcal{A}(\mu, x) \in (1 \pm \varepsilon)\mu(x)] > 1 - e^{-20}$ for every $x \in G_\mu$. In this setting, $\mathcal{A}$ must make at least $\frac{n^2}{2.8 \cdot 10^{25} \varepsilon^2}$ marginal prefix conditional samples that contain x in expectation.*

Proof. Observe that, for every $w \in \{0,1\}^{<n}$, the marginal prefix conditional sample $\mu|_{|w|+1}^{w \times \{0,1\}^{n-|w|}}$ is identical to drawing a bit from $\text{Ber}\left(\frac{1+s_w\delta}{2}\right)$. By Lemma 36, the random variables $\{s_w\}_{w \in I_x}$, for $I_x = \{0,1\}^{<n} \setminus \{1 \leq i \leq n : x_{1,\ldots,i-1}\}$, are independent, and distribute the same in D_{yes} and in D_{no}. Hence, sampling them is redundant.

In other words, in every non-redundant step, the algorithm chooses some $1 \leq i \leq n$ and samples a bit whose probability to be 1 is $\frac{1+s_{x_{1,\ldots,i-1}}\delta}{2}$. For every $1 \leq i \leq n$, let $p_i = \frac{1+s_{x_{1,\ldots,i-1}}\delta}{2}$.

In D_{yes}, every s_w is uniformly drawn from $\{+1, -1\}$, and hence, the p_is are uniformly drawn from $\frac{1 \pm \delta}{2}$. This matches the $D_n(\delta, 0)$ distribution of the sequence-distinguishing task. In D_{no}, when conditioned on drawing x from μ', every s_w (for w on the path of x) is $+1$ with probability $\frac{1-r}{2}$ and otherwise -1. This matches the $D_n(\delta, r)$ distribution of the sequence-distinguishing task.

Note that this analysis is oblivious of the dependence between the s_ws and x. Observe that if we denote $s_{x_{1,\dots,i-1}}$ by $\hat{s}_{i-1}$, then the sequence $(\hat{s}_0,\dots,\hat{s}_{n-1})$ is independent of x and iid.

Let q be the expected number of non-redundant steps. By Markov's inequality, with probability at least $1-e^{-9}$ it is bounded by $e^9 q$.

If $e^9 q \le \frac{(e^{-9})^4}{4\cdot 10^5\delta^2}n = \frac{n^2}{e^{36}\cdot 4\cdot 10^5\cdot 2\varepsilon^2}$, then by Lemma 56, the total variation distance between the runs is less than e^{-9}.

Overall, if $q \le \frac{n^2}{2.8\cdot 10^{25}\varepsilon^2} \le \frac{n^2}{e^9\cdot e^{36}\cdot 4\cdot 10^5\cdot 2\varepsilon^2}$, then the total-variation distance between the run is bounded by $e^{-9}+e^{-9} < e^{-8.25}$. By Lemma 45, a "good" estimation algorithm behaves more differently ($d_{\mathrm{TV}} > e^{-8.25}$) on D_{yes} on D_{no}, and hence, every such an algorithm must make at least $\frac{n^2}{2.8\cdot 10^{25}\varepsilon^2}$ prefix conditional queries. ◀

We describe a setting for the following lemma.

▶ **Definition 47** (Setting for Lemma 48). *Let $x \in \{0,1\}^n$, $1 \le i \le n$ and $w \in \{0,1\}^{i-1}$ be a prefix. Let $X_i,\dots,X_n$ be the bits of a prefix conditional sample $\mu|^{w\times\{0,1\}^{n-i}}$. Let $W_{i-1},\dots,W_{n-1}$ be the intermediate prefixes ($W_{i-1}=w$, $W_{j-1}=W_{j-2}X_{j-1}$ for $i+1\le j\le n$). Also, let $N_{\mathrm{effective}} = |\{i\le j\le n : W_{j-1} \text{ is a prefix of } x\}|$.*

As observed before, the sampling from $\mu|^{w\times\{0,1\}^{n-i}}$ can be decomposed into $n-i+1$ marginal samplings such that for $i\le j\le n$, after W_{i-1} is determined, X_j distributes as $\mu|_j^{W_{j-1}\times\{0,1\}^{n-j}}$. Therefore, $N_{\mathrm{effective}}$ describes the number of effective marginal samples.

▶ **Lemma 48.** *In the setting of Definition 47, if $n \ge 20$, then $\mathrm{E}[N_{\mathrm{effective}}] \le 3$.*

▶ **Theorem 49.** *For $n \ge 4.5\cdot 10^{16}$ and $\varepsilon \le e^{-11}$, let $\mathcal{A}$ be an algorithm that uses prefix conditional samples and results in a real number such that for every distribution μ over $\Omega = \{0,1\}^n$ there exists a set $G_\mu \subseteq \Omega$ of mass $\Pr_\mu[G_\mu] > 1-e^{-20}$ for which $\Pr[\mathcal{A}(\mu,x)\in(1\pm\varepsilon)\mu(x)] > 1-e^{-20}$ for every $x\in G_\mu$. In this setting, $\mathcal{A}$ must use $\Omega(n^2/\varepsilon^2)$ prefix conditional samples.*

Proof. Recall that we can see every prefix condition sampling with k free bits as a (random) sequence of k marginal prefix condition sampling. In the ith step, we condition on the first already-fixed $n-k$ bits and on the additional $i-1$ already-sampled bits to obtain the $n-k+i$th bit. By Lemma 48, for every individual prefix sample, the expected number of marginal samples whose condition contains x is bounded by 3. By linearity of expectation, the expected number of marginal samples whose prefix condition contains x is bounded by $3q$.

By Lemma 46, since the expected number of "non-redundant" samples is $O(q)$, the algorithm must make $q=\Omega(n^2/\varepsilon^2)$ prefix conditional samples. ◀

A Lower bound for the sequence-distinguishing task

In this appendix we show a lower bound for the sequence-distinguishing task. The goal is distinguishing between the following random sequences, regarding the parameters $\delta > 0$ and $r \geq 0$:

- $D_n(\delta, 0)$: $p_i = (1+\delta)/2$ with probability $1/2$, and otherwise $p_i = (1-\delta)/2$, independently for every $1 \le i \le n$.
- $D_n(\delta, r)$: $p_i = (1+\delta)/2$ with probability $(1-r)/2$, and otherwise $p_i = (1-\delta)/2$, independently for every $1 \le i \le n$.

In each step, the algorithm can choose an index $1 \le i \le n$ and obtain a bit drawn from $\mathrm{Ber}(p_i)$.

We show that, if $n \le 64/r^2$, then we must make $\Omega(1/r^2\delta^2)$ queries, even if we allow adaptive behavior.

A.1 Technical lemmas

We first state a few technical lemmas.

▶ **Lemma 50.** *Let $0 \le t \le 1/4$. For two distributions μ and ν over Ω for which $\mu(x) \in (1 \pm t)\nu(x)$ for every $x \in \Omega$, $D_{\mathrm{KL}}(\mu \parallel \nu) \le t^2/\ln 2$.*

▶ **Lemma 51.** *Let μ and ν be two distributions over a domain Ω. It holds that:*

$$\sum_{x \in \Omega} \frac{(\mu(x) - \nu(x))^2}{\mu(x) + \nu(x)} \le (D_{\mathrm{KL}}(\mu \parallel \nu) + D_{\mathrm{KL}}(\nu \parallel \mu)) \cdot \ln 2$$

▶ **Lemma 52.** *Let μ and ν be two distributions over a domain Ω. If $|r| < \frac{1}{2}$, then:*

$$D_{\mathrm{KL}}\left(\frac{1}{2}\mu + \frac{1}{2}\nu \,\middle\|\, \frac{1+r}{2}\mu + \frac{1-r}{2}\nu\right) \le \frac{1}{2}r^2(D_{\mathrm{KL}}(\mu \parallel \nu) + D_{\mathrm{KL}}(\nu \parallel \mu))$$

A.2 Lower bound for non-adaptive algorithms

Before we introduce the lower bound against adaptive algorithms, we state a lower bound for non-adaptive algorithms. A non-adaptive algorithm draws m_i samples from the ith index for every $1 \le i \le n$. The sample complexity is $q = \sum_{i=1}^{n} m_i$.

▶ **Lemma 53.** *For $\delta < 1/3$, consider an algorithm that for every $i \ge 1$ draws m_i samples from the ith index, and let $q = \sum_{i=1}^{n} m_i$. The KL-divergence of runs over inputs drawn from $D_n(\delta, 0)$ and from runs over inputs drawn from $D_n(\delta, r)$ is bounded by $5r^2\delta^2 q$.*

A.3 Lower bound for adaptive algorithms

Adaptive algorithms are allowed to choose their next step based on past samples. Therefore, their analysis is more difficult. By Yao's principle [18], a probabilistic algorithm is equivalent to a distribution over deterministic algorithms. Moreover, the success probability of a probabilistic algorithm is the expected success probability over the choice of a deterministic algorithm.

Every deterministic adaptive algorithm can be described as a decision tree, where edges correspond to samples (0 and 1) and every non-leaf node is associated with the index $1 \le i \le n$ to sample in the following step. A run of a deterministic algorithm is its execution path, which corresponds to the leaf the algorithm reaches in its last step.

To show a lower bound of q samples, we have to show that for every decision tree of height q, the total-variation distance between the distribution of leaves reached when the input is drawn from $D_n(\delta, 0)$ and their distribution when the input is drawn from $D_n(\delta, r)$ is bounded by some $d < 1/3$. This implies that the success probability, which cannot exceed the maximal success probability of a deterministic algorithm, is at most $1 - d$. By Pinsker's inequality, it suffices to bound the KL-divergence of the leaf distributions by $2d^2$.

We repeatedly apply the chain-rule for KL-divergence (Lemma 62) to obtain that the KL-divergence of the leaf distributions is bounded by the expected KL-divergence of every step individually.

To analyze an adaptive algorithm, whose structure can be arbitrarily detailed, we simulate it using a stronger model whose runs have shorter descriptions. Let $m = \left\lfloor \frac{d^2}{400\delta^2} \right\rfloor$ and $q \leq \frac{d^2}{1000}mn$. At the initialization phase, we run an m-height rectangle algorithm, which is a non-adaptive algorithm that makes m queries in each index $1 \leq i \leq n$, obtaining a pre-processing sampling matrix $M \in \{0,1\}^{m \times n}$ at the cost of mn samples. For every individual index $1 \leq i \leq n$, the first m queries are answered based on the pre-processing sampling matrix. Once the algorithm makes the $m+1$st sample on the ith index, the simulator reveals the exact value of p_i, and exactly simulates further queries to the ith index using the full-knowledge about p_i.

▶ **Observation 54.** *Let $d > 0$. An adaptive algorithm that draws $q \leq \frac{d^2}{1000}mn$ samples has at most $\frac{d^2}{1000}n$ indexes sampled more than m times.*

▶ **Observation 55.** *Every run of an adaptive algorithm with $q \leq \frac{d^2}{1000}mn$ samples can be described as a tuple of the pre-processing sampling matrix M, the set I of at most $\frac{d^2}{1000}n$ fully-revealed indexes and a map $f : I \to \{+,-\}$ corresponding to the exact value of $p_i \in \frac{1\pm\delta}{2}$.*

▶ **Lemma 56.** *Let $\delta < 1/3$, $r < 1/12$, $n \leq 64/r^2$ and $d > 0$. For every adaptive algorithm with $q \leq \frac{d^4}{4\cdot 10^5 \delta^2}n$ samples, the distance between runs over inputs drawn from $D_n(\delta, 0)$ and runs over inputs drawn from $D_n(\delta, r)$ is bounded by d.*

B Common distributions and fact sheet

B.1 Common distributions

▶ **Definition 57** (Bernoulli distribution). *Bernoulli distribution* $\mathrm{Ber}(p)$ *is the distribution over* $\{0,1\}$ *for which* $\Pr[1] = p$ *and* $\Pr[0] = 1-p$.

▶ **Definition 58** (Binomial distribution). *The binomial distribution* $\mathrm{Bin}(n,p)$ *is the sum of* n *independent samples from the Bernoulli distribution* $\mathrm{Ber}(p)$.

B.2 Fact sheet

In the following we provide some well-known bounds and identities.

▶ **Lemma 59** (Pinsker's inequality). $D_{\mathrm{KL}}(\mu \parallel \tau) \geq 2(d_{\mathrm{TV}}(\mu,\tau))^2$.

▶ **Lemma 60.** *For $x \geq -2/3$, $-\ln(1+x) \leq -x + x^2$.*

▶ **Lemma 61** (see [8]). *For $p, q \in [0,1]$, $D_{\mathrm{KL}}(p,q) \leq \frac{(p-q)^2}{q(1-q)}$.*

▶ **Lemma 62** (Chain rule for D_{KL}). *Let μ and τ be two distributions over $A \times B$. In this setting, $D_{\mathrm{KL}}(\mu \parallel \tau) = D_{\mathrm{KL}}(\mu|_A \parallel \tau|_A) + \mathrm{E}_{a\sim\mu|_A}\left[D_{\mathrm{KL}}\left(\mu|^{\{a\}\times B} \,\middle\|\, \tau|^{\{a\}\times B}\right)\right]$.*

Abstract

We study the problem of estimating the number of edges in an unknown graph. We consider a hybrid model in which an algorithm may issue independent set, degree, and neighbor queries. We show that this model admits strictly more efficient edge estimation than either access type alone. Specifically, we give a randomized algorithm that outputs a $(1 \pm \varepsilon)$-approximation of the number of edges using $O\left(\min\left(\sqrt{m}, \sqrt{\frac{n}{\sqrt{m}}}\right) \cdot \frac{\log n}{\varepsilon^{5/2}}\right)$ queries, and prove a nearly matching lower bound. In contrast, prior work shows that in the local query model (Goldreich and Ron, *Random Structures & Algorithms* 2008) and in the independent set query model (Beame *et al.* ITCS 2018, Chen *et al.* SODA 2020), edge estimation requires $\widetilde{\Theta}(n/\sqrt{m})$ queries in the same parameter regimes. Our results therefore yield a quadratic improvement in the hybrid model, and no asymptotically better improvement is possible.

1 Introduction

Estimating the number of edges in an unknown graph is a central problem in sublinear algorithms. Formally, given query access to a graph $G = (V, E)$ on n vertices, the goal is to approximate $m = |E|$ within a $(1 \pm \varepsilon)$-multiplicative factor while making as few queries as possible. The problem captures the inherent tension between accuracy and information constraints and has been extensively studied (see e.g., [21, 22, 20, 19, 5, 23, 28, 8, 12])

A key theme in this line of work is that the achievable query complexity depends critically on the type of access allowed to the graph. Different query models expose fundamentally different kinds of information, leading to qualitatively different algorithmic techniques.

Until recently, most work in the sublinear algorithms community focused on *local access models*, where queries are restricted to a vertex and its neighborhood. Typical examples include degree queries, which return a vertex's degree, and neighbor queries, which return a specified neighbor. Such queries provide fine-grained, precise information about the graph.

Beame, Har-Peled, Ramamoorthy, Rashtchian, and Sinha [6] introduced a markedly different access model, the *independent-set (IS) oracle*. In this model, an algorithm may query any subset $S \subseteq V$, and the oracle responds with a single bit indicating whether S induces an edge-free subgraph. Unlike local queries, IS queries do not reveal the identity or

location of edges. Instead, they provide a coarse *non-local* information about the presence or absence of edges within a queried set. This model can be viewed as a form of combinatorial group testing, where a single query can simultaneously probe a large portion of the graph. As such, IS queries expose structural information that is fundamentally inaccessible through purely local inspection.

[6] first analyzed edge estimation in the IS model and obtained an upper bound of $\widetilde{O}(n^{2/3})$ queries. Chen, Levi, and Waingarten [15] refined this analysis and established nearly optimal bounds: $(1 \pm \varepsilon)$-approximate edge estimation can be performed using $\widetilde{O}\left(\min\left(\sqrt{m}, \frac{n}{\sqrt{m}}\right)\right)$ IS queries, and show that this dependence on n and m is optimal up to polylogarithmic factors.

Local queries and IS queries exhibit inherently different strengths. Local queries provide detailed information about individual vertices and their neighborhoods, whereas IS queries give coarse binary feedback over subsets. When considering the local model, (nearly) tight bounds of $\widetilde{\Theta}(n/\sqrt{m})$ queries for edge estimation are known [22, 21]. Therefore, there exist settings in which both oracles require the same asymptotic number of queries, but for entirely different reasons: local queries are limited by the need to sample enough edges from sparse regions, while IS queries are limited by the coarse granularity of global binary feedback. This illustrates that even when the query complexities coincide, the information revealed by each oracle is *fundamentally different*, reflecting their complementary powers.

This contrast naturally motivates the study of *hybrid* access models, in which an algorithm is allowed to use both local queries and IS queries. Such a model offers the potential to combine non-local aggregation with local precision: local queries can be used to identify informative regions of the graph or reveal degrees, whereas IS queries can efficiently summarize the presence of edges across large subsets. Understanding the power and limitations of this hybrid model is essential for clarifying how different forms of partial information interact, and for determining whether combining query types can lead to provable improvements over either model alone.

1.1 Our Results

In this work, we provide a tight characterization of this hybrid model.

▶ **Theorem 1** (Upper Bound). *Consider the query model consisting of IS, degree, and neighbor queries to an unknown graph $G = (V, E)$ with $|V| = n$ and $|E| = m$. For every $0 < \varepsilon < 1$, there exists a randomized algorithm that uses $O\left(\min\left(\sqrt{m}, \sqrt{\frac{n}{\sqrt{m}}}\right) \cdot \frac{\log n}{\varepsilon^{5/2}}\right)$ queries in expectation and outputs a $(1 \pm \varepsilon)$-approximation of m with probability at least $2/3$.*

▶ **Theorem 2** (Lower Bound). *For every $\varepsilon \in (0, 1)$, in the query model allowing independent set, degree, and neighbor queries, any randomized algorithm that estimates the number of edges m of an n-vertex graph to within a $(1 \pm \varepsilon)$ factor with success probability at least $2/3$ requires $\Omega\left(\min\left(\sqrt{m}, \sqrt{\frac{n}{\varepsilon\sqrt{m}}}\right)\right)$ queries.*

In particular, in regimes where each individual model would require $\widetilde{\Theta}(n/\sqrt{m})$ queries, the combination yields a *quadratic improvement*, whereas in other regimes it matches the best of the two models. These results demonstrate that IS and local queries are synergistic yet complementary, and that the hybrid model achieves the maximum possible improvement for the task of edge estimation.

1.2 Technical overview

1.2.1 Upper-Bound

Our algorithm is advice-based: it receives a guess $\bar{m}$ for the number of edges m, but treats this guess as untrusted. For each guess, the algorithm must either produce a $(1\pm\varepsilon)$-approximation to m, or determine that $\bar{m}$ is not within the correct scale. The goal is to obtain query complexity $\widetilde{O}\left(\min\left(\sqrt{m}, \sqrt{n/\sqrt{m}}\right)\right)$.

To achieve this goal, we interleave two exponentially progressing sequences of guesses. The upper sequence starts from n^2 and decreases geometrically, taking $\bar{m} = 2^{-\ell}n^2$ at iteration ℓ. The lower sequence increases geometrically, taking $\bar{m} = 2^{\ell/2}$. The different rates are chosen so that the cost of handling a guess from either sequence is comparable within the same iteration.

For a fixed guess $\bar{m}$, the algorithm partitions vertices according to a degree threshold k, classifying vertices as low-degree or high-degree. This induces a decomposition of the edge set into edges between two low-degree vertices (m_{LL}), edges between low- and high-degree vertices (m_{LH}), and edges between two high-degree vertices (m_{HH}). These components are handled separately, exploiting the fact that high-degree vertices are rare once k is chosen appropriately.

The main component is estimating m_{LL}. We adapt the edge-sampling approach of [6], which samples an induced subgraph by including each vertex independently with probability $1/\sqrt{\bar{m}}$. If all vertices were low-degree, then this estimator would have low variance. We use the degree oracle to identify edges incident to high-degree vertices and exclude them from counting to keep the variance low while preserving unbiasedness.

Edges between high-degree vertices have small contribution overall. For an appropriate choice of k, the number of such edges is $O(\varepsilon m)$, which can be absorbed into the allowed additive error. For low-high edges, we further refine the low-degree vertices by introducing a second threshold k', defining very-low-degree vertices, and only count the edges between them to high-degree vertices. With this refinement, for an appropriate choice of k, the number of excluded edges is $O(\varepsilon m)$, allowing us to only consider edges between very-low-degree vertices and high-degree vertices.

The remaining quantity, denoted m_{L_1H} (between very-low-degree vertices and high-degree vertices), is estimated via a weighted sampling procedure. We sample a vertex, then sample one of its neighbors, and count the edge with weight proportional to the degree of the sampled vertex whenever it is very-low-degree and its neighbor is high-degree. This yields an unbiased estimator whose variance is controlled using $O(n/(\varepsilon^3 k))$ samples.

We analyze the algorithm separately for the two guess sequences. We first consider the upper guess sequence, for which $\bar{m} \geq m$ holds throughout until a correct-scale guess is reached. In this regime, we set $k = \Theta\left(\sqrt{n\sqrt{\bar{m}}/\varepsilon}\right)$, except in the very dense case $\bar{m} = \Omega(\varepsilon n^2)$, where a separate optimization applies. With this choice, the combined cost of estimating m_{LL} and m_{L_1H} is $O\left(\frac{\log n}{\varepsilon^{5/2}} \cdot \sqrt{\frac{n}{\sqrt{\bar{m}}}}\right)$.

When $\bar{m} = \Theta(m)$, the algorithm outputs $\tilde{m} = (1 \pm O(\varepsilon))m$ with high probability. More generally, when $\bar{m}$ is larger than the true value, the output is noticeably smaller than $\bar{m}$, and in particular bounded by $m + \varepsilon\bar{m} \ll \bar{m}$ when $\bar{m} \gg m$. This gap allows the algorithm to reliably detect overly large guesses and continue to smaller ones.

For the lower guess sequence, the algorithm cannot assume that $\bar{m} \geq m$. Instead, it sets the degree threshold to $k = \min(\bar{m}, n-1)$ and attempts to verify that no vertex exceeds this degree. If this verification succeeds, then all vertices are low-degree and $m_{LL} = m$, so

estimating m_{LL} alone suffices. If the guess $\bar{m}$ is too small, then either $m_{LL} > 2\bar{m}$, or there exist $\Omega(m)$ edges adjacent to vertices of degree larger than $\bar{m}$ (in particular, there exists a vertex of degree larger than $\bar{m}$). These cases are detected by running a complexity-safe version of the m_{LL} estimator, which aborts if it exceeds the cost expected when assuming that $\bar{m} \geq m$, and by searching for a high-degree vertex. The resulting cost per lower-sequence iteration is $O\left(\frac{\log n}{\varepsilon^2}\sqrt{\bar{m}}\right)$.

Standard amplification could be applied to each iteration to ensure correctness with high probability. However, a more refined analysis shows that such amplification is unnecessary. The failure probability of an upper-sequence iteration is $O(m/\bar{m})$, while that of a lower-sequence iteration is $O(\bar{m}/m)$. Since both guess sequences are exponential, the total failure probability accumulated over all iterations preceding the one with $\bar{m} \approx m$ remains bounded by a constant. The iteration for which $\bar{m} = \Theta(m)$ therefore succeeds with constant probability.

Finally, while the above discussion yields the desired query complexity with high probability, controlling the expected complexity requires care due to the possibility that "the" correct guess fails, and then further high-sequence guesses are smaller than m and low-sequence guesses are greater than m, making the rest of the run incompatible with the correctness analysis (even though complexity analysis still holds). To address this, we execute the guesses using an iterative deepening schedule. We first consider iteration 0, then iterations $(0, 1)$, then $(0, 1, 2)$, and so on. This scheduling ensures that the tail of the running-time distribution decays sufficiently fast, so that the expected query complexity matches the high-probability bound asymptotically.

1.2.2 Lower bound

We show that any deterministic algorithm with access to degree, neighbor and independent-set oracles cannot distinguish between two distributions over graph whose degrees are separated by a $(1+\Omega(\varepsilon))$-factor, unless it makes $\Omega\left(\min\left(\sqrt{m}, \sqrt{n/\varepsilon\sqrt{m}}\right)\right)$ queries in expectation (note that the input distribution is the source of randomness). By Yao's principle [29], this lower bound also applies to probabilistic algorithms with the same expected query complexity.

Canonical graph construction

To define the canonical graph $G_{n,d,\varepsilon}$, let $d_0(n, \epsilon) \stackrel{\text{def}}{=} 1/(n^{1/3}\epsilon^{2/3})$. For the simplicity of the overview, we focus on the case where $d \geq d_0(n, \varepsilon)$, whose lower bound is $\Omega(\sqrt{n/\varepsilon\sqrt{m}})$. The input graph consists of disjoint vertex sets K, L, H, and A whose sizes are:

$$n_k = \left\lfloor \sqrt{2nd} \right\rfloor, \quad n_h = \left\lceil \varepsilon^{1/2} n^{1/4} d^{3/4} \right\rceil, n_\ell = \left\lceil \varepsilon^{1/2} n^{3/4} d^{1/4} \right\rceil, \quad n_a = n - (n_k + n_h + n_\ell).$$

For the graph edges: the set K forms a clique, the sets L and H are the sides of a biclique and A consists of isolated vertices. The K-clique contributes $\Omega(m)$ edges (but not more than m), and the L-H graph contributes $\Theta(\varepsilon m)$ edges. Therefore, the number of edges is $\Theta(m)$ and the average degree is $\Theta(d)$.

Graph distributions

In the first distribution we permute the vertices of $G_{n,d,0}$, that is, the graph only consists of a clique but not a biclique, and it has at most m edges. In the second distribution we permute the vertices of $G_{n,d,\varepsilon}$, which has at least εm additional edges.

Intuition

As long as the algorithm does not query a vertex in the biclique or find a biclique-edge, the input distributions are indistinguishable. For local queries, the probability of hitting the biclique scales with the size of L. For independent-set queries, a query must include at least one vertex from H to detect an edge in the biclique. Large IS-queries are limited by the clique size $|K|$, since including two vertices from K makes the queried set not-independent regardless of whether or not it has a biclique-edge.

A more careful argument shows that for degree and neighbor queries, the probability of sampling a biclique vertex is $O((n_\ell + n_h)/n) = O(n_\ell/n)$. Hence, $\Omega\left(\frac{n}{n_\ell}\right) = \Omega\left(\sqrt{\frac{n}{\varepsilon\sqrt{m}}}\right)$ queries are needed to hit a biclique vertex with $\Omega(1)$ probability.

For IS-queries, the clique K limits the effective query size to $O(n/n_k) = O(\sqrt{n/d})$, and the probability of hitting H using such query is $O\left(\frac{n_h}{n} \cdot \sqrt{\frac{n}{d}}\right) = O\left(\frac{n_h}{\sqrt{nd}}\right)$. This probability leads to the same lower bound as before. Overall, as $d = \Theta(m/n)$, distinguishing the two distributions with probability $\Omega(1)$ requires $\Omega\left(\sqrt{\frac{n}{\varepsilon\sqrt{m}}}\right)$ queries, which establishes the desired lower bound.

For $d < d_0(n, \epsilon)$, we observe that the definition of n_h is fixed to 1, and therefore, we can reduce n_ℓ to $\lceil \varepsilon nd \rceil$. Besides the alternative value of n_ℓ, the construction is the same. Analyzing this small-d case uses similar ideas and results in an $\Omega(\sqrt{m})$ lower bound.

1.3 Related work

A generalization of independent set queries appears in a broader line of work investigating the relationship between decision and counting problems [25, 26, 24, 16, 17, 11]. Independent set queries also have deep connections to group testing, where one tests large collections of items to detect the presence of rare events [18, 27, 14]. Independent set queries also have close connections to learning theory. In particular, a classical line of work on learning hidden graphs studies *edge-detecting queries*, which are equivalent to independent set queries [3, 4, 1].

Several works have explored combinatorial or global query primitives beyond purely local access. Beyond standard IS queries, Beame *et al.* [6] introduced *bipartite independent set (BIS) queries*, which ask whether there exists at least one edge between two given vertex subsets, and used them to obtain tight sublinear bounds for edge count estimation. Subsequently, [2] designed *non-adaptive* algorithms for edge counting and sampling in the BIS model. The BIS model was later extended to more general settings (see e.g., [9, 13, 10]).

Perhaps the work most closely related to ours is that of Beretta, Chakrabarty, and Seshadhri [7], which studies average-degree estimation under a query model combining random-edge sampling with structural queries (e.g., pair queries and full neighborhood access). They also discuss a structural oracle that, given a set $S \subseteq V$, returns the number of edges induced by S at a cost proportional to $|S|$. These structural queries provide precise local or aggregate information but follow a different cost model than IS queries. In particular, it is possible to show that IS oracle can simulate their structural oracle using (almost) linear number of IS queries.

2 Preliminaries

Given a positive integer n, we denote $[n] = \{1, ..., n\}$. For a set A, we denote the power set of A by 2^A. All graphs $G = (V, E)$ considered in this paper are undirected and simple (meaning that there are no parallel edges or loops), with $V = [n]$ as their vertex set (we

often just write $G = ([n], E)$). We also let $m = |E|$ be the number of edges in the graph and $d = 2m/n$ be the average degree in the graph. We use $\deg(v)$ to denote the degree of a vertex $v \in [n]$. We use boldface letters (such as $\mathbf{X}$) to denote random variables. We use the notation $\tilde{x} = (1 \pm \varepsilon)x$ to denote that $(1-\varepsilon)x \leq \tilde{x} \leq (1+\varepsilon)x$.

An algorithm is allowed to perform three types of queries to access the (otherwise hidden) edge set of the graph E, as defined by the following oracles:

▶ **Definition 3** (Degree oracle). *Given an undirected graph $G = ([n], E)$, its* degree oracle *is a map $\mathsf{Deg} : [n] \to [n-1] \cup \{0\}$, which for a vertex $u \in [n]$ returns the degree* $\deg(u)$.

▶ **Definition 4** (Random Neighbor oracle). *Given an undirected graph $G = ([n], E)$, its* random neighbor oracle *is a map $\mathsf{Neigh} : [n] \to [n]$, which for a vertex $u \in [n]$ returns a uniformly random neighbor of u. If u has no neighbors, it returns a special character to signify it.*

▶ **Definition 5** (Independent set oracle). *Given an undirected graph $G = ([n], E)$, its* independent set oracle *is a boolean map $\mathsf{IS} : 2^{[n]} \to \{0, 1\}$, which for a subset of vertices $U \subseteq [n]$ returns 1 if and only if U is an independent set of G (i.e., the subgraph induced on U contains no edges).*

Some of our algorithms will include the assumption that $m \geq 1$, note that we can distinguish this from the case that $m = 0$ using a single query to IS.

2.1 Classifying vertices and edges

We classify the vertices in V into three disjoint sets by their degrees, and use those sets to classify the edges in the graph:

▶ **Definition 6.** *Given a graph $G = (V, E)$, let k' and k be two degree thresholds (not necessarily integers) for which $k \geq k' \geq 0$ (where $n = |V|$). Let V_{L_1}, V_{L_2}, V_H be a partition of $[n]$ into disjoint sets such that:*

$$V_{L_1} = \{u \in V : \deg(u) \leq k'\}, V_{L_2} = \{u \in V : k' < \deg(u) \leq k\}, V_H = \{u \in V : \deg(u) > k\}.$$

Also, let $V_L = V_{L_1} \cup V_{L_2} = \{u \in V : \deg(u) \leq k\}$.

For two labels $\sigma_1, \sigma_2 \in \{L_1, L_2, L, H\}$, we use $E_{\sigma_1\sigma_2}$ to denote the set of edges between V_{σ_1} and V_{σ_2} (note that $E_{\sigma_1\sigma_2}$ and $E_{\sigma_2\sigma_1}$ are identical). Also, we let $m_{\sigma_1\sigma_2} = |E_{\sigma_1\sigma_2}|$ be the number of these edges.

At top-level, we "guess" (formally, search for) an advice $\bar{m}$, hopefully just slightly greater than the correct answer m. Based on $\bar{m}$ we define the threshold degrees k and k', and use different logic to estimate the number of edges between every pair of subsets. For some pairs the estimation is zero, since the choice of k, k' means that the number of relevant edges is no more than linear in the allowed additive error and thus are negligible.

For $\bar{m} > 0$ and $0 < \varepsilon < 1$, let $k(\bar{m}, \varepsilon) \stackrel{\text{def}}{=} \sqrt{\frac{2n\sqrt{\bar{m}}}{\varepsilon}}$ and $k' = \min(k, \bar{m}/\varepsilon k)$, and recall the sets of Definition 6. Clearly, both k and $\bar{m}/\varepsilon k$ are monotone increasing in $\bar{m}$ (when n and ε are considered fixed). Therefore, the set $V_H(\bar{m}, \varepsilon)$ and the union set $V_{L_2}(\bar{m}, \varepsilon) \cup V_H(\bar{m}, \varepsilon)$ are monotone non-increasing in $\bar{m}$. Note that when $k' = k$, we have $|V_{L_2}| = 0$ and thus $V_L = V_{L_1}$.

▶ **Lemma 7.** *Let $k(\bar{m}, \varepsilon) = \sqrt{2n\sqrt{\bar{m}}/\varepsilon}$. If $\bar{m} \geq \frac{1}{4}m$, then the number of edges between $V_{L_2} \cup V_H$ and V_H is at most $64\varepsilon\bar{m}$.*

▶ **Lemma 8.** *If $\bar{m} \geq \frac{1}{4}m$ and $k(\bar{m}, \varepsilon) = \sqrt{2n\sqrt{\bar{m}}/\varepsilon}$, then $m_{LL} + m_{L_1H} \geq m - 64\varepsilon\bar{m}$.*

3 Upper Bound

In this section, we prove an upper bound on the number of queries an algorithm with access to Deg, Neigh, IS needs to make in order to achieve a $1 \pm \varepsilon$ estimation of the number of edges in a graph. Specifically, we prove the following:

▶ **Theorem 9.** *There exists an algorithm Estimate-Edges(n, ε, G) that takes as input integer $n \geq 1$, parameter $\varepsilon \in (0, 1]$, and access to the oracles Deg, Neigh, IS of a graph $G = ([n], E)$ with $m = |E|$. Estimate-Edges makes an expected number of $O\left(\frac{\log n}{\varepsilon^{5/2}} \min\left(\sqrt{\frac{n}{\sqrt{m}}}, \sqrt{m}\right)\right)$ queries to the oracles and outputs a number $\tilde{\boldsymbol{m}}$ such that with probability at least $2/3$ satisfies $(1-\varepsilon)m \leq \tilde{\boldsymbol{m}} \leq (1+\varepsilon)m$.*

We prove Theorem 9 through Lemma 22, which is logically equivalent. We use the parameters and notation described in Table 1 throughout the paper.

Table 1 Notation and parameters used throughout this section.

Symbol	Description
$G = (V, E)$	The input graph.
n	Number of vertices in the graph ($n = \|V\|$).
m	Number of edges in the graph ($m = \|E\|$).
$\bar{m}$	Untrusted advice for the number of edges m, where $\bar{m} > 0$.
$\tilde{\boldsymbol{m}}$	Random variable output of an estimation procedure.
k	Degree threshold: vertices of degree at most k are *low-degree*, and vertices of degree greater than k are *high-degree*, with $k \geq 0$.
k'	Secondary degree threshold, satisfying $0 \leq k' \leq k$.

3.1 Estimating m_{LL} (with advice)

We restate the following lemma from [6]:

▶ **Lemma 10** ([6])**.** *There exists a deterministic procedure Enumerate-Edges whose input is a graph $G = (V, E)$ accessible through the independent-set oracle and a vertex set $A \subseteq V$, and its output is a list of all edges in the subgraph induced on A's vertices. The query complexity of this procedure is $O(1 + |E_A| \log n)$, where $n = |V|$ is the number of vertices and E_A is the set of edges in the subgraph induced on A's vertices.*

Procedure Sample-LL-Edges-Sparse, implemented in Algorithm 1, is an unbiased estimator for $\frac{m_{LL}}{\bar{m}}$. It draws a set $\mathbf{S} \subseteq V$ that every vertex belongs to with probability $1/\sqrt{\bar{m}}$, and then enumerates the edges in the subgraph induced on $\mathbf{S}$. Only edges between two low-degree vertices $(\deg(u), \deg(v) \leq k)$ are counted.

▶ **Lemma 11.** *The output of Procedure Sample-LL-Edges-Sparse (Algorithm 1) is a random variable whose expected value is $\frac{m_{LL}}{\bar{m}}$ and variance is at most $\left(1 + \frac{2k}{\sqrt{\bar{m}}}\right)\frac{m_{LL}}{\bar{m}}$. Moreover, the procedure's expected query complexity is $O(1 + \frac{m}{\bar{m}} \log n)$.*

In procedure Estimate-LL-Edges-Advice (Algorithm 2), we estimate m_{LL} by averaging the outcomes of $O\left(\frac{1+k/\sqrt{\bar{m}}}{\varepsilon^2}\right)$ invocations of Sample-LL-Edges-Sparse. Since each invocation has expected value $m_{LL}/\bar{m}$, this averaging yields good concentration around the mean.

Algorithm 1: Procedure Sample-LL-Edges-Sparse$(G, \bar{m}, k)$.

Input: Integer $n \geq 1$, parameters $k \geq 0$, $\bar{m} > 0$.
Input: Access to the oracles IS, Deg of a graph $G = ([n], E)$ with $m = |E|$.
Output: An unbiased estimation $\mathbf{X}$, for $\frac{m_{LL}}{\bar{m}}$.

1. Draw a subset $\mathbf{S} \subseteq V$ that every vertex belongs to with probability $1/\sqrt{\bar{m}}$, independently.
2. Run Enumerate-Edges$(G, \mathbf{S})$, and let $E_{\mathbf{S}}$ be the resulting list of edges.
3. Initialize $\mathbf{X} \leftarrow 0$.
4. For each edge $(\boldsymbol{u}, \boldsymbol{v}) \in E_{\mathbf{S}}$:
   a. Let $d_{\boldsymbol{u}} \leftarrow \deg(\boldsymbol{u})$ (via Deg).
   b. Let $d_{\boldsymbol{v}} \leftarrow \deg(\boldsymbol{v})$ (via Deg).
   c. If $d_{\boldsymbol{u}} \leq k$ and $d_{\boldsymbol{v}} \leq k$:
      i. Increment $\mathbf{X} \leftarrow \mathbf{X} + 1$.
5. Return $\mathbf{X}$.

Algorithm 2: Procedure Estimate-LL-Edges-Advice$(n, \varepsilon, G, \bar{m}, k)$.

Input: Integer $n \geq 1$, parameters $\varepsilon \in (0, 1], k \geq 0$, $\bar{m} > 0$.
Input: Access to the oracles IS, Deg of a graph $G = ([n], E)$ with $m = |E|$.
Output: A number $\tilde{\boldsymbol{m}}_{LL}$.

1. Let $\boldsymbol{c} \leftarrow 0$, $q \leftarrow \left\lceil \frac{600}{\varepsilon^2} \max\left(1, \frac{k}{\sqrt{\bar{m}}}\right) \right\rceil$.
2. For $i = 1, ..., q$:
   a. Run Sample-LL-Edges-Sparse$(n, G, \bar{m}, k)$ and let $\mathbf{X}_i$ be its result.
   b. Increment $\boldsymbol{c} \leftarrow \boldsymbol{c} + \frac{1}{q}\mathbf{X}_i$.
3. Return $\tilde{\boldsymbol{m}}_{LL} = \bar{m} \cdot \boldsymbol{c}$.

▶ **Lemma 12.** *Let $\tilde{\boldsymbol{m}}_{LL}$ be the (random) output of procedure Estimate-LL-Edges-Advice (Algorithm 2).*

- *If $\bar{m} \geq \frac{1}{4}m_{LL}$, then with probability at least $1 - \frac{m_{LL}}{200\bar{m}}$, $|\tilde{\boldsymbol{m}}_{LL} - m_{LL}| \leq \varepsilon\bar{m}$.*
- *If $\bar{m} < m_{LL}$, then with probability at least $1 - \frac{\bar{m}}{200m_{LL}}$, $\tilde{\boldsymbol{m}}_{LL} > (1 - \varepsilon)\bar{m}$.*

Moreover, the expected query complexity is $O\left(\frac{\log n}{\varepsilon^2}\left(1 + \frac{k}{\sqrt{\bar{m}}}\right)\left(1 + \frac{m}{\bar{m}}\right)\right)$. Note that if $\frac{1}{4}m_{LL} \leq \bar{m} < m_{LL}$, then both guarantees hold simultaneously.

3.2 Estimating m_{LH} (with advice)

In this subsection we provide an estimation algorithm for the number of edges between low-degree vertices ($\deg(u) \leq k$) and high-degree vertices ($\deg(u) > k$). Recall that the number of low-high edges is denoted by m_{LH}, and the set of these edges is denoted by E_{LH}.

We define the "very-low" degree threshold as $k' = \min(k, \bar{m}/\varepsilon k)$. Let V_{L_1} denote the set of vertices of degree at most k', let E_{L_1H} be the set of edges between vertices in V_{L_1} and high-degree vertices, and let $m_{L_1H} = |E_{L_1H}|$. Since $V_{L_1} \subseteq V_L$, it follows that $m_{L_1H} \leq m_{LH}$. Moreover, Lemma 7 implies that the number of edges between high-degree vertices and vertices of degree exceeding k' is at most $4\varepsilon\bar{m}$. Consequently, $m_{L_1H} \leq m_{LH} \leq m_{L_1H} + 4\varepsilon\bar{m}$.

The estimator for m_{L_1H}, implemented as procedure Estimate-L_1H-Edges-Advice (Algorithm 3), averages over $O(nk'/\varepsilon^2\bar{m})$ samples as follows: we uniformly draw a vertex $\boldsymbol{u}$ and a neighbor $\boldsymbol{v}$ of $\boldsymbol{u}$ (if $\deg(\boldsymbol{u}) = 0$, we proceed to the next sample). If $\boldsymbol{u}$'s degree is "very-low" (i.e., $\deg(\boldsymbol{u}) \le k'$) and $\boldsymbol{v}$'s degree is high ($\deg(\boldsymbol{v}) > k$), then we add $\deg(\boldsymbol{u})$ to a counter $\boldsymbol{c}$. For all other cases, we do not increment the counter. The result is normalized by an n factor.

Algorithm 3: Procedure Estimate-L_1H-Edges-Advice$(n, \varepsilon, G, \bar{m}, k)$.

Input: Integers $n \ge 1$, parameters $\varepsilon \in (0, 1], k \ge 0$, $\bar{m} > 0$.
Input: Access to the oracles Deg, Neigh of a graph $G = ([n], E)$ with $m = |E|$.
Output: An unbiased estimator $\tilde{\boldsymbol{m}}_{L_1H}$ for m_{L_1H}.

1. Initialize $\boldsymbol{c} \leftarrow 0$.
2. Let $k' \leftarrow \min\left(k, \frac{\bar{m}}{\varepsilon k}\right)$.
3. Let $t \leftarrow \left\lceil \frac{200nk'}{\varepsilon^2\bar{m}} \right\rceil$.
4. For $i = 1, ..., t$:
   a. Sample a vertex $\boldsymbol{u} \in V$ uniformly at random.
   b. Sample a neighbor $\boldsymbol{v}$ of $\boldsymbol{u}$ uniformly at random (via Neigh).
   c. Let $\boldsymbol{d}_u \leftarrow \deg(\boldsymbol{u})$ (via Deg).
   d. Let $\boldsymbol{d}_v \leftarrow \deg(\boldsymbol{v})$ (via Deg).
   e. If $\boldsymbol{d}_u \le k'$ and $\boldsymbol{d}_v > k$:
      i. Increment $\boldsymbol{c} \leftarrow \boldsymbol{c} + \boldsymbol{d}_u$.
5. Return $\tilde{\boldsymbol{m}}_{L_1H} = \frac{n}{t}\boldsymbol{c}$.

▶ **Lemma 13.** *Let $\tilde{\boldsymbol{m}}_{L_1,H}$ be the (random) output of Estimate-L_1H-Edges-Advice (Algorithm 3) when executed with parameters $(G, \varepsilon, \bar{m}, k)$.*

- *If $\bar{m} \ge \frac{1}{4}m_{L_1H}$, then with probability at least $1 - \frac{m_{L_1H}}{200\bar{m}}$, $|\tilde{\boldsymbol{m}}_{L_1H} - m_{L_1H}| \le \varepsilon\bar{m}$.*
- *If $\bar{m} < m_{L_1H}$, then with probability at least $1 - \frac{\bar{m}}{200m_{L_1H}}$, $\tilde{\boldsymbol{m}}_{L_1H} > (1-\varepsilon)\bar{m}$.*

Moreover, the query complexity is bounded by $O(n/\varepsilon^3 k)$.

3.3 Handling the case where $\bar{m} < m$

Beame's algorithm (Enumerate-Edges) is meant to be executed as a whole. For our algorithm, we need a more fine-grained analysis.

▶ **Lemma 14.** *Enumerate-Edges (Lemma 10) can be implemented with an additional guarantee: for every $1 \le t \le |E_A|$, the t-th edge is added to the list after performing at most $O(1+t\log n)$ queries. In other words, it has $O(1)$ initialization phase and amortized $O(\log n)$ "next-element" phase.*

Procedure Small-$\bar{m}$-Guard (Algorithm 6) separates the regime in which the advice $\bar{m}$ is valid ($\bar{m} \ge m$) from the regime in which it is substantially underestimated ($\bar{m} < m/4$) or when it is structurally wrong ($\max_u \deg(u) > \bar{m}$). In the former case, the procedure accepts with probability at least $1 - 1/1000$ (completeness), while in the latter it rejects with probability at least $1 - \bar{m}/1000m$ (soundness). The procedure searches for vertices whose degree exceeds $\bar{m}$ and applies a moderated variant of Sample-LL-Edges-Sparse in order to reject instances in which the number of edges is significantly larger than what is consistent with the assumption $\bar{m} \ge m$.

For readability, we provide a parameterized algorithm and a corresponding parameterized analysis for completeness $1 - c$ and soundness $1 - c\bar{m}/m$, where $c \leq 1$. For the lemma statement, we use $c = 1/1000$.

Case 0 (trivial)

$m = O(\text{poly}(1/c))$. This is an easy case since we can just look for $O(\text{poly}(1/c))$ edges at the cost of $O_c(\log n)$ queries to find out whether or not $\bar{m} \geq \min(m, \text{poly}(1/c)) = m$.

Case I (typical)

$m_{LL} \geq \frac{3}{4}m$, where the threshold degree k is defined as $\min(\bar{m}, n-1)$.

Case II (very-high degree)

There exists a vertex of degree at least $\sqrt{\bar{m}}\ln(m/c)$.

Case III (sparse)

$m = \Omega(\text{poly}(1/c))$ and $m_{LL} < \frac{3}{4}m$ (where the threshold degree k is defined as $\min(\bar{m}, n-1)$) and the maximum degree is at most $\sqrt{\bar{m}}\ln(m/c)$.

Observe that Case I is "quantitative" (to be resolved by large-deviation inequalities), whereas Case II is a "qualitative" (to be resolved by looking for a witness), and therefore, they are treated using different algorithms. Case III is analyzed through the qualitative algorithm resolving Case II.

3.3.1 Quantity test (Case I)

In the quantity test (Guard-Quantity, Algorithm 4) we execute an edge sampler similar to Estimate-LL-Edges-Advice (Algorithm 2), but we use the lazy variant of Enumerate-Edges (Lemma 14) to keep the query complexity low even if $\bar{m}$ is significantly smaller than m. Additionally, if we happen to encounter a vertex whose degree is greater than $\bar{m}$, then we reject immediately.

▶ **Observation 15.** *Considering Algorithm 4 (Guard-Quantity), ignoring the possibility of an early termination (but without counting the high-degree-adjacent edges that would cause it), the gain in* $\mathbf{X}$ *in every iteration distributes the same as in Algorithm 1 (Sample-LL-Edges-Sparse).*

▶ **Observation 16.** *Assume that* $\bar{m} \geq 1$. *Considering Algorithm 4 (Guard-Quantity), ignoring the possibility of an early termination (but without counting the high-degree-adjacent edges that would cause it), the gain in* $\mathbf{X}$ *in every iteration has expected value* $\frac{m_{LL}}{\bar{m}}$ *and its variance is bounded by* $3\sqrt{\bar{m}} \cdot \frac{m_{LL}}{\bar{m}}$.

3.3.2 Quality test (Case II, Case III)

In the quality test (Guard-Quality, Algorithm 5) we use a similar logic to the quantitative test, but instead of having independent iterations, we choose the sets such that every vertex belongs to exactly one iteration. This guarantees that every potential witness belongs to the union of the iteration sets, which is not guaranteed in Algorithm 4. We reject as soon as we encounter a vertex whose degree is strictly greater than $\bar{m}$, or when we find significantly more edges than what we expect to if we would run Estimate-LL-Edges-Advice.

Algorithm 4: Procedure Guard-Quantity$(c; G, \bar{m})$.

Complexity: $O(\frac{1}{c}\sqrt{\bar{m}}\log n)$.
Completeness: If $\bar{m} \geq m$, then we accept with probability at least $1 - c/2$.
Soundness: If $\bar{m} < \frac{1}{4}m$ and $m_{LL} \geq \frac{3}{4}m$, then we reject with probability at least $1 - \frac{c\bar{m}}{m}$.
Soundness: If $m_{LL} < \frac{1}{2}m$ and the maximum degree in G is less than $\sqrt{\bar{m}}\ln(m/c)$, then we reject with probability at least $1 - \frac{c\bar{m}}{m}$.

1. Initialize $\mathbf{X} \leftarrow 0$.
2. Let $t \leftarrow \lceil \frac{96}{c}\sqrt{\bar{m}} \rceil$.
3. For t times:
   a. Draw a set $\mathbf{S} \subseteq V$ that every vertex belongs to with probability $\frac{1}{\sqrt{\bar{m}}}$, iid.
   b. Initialize Enumerate-Edges, let $L_{\mathbf{S}}$ be the result, accessible sequentially.
   c. While $L_{\mathbf{S}}$ has an unfeteched edge:
      i. Fetch $(\boldsymbol{u}, \boldsymbol{v}) \in L_{\mathbf{S}}$.
      ii. Let $d_{\boldsymbol{u}} \leftarrow \deg(\boldsymbol{u})$ via Deg query.
      iii. Let $d_{\boldsymbol{v}} \leftarrow \deg(\boldsymbol{v})$ via Deg query.
      iv. If $d_{\boldsymbol{u}} > \bar{m}$ or $d_{\boldsymbol{v}} > \bar{m}$:
         A. Return REJECT.
      v. Increment $\mathbf{X} \leftarrow \mathbf{X} + 1$.
      vi. If $\mathbf{X} \geq (5/4)t$:
         A. Return REJECT.
4. Return ACCEPT.

3.3.3 The guard procedure

The guard procedure is merely a conjunction of a deterministic fixed-count edge enumeration (to detect Case 0), the quantitative guard procedure (to detect Case I) and the qualitative procedure (to detect Case II and Case III).

3.4 Estimating m (with advice)

We combine the previously described partial-estimation procedures into two estimation procedures: Estimate-Edges-Advice-High, which is optimized for large ms, and Estimate-Edges-Advice-High, which is optimized for small ms.

In Estimate-Edges-Advice-High, we use the threshold degree $k = \Theta(\sqrt{n\sqrt{\bar{m}}/\varepsilon})$, unless $m = \Omega(\varepsilon n^2)$, in which case we use $k = n - 1$.

▶ **Lemma 17.** *Let $\tilde{\boldsymbol{m}}$ be the (random) output of Estimate-Edges-Advice-High (Algorithm 7) when given parameters ε, $G = (V, E)$ and $\bar{m}$. If $\bar{m} \geq \frac{1}{4}m$, then $|\tilde{\boldsymbol{m}} - m| \leq 70\varepsilon\bar{m}$ with probability at least $1 - \frac{m}{100\bar{m}}$.*

▶ **Lemma 18.** *Let $\tilde{\boldsymbol{m}}$ be the (random) output of Estimate-Edges-Advice-Low (Algorithm 8) when given parameters ε, $G = (V, E)$ and $\bar{m}$. The following is guaranteed for $m = |E|$ (unknown to the algorithm):*

- *If $\bar{m} \geq m$, then with probability at least $1 - \frac{m}{200\bar{m}} - \frac{1}{1000}$, $|\tilde{\boldsymbol{m}} - m| \leq \varepsilon\bar{m}$.*
- *If $\bar{m} \geq \frac{1}{4}m$, then with probability at least $1 - \frac{m}{200\bar{m}}$, $|\tilde{\boldsymbol{m}} - m| \leq \varepsilon\bar{m}$ or $\tilde{\boldsymbol{m}} > (1 - \varepsilon)\bar{m}$.*
- *$1 \leq \bar{m} < m$, then with probability at least $1 - \frac{\bar{m}}{200m}$, $\tilde{\boldsymbol{m}} > (1 - \varepsilon)\bar{m}$.*

Algorithm 5: Procedure Guard-Quality$(c; G, \bar{m})$.

Complexity: $O(\frac{1}{c}\sqrt{\bar{m}}\log n)$.
Completeness: If $\bar{m} \geq m$, then we accept with probability at least $1 - c/2$.
Soundness: If $\max_u \deg(u) \geq \sqrt{\bar{m}}\ln(m/c)$, then we reject with probability at least $1 - \frac{c\bar{m}}{m}$.

1. Let $t \leftarrow \lceil\sqrt{\bar{m}}\rceil$.
2. For each $u \in V$:
   a. Draw $\boldsymbol{i}_u \in \{1, \ldots, t\}$ uniformly and independently.
3. Initialize $\mathbf{X} \leftarrow 0$.
4. For i from 1 to t:
   a. Let $\mathbf{S}_i \leftarrow \{u \in V : \boldsymbol{i}_u = i\}$.
   b. Initialize Enumerate-Edges, let $L_{\mathbf{S}}$ be the result, accessible sequentially.
   c. While $L_{\mathbf{S}}$ has an unfeteched edge:
      i. Fetch $(\boldsymbol{u}, \boldsymbol{v}) \in L_{\mathbf{S}}$.
      ii. Let $d_{\boldsymbol{u}} \leftarrow \deg(\boldsymbol{u})$ via Deg query.
      iii. Let $d_{\boldsymbol{v}} \leftarrow \deg(\boldsymbol{v})$ via Deg query.
      iv. If $d_{\boldsymbol{u}} > \bar{m}$ or $d_{\boldsymbol{v}} > \bar{m}$:
         A. Return REJECT.
      v. Increment $\mathbf{X} \leftarrow \mathbf{X} + 1$.
      vi. If $\mathbf{X} \geq 2t/c$:
         A. Return REJECT.
5. Return ACCEPT.

3.5 Estimating m without any advice

In this subsection we introduce our main procedure, Estimate-Edges. At a high level, the algorithm begins with an extreme initial estimate for $\bar{m}$ and iteratively refines it toward an accurate value of m. A straightforward serial execution of these iterations (a simple for-loop) achieves correctness with high probability, but its query complexity is small only with high probability rather than in expectation. Therefore, we execute the iterations in an iterative-deepening schedule, i.e., in rounds where we run the prefixes (0), (0, 1), (0, 1, 2), and so on.

We start by presenting a single iteration of the algorithm (Algorithm 9). We then give an iteration-bounded variant, Estimate-Edges-Bounded (Algorithm 10), which attains a correct estimate with high probability once the number of iterations is sufficiently large; however, this version guarantees low query complexity only with high probability, not in expectation.

Finally, we provide the iteration-unbounded version, Estimate-Edges (Algorithm 11), which preserves correctness while ensuring that the expected query complexity remains small.

To analyze Estimate-Edges-Iteration (and its callers) when executed on an input graph G with n vertices (where n is known to the algorithm) and m edges (unknown to the algorithm), we define the following parameters:

- $\ell_{\text{big}}(G)$ – the unique integer for which $\sqrt{2}m \leq 2^{-\ell}n^2 < \sqrt{8}m$.
- $\ell_{\text{small}}(G)$ – the unique integer for which $\sqrt{2}m \leq 2^{\ell/2} < 2m$.
- $\ell_0(G) = \min(\ell_{\text{big}}(G), \ell_{\text{small}}(G))$.

For convenience, we usually omit the G parameter and refer to ℓ_{big}, ℓ_{small} and ℓ_0.

Algorithm 6: Procedure Small-$\bar{m}$-Guard$(G, \bar{m})$.

Complexity: $O(\sqrt{\bar{m}} \log n)$.
Completeness: If $\bar{m} \geq m$ and $\max_u \deg(u) \leq \bar{m}$, then we accept with probability at least $1 - \frac{1}{1000}$.
Soundness: If $\bar{m} < \frac{1}{4}m$, then we reject with probability at least $1 - \frac{\bar{m}}{1000m}$.
Soundness: If $\max_u \deg(u) > \bar{m}$, then we reject with probability at least $1 - \frac{\bar{m}}{1000m}$.

1. Let $c \leftarrow 1/1000$.
2. Let $\bar{m}^* \leftarrow \max(16(1 + \ln c^{-1})^{14}, 1/c)$.
3. Initialize Enumerate-Edges for the whole graph, let L be the result list, accessible sequentially.
4. Initialize $X \leftarrow 0$.
5. While $X \leq \bar{m}^*$ and L has an unfeteched edge:
   a. Consume an arbitrary edge of L.
   b. Increment $X \leftarrow X + 1$.
6. If $X > \bar{m}$:
   a. Return REJECT.
7. Run Guard-Quantity$(c; G, \bar{m})$.
8. If The quantity guard rejects:
   a. Return REJECT.
9. Run Guard-Quality$(c; G, \bar{m})$.
10. If The quality guard rejects:
    a. Return REJECT.
11. Return ACCEPT.

Algorithm 7: Procedure Estimate-Edges-Advice-High$(\varepsilon, G, \bar{m})$.

Input: A graph $G = (V, E)$ (V is explicitly given) accessible through Deg, Neigh, IS.
Input: An accuracy parameter $\varepsilon > 0$.
Input: $n \geq 2/\varepsilon^2$.
Input: An untrusted advice $\bar{m} > 0$.
Output: A number $\tilde{\boldsymbol{m}}$.
Complexity: $O\left(\frac{\log n}{\varepsilon^{5/2}}(1 + \frac{m}{\bar{m}})\sqrt{n/\sqrt{\bar{m}}}\right)$.

1. If $\bar{m} \geq \frac{1}{4}\varepsilon n^2$:
   a. Set $k \leftarrow n - 1$.
   b. Run Estimate-LL-Edges-Advice$(n, \varepsilon, G, \bar{m}, k)$ and return the result as $\tilde{\boldsymbol{m}}$.
   c. Return $\tilde{\boldsymbol{m}}$.
2. Else:
   a. Set $k \leftarrow \frac{\sqrt{2}}{\sqrt{\varepsilon}} n^{\frac{1}{2}} \bar{m}^{\frac{1}{4}}$.
   b. Run Estimate-LL-Edges-Advice$(n, \varepsilon, G, \bar{m}, k)$ and let $\tilde{\boldsymbol{m}}_{LL}$ be the result.
   c. Run Estimate-L$_1$H-Edges-Advice$(n, \varepsilon, G, \bar{m}, k)$ and let $\tilde{\boldsymbol{m}}_{L_1H}$ be the result.
   d. Return $\tilde{\boldsymbol{m}} = \tilde{\boldsymbol{m}}_{LL} + \tilde{\boldsymbol{m}}_{L_1H}$.

Algorithm 8: Procedure Estimate-Edges-Advice-Low$(\varepsilon, G, \bar{m})$.

Input: A graph $G = (V, E)$ (V is explicitly given) accessible through Deg, Neigh, IS.
Input: An accuracy parameter $\varepsilon > 0$.
Input: An untrusted advice $\bar{m} \geq 1$.
Output: A number $\tilde{\boldsymbol{m}}$.
Complexity: $O(\frac{\log n}{\varepsilon^2}\sqrt{\bar{m}})$.

1. Set $k \leftarrow \min(\bar{m}, n-1)$.
2. If Small-$\bar{m}$-Guard$(G, \bar{m})$ accepts:
   a. Run Estimate-LL-Edges-Advice$(n, \frac{\varepsilon}{10}, G, \bar{m}, k)$ and return the result as $\tilde{\boldsymbol{m}}$.
3. Return $+\infty$.

Algorithm 9: Procedure Estimate-Edges-Iteration$(n, \varepsilon, G, \ell)$.

Input: $0 < \varepsilon \leq \frac{1}{15}$.
Input: G has n vertices (explicitly given) and $m \geq 1$ edges (unknown to the algorithm).
Complexity: $O(2^{\max(0,\ell-\ell_0)} \cdot 2^{\ell/4} \cdot \log n/\varepsilon^{5/2})$.

1. Let $\bar{m}_{\text{big}} \leftarrow \frac{n^2}{2^\ell}$, $\bar{m}_{\text{small}} \leftarrow 2^{\ell/2}$. (*cannot* assume that $\bar{m}_{\text{big}} \geq \bar{m}_{\text{small}}$)
2. Call Estimate-Edges-Advice-High$(n, \frac{1}{1000}\varepsilon, G, \bar{m}_{\text{big}})$ and let $\tilde{\boldsymbol{m}}_{\text{big}}$ be the result.
3. If $\frac{1}{4}\bar{m}_{\text{big}} \leq \tilde{\boldsymbol{m}}_{\text{big}} \leq \frac{4}{5}\bar{m}_{\text{big}}$:
   a. Return $\tilde{\boldsymbol{m}}_{\text{big}}$ as $\tilde{\boldsymbol{m}}$.
4. Call Estimate-Edges-Advice-Low$(n, \frac{1}{10}\varepsilon, G, \bar{m}_{\text{small}})$ and let $\tilde{\boldsymbol{m}}_{\text{small}}$ be the result.
5. If $\tilde{\boldsymbol{m}}_{\text{small}} \leq \frac{1}{\sqrt[4]{2}}\bar{m}_{\text{small}}$:
   a. Return $\tilde{\boldsymbol{m}}_{\text{small}}$ as $\tilde{\boldsymbol{m}}$.
6. Return REJECT.

▶ **Lemma 19.** *Assume that $\varepsilon \leq \frac{1}{15}$. If $\ell \leq \ell_0 - 2$, then with probability at least $1 - \frac{1}{50} \cdot 2^{(\ell-\ell_0)/2}$, Estimate-Edges-Iteration (Algorithm 9) either rejects or returns a number in the range $(1 \pm \varepsilon)m$. If $\ell = \ell_0 - 1$, then this probability is at least $1 - \frac{1}{100} \cdot 2^{(\ell-\ell_0)/2} - \frac{1}{100}$.*

▶ **Lemma 20.** *For $\varepsilon \leq \frac{1}{15}$, if $\ell = \ell_0$, then Estimate-Edges-Iteration (Algorithm 9) returns a number in the range $(1 \pm \varepsilon)m$ with probability at least $1 - \frac{1}{55}$.*

▶ **Lemma 21.** *Assume that $\varepsilon \leq \frac{1}{15}$. Considering Estimate-Edges-Bounded:*

- *If $\ell_{\max} \leq \ell_0 - 2$, then the probability of the ℓth call to Estimate-Edges-Iteration to return a non-reject value outside the range $(1 \pm \varepsilon)m$ is bounded by $\frac{2+\sqrt{2}}{50} \cdot 2^{(\ell-\ell_0)/2}$.*
- *If $\ell_{\max} = \ell_0 - 1$, then the probability to return a number outside the range $(1 \pm \varepsilon)m$ is bounded by $\frac{3}{50}$.*
- *If $\ell_{\max} \geq \ell_0$, then the probability to return a number in the range $(1 \pm \varepsilon)m$ is at least $1 - 3/34$.*

▶ **Lemma 22.** *For $\varepsilon \leq \frac{1}{15}$ and an input graph G with n vertices and m edges. Estimate-Edges (Algorithm 11) returns a number in the range $(1 \pm \varepsilon)m$ with probability at least $2/3$. Moreover, its expected query complexity bounded by $O\left(\frac{\log n}{\varepsilon^{5/2}} \min\left(\sqrt{m}, \sqrt{\frac{n}{\sqrt{m}}}\right)\right)$.*

Algorithm 10: Procedure Estimate-Edges-Bounded$(n, \varepsilon, G, \ell_{\max})$.

Input: $0 < \varepsilon \leq \frac{1}{10}$.
Input: G has n vertices (explicitly given) and m edges (unknown to the algorithm).
Input: $m \geq 1$.

1. For ℓ from 0 to $\ell_{\max}$:
   a. Cal Estimate-Edges-Iteration$(n, \varepsilon, G, \ell)$ and let $\tilde{\boldsymbol{m}}$ be its result.
   b. If $\tilde{\boldsymbol{m}} \neq$ REJECT:
      i. Return $\tilde{\boldsymbol{m}}$.
2. Return REJECT.

Algorithm 11: Procedure Estimate-Edges(n, ε, G).

Input: Integer n, parameter $\varepsilon \in (0, 1]$.
Input: Access to the oracles Deg, Neigh, IS of a graph $G = ([n], E)$.
Output: A number $\tilde{\boldsymbol{m}}$, an estimate for m.

1. If $\varepsilon > \frac{1}{15}$:
   a. Set $\varepsilon \leftarrow \frac{1}{15}$.
2. If IS$(V) = 1$:
   a. Return 0.
3. If $n < 2/\varepsilon^2$:
   a. For each $u \in V$:
      i. Let $d_u \leftarrow \deg(u)$ (via Deg).
   b. Return $\frac{1}{2}\sum_{u \in V} d_u$.
4. Let $\ell \leftarrow 0$.
5. While TRUE:
   a. Call Estimate-Edges-Bounded$(n, \varepsilon, G, \ell)$ and let $\tilde{\boldsymbol{m}}$ be its result.
   b. If $\tilde{\boldsymbol{m}} \neq$ REJECT:
      i. Return $\tilde{\boldsymbol{m}}$.
   c. $\ell \leftarrow \ell + 1$.

4 Lower Bound

In this section we prove the following lower-bound for edge estimation in the hybrid model. In particular, the lower bound follows from the following (stronger) statement.

▶ **Theorem 23.** *Consider any algorithm that is given query access to an unknown graph $G = (V, E)$ on n vertices and m edges via degree queries, neighbor queries and IS queries. Let $\varepsilon \in (0, 1)$ and define $R \stackrel{\text{def}}{=} \frac{1}{30} \min\left(\sqrt{m}, \sqrt{\frac{n}{\varepsilon\sqrt{m}}}\right)$. For any such algorithm whose expected number of queries is q (where q may depend on G), the probability that the algorithm outputs an estimate $\widehat{\boldsymbol{m}}$ satisfying $(1-\varepsilon)m \leq \widehat{\boldsymbol{m}} \leq (1+\varepsilon)m$ is at most $\frac{1}{2} + q/R$.*

Theorem 23 above bounds the success probability of any algorithm as a function of its expected number of queries. Rearranging this bound and applying Markov's inequality yields the following corollary for algorithms that succeed with probability at least 2/3.

▶ **Corollary 24.** *Let $\varepsilon \in (0,1)$. Every algorithm whose input is an access to a graph G of m edges (where m is unknown to the algorithm) through degree queries, neighbor queries and IS queries, whose output $\widehat{\boldsymbol{m}}$ satisfies $(1-\varepsilon)m \leq \widehat{\boldsymbol{m}} \leq (1+\varepsilon)m$ with probability at least $2/3$, must make $\Omega\left(\min\left(\sqrt{m}, \sqrt{\frac{n}{\varepsilon\sqrt{m}}}\right)\right)$ queries.*

The proof of Theorem 23 proceeds via a reduction from a specially designed string-testing problem to the problem of estimating the number of edges in a graph with a particular structure.

4.1 The string distinction problem

Let s be a string of length n over the alphabet $\Sigma = \{\mathrm{A}, \mathrm{K}, \mathrm{L}, \mathrm{H}\}$. We define a duality map as follows: A and K are the dual of themselves ($\overline{\mathrm{A}} = \mathrm{A}$, $\overline{\mathrm{K}} = \mathrm{K}$), and L and H are the dual of each other ($\overline{\mathrm{L}} = \mathrm{H}$, $\overline{\mathrm{H}} = \mathrm{L}$).

For $\sigma \in \Sigma$ and a string $s \in \Sigma^n$, let $n_\sigma(s) = |\{1 \leq i \leq n : s(i) = \sigma\}|$. For every $1 \leq i \leq n$, let

$$U_i \stackrel{\text{def}}{=} \begin{cases} \emptyset, & \text{if } s(i) = \mathrm{A}, \\ \{\, j \in [n] \setminus \{i\} : s(j) = \overline{s(i)} \,\}, & \text{otherwise.} \end{cases}$$

We assume that s is accessible through two oracles:

- **Full query.** Given an index $1 \leq i \leq n$, the oracle returns three entries:
  - The symbol $s(i)$.
  - The value $|U_i|$.
  - A uniformly random index from U_i, or $\perp$ if $U_i = \emptyset$.
- **Light query.** Given an index $1 \leq i \leq n$, the oracle returns the symbol $s(i)$.

We consider the task of distinguishing between strings of length n for which $n_{\mathrm{L}}(s) \cdot n_{\mathrm{H}}(s) = 0$ and strings for which $n_{\mathrm{L}}(s) \cdot n_{\mathrm{H}}(s) > \varepsilon\binom{n_{\mathrm{K}}(s)}{2}$. We say that an algorithm *distinguishes* between the above cases if one of the following occurs:

▶ **Definition 25** (Full-query distinguishing predicate)**.** *An algorithm performs a full query on a vertex i for which $s(i) \in \{\mathrm{L}, \mathrm{H}\}$ and obtained a non-$\perp$ index as the third entry of the result tuple.*

▶ **Definition 26** (Light-query distinguishing predicate)**.** *An algorithm performs a light query on a vertex i for which $s(i) = \mathrm{H}$ and another light query on a vertex j for which $s(j) = \mathrm{L}$.*

Observe that if either predicate occurs, the algorithm can deduce that $n_{\mathrm{L}}(s) \cdot n_{\mathrm{H}}(s) \neq 0$. Conversely, if neither predicate occurs, the algorithm cannot distinguish between the case where all $\{\mathrm{L}, \mathrm{H}\}$ symbols are the same (all L or all H) and the case where they are not.

4.2 Reduction to edge estimation

We can interpret a string s as a description of a graph of the following structure. A clique over the set $\{i : s(i) = \mathrm{K}\}$ and a biclique whose sides are $\{i : s(i) = \mathrm{L}\}$ and $\{i : s(i) = \mathrm{H}\}$. The number of edges is exactly $\binom{n_{\mathrm{K}}(s)}{2} + n_{\mathrm{L}}(s) \cdot n_{\mathrm{H}}(s)$. More formally,

▶ **Definition 27** (Reduction graph)**.** *Let $s \in \Sigma^n$ be a string. The* reduction graph *G_s is the graph with vertex set $\{1, \ldots, n\}$ defined as follows. An edge is placed between every pair of vertices i, j such that $s(i) = s(j) = \mathrm{K}$, and between every pair of vertices i, j such that*

$s(i) = \mathrm{L}$ *and* $s(j) = \mathrm{H}$. *Equivalently,* G_s *consists of a clique induced by the vertices labeled* K *and a complete bipartite graph between the vertices labeled* L *and those labeled* H. *Figure 1 illustrates the structure of* G_s.

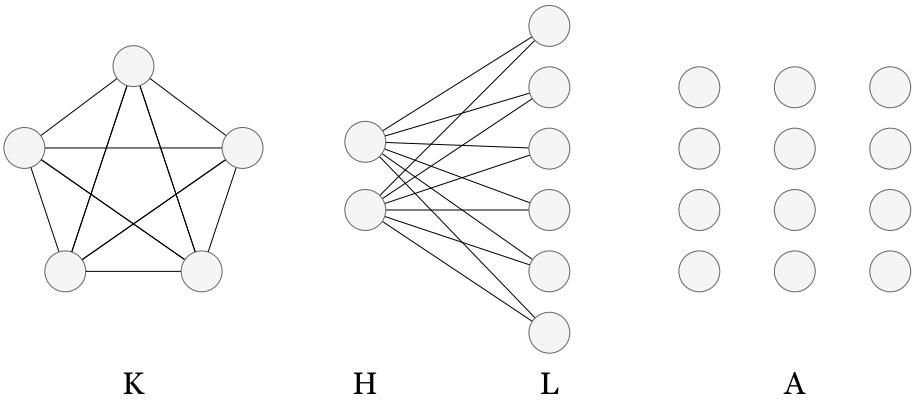

Figure 1 A diagram of the graph structure.

We describe a reduction that simulates graph queries using string queries. At the t-th step of the simulation, the following process is executed:

1. The t-th graph query, denoted Λ_t, is determined as a function of the outcomes of the preceding graph queries and the randomness of the algorithm.
2. The query Λ_t is translated into a sequence of string queries to the string s. Let $I_{t,1}, \ldots, I_{t,M_t}$ denote this sequence, where M_t is the number of string queries performed at step t. The value of M_t may depend on the outcomes of previous string queries, on the string s, and on the internal randomness of the translation algorithm.
3. Using the responses to the string queries $I_{t,1}, \ldots, I_{t,M_t}$, the simulation deterministically computes Y_t, the outcome of the t-th graph query.

At this point we describe the translation algorithm. Degree and neighbor queries are simulated using a single full string query, whereas an independent-set query is simulated by a randomized, adaptively determined sequence of light string queries.

Formally, the simulation proceeds as follows.

- **Degree query.** Given a vertex u we issue a full string query to s at position u and return the second component of the resulting triplet.
- **Neighbor query.** Given a vertex u we issue a full string query to s at position u and return the third component of the resulting triplet.
- **Independent-set query.** Given a vertex set S we first apply a uniformly random permutation to the vertices of S. We then process the vertices in this order, issuing light string queries, until one of the following stopping conditions is met:
  1. Two vertices labeled K are revealed, certifying that S is not an independent set.
  2. One vertex labeled L and one vertex labeled H are revealed, certifying that S is not an independent set.
  3. All vertices in S have been processed without triggering either of the above conditions, in which case S is declared an independent set.

▶ Remark 28. In the simulation of an independent-set query, whenever the symbol of a vertex has already been revealed, either by a previous string query or as part of the output of another query, we reuse this information and do not issue an additional query for that vertex.

The correctness of the simulation is trivial by the construction details. In the following we bound the simulation complexity. For local queries this is directly implied from the implementation:

▶ **Observation 29.** *The simulation of any local query (degree or neighbor) incurs exactly one full string query.*

It remains to bound the expected number of light string queries used in the simulation of an independent-set query.

▶ **Lemma 30.** *A vertex is said to be* involved *in a string query if it is either (i) directly queried, or (ii) appears in the output of that query. Every simulated graph query involves at most two vertices u such that $s(u) = \mathrm{K}$.*

Proof. We consider the two types of simulated graph queries.

For a local query (degree or neighbor), the simulation performs a single full string query. Such a query involves the queried vertex and at most one additional vertex appearing as part of the output (as the third entry). Hence, the simulation of a local query involves at most two vertices in total, and therefore at most two vertices labeled K.

For an independent-set query, the simulation issues a sequence of light string queries, each involving exactly one vertex (the queried vertex). By construction, the simulation halts immediately once it has revealed two vertices u with $s(u) = \mathrm{K}$. Consequently, throughout the execution of the simulation, at most two K-vertices can be involved in the string query. ◀

▶ **Lemma 31.** *Assume that $\boldsymbol{s} \in \{\mathrm{K}, \mathrm{A}\}^n$ is drawn from a distribution that is invariant under permutations of its coordinates; that is, all permutations of $\boldsymbol{s}$ have equal probability (while strings that are not permutations of one another may have different probabilities). Suppose that the t-th query issued by the graph algorithm is an independent-set query. If $t < \frac{1}{2} n_{\mathrm{K}}(\boldsymbol{s})$, then conditioned on any outcomes of the first $t-1$ queries, the simulation of the t-th query performs at most $\frac{2n}{n_{\mathrm{K}}(\boldsymbol{s}) - 2t}$ light string queries in expectation.*

4.3 A hard to distinguish construction

To construct a pair of hard-to-distinguish graphs, we define a few parameters. For given ε, n and n_k, let $d = n_k/2n$ (so that $\sqrt{2nd} = n_k$). Based on n, n_k, we define n_h and n_ℓ as following:

- $n_h = \left\lceil \sqrt{\varepsilon} n^{1/4} d^{3/4} \right\rceil$.
- $n_\ell = \left\lceil \sqrt{\varepsilon} n^{3/4} d^{1/4} \right\rceil$ if $n_h \geq 2$, and otherwise $n_\ell = \lceil \varepsilon n d \rceil$.

We state the following simple observation.

▶ **Observation 32.** *Let n_ℓ and n_h be defined as above. Then,*

1. *$n_h = 1$ if and only if $d \leq 1/(\varepsilon^{2/3} n^{1/3})$.*
2. *If $n_h = 1$, then $n_\ell + n_h \leq 3n/\sqrt{nd}$.*
3. *If $n_h \geq 2$, then $n_\ell + n_h \leq 4\sqrt{\varepsilon}\, n^{3/4} d^{1/4}$.*

We now define a distribution over hard-to-distinguish pairs of strings.

▶ **Definition 33** (Hard-to-distinguish strings)**.** *Let n_k, n_h, and n_ℓ be given. We draw a pair of strings $(\boldsymbol{s}_1, \boldsymbol{s}_2)$ as follows:*

- *Choose a set $\mathbf{K} \subseteq \{1, \ldots, n\}$ of size n_k uniformly at random.*
- *Define $\mathbf{A}_1 = \{1, \ldots, n\} \setminus \mathbf{K}$.*

- *Define* $\boldsymbol{s}_1$ *by* $\boldsymbol{s}_1(i) = \begin{cases} \text{K} & \text{if } i \in \mathbf{K}, \\ \text{A}, & \text{if } i \in \mathbf{A}_1. \end{cases}$
- *Choose a set* $\mathbf{H}_2 \subseteq \mathbf{A}_1$ *of size* n_h *uniformly at random.*
- *Choose a set* $\mathbf{L}_2 \subseteq (\mathbf{A}_1 \setminus \mathbf{H}_2)$ *of size* n_ℓ *uniformly at random.*
- *Define* $\mathbf{A}_2 = \mathbf{A}_1 \setminus (\mathbf{H}_2 \cup \mathbf{L}_2)$.
- *Define* $\boldsymbol{s}_2$ *by* $\boldsymbol{s}_2(i) = \begin{cases} \text{K} & \text{if } i \in \mathbf{K}, \\ \text{H} & \text{if } i \in \mathbf{H}_2, \\ \text{L}, & \text{if } i \in \mathbf{L}_2, \\ \text{A}, & \text{if } i \in \mathbf{A}_2. \end{cases}$

A pair of hard-to-distinguish graphs is obtained by sampling $(\boldsymbol{s}_1, \boldsymbol{s}_2)$ according to this distribution and defining the corresponding graphs $G_{\boldsymbol{s}_1}$ and $G_{\boldsymbol{s}_2}$.

▶ **Lemma 34.** *For given* $0 < \varepsilon \leq \frac{1}{11}$, $n \geq 16$ *and* $1 \leq n_k \leq \frac{1}{2}n$, *let* $R = \frac{1}{20}\min\left(n_k, \sqrt{\frac{n}{\varepsilon n_k}}\right)$. *Assume that we draw a hard-to-distinguish pair* $(\boldsymbol{s}_1, \boldsymbol{s}_2)$ *based on the parameters* ε, n *and* n_k. *Then, for any randomized algorithm making at most* q *graph queries in expectation, the probability that the sequences of query answers produced on inputs* $G_{\boldsymbol{s}_1}$ *and* $G_{\boldsymbol{s}_2}$ *differ is at most* q/R.

We can now finish with the proof of the lower bound.

Proof of Theorem 23. Consider a randomized algorithm $\mathcal{A}$ that makes at most q queries.

We draw a $(\boldsymbol{s}_1, \boldsymbol{s}_2)$ according to the parameters $\varepsilon' = 3\varepsilon$, n and $n_k = \lfloor\sqrt{2m}\rfloor$. Note that for $m \geq 6$ we have that $\sqrt{m} \leq n_k \leq 2\sqrt{m}$.

By Lemma 34, the query answer sequences of $\mathcal{A}$ on $G_{\boldsymbol{s}_1}$ and $G_{\boldsymbol{s}_2}$ are $20q/\min(n_k, \sqrt{n/(\varepsilon n_k)})$-close. Consequently, the probability that $\mathcal{A}$ distinguishes $G_{\boldsymbol{s}_1}$ from $G_{\boldsymbol{s}_2}$ is bounded by

$$\mathbf{Pr}[\mathcal{A}(G_{\boldsymbol{s}_1}) \neq \mathcal{A}(G_{\boldsymbol{s}_2})] \leq \frac{1}{2} + \frac{20q}{\min\left(n_k, \sqrt{\frac{n}{\varepsilon n_k}}\right)} \leq \frac{1}{2} + \frac{20q}{\min\left(\sqrt{m}, \sqrt{\frac{n}{\varepsilon\sqrt{2m}}}\right)} < \frac{1}{2} + \frac{q}{R}.$$

Let m_1, m_2 be the number of edges in $G_{\boldsymbol{s}_1}$ and $G_{\boldsymbol{s}_2}$ respectively. Observe that $m_1 = \binom{n_k}{2} \leq \frac{1}{2}(n_k)^2 \leq m$ and that $m_2 \geq m_1 + \varepsilon' m \geq (1+\varepsilon')m_1 = (1+3\varepsilon)m_1$. If $\mathcal{A}$ would estimate the number of edges in G within $(1 \pm \varepsilon)$-multiplicative error with probability at least $\frac{1}{2} + q/R$, then it would be a contradiction, since $(1+\varepsilon)m_1 < (1-\varepsilon)(1+3\varepsilon)m_1 \leq (1-\varepsilon)m_2$. ◀

Abstract

We present the first explicit construction of *two-sided* lossless expanders in the unbalanced setting (bipartite graphs that have polynomially many more nodes on the left than on the right). Prior to our work, all known explicit constructions in the unbalanced setting achieved only one-sided lossless expansion.

Specifically, we show that the one-sided lossless expanders constructed by Kalev and Ta-Shma (RANDOM'22) – that are based on multiplicity codes introduced by Kopparty, Saraf, and Yekhanin (STOC'11) – are, in fact, two-sided lossless expanders. Moreover, we show that our result is tight, thus completely characterizing the graph of Kalev and Ta-Shma.

1 Introduction

Lossless expanders are graphs in which small sets of vertices have almost as many neighbors as possible. Formally, we say that a d-regular graph $G = (V, E)$ is a (K, A)-*expander* if for all sets $S \subseteq V$ of size at most K we have that $|\Gamma(S)| \geq A\,|S|$ where $\Gamma(S)$ is the neighborhood of S. Generally, we desire that K is as large as possible with $K = \Omega(|V|/d)$. When $A = (1-\varepsilon)d$

for some small ε, we say that G is a (K, ε)-*lossless expander* since only a small fraction of the total number of possible neighbors is lost. It is well-known that a random d-regular graph is a $(K = \gamma n, \varepsilon = 0.01)$-lossless expander with high probability, for some constant $\gamma > 0$.

A reasonable question after seeing this definition is whether other notions of expansion, such as spectral or edge expansion, can be used to derive such graphs. Unfortunately, while Ramanujan graphs (optimal spectral expanders) do have expansion factor arbitrarily close to $A = d/2$, there also exist examples of Ramanujan graphs with expansion factor exactly $A = d/2$, showing that spectral expansion does not necessarily give rise to lossless expansion [14].

The study of lossless expanders has paid special attention to bipartite graphs due to their connection with randomness condensers. A *one-sided lossless* expander is a bipartite graph $G = (L \sqcup R, E)$ where every "small enough" set on the left expands losslessly to the right. It is standard to view lossless condensers and one-sided bipartite lossless expanders as related objects. For this purpose, it is natural to talk about highly unbalanced bipartite graphs in which $|L| \gg |R|$, that is, the neighbor function that takes in a left vertex and the index of a neighbor and outputs the right vertex has a much shorter output length than input length. Current explicit constructions for unbalanced one-sided lossless expanders [21, 22, 10, 15] – with the best parameters achieved by [10, 15] [1] – have found a wide array of applications in coding theory [20], extractor constructions [21, 22, 10, 7], derandomization [5],[2] and probabilistic data structures [23, 1], with the unbalanced nature of the graph being essential.

We say a bipartite graph is a *two-sided lossless* expander if lossless expansion happens in both directions. Intuitively, in the unbalanced case where $|L| \gg |R|$, lossless expansion is hard to achieve from left to right because there is little room on the smaller side to allow for expansion from the much larger side; on the other hand, the right-to-left expansion seems to be much easier at first sight for the same reason. However, despite aforementioned constructions for one-sided lossless expanders as well as their broad applications, there has been no known explicit construction of unbalanced two-sided lossless expanders before this work. Therefore, it is an extremely intriguing direction to further the theory of lossless expanders. We are not aware of any existing applications of two-sided lossless expanders with a polynomial imbalance between the left and right – we leave this as an interesting open problem – but we believe that a deeper understanding of the structure of these objects is the first step towards making connections with other topics and finding new applications.

In this work, we try to fill the gap, namely, the lack of explicit unbalanced two-sided lossless expanders by closely studying the bipartite graph of [15] based on the multiplicity codes of [16]. [3] For simplicity, we refer to this graph as the "KT graph" (see Definition 20). As our main result, we show that the KT graph is a two-sided lossless expander. Moreover, we prove that the expansion is tight up to a constant multiplicative factor.

We note that lossless expanders have been extensively studied in the *balanced* setting as well. We discuss this in Section 1.2.

1.1 Our results

We first define a two-sided lossless expander formally:

[1] The lossless expanders of [15] have slightly better dependence on constants compared to [10].
[2] [5] instantiated Goldreich's PRG [8] with the lossless expander of [15].
[3] It is natural to consider whether the unbalanced expander from [10] is a two-sided lossless expander. It will be interesting to determine this since the GUV graph is not even right-regular – see Appendix B for details.

▶ **Definition 1** (Two-sided lossless expander). *We say that a (D_L, D_R)-regular bipartite graph $G = (L \sqcup R, E)$ is a* two-sided (K_L, A_L, K_R, A_R)-expander *if for any subset $S_L \subseteq L$ such that $|S_L| \leq K_L$ we have that $|\Gamma_{\rightarrow}(S_L)| \geq A_L |S_L|$ and similarly that for any subset $S_R \subseteq R$ such that $|S_R| \leq K_R$ we have that $|\Gamma_{\leftarrow}(S_R)| \geq A_R |S_R|$. When $A_L = (1-\varepsilon_L)D_L$ and $A_R = (1-\varepsilon_R)D_R$ for small $\varepsilon_L, \varepsilon_R > 0$, we say that G is a* two-sided $(K_L, \varepsilon_L, K_R, \varepsilon_R)$-lossless expander.

With the above definition, we are ready to state the main theorems:

▶ **Theorem 2** (Informal version of Theorem 30, bipartite two-sided lossless expander). *For infinitely many N and all constant $0 < \delta \leq 0.99$, there exists an explicit, biregular, two-sided $(K_L, \varepsilon_L = 0.01, K_R, \varepsilon_R = 0.01)$ lossless expander $\Gamma_{\rightarrow} : [N] \times [D_L] \to [M]$ where $D_L = \text{poly}(\log N)$, $N^{1.01\delta - o(1)} \leq M \leq D_L \cdot N^{1.01\delta}$, $K_L = N^{\delta}$, and finally $K_R = \min(O(M/D_L), O(N/(MD_L)))$.*

On the other hand, for any of the explicit graphs constructed here, there exists a set $S \subseteq R$, $|S| = O(K_R)$, on the right side which has less than $(1 - \varepsilon_R/2) \cdot D_R \cdot |S|$ neighbors on the left.

▶ Remark 3. Because [15] has optimal left degree of their bipartite graph (up to polynomial factors), we achieve optimal left-degree as well and, with respect to this, achieve optimal right degree, optimal expansion constant, optimal size of sets of vertices on left side that losslessly expand, and optimal size of sets of vertices on right side that losslessly expand when $M \leq \sqrt{N}$. [4]

▶ Remark 4. When $\delta \leq 0.49$, the value of K is almost optimal (a trivial upper bound is $K \leq N/D$) since in that regime, $K = N^{\delta} \geq (N/D)^{0.99}$.

1.2 Lossless expanders in the balanced setting

A parallel line of work considers *balanced* bipartite lossless expanders, with motivations from coding theory. There have been explicit constructions of balanced one-sided lossless expanders [2, 4, 9], with which one can construct good error correcting codes [20]. There has also been progress in understanding two-sided lossless expanders in the balanced setting. Lossless expansion was shown to be feasible in high-girth regular graphs [18, 13], taking the bipartite double cover of which implies a balanced two-sided lossless expander. Chen [3] achieved balanced two-sided lossless expansion for polynomial-sized sets as one of their several results; however, their size of expanding sets is not optimal in the balanced setting. Our analysis proves optimal expanding set size in the unbalanced setting (see Remark 3).

It was shown in [17] that balanced two-sided lossless expanders with constant degree, constant imbalance, and certain algebraic properties have applications to good quantum low-density parity check (qLDPC) codes. A line of recent works [13, 11, 12] recently explicitly constructed these two-sided lossless expanders with the required algebraic property and successfully instantiated the qLDPC construction of [17]. Our work in the polynomially unbalanced setting is incomparable to the balanced setting, as it is possible to achieve constant degree in the balanced setting, while having a polynomial imbalance in left and right nodes forces the graph to have non-constant degrees.

[4] To see that this setting of K_R is indeed optimal, note that in a (D_L, D_R)-biregular graph it must be that $N \cdot D_L = M \cdot D_R$ and so $\frac{M}{D_L} = \frac{N}{D_R}$. Hence, $K_R = O(M/D_L) = O(N/D_R)$, the largest possible size.

2 Proof Overview

In this section, we outline the proof of Theorem 2 – our two-sided lossless expander.

2.1 Two-sided lossless expander

We show that the bipartite graph defined in [15] based on multiplicity codes is a two-sided lossless expander. The left-to-right lossless expansion was shown in [15]. Our main contribution is showing that the KT graph also expands losslessly from right to left. To do this, we first show that the KT graph is right-regular. Second, for any pair of right vertices, we compute the exact number of common left neighbors they have. Finally, for any not-too-large subset on the right, we lower bound the number of its left neighbors by using the inclusion-exclusion principle to subtract all possible double counted common left neighbors from the total number of outgoing edges.

We state an informal version of our result and present details on the strategy sketched above.

▶ **Theorem 5** (Informal version of Theorem 23). *For every field $\mathbb{F}_q$ and $n, s \in \mathbb{N}$ with $15 \leq (s+1) < n < char(\mathbb{F}_q)$, and any $\delta > 0$, there exists an explicit bipartite graph $G = (L \sqcup R, E)$ with $L = \mathbb{F}_q^n, R = \mathbb{F}_q^{s+2}$ with left degree $d_L = q$ and right degree $d_R = q^{n-(s+1)}$ such that G is a two-sided (K_L, A_L, K_R, A_R) expander where $K_L = \Omega(q^{s+1})$, $A_L = q - n(s+2)$, $K_R = \delta q^{\min(s+1, n-(s+1))}$, $A_R = \left(1 - O\left(\delta \cdot \frac{q-1}{q}\right)\right) q^{n-(s+1)}$.*

Theorem 2 is obtained from Theorem 5 by instantiating the parameters appropriately (see Section 4.3 for more details). We now define the KT graph and then claim that it is a lossless right expander.

▶ **Definition 6** (The KT graph [15]). *Let $q, n, s \in \mathbb{N}$ be such that q is a prime power, characteristic of the finite field $\mathbb{F}_q \geq n$ and $s + 2 \leq n$. We define $G = (L \sqcup R, E)$ where $L = \mathbb{F}_q^n, R = \mathbb{F}_q^{s+2}$. The left degree is q and for any $f \in \mathbb{F}_q^n$ and $y \in \mathbb{F}_q$, the y'th neighbor of f is defined as follows: Identify f as member of $\mathbb{F}_q[X]$ with degree of f at most $n-1$; then, the neighbor $\Gamma_{\rightarrow}(f, y)$ will be $(y, f^{(0)}(y), \ldots, f^{(s)}(y))$ where $f^{(i)}$ is the i'th iterative derivative of f.*[5]

▶ **Theorem 7** (The KT graph losslessly expands from the right). *The KT graph G is a right (K_R, A_R)-lossless expander where $K_R = \delta \min(|R|, |L|/|R|)$, $\varepsilon_R = O(\delta \cdot \frac{q-1}{q})$ for arbitrary $0 < \delta < 1$. In other words, for any subset $T \subseteq R$, $|T| \leq K_R$, T has at least $(1 - \varepsilon_R) d_R |T|$ neighbors on the left.*

Theorem 5 immediately follows from left expansion shown by [15] and Theorem 7. For the rest of this section, we focus on proving Theorem 7 that relies on the following two key lemmas.

▶ **Lemma 8** (Right regularity). *The KT graph G is right-regular and has right-degree $d_R = q^{n-(s+1)}$.*

▶ **Lemma 9** (Number of common left neighbors). *For any pair of right-vertices $w_1, w_2 \in \mathbb{F}_q^{s+2}$ such that $w_1 = (y_1, z_1), w_2 = (y_2, z_2)$ where $y_1 \neq y_2 \in \mathbb{F}_q$ and $z_1, z_2 \in \mathbb{F}_q^{s+1}$, we have $|\Gamma_{\leftarrow}(y_1, z_1) \cap \Gamma_{\leftarrow}(y_2, z_2)| = q^{n-(2s+2)}$ if $n \geq 2s+2$ and $|\Gamma_{\leftarrow}(y_1, z_1) \cap \Gamma_{\leftarrow}(y_2, z_2)| \leq 1$ if $n \leq 2s+2$.*

[5] Recall that the i-th iterative derivative of f is simply the the standard derivatve $\frac{\mathrm{d}}{\mathrm{d}x}$ applied i times to f.

Theorem 7 then follows by an application of the inclusion-exclusion principle – subtracting the maximum number of common neighbors between any pair of vertices in T from the total number of edges leaving T – we get the required lower bound on the size of T's left neighborhood.

We now discuss the proof techniques for showing Lemma 8 and Lemma 9. We start by making a simple but useful observation on the structure of the KT graph G.

▶ **Observation 10.** *Fix $w = (y, z_0, \cdots, z_s) \in R$ and let $f \in L$ be any left-neighbor of w. Then it must be the case that w is the y'th neighbor of f. Now for any $w' \in R$ such that $w' = (y, z'_0, \cdots, z'_s)$, it holds that $f \notin \Gamma_{\leftarrow}(w')$. This is saying that any pair of right vertices (w, w') that come from the same seed* [6] *must have disjoint left neighborhoods.*

Central to our analysis of the right degree and the number of common left neighbors are the following linear maps.

▶ **Definition 11.** *For $y \in \mathbb{F}_q$, define the map $\psi_y(f) : \mathbb{F}_q^n \to \mathbb{F}_q^{s+1}$ as follows: Interpret $f \in \mathbb{F}_q[X]$ as a degree $\leq n-1$ polynomial and map it to $(f^{(0)}(y), \ldots, f^{(s)}(y))$ where $f^{(i)}$ is the i'th iterative derivative of f.*

We note that ψ_y is a $\mathbb{F}_q$-linear map, for any $y \in \mathbb{F}_q$.

▶ **Definition 12.** *For $y_1, y_2 \in \mathbb{F}_q$, $y_1 \neq y_2$, define the map $\psi_{y_1,y_2}(f) : \mathbb{F}_q^n \to \mathbb{F}_q^{2(s+1)}$ as the concatenation of the respective linear maps, that is, $\psi_{y_1,y_2}(f) = (\psi_{y_1}(f), \psi_{y_2}(f))$.*

Proving the above lemmas (about the KT graph) now boils down to analyzing both ψ_y and ψ_{y_1,y_2} for all $y, y_1, y_2 \in \mathbb{F}_q$.

1. We show that ψ_y for $y \in \mathbb{F}_q$ is surjective, which along with Observation 10 implies Lemma 8: For any $w = (y, z_0, \cdots, z_s) \in R$, the set of its left neighbors is $\{f \in L \mid (y, \psi_y(f)) = w\} = \psi_y^{-1}(z_0, \cdots, z_s)$. Therefore, the right degree $D_R = \left|\psi_y^{-1}(z_0, \cdots, z_s)\right| = q^n/q^{s+1} = q^{n-(s+1)}$.
2. We show ψ_{y_1,y_2} is surjective when $n \geq 2s+2$ and injective $n \leq 2s+2$, which implies Lemma 9: Similar to above, let $w_1 = (y_1, z_1) \in R$ and $w_2 = (y_2, z_2) \in R$, $y_1 \neq y_2$, be any pair of right vertices from *different* seeds. We extend Observation 10 to see that the number of $f \in L$ such that $(y_1, \psi_{y_1}(f)) = w_1$ and $(y_2, \psi_{y_2}(f)) = w_2$ is exactly $\left|\psi_{y_1,y_2}^{-1}(z_1, z_2)\right|$. When $n \geq 2s+2$, this map is surjective, and the number of left neighbors shared by w_1 and w_2 is $q^{n-(2s+2)}$. When $n \leq 2s+2$, this map is injective and the number of shared neighbors is at most 1.

To conclude the proof, we carry out Hermite interpolation (see Lemma 27) by applying the Chinese remainder theorem to show the surjectivity and injectivity of the maps ψ_y, ψ_{y_1} and ψ_{y_2}.

2.1.1 Tightness of right expansion

We will show that our parameters from Theorem 7 are tight. Throughout this section, we let $P_d \subseteq \mathbb{F}_q[x]$ be the polynomials of degree exactly d and $P_{<d} \subseteq \mathbb{F}_q[x]$ be the vector space over $\mathbb{F}_q$ of polynomials of degree strictly less than d. First, notice that when $|R| > |L|/|R|$, the right expansion is optimal by Remark 3. Hence, we only focus on the case when $s+1 < n < 2s+2$ and show the following:

[6] We sometimes refer to $y \in \mathbb{F}_q$ as the "seed", like in the condensers literature.

▶ **Theorem 13** (Informal version of Theorem 32). *For $s+1 < n < 2s+2$ and any $0 < \delta \leq 2$, there exists $T \subseteq R$ such that $|T| = \delta q^{n-s-1}$ and $|\Gamma_{\leftarrow}(T)| = (1-\varepsilon)D_R|T|$ with $\varepsilon = \delta/4$.*

For fixed $y_1 \neq y_2 \in \mathbb{F}_q$, we will construct $T = T_1 \sqcup T_2$ satisfying the following:

- $|T_1|, |T_2| = (\delta/2)q^{n-s-1}$.
- The first coordinate of every element of T_1 is always y_1 and of T_2 is always y_2.
- For all $t_1 \in T_1$ and $t_2 \in T_2$, there exists a degree less than n polynomial f such that $\Gamma_{\rightarrow}(f, y_1) = t_1$ and $\Gamma_{\rightarrow}(f, y_2) = t_2$.

We then observe that $|\Gamma_{\leftarrow}(T)| = |\Gamma_{\leftarrow}(T_1)| + |\Gamma_{\leftarrow}(T_2)| - |T_1| \cdot |T_2|$. Since the right degree of G is q^{n-s-1}, we have that $|\Gamma_{\leftarrow}(T_1)| = |\Gamma_{\leftarrow}(T_2)| = (\delta/2)q^{2n-2s-2}$. Hence, we compute that $|\Gamma_{\leftarrow}(T)| = (\delta - \delta^2/4)q^{2n-2s-2} = (1-\delta/4)D_R|T|$, proving Theorem 13.

To construct such T_1, T_2, it suffices to construct $S_1, S_2 \subset \mathbb{F}_q^{s+1}$ with $|S_1| = |S_2| = K/2$ such that $S_1 \times S_2 \subset \psi_{y_1,y_2}(P_{<n})$ (see Lemma 35 for a formal claim). Indeed, we can let $T_1 = (y_1, S_1)$ and $T_2 = (y_2, S_2)$ and check that T_1 and T_2 have the desired properties.

Before we show how to construct such S_1 and S_2, we will need to introduce a few algebraic objects. Let $g_1(x) = (x-y_1)^{s+1}, g_2(x) = (x-y_2)^{s+1}$, and let $\varphi : \mathbb{F}_q[x] \to \mathbb{F}_q[x]/g_1 \times \mathbb{F}_q[x]/g_2$ as $\varphi(f) = (f \mod g_1, f \mod g_2)$.

We then prove a structural result regarding φ:

▶ **Lemma 14** (Informal version of Lemma 41). *For $s+1 < d < 2s+2$, we have*

$$\varphi(P_{<d}) = \bigcup_{h \in P_{<d-(s+1)}} \{(f, f+\sigma(h)) \mid f \in P_{\leq s}\}.$$

Here, $\sigma : P_{\leq n-(s+1)} \to P_{\leq s}$ is a specially chosen injective homomorphism that we define later.

To construct such S_1 and S_2, we construct $R_1 \subset \mathbb{F}_q[x]/g_1, R_2 \subset F_q[x]/g_2$ such that $R_1 \times R_2 \subset \varphi(P_{<n})$ (see Lemma 39 for formal claim). Once we have such R_1, R_2, we let $S_1 = \psi_{y_1}(R_1)$ and $S_2 = \psi_{y_2}(R_2)$. We then check that if $f \in P_{<n}$ is such that $\varphi(f) = (r_1, r_2)$, then $f(y_1) = r_1(y_1) = s_1$ and $f(y_2) = r_2(y_2) = s_2$, showing that $S_1 \times S_2 \subset \psi_{y_1,y_2}(P_{<d})$, as desired.

We now construct such R_1 and R_2. Let R_1 and R_2 be arbitrary size $K/2$ subsets of $\sigma(P_{<n-(s+1)})$. Note that since σ is injective, $\left|\sigma(P_{<n-(s+1)})\right| = q^{n-s-1} \geq K/2$ and so we can indeed pick such R_1 and R_2. We claim that for any $r_1 \in R_1, r_2 \in R_2$, it holds that $(r_1, r_2) \in \varphi(P_{<n})$. Using Lemma 14, it suffices to show that $(r_1, r_2) = (f, f+\sigma(h))$ for some $f \in P_{<n}$ and $h \in P_{n-(s+1)}$. Since $R_1, R_2 \subseteq \sigma(P_{<n-(s+1)})$, we know that $r_1 = \sigma(h_1)$ and $r_2 = \sigma(h_2)$ for some $h_1, h_2 \in P_{<n-(s+1)}$. Consequently,

$$(r_1, r_2) = (\sigma(h_1), \sigma(h_2)) = (\sigma(h_1), \sigma(h_1) + \sigma(h_2 - h_1))$$

as desired. In the last line, we used the fact that σ is a homomorphism and that $h_1, h_2 \in P_{<n-(s+1)}$.

We finally define σ:

▶ **Definition 15.** *Recall that $\sigma : P_{<n-(s+1)} \to P_{\leq s}$. To compute $\sigma(h_1)$, we let $f \in P_{<n}$ be any polynomial such that $f = h_1 g_1 + r_1$ where $r_1 \in P_{\leq s}$ is the remainder of f modulo g_1. We then write $f = h_2 g_2 + r_2$ where $r_2 \in P_{\leq s}$ is the remainder of f modulo g_2. The output of $\sigma(h_1)$ is $r_2 - r_1$.*

At first glance, it seems unclear whether σ is even a well defined function. To help show this, we define $\rho : P_{<n-(s+1)} \to P_{<n-(s+1)}$ such that $\rho(h_1) = h_2$ where h_1, h_2 are defined as above. We first show that ρ is an isomorphism. To do this, we observe that

$h_1g_1 - h_2g_2 = r_2 - r_1$ has degree at most s, and so it must be that h_1g_1 and h_2g_2 agree on all coefficients corresponding to degree $\geq s+1$. We compare these coefficients and, using linear algebra, show that we can indeed obtain a unique h_2 from h_1, showing it is indeed a function. This argument in fact directly shows that ρ is an isomorphism.

Once we have that ρ is an isomorphism, we can then define $\sigma(h_1) = h_1g_1 - \rho(h_2)g_2$. Using this, it easily follows that σ is a homomorphism. From this we obtain Lemma 14. By a further counting argument, we can show that σ is injective. For details, see Section 5.2.

2.2 Organization

We use Section 3 to introduce necessary preliminaries. Then in Section 4.1 we show how our main theorem is proved assuming right regularity and knowing the overlap between two neighborhoods of right vertices. These facts are then proved in Section 4.2. In Section 4.3, we plug in parameters to get our two-sided lossless expander. In Section 5 we prove tightness of our right-to-left expansion analysis of the KT graph.

We prove that our constructions are explicit in Appendix A, and discuss why our techniques do not work for the [10] graph in Appendix B.

3 Preliminaries

3.1 Notation

For a function $f \in \mathbb{F}_q[X]$, we we use $f^{(j)}$ to denote the j'th iterated derivative of f. We will often use the notation b_i for $i \in \mathbb{N}$ to refer to the polynomial $x^i \in \mathbb{F}_q[x]$ and we will often use the fact that $(b_0, \ldots, b_n)$ form a basis for the polynomials of degree at most n. For a (D_L, D_R)-biregular bipartite graph $G = (L \sqcup R)$, we use $\Gamma_\rightarrow : L \times [D_L] \to R$ to be the function that maps vertices in L to their neighbors in R as given by G; we use $\Gamma_\leftarrow : R \times [D_R] \to L$ to be the function that maps vertices in R to their neighbors in L as given by G. Often, we will define graph G by only defining the associated $\Gamma_\rightarrow$. When clear from context, we sometimes abuse notation and use $\Gamma_\rightarrow(w)$ to denote the right neighborhood of $w \in L$, and similarly $\Gamma_\leftarrow(w)$ for the left neighborhood of $w \in R$.

3.2 Lossless expansion

Throughout this paper, we will be focusing on the notion of vertex expansion as opposed to other definitions (e.g., edge, spectral) of expansion. Defining vertex expansion of a regular graph is straightforward.

▶ **Definition 16.** *A D-regular graph $G = (V, E)$ is a* (K, A)-expander *if for all $S \subseteq V$ such that $|S| \leq K$ we have that $|\Gamma(S)| \geq A\,|S|$. If $A = 1 - \varepsilon$, then we say that G is a* (K, ε)-lossless expander.

For biregular bipartite graphs, we must consider the degree of each side to define expansion.

▶ **Definition 17.** *A (D_L, D_R)-biregular graph $G = (L \sqcup R, E)$ is a* (K_L, A_L, K_R, A_R)-two-sided expander *if for all $S \subseteq L$ of size at most K_L we have $|\Gamma_\rightarrow(S)| \geq A_L\,|S|$ and for all $S \subseteq R$ of size at most K_R we have $|\Gamma_\leftarrow(S)| \geq A_R\,|S|$. If $A_L = 1 - \varepsilon_L$ and $A_R = 1 - \varepsilon_R$, then we call G a* $(K_L, \varepsilon_L, K_R, \varepsilon_R)$-lossless two-sided expander.

For irregular graphs, we can generalize Definition 16 in two ways. The first way is considering expansion with respect to the maximum number of neighbors of a set.

▶ **Definition 18.** *An irregular graph $G = (V, E)$ is a* (K, ε)-lossless expander *(where we abuse the word "expander" for both regular and irregular graphs) if for any set $S \subseteq V$ of size at most K we have that $|\Gamma(S)| \geq (1 - \varepsilon) \sum_{v \in S} d(v)$ where $d(v)$ represents the degree of vertex v.*

The second, stronger notion of lossless expansion is with respect to the highest degree of a node present in a graph.

▶ **Definition 19.** *An irregular graph $G = (V, E)$ is a* max-degree (K, ε)-lossless expander *if for any set $S \subseteq V$ of size at most K we have that $|\Gamma(S)| \geq (1 - \varepsilon) D |S|$ where $D = \max_{v \in V} d(v)$, the maximum degree of any vertex in G.*

3.3 The KT graph

Throughout the paper, we will use construction of bipartite (left) lossless expanders from [15] based on multiplicity codes from [16]. We will often refer to this graph "the KT graph":

▶ **Definition 20** (The KT graph)**.** *Let $q, n, s \in \mathbb{N}$ be such that q is a prime power, characteristic of the finite field $\mathbb{F}_q \geq n$ and $s \leq n/2$. Define $G = (L \sqcup R, E)$ where $L = \mathbb{F}_q^n, R = \mathbb{F}_q^{s+2}$. The left degree is q and for any $f \in \mathbb{F}_q^n$ and $y \in \mathbb{F}_q$, the y'th neighbor of f is defined as follows: Identify f as member of $\mathbb{F}_q[X]$ with degree of f at most $n - 1$; then, the neighbor $\Gamma_{\rightarrow}(f, y)$ will be $(y, f^{(0)}(y), \ldots, f^{(s)}(y))$ where $f^{(j)}$ is the j'th iterative derivative of f.*

▶ Remark 21. In the paper [15], the final lossless expander graph construction slightly differs from ours. While they do construct the KT-graph G defined as above and show it has great (left) expanding properties, the final (left) lossless expander graph actually is defined as $H = (L \sqcup R, E)$ where $L = 2^n, R = \mathbb{F}_q^{s+2}$ and the left degree is q. H is constructed by considering the subgraph of G induced by vertices on the left side corresponding to $\{0, 1\}^n$. For us, the final two-sided lossless expander graph will be G itself. This is why, our two-sided lossless expander graph has slightly worse parameters (worse constants) compared to the left lossless expander graph from [15].

3.4 A useful inequality

We will use the following inequality based on an application of the Cauchy-Schwarz inequality:

▷ Claim 22. Fix $n \in \mathbb{N}, S \in \mathbb{R}$. Let $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$ be such that $\sum_{1 \leq i \leq n} x_i = S$. Then,

$$\sum_{1 \leq i < j \leq n} x_i x_j \leq \frac{(n-1)S^2}{2n}$$

Proof. Recall the Cauchy-Schwarz inequality:

$$\left(\sum_{1 \leq i \leq n} a_i b_i \right)^2 \leq \left(\sum_{1 \leq i \leq n} a_i^2 \right) \left(\sum_{1 \leq i \leq n} b_i^2 \right).$$

We apply this with $a_1 = x_1, \ldots, a_n = x_n$ and $b_1 = b_2 = \cdots = b_n = 1$ to infer that

$$S^2 \leq \left(\sum_{1 \leq i \leq n} x_i^2 \right) \cdot n = \left(S^2 - 2 \sum_{1 \leq i < j \leq n} x_i x_j \right) \cdot n$$

Rearranging, we infer that

$$\sum_{1\le i<j\le n} x_i x_j \le \frac{(n-1)S^2}{2n}$$

as desired. ◁

4 An Explicit Two-sided Lossless Expander

In this section, we first describe how to prove our main theorem using right regularity and the size of the overlap in neighborhoods between any two right vertices. Then we prove these two facts in Section 4.2.

4.1 Main theorem

Putting together all of our results with the left-to-right expansion of [15] yields our main theorem.

▶ **Theorem 23.** *For all finite fields $\mathbb{F}_q$ and $n, s \in \mathbb{N}$ with $15 \le (s+1) < n < char(\mathbb{F}_q)$, there exists an explicit bipartite graph $G = (L \sqcup R, E)$ with $L = \mathbb{F}_q^n, R = \mathbb{F}_q^{s+2}$, left degree equal to q and right degree $q^{n-(s+1)}$ such that G is a two-sided (K_L, A_L, K_R, A_R) expander with $A_L = q - \frac{n(s+2)}{2} \cdot (qK_L)^{1/(s+2)}$ and $A_R = \left(1 - \frac{K_R}{q^{\min(s+2,n-s)}} \cdot \frac{q-1}{2}\right) q^{n-(s+1)}$.*

Proof. The left-to-right expansion follows from Theorem 3 from [15]. The right-to-left expansion follows from Theorem 24 below. The explicitness of G follows from Claim 47. ◀

Our main achievement is showing the right-to-left expansion of the KT graph in Theorem 24 below.

▶ **Theorem 24.** *If $n \ge s+1$, then the KT graph G in Definition 6 is a right (K_{max}, ε)-lossless expander for $K_{max} = \delta q^{s+1}$ and $\varepsilon = \frac{\delta(q-1)}{2q} \cdot q^{\max(2s+2-n,0)}$ where $0 < \delta < 1$ is arbitrary.*

We prove Theorem 24 via the following properties of G:

▶ **Lemma 25.** *When $n \ge s+1$, G is right-regular and the right degree is $q^{n-(s+1)}$.*

▶ **Lemma 26.** *For any pair of right-vertices w_1, w_2 such that $w_1 = (y_1, z_1), w_2 = (y_2, z_2) \in \mathbb{F}_q^{s+2}$ where $y_1 \ne y_2 \in \mathbb{F}_q$ and $z_1, z_2 \in \mathbb{F}_q^{s+1}$, we have*

$$|\Gamma_{\leftarrow}(y_1, z_1) \cap \Gamma_{\leftarrow}(y_2, z_2)| \le \begin{cases} q^{n-(2s+2)} & n \ge 2s+2 \\ 1 & n \le 2s+2 \end{cases}$$

We will prove both these lemmas in Section 4.2.

With the exact right-regularity of G and the number of common left-neighbors shared by any pair of right-vertices generated by different seeds, we are ready to prove Theorem 24.

Proof of Theorem 24. Our goal is to show that any right subset $T \subseteq \mathbb{F}_q^{s+2}$ of size at most δq^{s+1} has a neighborhood of size at least $(1-\varepsilon)q^{n-(s+1)}|T|$ on the left.

To do this, we consider T as the disjoint union $T = \bigsqcup_{y \in \mathbb{F}_q} T_y$ of buckets $T_y = \{(y, \alpha) : \alpha \in \mathbb{F}_q^{s+1}\}$ where $|T_y| = t_y = \delta_y q^{s+1}$. Let $\delta = \sum_{y \in \mathbb{F}_q} \delta_y$. So, $|T| = \delta q^{s+1}$. By Lemma 25, the number of edges leaving T is $|T| \cdot q^{n-(s+1)} = \delta q^n$.

We now consider cases on whether $n \ge 2s+2$ or not:

Case 1. $n \geq 2s+2$.

In this case, $\varepsilon = \frac{\delta(q-1)}{2q}$. By Lemma 26, the maximum number of double-counted left vertices is

$$\sum_{\substack{i,j\in[q]\\ i<j}} t_i t_j q^{n-2(s+1)} = \sum_{\substack{i,j\in[q]\\ i<j}} \delta_i q^{s+1} \cdot \delta_j q^{s+1} \cdot q^{n-2(s+1)} = q^n \sum_{\substack{i,j\in[q]\\ i<j}} \delta_i \delta_j \leq q^n \cdot \frac{q-1}{2q} \cdot \delta^2$$

where for the last inequality, we used Claim 22. Applying one level of inclusion-exclusion reveals that

$$|\Gamma_{\leftarrow}(T)| \geq \delta q^n - q^n \cdot \frac{q-1}{2q} \cdot \delta^2 = \left(1 - \frac{\delta(q-1)}{2q}\right) \delta q^n = (1-\varepsilon)\, q^{n-(s+1)} |T|$$

where the last equality follows because $\varepsilon = \frac{\delta(q-1)}{2q}$.

Case 2. $2s+2 \geq n \geq s+1$.

In this case, $\varepsilon = \frac{\delta(q-1)}{2q} \cdot q^{2s+2-n}$. By Lemma 26, the maximum number of double-counted left vertices is

$$\sum_{\substack{i,j\in[q]\\ i<j}} t_i t_j = \sum_{\substack{i,j\in[q]\\ i<j}} \delta_i q^{s+1} \cdot \delta_j q^{s+1} = q^{2s+2} \sum_{\substack{i,j\in[q]\\ i<j}} \delta_i \delta_j \leq q^{2s+2} \cdot \frac{q-1}{2q} \cdot \delta^2$$

where for the last inequality, we used Claim 22. We again apply one level of inclusion-exclusion to conclude that

$$|\Gamma_{\leftarrow}(T)| \geq \delta q^n - q^{2s+2} \cdot \frac{q-1}{2q} \cdot \delta^2 = \left(1 - \frac{\delta(q-1)}{2q} \cdot q^{2s+2-n}\right) \delta q^n = (1-\varepsilon)\, q^{n-(s+1)} |T|$$

where the last equality follows because $\varepsilon = \frac{\delta(q-1)}{2q} \cdot q^{2s+2-n}$. ◀

4.2 Right regularity and bounding common neighbors: Hermite interpolation

In this section, we show the $(q^{n-(s+1)})$-right-regularity of the KT graph G, and bound the number of common left neighbors shared by any pair of right vertices with different seeds. Both tasks are essentially a question of Hermite interpolation – we wish to find polynomials $f \in \mathbb{F}_q[Y]$ of degree at most $n-1$ such that when evaluating at some point $y \in \mathbb{F}_q$, the function value $f(y)$ and its first s derivatives $(f^{(0)}(y), f^{(1)}(y), \cdots, f^{(s)}(y))$ match the values given by the right vertices.

▶ **Lemma 27** (Hermite interpolation). *Let $y_1, \cdots, y_k \in \mathbb{F}_q$ be distinct, and for $i \in [k]$, let $z_{i,0}, \cdots, z_{i,s} \in \mathbb{F}_q$. Then there exists a unique polynomial $f \in \mathbb{F}_q[Y]$ with degree at most $k(s+1)$ such that $f^{(j)}(y_i) = z_{i,j}$ for $i \in [k]$ and $j \in \{0\} \cup [s]$.*

Proof. Consider the following k congruences,

$$f(Y) \equiv f_1(Y) \mod (Y-y_1)^{s+1}, \ \cdots, \ f(Y) \equiv f_k(Y) \mod (Y-y_k)^{s+1}$$

Any polynomial f that satisfies the above k congruences must also satisfy $f^{(j)}(y_i) = z_{i,j}$ for $i \in [k]$ and $j \in \{0\} \cup [s]$ – thus solving the interpolation – because $f_i(Y)$ is the order s Taylor polynomial of f at y_i.

We conclude the proof by applying the Chinese remainder theorem for univariate polynomials which asserts that there exists a *unique* polynomial $f \in \mathbb{F}_q[Y]$ of degree at most $k(s+1)$ that satisfies the above congruences. ◀

Recall the maps $\psi_{y_1} : \mathbb{F}_q^n \to \mathbb{F}_q^{s+1}$, and $\psi_{y_1,y_2} : \mathbb{F}_q^n \to \mathbb{F}_q^{2s+2}$ where we have $\psi_y(f) = (f^{(0)}(y), \ldots, f^{(s)}(y))$ and $\psi_{y_1,y_2} = (\psi_{y_1}(f), \psi_{y_2}(f))$. We will use the following fact regarding linearity of derivatives:

▶ **Fact 28** ([19]). *For all $\alpha, \beta \in \mathbb{F}_q$, $f, g \in \mathbb{F}_q[X]$ and $j \geq 0$, it holds that $(\alpha f + \beta g)^{(j)} = \alpha f^{(j)} + \beta g^{(j)}$.*

From this fact, we directly obtain that ψ_y is a linear map:

▶ **Corollary 29.** *For all $y \in \mathbb{F}_q$, ψ_y is an $\mathbb{F}_q$-linear map.*

Now we prove the right-regularity of G (Lemma 25) and bound the number of overlapping left neighbors (Lemma 26) as special cases of Lemma 27.

Proof of Lemma 25. Let $w_1 \in \mathbb{F}_q^{s+2}$ where $w_1 = (y_1, z_{1,0}, \cdots, z_{1,s})$. Take $k = 1$ in Lemma 27, we get that there exists a unique polynomial f of degree at most $s+1$ such that $f^{(j)}(y_1) = z_{1,j}$ for $j \in \{0\} \cup [s]$. This means the linear map $\psi_{y_1} : \mathbb{F}_q^n \to \mathbb{F}_q^{s+1}$ is surjective. Therefore, the number of left neighbors of any right vertex w_1 is exactly $|\psi_{y_1}^{-1}(z_{1,0}, \cdots, z_{1,s})| = q^{n-(s+1)}$. ◀

Proof of Lemma 26. Let $w_1, w_2 \in \mathbb{F}_q^{s+2}$ where $w_1 = (y_1, z_{1,0}, \cdots, z_{1,s})$ and similarly $w_2 = (y_2, z_{2,0}, \cdots, z_{2,s})$ with $y_1 \neq y_2$. Take $k = 2$ in Lemma 27, we get that there exists a unique polynomial f of degree at most $2(s+1)$ such that $f^{(j)}(y_i) = z_{i,j}$ for $i \in \{1,2\}, j \in \{0\} \cup [s]$. This means,

- When $n > 2s+2$, $\psi_{y_1,y_2} : \mathbb{F}_q^n \to \mathbb{F}_q^{2s+2}$ is surjective, the number of common neighbors shared by w_1, w_2 is exactly $|\psi_{y_1,y_2}^{-1}(z_{1,0}, \cdots, z_{1,s}, z_{2,0}, \cdots, z_{2,s})| = q^{n-2(s+1)}$.
- When $n \leq 2s+2$, $\psi_{y_1,y_2} : \mathbb{F}_q^n \to \mathbb{F}_q^{2s+2}$ is injective, w_1, w_2 share *at most* 1 common left neighbor. ◀

4.3 Plugging in the Parameters

We record our main results regarding two sided lossless expanders:

▶ **Theorem 30** (Formal version of Theorem 2). *For infinitely many N and all $0 < \delta < 0.99$, there exists an explicit biregular two-sided $(K_L, \varepsilon_L = 0.01, K_R, \varepsilon_R = 0.01)$ lossless expander $\Gamma_\to : [N] \times [D_L] \to [M]$ where $D_L \leq O(\log^{204}(N))$, $N^{1.01\cdot\delta - o(1)} \leq M \leq D_L \cdot N^{1.01\cdot\delta}$, $K_L = N^\delta$, $K_R = \frac{1}{50} \cdot (1/D_L) \cdot \min(M, N/M)$.* [7]

These will follow from the following technical lemma:

▶ **Lemma 31.** *Let $\alpha, \varepsilon_L, \varepsilon_R \in (0,1)$ and $K_R, n, k_L, q \in \mathbb{N}$ be such that q is a prime number, $\frac{h^{1+\alpha}}{2} \leq q \leq h^{1+\alpha}$ where $h = (4nk_L/\varepsilon_L)^{1/\alpha}$ and such that both $\frac{4}{k_L}\log(2n/\varepsilon_L) \leq \alpha$ and $k_L(1+\alpha) \leq n$. Then, there exists an explicit biregular $(K_L, \varepsilon_L, K_R, \varepsilon_R)$ two-sided lossless expander $\Gamma_\to : [N] \times [D_L] \to [M]$ where $N = q^n, K_L = q^{k_L}, K_L^{1+\alpha-1/\log(h)} \leq M \leq D_L \cdot K_L^{1+\alpha}$, $D_L \leq O(\log(N)\log(K_L)/\varepsilon_L)^{1+1/\alpha+o(1)}$, $\frac{K_R}{q^{\min(s+2,n-s)}} \cdot \frac{q-1}{2} \leq \varepsilon_R$ where $s+2 = \lceil k_L/\log_q(h) \rceil$.*

We will instantiate this lemma using simple parameters to obtain our main theorems:

Proof of Theorem 30. We plug in $\alpha = 0.01, \varepsilon_L = 0.01, \varepsilon_R = 0.01, k_L = \delta n$ in Lemma 31 to obtain the desired lossless expander. ◀

[7] Our theorem statement doesn't have any additional constraint on D_R since it can be uniquely inferred from N, M, D_L.

We finally prove our main technical lemma using two-sided expander from Theorem 23:

Proof of Lemma 31. As $s+2 = \lceil k_L/\log_q(h) \rceil$, we have that $h^{s+1} \leq K_L \leq h^{s+2}$. Observe that

$$s+1 < \frac{k_L \log(q)}{\log(h)} \leq k_L(1+\alpha) \leq n$$

So, we can apply Theorem 23 and infer that there exists a graph $\Gamma_{\rightarrow} : \mathbb{F}_q^n \times \mathbb{F}_q \rightarrow \mathbb{F}_q^{s+2}$ that is a $(\leq h^{s+2}, A_L)$ left expander and $(\leq K_R, A_R)$ right expander where $A_L = q - \frac{n(s+2)}{2} \cdot (qh^{s+2})^{1/(s+2)}$ and $A_R = \left(1 - \frac{K_R}{q^{\min(s+2,n-s)}} \cdot \frac{q-1}{2}\right) q^{n-(s+1)}$. Notice that as $K_L \leq h^{s+2}$, $\Gamma_{\rightarrow}$ is indeed a (K_L, A_L) expander.

- We first bound the left degree D_L:

  $$\begin{aligned} D_L = q &\leq h^{1+\alpha} = (4nk_L/\varepsilon_L)^{1+1/\alpha} = (4\log(N)\log(K_L)/\log^2(q)\varepsilon_L)^{1+1/\alpha} \\ &= (4\log(N)\log(K_L)/\varepsilon_L)^{1+1/\alpha} \cdot \log^{2+2/\alpha}(q) \end{aligned}$$

  This implies that

  $$D_L = q \leq (4\log(N)\log(K_L)/\varepsilon_L)^{1+1/\alpha} \left(\log\left(8\log(N)\log(K_L)/\varepsilon_L\right)\right)^{2+2/\alpha}$$

  Then indeed, $D_L \leq O(\log(N)\log(K_L)/\varepsilon_L)^{1+1/\alpha+o(1)}$.
- We now bound the number of right vertices M:

  $$M = q^{s+2} \leq q \cdot h^{(1+\alpha)(s+1)} \leq q \cdot K_L^{1+\alpha}$$

  Additionally,

  $$M = q^{s+2} \geq q^{K_L \log(q)/\log(h)} \geq q^{K_L((1+\alpha)(\log h)-1)/\log(h)} = q^{K_L(1+\alpha)-K_L/\log(h)}$$

- We now show lossless expansion from the right side:

  $$A_R = \left(1 - \frac{K_R}{q^{s+2}} \cdot \frac{q-1}{2}\right) q^{n-(s+1)} \geq (1-\varepsilon_R) D_R$$

  where the last inequality follows because $\frac{K_R}{q^{\min(s+2,n-s)}} \cdot \frac{q-1}{2} \leq \varepsilon_R$.
- We finally show lossless expansion from the left side: First, we note that $s+2 \leq 2k_L$. Indeed, $s+2 \leq k_L \log_q(h) + 1 = k_L \frac{\log(h)}{\log(q)} + 1 \leq k_L(1+\alpha)+1 \leq 2k_L$. Then,

  $$\begin{aligned} A_L &= q - \frac{n(s+2)}{2} \cdot (qh^{s+2})^{1/(s+2)} \\ &= q - \frac{n(s+2)h}{2} \cdot (q)^{1/(s+2)} \\ &\geq q - nk_L h \cdot (q)^{1/(s+2)} && \text{(since } s+2 \leq 2k_L\text{)} \\ &= q - \frac{\varepsilon_L \cdot h^{\alpha}}{4} \cdot h \cdot (q)^{1/(s+2)} && \text{(since } nk_L = (\varepsilon_L \cdot h^{\alpha})/4\text{)} \\ &= q - \varepsilon_L \cdot \frac{h^{1+\alpha}}{4} \cdot (q)^{1/(s+2)} \\ &\geq q - \frac{\varepsilon_L}{2} \cdot q \cdot (q)^{1/(s+2)} && \text{(since } h^{1+\alpha}/2 \leq q\text{)} \\ &= q\left(1 - \varepsilon_L \cdot \frac{(q)^{1/(s+2)}}{2}\right) \\ &\geq q(1-\varepsilon_L) \end{aligned}$$

The last inequality $(q)^{1/(s+2)} \leq 2$ follows because we claim that $s+2 \geq \log(q)$. This suffices to prove the last inequality since then $(q)^{1/(s+2)} \leq q^{1/\log(q)} \leq 2$. We indeed compute that

$$s+2 \geq \frac{k_L}{\log_q(h)} \geq \frac{k_L((1+\alpha)\log(h)-1))}{\log(h)} \geq k_L$$

Moreover, as $\alpha \geq \frac{4}{k_L}\log(2n/\varepsilon_L)$, we infer that $k_L \geq \frac{4}{\alpha}\cdot\log(2n/\varepsilon_L)$. Hence indeed,

$$s+2 \geq \frac{4}{\alpha}\cdot\log(2n/\varepsilon_L) \geq \frac{2}{\alpha}\cdot\log(2nk_L/\varepsilon_L) \geq 2\log(h) \geq (1+\alpha)\log(h) \geq \log(q) \quad \blacktriangleleft$$

5 Tightness of Our Construction

In this section we show that the right-to-left expansion of Theorem 24 is tight. In particular, when $n < 2s+2$ Theorem 24 gives a trade-off between the expansion parameter ε and the max size of expanding sets K_{max}. We show that this trade-off is tight up to constants, and thus fully characterize the behavior of the KT graph. Importantly, we show that in the balanced setting where $n = s + O(1)$, the KT graph is *not* a two-sided lossless expander.

Recall that when $n \geq 2s+2$ we know that our result is tight as stated in Remark 3. Consequently, our main theorem in this section deals with the regime where $s+1 < n < 2s+2$. In this setting, Theorem 24 gives us that sets $S \subseteq R$ on the right of size at most $K_{max} = \delta q^{s+1}$ expand with parameter $\varepsilon = \frac{\delta(q-1)}{2q}\cdot q^{2s+2-n}$. Equivalently, it gives us that sets of size at most $K_{max} = \delta q^{n-s-1}$ expand with parameter $\varepsilon = \frac{\delta(q-1)}{2q}$. Our main theorem in this section upper bounds this expansion.

▶ **Theorem 32.** *When $s+1 < n < 2s+2$, there exists a subset $S \subseteq R$ of the right vertices such that $|S| = K_{max} = \delta q^{n-s-1}$ and $|\Gamma_{\leftarrow}(S)| = (1-\varepsilon)D_R|S|$ with $\varepsilon = \frac{\delta}{4}$ where $\delta > 0$.*

This means that our right-to-left expansion of *Theorem* 24 is tight up to a constant factor of 1/2. The proof of our main theorem comes from the construction of two disjoint subsets of right vertices each in different buckets that have the maximum number of overlapping neighbors on the left. Recall that the y-th bucket T_y is defined as $T_y = \{(y,\alpha) : \alpha \in \mathbb{F}_q^{s+1}\}$

▶ **Lemma 33.** *Let $y_1, y_2 \in \mathbb{F}_q$ be arbitrary such that $y_1 \neq y_2$. Then there exist sets $S_1 \subseteq T_{y_1}$ and $S_2 \subseteq T_{y_2}$ such that $|S_1| = |S_2| = \frac{K_{max}}{2}$ and $|\Gamma_{\leftarrow}(S_1) \cap \Gamma_{\leftarrow}(S_2)| = |S_1|\cdot|S_2|$.*

Using this lemma, our main theorem is a result of straightforward computations.

Proof of Theorem 32. Take any $y_1, y_2 \in \mathbb{F}_q$ such that $y_1 \neq y_2$ and the S_1 and S_2 from Lemma 33. Let $S = S_1 \cup S_2$, so indeed $|S| = K_{max}$. To count $|\Gamma_{\leftarrow}(S)|$, all we need to do is to subtract the number of 2-wise overlaps of left neighbors S_1 and S_2 from the total number of possible neighbors of S_1 and S_2. The latter value is simply $|S|\cdot D_R = K_{max}\cdot D_R$, and the former is given to us by Lemma 33 as $|S_1|\cdot|S_2| = \frac{K_{max}^2}{4}$. Therefore, we can compute

$$|\Gamma_{\leftarrow}(S)| = K_{max}\cdot D_R - \frac{K_{max}^2}{4} = K_{max}\cdot D_R\left(1 - \frac{K_{max}}{4D_R}\right),$$

showing that

$$\varepsilon = \frac{K_{max}}{4D_R} = \frac{\delta q^{n-(s+1)}}{4q^{n-(s+1)}} = \frac{\delta}{4}. \quad \blacktriangleleft$$

The proof of Lemma 33 relies on choosing S_1 and S_2 to contain only the derivatives of polynomials of degree at most $n-(s+1)$. In the following proofs, we will consider vector spaces of polynomials over $\mathbb{F}_q$.

▶ **Definition 34.** *Define the set* $P_d = \{f \in \mathbb{F}_q[x] \mid \deg(f) = d\}$ *and let* $P_{<d} = \{f \in \mathbb{F}_q[x] \mid \deg(f) < d\}$ *be a vector space over* $\mathbb{F}_q$ *with addition and multiplication coming from* $\mathbb{F}_q[x]$.

5.1 Constructing sets with the smallest expansion possible

We prove Lemma 33 by restricting the KT graph to the subgraph containing the two buckets T_{y_1} and T_{y_2} and analyzing the behavior of this subgraph. Consequently, we rephrase Lemma 33 as follows.

▶ **Lemma 35** (Technical version of Lemma 33). *For any* $K \in [q^{n-(s+1)}]$ *and distinct* $y_1, y_2 \in \mathbb{F}_q$, *there exist sets* $S_1, S_2 \subseteq \mathbb{F}_q^{s+1}$ *such that* $|S_1| + |S_2| = K$ *and* $S_1 \times S_2 \in \psi_{y_1,y_2}(P_{<n})$.

To create these S_1 and S_2, we actually first create analogous sets in the image of the Chinese Remainder Theorem map, defined below.

▶ **Definition 36.** *For distinct* $y_1, y_2 \in \mathbb{F}_q$ *let* $g_1(x) = (x-y_1)^{s+1}$ *and* $g_2(x) = (x-y_2)^{s+1}$, *let* $\pi_1 : \mathbb{F}_q[x] \to \mathbb{F}_q[x]/(g_1)$ *and* $\pi_2 : \mathbb{F}_q[x] \to \mathbb{F}_q[x]/(g_2)$ *be the associated quotient maps. Then let* $\varphi : \mathbb{F}_q[x]/(g_1g_2) \to \mathbb{F}_q[x]/(g_1) \times \mathbb{F}_q[x]/(g_2)$ *be defined as* $\varphi = \pi_1 \otimes \pi_2$.

This is exactly the map that the Chinese Remainder Theorem acts on.

▷ Claim 37. The Chinese Remainder Theorem says that φ is an isomorphism of rings.[8]

▶ **Corollary 38.** *As a consequence, we may also think of* φ *as an isomorphism of* $\mathbb{F}_q$*-vector spaces* $\varphi : P_{<2s+2} \to P_{<s+1} \times P_{<s+1}$.

Whereas $\psi_{y_1,y_2}(f)$ tells us about the first s derivatives of f at y_1 and y_2, $\varphi(f)$ tells us about f quotiented by g_1 and g_2. In fact, as we will see, φ and ψ_{y_1,y_2} provide us with the same information about a particular polynomial. With this in mind, we prove a lemma similar to Lemma 35 but for φ.

▶ **Lemma 39.** *For any* $K \in [q^{n-(s+1)}]$ *and distinct* $y_1, y_2 \in \mathbb{F}_q$, *there exist sets* $S_1 \subseteq \mathbb{F}_q[x]/(g_1)$ *and* $S_2 \subseteq \mathbb{F}_q[x]/(g_2)$ *such that* $|S_1| + |S_2| = K$ *and* $S_1 \times S_2 \in \varphi(P_{<n})$.

Using this relation between φ and ψ_{y_1,y_2}, we prove Lemma 35.

Proof of Lemma 35. Use Lemma 39 to create $R_1 \subseteq \mathbb{F}_q[x]/(g_1)$ and $R_2 \subseteq \mathbb{F}_q[x]/(g_2)$ such that $|R_1| + |R_2| = K$ and $R_1 \times R_2 \in \varphi(P_{<n})$. Let $S_1 = \psi_{y_1} \circ \pi_1^{-1}(R_1)$ and $S_2 = \psi_{y_2} \circ \pi_2^{-1}(R_2)$ where π_1^{-1} and π_2^{-1} are the natural inclusions of $\mathbb{F}_q[x]/(g_1)$ and $\mathbb{F}_q[x]/(g_2)$ into $\mathbb{F}_q[x]$, respectively. We claim that $S_1 \times S_2 \in \psi_{y_1,y_2}(P_{<n})$.

Since the polynomials in the images of π_1^{-1} and π_2^{-1} are of degree strictly less than $s+1$, we have that $\psi_{y_1} \circ \pi_1^{-1}$ and $\psi_{y_2} \circ \pi_2^{-1}$ are injective, so $|S_1| + |S_2| = |R_1| + |R_2| = K$. Moreover, for a pair $(s_1, s_2) \in S_1 \times S_2$, we can take the unique $(r_1, r_2) \in R_1 \times R_2$ such that $s_1 = \psi_{y_1} \circ \pi_1^{-1}(r_1)$ and $s_2 = \psi_{y_2} \circ \pi_2^{-1}(r_2)$. Thus, $(s_1, s_2) = \psi_{y_1,y_2}(\pi_1^{-1}(r_1), \pi_2^{-1}(r_2)) \in \psi_{y_1,y_2}(P_{<n})$, as claimed. ◀

Our proof of Lemma 39 relies on a result about the structure of the image of φ which we prove in Section 5.2 but state here.

[8] For an introduction to the Chinese Remainder Theorem, see Chapter 7.6 of [6].

▶ **Definition 40.** *For any $b \in \mathbb{F}_q^{s+1}$ define the line $\ell_b = \{(f, f+b) \mid f \in \mathbb{F}_q^{s+1}\}$.*

We now show that the image of φ is actually composed of many of these lines with shifts given by the injective homomorphism $\sigma : P_{<n-(s+1)} \to P_{<s+1}$ that we introduce later in Definition 45.

▶ **Lemma 41.** *We show that:*
1. $\varphi(P_{<s+1}) = \ell_0$
2. *For $2s+2 > d \geq s+1$ we have $\varphi(P_d) = \bigcup_{h \in P_{d-(s+1)}} \ell_{\sigma(h)}$.*

Thus, we can conclude that $\varphi(P_{<n}) = \bigcup_{h \in P_{<n-(s+1)}} \ell_{\sigma(h)}$ where σ is an injective homomorphism.

This structural result on the image of φ allows us to prove Lemma 39.

Proof of Lemma 39. Let $S_1, S_2 \subseteq \sigma(P_{<n-(s+1)})$ such that $|S_1| = |S_2| = \frac{K_{max}}{2}$. Recall that σ is injective so $\left|\sigma(P_{<n-(s+1)})\right| = \left|P_{<n-(s+1)}\right| = q^{n-(s+1)}$ and we have enough elements to choose from. We claim that any such choice of S_1 and S_2 satisfies the lemma statement.

To prove this claim, we have to show that any pair $(s_1, s_2) \in S_1 \times S_2$ lies in $\varphi(P_{<n})$. By Lemma 41, this is equivalent to saying that (s_1, s_2) is of the form $(f, f + \sigma(h))$ for some $f \in P_{<s+1}$ and $h \in P_{<n-(s+1)}$. From our construction, we have that $s_1 = \sigma(h_1)$ and $s_2 = \sigma(h_2)$ for $h_1, h_2 \in P_{<n-(s+1)}$. So we are considering the point $(\sigma(h_1), \sigma(h_2))$. Using the fact that σ is a homomorphism from Claim 46, we can rewrite this point in our desired form:

$$\begin{aligned}(\sigma(h_1), \sigma(h_2)) &= (\sigma(h_1), \sigma(h_1) + \sigma(h_2) - \sigma(h_1)) \\ &= (\sigma(h_1), \sigma(h_1) + \sigma(h_2 - h_1)).\end{aligned}$$

Thus, $(s_1, s_2) \in \ell_{\sigma(h_2 - h_1)} \subseteq \varphi(P_{<n})$, as claimed. ◀

5.2 The structure of the image of φ

We end Section 5 by proving Lemma 41, that $\varphi(P_{<n}) = \bigcup_{h \in P_{<n-(s+1)}} \ell_{\sigma(h)}$. To do so we first define a new homomorphism ρ which we will use to define σ later on.

▶ **Definition 42.** *Let $\rho : P_{<n-(s+1)} \to P_{<n-(s+1)}$ be defined as follows. Given $h_1 \in P_{<n-(s+1)}$, let $f \in P_{<n}$ be such that $f = h_1 g_1 + r_1$ for some $r_1 \in P_{<s+1}$. Then let $h_2 \in P_{\deg(f)-(s+1)}$ and $r_2 \in P_{<s+1}$ be the unique polynomials such that $f = h_2 g_2 + r_2$. We define $\rho(h_1) := h_2$.*

Given this definition, the natural first question is whether ρ is even well-defined since there are q^{s+1} many choices of f that could be used. Lemma 43 shows that ρ is well-defined and that it is, in fact, just an invertible linear operator, meaning that ρ is an automorphism of $P_{<n-(s+1)}$.

▶ **Lemma 43.** *Let $f \in P_{<n}$ and take $h_1, h_2, r_1, r_2 \in \mathbb{F}_q[x]$ to be the unique polynomials such that*

$$f = h_1 g_1 + r_1$$
$$f = h_2 g_2 + r_2$$

where $\deg(h_1) = \deg(h_2) = \deg(f) - (s+1)$ and $\deg(r_1), \deg(r_2) < s+1$.

Then h_2 can be determined uniquely from h_1, g_1, and g_2. Similarly, h_1 can be determined uniquely from h_2, g_1, and g_2.

Proof of Lemma 43. Rearranging the equations in the lemma statement gives us that

$$h_1 g_1 - h_2 g_2 = r_2 - r_1.$$

Since the degrees of r_1 and r_2 are at most s, we have that $\deg(r_2 - r_1) < s+1$ as well, meaning that $\deg(h_1 g_1 - h_2 g_2) < s+1$. Consequently, the coefficients of x^k for $k \in \{s+1, \ldots, n-1\}$ of $h_1 g_1$ and $h_2 g_2$ must match, which uniquely determines h_2 from h_1.

Formally, if for $t \in \{1,2\}$ we write $h_t(x) = \sum_{k=0}^{n-1-(s+1)} \eta_k^{(t)} x^k$ for $\eta_k^{(t)} \in \mathbb{F}_q$ and expand out $g_t(x) = \sum_{k=0}^{s+1} \gamma_k^{(t)} x^k$ where $\gamma_k^{(t)} \in \mathbb{F}_q$ and $\gamma_{s+1}^{(t)} = 1$, then for each $k \in \{s+1, \ldots, n-1\}$ we have the linear equation

$$\sum_{j=k-(s+1)}^{n-1-(s+1)} \gamma_{k-j}^{(1)} \eta_j^{(1)} = \sum_{j=k-(s+1)}^{n-1-(s+1)} \gamma_{k-j}^{(2)} \eta_j^{(2)}.$$

This yields $n-s-1$ linear equations, which we can write as $M^{(1)}\eta^{(1)} = M^{(2)}\eta^{(2)}$ where for $t \in \{1,2\}$ we let $\eta^{(t)} = (\eta_0^{(t)}, \ldots, \eta_{n-s-2}^{(t)})^\intercal$ and $M^{(t)} \in \mathbb{F}_q^{(n-s-1)\times(n-s-1)}$ is the upper triangular matrix defined as

$$M_{i,j}^{(t)} = \begin{cases} \gamma_{s+1+i-j}^{(t)} & i \le j \\ 0 & i > j \end{cases}$$

Since g_t is monic, meaning that $\gamma_{s+1}^{(t)} = 1$, we clearly see that $\det(M^{(t)}) = 1$, so it is invertible and $\eta^{(2)} = \left(M^{(2)}\right)^{-1} M^{(1)} \eta^{(1)}$. Similarly, $\eta^{(1)} = \left(M^{(1)}\right)^{-1} M^{(2)} \eta^{(2)}$. ◀

▶ **Corollary 44.** *ρ is an automorphism of $P_{<n-(s+1)}$.*

Proof. Lemma 43 shows that we can equivalently define ρ as $\rho = \left(M^{(2)}\right)^{-1} M^{(1)}$, which is an invertible linear transformation. ◀

Now that we have defined ρ and shown that it is an isomorphism, we use it to build σ.

▶ **Definition 45.** *Let $\sigma : P_{<n-(s+1)} \to P_{<s+1}$ be defined as $\sigma(h) = hg_1 - \rho(h)g_2$. Note that while we consider multiplication here to occur in $\mathbb{F}_q[x]$, Lemma 43 tells us that this difference yields a polynomial in $P_{<s+1}$.*

Unsurprisingly, σ is a homomorphism of vector spaces since ρ is one.

▷ Claim 46. Since ρ is an isomorphism, σ is a homomorphism of vector spaces over $\mathbb{F}_q$.

Proof. The fact that σ is a homomorphism of vector spaces over $\mathbb{F}_q$ follows from ρ being a homomorphism and addition and multiplication commuting in $\mathbb{F}_q[x]$. ◁

Finally, we are ready to prove Lemma 41, that $\varphi(P_{<n}) = \bigcup_{h \in P_{<n-(s+1)}} \ell_{\sigma(h)}$.

Proof of Lemma 41. We can directly show the first item by the fact that that the remainder of dividing a polynomial by another of larger degree is the polynomial itself. That is, for any polynomial $f \in P_{<s+1}$, we have that $\pi_1(f) = \pi_2(f) = f$, so $\varphi(f) = (f, f)$. Consequently, going over all f of degree less than $s+1$ gives us $\varphi(P_{<s+1}) = \{(f,f) : f \in P_{<s+1}\} = \ell_0$.

Now, when considering P_d for $2s+2 > d \ge s+1$, quotienting by a degree $s+1$ polynomial does have a non-trivial effect. That is, for $f \in P_d$, there must exist unique $h_1, h_2, r_1, r_2 \in \mathbb{F}_q[x]$ such that

$$f = h_1 g_1 + r_1$$
$$f = h_2 g_2 + r_2$$

where $\deg(h_1) = \deg(h_2) = \deg(f) - (s+1)$ and $\deg(r_1), \deg(r_2) < s+1$. Recall that $g_1(x) = (x-y_1)^{s+1}$ and $g_2(x) = (x-y_2)^{s+1}$. Moreover, $\pi_1(f) = r_1$ and $\pi_2(f) = r_2$. By definition, we have that $h_2 = \rho(h_1)$, meaning that $r_2 = r_1 + h_1 g_1 - \rho(h_1) g_2 = r_1 + \sigma(h_1)$. Therefore, we have $\varphi(f) = (r_1, r_1 + \sigma(h_1))$.

With this in mind, we recall that because h_1 and r_1 uniquely identify f, we can iterate over all elements of P_d by iterating over all $h_1 \in P_{d-(s+1)}$ and $r_1 \in P_{<s+1}$. That is, $P_d = \{h_1 g_1 + r_1 : h_1 \in P_{d-(s+1)}, r_1 \in P_{<s+1}\}$. From this we can conclude that

$$\begin{aligned}
\varphi(P_d) &= \{\varphi(f) : f \in P_d\} \\
&= \{\varphi(h_1 g_1 + r_1) : h_1 \in P_{d-(s+1)}, r_1 \in P_{<s+1}\} \\
&= \{(r_1, r_1 + \sigma(h_1)) : h_1 \in P_{d-(s+1)}, r_1 \in P_{<s+1}\} \\
&= \bigcup_{h_1 \in P_{d-(s+1)}} \ell_{\sigma(h_1)},
\end{aligned}$$

as claimed.

Lastly, to see that σ is injective we recall that φ is an isomorphism and count cardinalities. For the left hand side of $\varphi(P_{<n}) = \bigcup_{h \in P_{<n-(s+1)}} \ell_{\sigma(h)}$, we have that $|\varphi(P_{<n})| = |P_{<n}| = q^n$. For the right hand side, we recall that $|\ell_b| = q^{s+1}$ for any b, so $\left|\bigcup_{h \in P_{<n-(s+1)}} \ell_{\sigma(h)}\right| = \left|\sigma(P_{<n-(s+1)})\right| \cdot q^{s+1}$. Therefore, $\left|\sigma(P_{<n-(s+1)})\right| = \frac{q^n}{q^{s+1}} = q^{n-(s+1)}$, showing that σ is injective since $\left|P_{<n-(s+1)}\right| = q^{n-(s+1)}$. ◀

A Explicitness

▷ Claim 47. The KT graph G as defined in Definition 20 is explicit, i.e., the left neighborhood function $\Gamma_{\rightarrow} : \mathbb{F}_q^n \times \mathbb{F}_q \to \mathbb{F}_q^{s+2}$ and right neighborhood function $\Gamma_{\leftarrow} : \mathbb{F}_q^{s+2} \times \mathbb{F}_q^{n-(s+1)} \to \mathbb{F}_q^n$ can be computed in $\text{poly}(n, \log(q))$ time.

Proof. To compute $\Gamma_{\rightarrow}(f, y)$, we treat f as an element of $\mathbb{F}_q[X]$ of degree at most $n-1$, and map it to $(y, f^{(0)}(y), \ldots, f^{(s)}(y))$. We can compute derivatives of f and evaluate it at y in time $\text{poly}(n, \log(q))$ and hence explicitly compute $\Gamma_{\rightarrow}(f, y)$.

To compute $\Gamma_{\leftarrow}(z, t)$, we proceed as follows. Let $z = (y, w)$ where $y \in \mathbb{F}_q$ and $w \in \mathbb{F}_q^{s+1}$. Then, we need to find f such that $\Gamma_{\rightarrow}(f, y) = z$. Define $\psi_y : \mathbb{F}_q^n \to \mathbb{F}_q^{s+1}$ as $\psi_y(f) = (f^{(0)}(y), \ldots, f^{(s)}(y))$. By Lemma 25, ψ_y is a full rank $\mathbb{F}_q$-linear map. As $n > s+1$, kernel of ψ_y has dimension $n-(s+1) > 0$. By considering the matrix associated with ψ_y and using standard linear algebra algorithms, we construct an injective linear map $K_y : \mathbb{F}_q^{n-(s+1)} \to \mathbb{F}_q^n$ in $\text{poly}(n, \log(q))$ time such that the image of K_y is exactly the kernel of ψ_y. Furthermore, using Gaussian elimination on the matrix associated with ψ_y, we can, in $\text{poly}(n, \log(q))$ time, find some $g \in \mathbb{F}_q^n$ such that $\psi_y(g) = w$. Finally, we let $\Gamma_{\leftarrow}(z, t) = K_y(t) + g$. By linearity of ψ_y, we have that $\psi_y(K_y(t) + g) = \psi_y(g) = w$. As K_y is injective, for a fixed z, our computed function maps different t to different outputs as desired. ◁

Note that given any $n, k, \varepsilon, \alpha$, Lemma 31 sets $q = \text{poly}(n, k, 1/\varepsilon)$, so we can deterministically find such a prime q satisfying the requirements in $\text{poly}(n, 1/\varepsilon)$ time as well.

B The [10] Graph is Not Right Regular

One may naturally try to show that the predecessor to the KT graph, the [10] graph, is also a two-sided lossless expander. However, it turns out that the [10] graph is not even right regular. To see why, we give the definition of the [10] graph which is similar to the KT graph.

▶ **Definition 48** (The GUV graph, [10]). *Let $q, n, m, h \in \mathbb{N}$ be such that q is a prime power greater than h, characteristic of the finite field $\mathbb{F}_q \geq n$ and $m < n$. We define $G = (L \sqcup R, E)$ where $L = \mathbb{F}_q^n \cong \mathbb{F}_q[x]/(z(x))$ for some irreducible polynomial $z(x) \in \mathbb{F}_q(x)$ of degree n and $R = \mathbb{F}_q^{m+1}$. The left degree is q and for any $f \in \mathbb{F}_q[x]/(z(x))$ and $y \in \mathbb{F}_q$, the y'th neighbor of f is defined as*

$$\Gamma_{\rightarrow}(f, y) = \left(y, f(y), (f^h \bmod z(x))(y), (f^{h^2} \bmod z(x))(y), \ldots, (f^{h^{m-1}} \bmod z(x))(y)\right).$$

Our proof of right-regularity - Lemma 25 - relied on the fact that the map $\psi_y(f) \mapsto (f^{(0)}(y), \ldots, f^{(s)}(y))$ is full rank over $\mathbb{F}_q$. The analogous GUV map defined as $\varphi_y(f) = (f(y), f^h(y), \ldots, f^{h^{m-1}}(y))$ does not have this property because of two issues. First, it is not necessarily linear over $\mathbb{F}_q$, although it can be made linear over $\mathbb{F}_2$ when q is a power of 2. Second, even over $\mathbb{F}_2$, it does not necessarily have full rank, meaning we cannot guarantee right regularity.

Simulations bear this out. The GUV graph with $q = 2^4$, $n = 4$, $m = 2$, and $h = 2$ has 3072 right vertices with degree 256, 64 with degree 4096, and 960 isolated vertices. For more examples of parameter settings where the GUV graph is not right-regular, we invite the reader to run simulations with our code at `https://github.com/mjguru/GUV-Expander`.

Towards Tight Bounds for Testing k-Colorability

Nick Kushnir

Asaf Shapira
School of Mathematics, Tel Aviv University, Israel

Abstract

Determining the sample complexity for testing k-colorability is perhaps the most well studied problem in property testing. It was (implicitly) introduced almost 50 years ago by Bollobás, Erdős, Simonovits and Szemerédi, who used the regularity lemma in order to give a tower-type bound for this problem. This bound has been successively improved in a long list of works, bringing the state-of-the-art bounds to lie between $\Omega(1/\varepsilon)$ and $O((k/\varepsilon)\log^2(1/\varepsilon))$. We obtain the following new results:

(i) Our first main result is an improved $O((k/\varepsilon)\log(1/\varepsilon))$ upper bound, bringing the sample complexity closer to "truly" linear in ε. To prove this result, we improve upon a variant of the container method, introduced recently in the breakthrough paper of Blais and Seth.

(ii) Perhaps the most important gap in our understanding of this problem is that while the best known upper bound increases with k, the lower bound is independent of k. Our second main result fills this gap by providing a new $\Omega(\frac{\log k}{\varepsilon})$ lower bound, improving upon a result of Alon and Krivelevich from 2002. We conjecture that this is the true sample complexity of k-colorability.

1 Introduction

Given a graph $G = (V, E)$, we use $\chi(G)$ to denote its *chromatic number*, that is, the smallest integer k so that V can be colored with the colors $\{1, \ldots, k\}$ so that for each edge $(u, v) \in E$ the vertices u, v are colored differently. Computing $\chi(G)$, or even just determining if $\chi(G) \leq 3$, is of course one of the classical NP-hard problems. One of the best "combinatorial evidence" for the hardness of determining $\chi(G)$ is a classical result of Erdős [12], which states that for arbitrary k and n, there are n-vertex graphs of chromatic number k in which *every* set of $\Omega(n)$ vertices induces a 3-colorable graph. Qualitatively, this means that the chromatic number of a graph lacks any relation between its global and local aspects. Suppose now that we strengthen our global assumption on G, and instead of just assuming that it has large chromatic number, we further assume that it is "far" from having small chromatic number. Can we then show that G has a subgraph on a small number of vertices which witnesses this fact? Interestingly, the answer in this case is dramatically different. We now make this statement more precise.

For a fixed $\varepsilon > 0$ we say that G is ε-far from being k-colorable, if one should remove from G at least εn^2 edges in order to obtain a graph which is k-colorable[1]. A result of Bollobás, Erdős, Simonovits and Szemerédi [10] from 1978 states that if G is ε-far from being 2-colorable then G contains a set of vertices of size $C(\varepsilon)$ which spans a non 2-colorable graph. This result was later extended by Rödl and Duke to arbitrary fixed k. Both proofs [10, 25] relied on Szemerédi's regularity lemma [29], therefore they only supplied tower-type bounds for $C(\varepsilon)$. Interestingly, both proofs in fact show that a random sample of $C(\varepsilon)$ vertices spans a non-k-colorable subgraph with probability at least 2/3. Let us then define $S_k(\varepsilon)$ to be the smallest q such that if G is ε-far from being k-colorable then a sample of q vertices spans a non-k-colorable subgraph with probability at least 2/3. We call $S_k(\varepsilon)$ the *sample complexity* of k-colorability.

We pause our discussion for a moment and observe that the fact that $S_k(\varepsilon)$ is independent of n has an immediate surprising algorithmic implication. A randomized algorithm is said to be an ε-tester for k-colorability if it accepts k-colorable graphs with probability at least 2/3 and rejects those that are ε-far from being k-colorable with probability at least 2/3. It is now easy to see that we can obtain an ε-tester for k-colorability which simply samples $S_k(\varepsilon)$ vertices, and checks[2] if the subgraph they induce is k-colorable. This observation was made explicit by Goldreich, Goldwasser and Ron [17] in their seminal paper which introduced[3] the area of property testing, and where similar algorithms were designed for more general partition properties. See [5, 16] for more details on property testing. The take-home message here is that besides the purely graph theoretic interest in understanding $S_k(\varepsilon)$, an additional motivation stems from its algorithmic application.

The study of the sample complexity of k-colorability took two dramatic turns in the mid 90's. First, Frieze and Kannan [14, 15] made the crucial observation that in order to study $S_k(\varepsilon)$ one does not need the full power of Szemerédi's regularity lemma [29], and that a weaker regularity lemma suffices. This observation brought down the sample complexity to $2^{(k/\varepsilon)^{O(1)}}$, already making a significant improvement over the regularity-based tower-type bound of Rödl and Duke [25]. Independently of [14, 15], Goldreich, Goldwasser and Ron [17] obtained the first polynomial bound for $S_k(\varepsilon)$. They did so by completely doing away with the regularity lemma method, showing that $S_k(\varepsilon) = \tilde{O}(k^2/\varepsilon^3)$. This bound was later improved by Alon and Krivelevich [1] to $\tilde{O}(k/\varepsilon^2)$. A significant breakthrough was obtained by Sohler [28] who improved the dependence on ε to near linear, giving an upper bound of $\tilde{O}(k^6/\varepsilon)$. In a recent breakthrough, Blais and Seth [7] further improved this, showing that $S_k(\varepsilon) = O((k/\varepsilon)\log^2(1/\varepsilon))$. In terms of lower bounds, Alon and Krivelevich [1] proved that $S_k(\varepsilon) = \Omega(1/\varepsilon)$.

As is evident, determining the correct order of $S_k(\varepsilon)$ has long served as a testbed for developing many of the most important techniques that became ubiquitous in the area of graph property testing. Consequently, resolving this problem was raised as an open problem

---

[1] Observe that every graph can be made k-colorable by partitioning the vertices into k sets of equal size and removing the edges within these sets. We thus remove at most n^2/k, hence we can always assume that $k \leq 1/\varepsilon$.

[2] Note that this algorithm actually accepts with probability 1 every k-colorable input.

[3] We should point out that [17] used the notion of *query complexity* which is the number of edges we need to sample from G in order to design an ε-tester for k-colorability. Clearly the query complexity is at most quadratic in $S_k(\varepsilon)$, since we can simply query all edges inside the sampled set of vertices. Interestingly, there is a theorem of Goldreich and Trevisan [19] stating that this quadratic gap actually holds for every graph property, and a recent theorem of Goldreich and Wigderson [20] stating that it is sometimes unavoidable. See [21, 18] for further discussion. Since almost all works on k-colorability used the notion of sample complexity, we also use it here.

in several papers[4], for example in 2002 by Alon and Krivelevich [1] and more recently by Blais and Seth [7]. Observe that a striking inconsistency has persisted for the past 20 years: while all upper bounds for $S_k(\varepsilon)$ increase with k, the only known lower bound is independent of k. Our first main result in this paper fills this qualitative gap, improving upon the lower bound obtained in 2002 by Alon and Krivelevich [1].

▶ **Theorem 1.1.** *The sample complexity of k-colorability satisfies $S_k(\varepsilon) = \Omega(\frac{\log k}{\varepsilon})$.*

The main idea of the proof of Theorem 1.1 is the following. As we mentioned above Erdős [12] showed that there is a graph of chromatic number k in which every set of vertices of linear size is 3-colorable. Alon and Krivelevich [1] showed that by taking a blowup of such a graph one can obtain an $\Omega(1/\varepsilon)$ lower bound. The parameters in Erdős's example are tight if one insists that *every* set of vertices of linear size has small chromatic number. Our main innovation here is that in the setting of testing it is enough that most sets satisfy this condition, which allows us to use a theorem of Łuczak [23] on the chromatic number of sparse random graphs.

Our second main result in this paper improves the state of the art upper bound as follows.

▶ **Theorem 1.2.** *The sample complexity of k-colorability satisfies $S_k(\varepsilon) = O(\frac{k}{\varepsilon}\log\frac{1}{\varepsilon})$.*

The proof of Theorem 1.2 builds on the approach introduced in the recent breakthrough of Blais and Seth [7, 6], which itself is a variant of the *Container Method* in extremal combinatorics. This method very roughly states that if the edges of a (hyper)graph are reasonably well distributed then there is a small collection of vertex subsets $C_1, \ldots, C_t$ called *containers*, so that every independent set is a subset of one of these containers. The main advantage is that this lemma allows one to improve upon naive union bounds since instead of having to union bound over all independent sets, one only needs to consider the sets C_i. This method has its origins in the works of Kleitman and Winston [22] and Sapozhenko [26] who considered containers in graphs. A major breakthrough was obtained about 10 years ago by Balogh, Morris, and Samotij [4] and by Saxton and Thomason [27] who extended this method also to hypergraphs, allowing many more applications of this method. Blais and Seth [7, 6] found a clever way of applying this method in the setting of testing graph properties. As in [4, 27] the main challenge is to design an algorithm[5] which receives the graph and constructs the containers. Our main contribution here is in improving the analysis of the algorithm presented in [6]. More concretely, in Lemma 3.10 we remove a $\log 1/\varepsilon$ factor from the bound obtained in [6] for the same lemma (Lemma 6[6] in [6]), which results in the improved upper bound in Theorem 1.2.

The two main differences between our analysis here and the ones in [7, 6] are the following: First, we use the reduction of [6] which reduces testing k-colorability to finding a single independent set in an appropriate graph (the one in [7] requires k independent sets which is more costly), but we run on this graph the container algorithm of [7], which is much simpler to analyse and adapt to our needs. The second idea is to break the analysis of the container

[4] It is worth mentioning that some papers [8, 9] focused on the special case of determining $S_2(\varepsilon)$ (which might be simpler given the simple structure of bipartite graphs) while other papers [2, 6, 11] studied the more general problem of hypergraph colorability.

[5] We stress that by "algorithm" we refer to the procedure that (explicitly) constructs the containers, and not to any algorithmic aspect of testing k-colorability.

[6] The result of [6] actually applies to more general hypergraph coloring properties. Our improved bound can be easily extended to that setting, but we chose to focus on the graph setting in order to simplify the proofs.

algorithm of [7] into Claims 3.3, 3.4 and 3.5, which allows us to make the crucial observation in Claim 3.4. This claim allows us to save a $\log \frac{1}{\varepsilon}$ factor in the edge counts at the end of the proof of Lemma 3.10. To summarize, we combine the ideas presented in [7, 6] with the crucial observation in Claim 3.4.

Our new lower/upper bounds suggest the natural question: what is the true asymptotic behaviour of $S_k(\varepsilon)$? While the k term and the $\log 1/\varepsilon$ term in the upper bound seem like an artifact of the proof, it appears as if the $\log k$ term in the lower bound is much harder to improve upon. We thus suspect that the following holds.

▶ **Conjecture 1.3.** *The sample complexity of k-colorability satisfies $S_k(\varepsilon) = \Theta(\frac{\log k}{\varepsilon})$.*

For what it is worth, our feeling is that it will be hard to remove the final $\log \frac{1}{\varepsilon}$ factor from the upper bound on $S_k(\varepsilon)$ using the method of [7, 6], but that it should be possible to improve the dependence on k (perhaps even all the way to the optimal/conjectured $\log k$) using this method.

Two intermediate goals towards Conjecture 1.3 are to prove an upper bound of $C(k)/\varepsilon$ (for some arbitrary constant $C(k)$) and an upper bound of $\frac{(\log k)^C}{\varepsilon} \log \frac{1}{\varepsilon}$. Observe that a bound of the form $O(\log k/\varepsilon^C)$ (with $C = 7$) is known [3, 13], but is inferior to the known $O(\frac{k}{\varepsilon} \log^{O(1)} \frac{1}{\varepsilon})$ bounds as long as $C \geq 2$ since, as we mentioned earlier, we can assume that $k \leq 1/\varepsilon$. It would also be very interesting to investigate the sample complexity of *tolerantly* testing k-colorability [24], namely, estimating how far is an input from being k-colorable. While this can be done with sample complexity polynomial in $1/\varepsilon$ using the results of [17], determining the sample complexity of this problem seems very challenging.

Paper overview

In Section 2 we prove Theorem 1.1. We first state and prove Lemma 2.3 which is the main lemma in the section, and then use it to prove the lower bound. In Section 3 we prove Theorem 1.2 using the container method.

2 Proof of Theorem 1.1

Our proof of Theorem 1.1 will rely on the following theorem of Łuczak [23] regarding the chromatic number of $G(n, p)$.

▶ **Theorem 2.1.** *There exists a constant d_0 such that if $d = d(n) = n \cdot p(n) > d_0$ and $p(n) = o(1)$, then with probability $1 - o(1)$*

$$\chi(G(n,p)) \leq \frac{np}{\log np}$$

Łuczak [23] actually obtains the much stronger bound $\chi(G(n,p)) < (\frac{1}{2} + o(1))np/\log np$ but the above result suffices for our purposes here. We will also need the following basic Chernoff bound.

▶ **Lemma 2.2.** *Given $p_1, \ldots, p_n \in [0,1]$ and mutually independent random variables $X_1, \ldots, X_n$, taking values in $\{0,1\}$, with $\mathbb{P}[X_i = 1] = p_i$, denote $p = (p_1 + \cdots + p_n)/n$ and $X = X_1 + \cdots + X_n$. Then for every $0 < a \leq pn$*

$$\mathbb{P}[X - \mathbb{E}[X] < -a] < e^{-a^2/2pn}$$

In order to prove Theorem 1.1, we will first prove the following lemma.

▶ **Lemma 2.3.** *There is k_0 so that for every $k > k_0$, and every large enough m there is an m-vertex graph H satisfying:*

- **(i)** *For every $1 \leq r \leq m/80$, a uniformly sampled subset of r vertices of H spans a k-colorable graph with probability at least $\frac{9}{10}$.*
- **(ii)** *One needs to remove from H at least $m \log k$ edges in order to make it k-colorable.*

Proof. Set $p = 40k \log k/m$. To prove the lemma, we will show that for all large enough m, the random graph $H = G(m,p)$ satisfies each of the two desired properties with probability at least $3/4$, and hence there is a graph satisfying both properties.

We first prove that property (i) holds with probability at least $3/4$ with respect to $r = m/80$. Fix a set R of $m/80$ vertices of $H = G(m,p)$. Due to the independence of the $G(m,p)$ model, we can think of the induced subgraph $H[R]$ as generated by $G(m/80,p)$. Thus, by Theorem 2.1, with the parameters $n = m/80, p = 40k \log k/m$, we deduce that for all large enough k[7] and all large enough m, with probability at least 0.99 we have

$$\chi(R) \leq \frac{np}{\log np} = \frac{k \log k}{2 \log\left(\frac{k \log k}{2}\right)} < k \; .$$

Let $X = X(H)$ denote the number of subgraphs of $H = G(m,p)$ of size $m/80$ that are not k-colorable. By the above assertion we have $\mathbb{E}[X] \leq 0.01 \cdot \binom{m}{m/80}$. Hence, by Markov's inequality

$$\mathbb{P}\left[X > 0.1\binom{m}{m/80}\right] < 1/4 \; .$$

Therefore, with probability at least $3/4$, at most $0.1\binom{m}{m/80}$ of the subsets of H of size $m/80$ span a non-k-colorable subgraph, which is exactly what property (i) states for $r = m/80$. Consider now any $r' < r$. We can sample a random set of size r' by first picking random set of size r and then picking from it a random set of size r'. By the above argument, the random set of size r spans a k-colorable graph with probability at least $9/10$, and since a subgraph of a k-colorable graph is also k-colorable, a random set of size r' is also k-colorable with probability at least $9/10$.

We now prove that property (ii) holds with probability at least $3/4$. Towards this, we first prove that with probability at least $3/4$ every set of vertices R in H of size $|R| = r \geq \frac{m}{2k}$ contains at least $2r \log k$ edges. Let us then fix a subset $R \subset V(H)$ of size r. From Lemma 2.2, with $n = \binom{r}{2}$, all $p_i = p$ and $a = \binom{r}{2}p - 2r \log k$, we have

$$\begin{aligned}
\mathbb{P}[|E(G[R])| < 2r \log k] &< e^{-\left(\binom{r}{2}p - 2r \log k\right)^2 / 2\binom{r}{2}p} \\
&< e^{-(rp - 5 \log k)^2/(4p)} \\
&< e^{-pr^2/10} \; .
\end{aligned}$$

[7] We need k to be large enough so that $pm = \frac{1}{2}k \log k$ is larger than d_0 in Theorem 2.1.

Hence, the probability that there is a subset R of size $m/2k \leq r \leq m$ violating the above property is at most

$$\begin{aligned}\sum_{m/2k\leq r\leq m}\binom{m}{r}e^{-pr^2/10} &\leq \sum_{m/2k\leq r\leq m}(2ek)^r\cdot e^{-pr^2/10}\\ &\leq \sum_{m/2k\leq r\leq m}e^{r(\ln(2ek)-pr/10)}\\ &\leq \sum_{m/2k\leq r\leq m}e^{r(\ln(2ek)-2\log k)}\\ &\leq \sum_{m/2k\leq r\leq m}e^{r(-\log k)}=o(1)\end{aligned}$$

We now prove that if the condition in the previous paragraph holds, then item (ii) holds as well, and hence it holds with probability at least 3/4. Indeed, take any partition of $V(H)$ into k sets $C_1,\ldots,C_k$. Since at most half of H's vertices belong to sets C_i of size at most $m/2k$ and since any C_i of size at least $m/2k$ contains at least $2|C_i|\log k$ edges, we conclude that H contains at least $m\log k$ edges within the sets $C_1,\ldots,C_k$. Since this is true for any partition into k sets, at least $m\log k$ edges need to be removed from H to make it k-colorable. ◀

Proof (of Theorem 1.1). Let k_0 be the constant in Lemma 2.3. We may clearly assume that $k > k_0$ since we can either absorb this into the constant in the $\Omega(\frac{\log k}{\varepsilon})$ bound or alternatively just use the $\Omega(\frac{1}{\varepsilon})$ lower bound of [1] which holds for all k. Given $k > k_0$ and all small enough $\varepsilon > 0$, we will show that there are infinitely many $n \in \mathbb{N}$ for which there is a graph G which is ε-far from being k-colorable, and yet a randomly chosen set of $\Omega(\frac{\log k}{\varepsilon})$ vertices spans a k-colorable graph with probability at least 9/10. Set

$$m = \frac{\ln k}{\varepsilon}\ . \tag{1}$$

Since we may assume that ε is small enough, we can assume that m is large enough for Lemma 2.3 to hold. Let H be the graph guaranteed by the lemma. For each integer n, let G be the n/m-blowup of H, that is, the graph obtained by replacing each vertex v of H with an independent set I_v of size n/m, and every edge (u,v) of H with a complete bipartite graph connecting the sets I_u, I_v. We will now show that G satisfies the two properties above, namely, that it is ε-far from being k-colorable, and that a sample of $s = m/80 = \Omega(\frac{\log k}{\varepsilon})$ of vertices spans a k-colorable graph with probability at least 9/10.

Let us number the vertices of H as $1,\ldots,m$ and the vertex sets that replaced them in G as $I_1,\ldots,I_m$. Given a set of vertices S in G, let $S_j = S \cap I_j$ and let S_H be the set of vertices $1 \leq j \leq m$ of H for which $S_j \neq \emptyset$. It is now easy to see that for each S, if the graph $H[S_H]$ is k-colorable then so is $G[S]$. Indeed, we can color all the vertices of I_j in G using the color assigned to vertex j in H. We also observe that by symmetry, if we randomly select a set S in G of size s, then for every $s' < s$, all sets of size s' are equally likely to form the set S_H. We deduce that conditioned on the size of S_H, the set S_H is a uniform subset of H of size at most $m/80$. By Lemma 2.3 a uniform set S_H of any fixed size at most $m/80$ in H is k-colorable with probability at least 9/10. Hence, if we randomly pick a set S of size $m/80$ with probability at least 9/10 the graph $H[S_H]$ is k-colorable. But from our observation above, this means that with probability at least 9/10 the graph $G[S]$ is also k-colorable.

We now prove that G is ε-far from being k-colorable. Take any partition of $V(G)$ into k color sets $C_1, \ldots, C_k$, and let M denote the number of monochromatic edges of this partition, namely, the number of edges within these k sets. Let use this k-coloring in order to (randomly) k-color H as follows: assign color q to a vertex u with probability $|C_q \cap I_u|/|I_u|$. The expected number of monochromatic edges of H in such a coloring is precisely

$$\begin{aligned}\sum_{(u,v)\in E(H)} \sum_{q=1}^{k} \frac{|C_q \cap I_u|}{|I_u|} \frac{|C_q \cap I_v|}{|I_v|} &= \frac{m^2}{n^2} \sum_{q=1}^{k} \sum_{(u,v)\in E(H)} |C_q \cap I_u||C_q \cap I_v| \\ &= \frac{m^2}{n^2} \sum_{q=1}^{k} |(x,y) \in E(G) : x, y \in C_q| \\ &= \frac{M \cdot m^2}{n^2} \,.\end{aligned}$$

By Item (ii) of Lemma 2.3, every k-coloring of H creates at least $m \log k$ monochromatic edges, implying that $\frac{M \cdot m^2}{n^2} \geq m \log k$ and recalling (1) this means that $M \geq \varepsilon n^2$. We conclude that every k-coloring of G creates at least εn^2 monochromatic edges, implying that G is ε-far from k-colorable. ◀

3 Proof of Theorem 1.2

As we mentioned in Section 1, our proof relies on the container method. Algorithm-1 described below receives as input an independent set I in a graph G and produces a sequence $C_1, C_2, \ldots$ of supersets of I, which we call "containers", together with a sequence $F_1, F_2, \ldots$ of subsets of I, which we call "fingerprints". As the name suggests, each fingerprint F_i determines the container C_i. The algorithm constructs these two sequences using a (surprisingly) simple greedy algorithm. Starting with $F_0 = \emptyset$ and $C_0 = V(G)$, in each iteration t the algorithm picks a new vertex $v_t \in I \setminus F_{t-1}$ to be added to the fingerprint. It does so by taking v_t to be the vertex in $I \setminus F_{t-1}$ of the highest degree in $G[C_{t-1}]$ (the graph induced by G on C_{t-1}). It then adds v_t to F_{t-1} to obtain F_t. It also removes all neighbors of v_t from C_{t-1} (none of them belongs to I since it is an independent set) as well as all vertices of C_{t-1} of degree larger than that of v_t (none of them belongs to I by choice of v_t). Note that the algorithm terminates after $|I|$ steps but we further set $C_t = F_t = I$ for $t > |I|$.

Algorithm 1 Fingerprint And Container Generator.

Input: A graph $H = (V, E)$ and an independent set $I \subseteq V$

Initialize $F_0 \leftarrow \emptyset$ and $C_0 \leftarrow V(H)$;
for $t = 1, 2, \ldots, |I|$ **do**
  $v_t \leftarrow$ the vertex in $I \setminus F_{t-1}$ that has the largest degree in $H[C_{t-1}]$;
  `// remove all vertices with higher degree than` v_t
  $X \leftarrow \{w \in C_{t-1} : \deg_{H[C_{t-1}]}(w) > \deg_{H[C_{t-1}]}(v_t)\}$;
  `// remove all neighbors of` v_t
  $Y \leftarrow \{w \in V : \{w, v_t\} \in E\}$;
  `// Add` v_t `to the fingerprint`
  $F_t \leftarrow F_{t-1} \cup \{v_t\}$;
  `// Update container set by removing` X `and` Y
  $C_t \leftarrow C_{t-1} \setminus (X \cup Y)$;
Return $F_1, \ldots, F_{|I|}$ and $C_1, \ldots, C_{|I|}$;

3.1 Basic Properties

We now prove several useful properties regarding Algorithm 1.

▶ **Definition 3.1.** *For a graph $H = (V, E)$ and an independent set ($I \subseteq V$), we write $C_t(I)$ for the container obtained after t iterations of the Algorithm when the algorithm is run with input I on the graph H. Similarly, $F_t(I)$ denotes the corresponding fingerprint after t iterations.*

By construction, we have

$$F_1 \subseteq F_2 \subseteq \cdots \subseteq F_{|I|} = I \subseteq C_{|I|} \subseteq C_{|I|-1} \subseteq \cdots \subseteq C_1 \subseteq C_0 \tag{2}$$

Let us state more useful properties of these sequences. Note that the construction of the containers and the fingerprints given the independent set I guarantees that the $C_t(I)$ equals $C_t(F_t(I))$. This is stated in the following claim:

▷ Claim 3.2. For any graph $H = (V, E)$ and any independent set I in H, and any t, the fingerprint $F_t(I)$ and container $C_t(I)$ of I satisfy

$$C_t\big(F_t(I)\big) = C_t(I).$$

Proof. Fix t to be the iteration index. We will prove that $C_t\big(F_t(I)\big) = C_t(I)$. We will prove by induction on the iteration index i that for every $i \leq t$ we have $C_i\big(F_t(I)\big) = C_i(I)$. For $i = 0$ the statement is trivial. Let us assume that the statement is true for i and prove it for $i + 1$. From the inductive assumption we know that $C_i\big(F_t(I)\big) = C_i(I)$. Consider the vertex v_{i+1} that was chosen in the $(i + 1) - th$ iteration of the algorithm (running on input I). By construction, the degree of v_{i+1} in $C_i(I)$ is the highest from $I \backslash F_i$. In particular, the degree is also the highest from the following set $F_t \backslash F_i$ in the graph $C_i(I)$ and hence also in $C_i\big(F_t(I)\big)$, and so it is chosen as the $i + 1$ vertex when the algorithm is running on $F_t(I)$ as well. As the current C_i are the same in both algorithms, and so is the chosen vertex in the $(i + 1)$-th iteration, it follows that $C_{i+1}\big(F_t(I)\big) = C_{i+1}(I)$. ◁

▷ Claim 3.3. Let $H = (V, E)$ be a graph, let I be an independent set in H, and let $0 \leq t \leq |I|$. Denote by Δ_t the maximal degree in C_t. Then, Δ_t is weakly decreasing w.r.t t.

Proof. Follows immediately from the fact that $C_t \subseteq C_{t-1}$ as stated in (2). ◁

▷ Claim 3.4. Let $H = (V, E)$ be a graph, let I be an independent set in H, let $1 \leq t \leq |I|$ and let Δ_t denote the maximum degree of $H[C_t(I)]$. Then $\Delta_t \leq |C_{t-1} \backslash C_t|$.

Proof. Suppose v_t is the vertex in $I \backslash F_{t-1}$ that has the largest degree in $H[C_{t-1}]$. Let $d(v_t)$ denote the degree of vertex v_t in $H[C_{t-1}]$. Then $|C_{t-1} \backslash C_t| \geq d(v_t)$ since Algorithm-1 removes from C_{t-1} the $d(v_t)$ neighbors of v_t in C_{t-1}. On the other hand $\Delta_t \leq d(v_t)$ since Algorithm-1 removes from C_{t-1} all vertices of degree larger than $d(v_t)$. ◁

▷ Claim 3.5. Let $H = (V, E)$ be a graph, let I be an independent set in H, and let $1 \leq t \leq |I|$. Then the maximum degree of $H[C_t]$ is at most $|V|/t$.

Proof. Fix $1 \leq t \leq |I|$. As stated in (2), we have $C_t \subseteq C_{t-1} \subseteq \cdots \subseteq C_1 \subseteq C_0$. Hence,

$$|V| \geq |C_0| - |C_t| = \sum_{i=1}^{t} \big(|C_{i-1}| - |C_i|\big) = \sum_{i=1}^{t} |C_{i-1} \setminus C_i| \,.$$

Therefore, there is some index $j \in [t]$ such that $|C_{j-1} \backslash C_j| \leq |V|/t$. Thus, in the notation of Claim 3.4, we have $\Delta_j \leq |V|/t$. By Claims 3.3 and 3.4 we have also $\Delta_t \leq |V|/t$. ◁

3.2 Graph Construction

A k-coloring of a graph G is given by k independent sets corresponding to the k color classes. Therefore, if we want to apply the container algorithm to such a description, we have to apply it k times, once for each of the k independent sets. We now describe a simple way to encode the k-colorings of a graph G using another graph H. The advantage is that now every k-coloring of G corresponds to a single independent set in H. This will simplify the analysis in the next two subsections.

▶ **Definition 3.6.** *Given a graph $G = (V, E)$ and an integer k, we define the graph $H_{G,k} = (\bar{V}, \bar{E})$ as follows. If the vertices of G are $V = \{v_1, \ldots, v_n\}$ then $H_{G,k}$ has the following $k \cdot n$ vertices: for each vertex $v_i \in V$, the vertex set $\bar{V}$ contains k vertices $v_{i,1}, \ldots, v_{i,k}$. For what follows, let $S_i = \{v_{i,1}, \ldots, v_{i,k}\}$. The edges of $H_{G,k}$ are the following: for every $v_i \in V$ we put a complete graph on S_v, and for every edge (v_i, v_j) of G and every $1 \leq q \leq k$ we have and edge $(v_{i,q}, v_{j,q})$.*

One should think of vertex $v_{i,q}$ as indicating the fact that v_i is colored q. The following follows immediately from the definition above.

▶ **Fact 3.7.** *Given a graph $G = (V, E)$ and an integer k let $H_{G,k} = (\bar{V}, \bar{E})$ be the graph from Definition 3.6. Suppose $S = \{v_1, \ldots, v_s\} \subseteq V(G)$ is such that $G[S]$ is k-colorable with k-coloring $\phi : S \mapsto [k]$. Then the set $S_\phi = \{v_{1,\phi(v_1)}, \ldots, v_{s,\phi(v_s)}\}$ is an independent set in $H_{G,k}$.*

▶ **Definition 3.8.** *Given a graph $G = (V, E)$ and an integer k, let $H_{G,k} = (\bar{V}, \bar{E})$ be the graph from Definition 3.6. If $U \subset \bar{V}$ then we use vert(U) to denote the set of vertices v for which $S_v \cap U \neq \emptyset$, that is, the set of vertices $v_i \in V(G)$ so that at least one vertex $v_{i,q}$ is in U.*

▶ **Observation 3.9.** *Given a graph $G = (V, E)$ and an integer k, let $H_{G,k} = (\bar{V}, \bar{E})$ be the graph from Definition 3.6. Suppose $U \subset \bar{V}$ satisfies vert$(U) = V(G)$ and $|U| = n$ (i.e. so that $|U \cap S_v| = 1$ for every $v \in V(G)$). Then U encodes a coloring $\phi : V \to [k]$ on the vertices of G. Furthermore, the number of edges in $H[U]$ is exactly the number of monochromatic edges in G w.r.t the coloring ϕ.*

Proof. Let $\phi : V \mapsto [k]$ be such that $\phi(v_i) = q$ if $v_{i,q} \in U$. It is then clear from definition of $H_{G,k}$ that every monochromatic edge created by ϕ corresponds to precisely one edge of $H[U]$. ◀

3.3 A New Container Lemma

The next lemma is the key tool we need for the proof of Theorem 1.2. It improves upon a similar lemma from [6] by a $\log 1/\varepsilon$ factor[8].

▶ **Lemma 3.10.** *Given a graph $G = (V, E)$ and an integer k let $H_{G,k} = (\bar{V}, \bar{E})$ be the graph from Definition 3.6. Suppose that for some $\varepsilon > 0$ the graph G is ε-far from being k-colorable. Then, if I is an independent set in $H_{G,k}$ then there exists $1 \leq t \leq 4k/\varepsilon$ such that*

$$|\text{vert}(C_t(I))| \leq \left(1 - \frac{\varepsilon t}{4k}\right) n \,.$$

Here, $C_t(I)$ refers to the container of Algorithm-1.

[8] We remark again that the analogous Lemma 6 in [6] applies also to hypergraph colorability properties, but it is easy to extend our improved bound to this more general setting.

Proof. Assuming by contradiction that for all $1 \leq t \leq 4k/\varepsilon$ we have

$$|\text{vert}(C_t(I))| > \left(1 - \frac{\varepsilon t}{4k}\right) n \ , \tag{3}$$

we will construct a coloring $\phi : V \to [k]$ of the vertices of G, with less than εn^2 monochromatic edges, contradicting the assumption of the lemma. Observe that by Observation 3.9 we can construct such a coloring by finding a set U of size n in $H_{G,k}$ which satisfies $\text{vert}(U) = V$ and which contains less than εn^2 edges. We will construct U as a union of sets $U_0, \ldots, U_{4k/\varepsilon}$ defined as follows.

Let $C_0(I), \ldots, C_{4k/\varepsilon}(I)$ be the containers produced by Algorithm-1 when applied to I in the graph $H_{G,k}$. Recall that $C_t(I) \subseteq C_{t-1}(I)$ so we will consider these containers in reverse order starting from $C_{4k/\varepsilon}(I)$. Given $C_{4k/\varepsilon}(I)$, let $U_{4k/\varepsilon} \subseteq C_{4k/\varepsilon}(I)$ be the following set: for each vertex $v_i \in G$ for which $S_i \cap C_{4k/\varepsilon}(I) \neq \emptyset$, put in $U_{4k/\varepsilon}$ an arbitrarily chosen vertex from $S_i \cap C_{4k/\varepsilon}(I)$.

We now repeat this for every $t = 4k/\varepsilon - 1, \ldots, 0$, constructing a set $U_t \subseteq C_t(I) \setminus C_{t+1}(I)$ as follows: Let R_t be the vertices $v_i \in V(G)$ so that none of the vertices of S_i belongs to $U_{4k/\varepsilon} \cup \ldots \cup U_{t+1}$. Then for each vertex $v_i \in R_t$ for which $S_i \cap (C_t(I) \setminus C_{t+1}(I)) \neq \emptyset$, put in U_t an arbitrarily chosen vertex from $S_i \cap (C_t(I) \setminus C_{t+1}(I))$.

Let $U = U_{4k/\varepsilon} \cup U_{4k/\varepsilon - 1} \cup \ldots \cup U_1 \cup U_0$. Note that our choice or R_t guarantees that U contains at most one vertex from each set S_i. Furthermore, since $C_0 = \bar{V}$ we conclude that U will contain a vertex from each S_i. More precisely, if $S_i \cap C_{4k/\varepsilon} \neq \emptyset$ then we add a vertex of S_i to $U_{4k/\varepsilon}$. Otherwise, if t is the largest[9] integer $1 \leq t \leq 4k/\varepsilon$ so that C_t contains vertices of S_i, then in step t we will add one of the vertices of S_i to U_t. We thus conclude from Observation 3.9 that U encodes a k-coloring of G. Hence, it remains to prove the U contains less than εn^2 edges.

We claim that $H[U_0 \cup U_1 \cup \cdots \cup U_{4k/\varepsilon}]$ contains less than εn^2 edges. Since $U_{4k/\varepsilon} \subseteq C_{4k/\varepsilon}(I)$, then by Claim 3.5 (with $|\bar{V}| = kn$), the maximum degree in the subgraph $H[U_{4k/\varepsilon}]$ is at most $\frac{kn}{4k/\varepsilon} = \frac{\varepsilon}{4} n$. Hence, $H[U_{4k/\varepsilon}]$ has at most $\frac{\varepsilon}{4} n^2$ edges. Now, consider adding to $U_{4k/\varepsilon}$ the vertices of $U_0 \cup \cdots \cup U_{4k/\varepsilon - 1}$ in reverse order. For any $0 \leq t \leq 4k/\varepsilon - 1$, we choose $U_t \subseteq C_t$, hence when adding U_t, the number of edges in $H[U_{4k/\varepsilon} \cup \ldots \cup U_t]$ increases by at most $|U_t| \cdot \Delta_t$ where Δ_t is the maximum degree of $H[C_t(I)]$. We conclude that the number of edges in U is at most

$$\frac{\varepsilon}{4} n^2 + \sum_{t=0}^{4k/\varepsilon - 1} |U_t| \Delta_t \ . \tag{4}$$

Note that our construction guarantees that for any $0 \leq t \leq 4k/\varepsilon - 1$ we have

$$\text{vert}(U_0 \cup \ldots \cup U_t) = V \setminus \text{vert}(C_{t+1}(I)) \ .$$

From our assumption in (3) we know that $|\text{vert}(C_{t+1}(I))| > \left(1 - \frac{\varepsilon(t+1)}{4k}\right) n$, which means that

$$|\text{vert}(U_0 \cup \ldots \cup U_t)| \leq \frac{\varepsilon(t+1)}{4k} n \ .$$

Note also that since (by construction) the sets $\text{vert}(U_0), \ldots, \text{vert}(U_{4k/\varepsilon})$ are disjoint then

$$|\text{vert}(U_0 \cup \ldots \cup U_t)| = \sum_{j=0}^{t} |\text{vert}(U_j)| = \sum_{j=0}^{t} |U_j| \ .$$

[9] Since we consider the containers in reverse order, t is the "first" index satisfying this condition.

We thus conclude that $\sum_{j=0}^{t}|U_j| \leq \frac{(t+1)\varepsilon n}{4k}$. By Claim 3.3, the sequence Δ_t is decreasing with respect to t. Hence, in (4), the contribution of $|U_t|$ decreases as t increases, implying that the sum is maximized when $|U_t| = \frac{\varepsilon n}{4k}$ for every $0 \leq t \leq 4k/\varepsilon - 1$. We can thus bound (4) from above by

$$\frac{\varepsilon}{4}n^2 + \frac{\varepsilon n}{4k}\sum_{t=0}^{4k/\varepsilon-1}\Delta_t = \frac{\varepsilon}{4}n^2 + \frac{\varepsilon n}{4k}\Delta_0 + \frac{\varepsilon n}{4k}\sum_{t=1}^{4k/\varepsilon-1}\Delta_t \leq \frac{\varepsilon}{2}n^2 + \frac{\varepsilon n}{4k}\sum_{t=1}^{4k/\varepsilon-1}\Delta_t\ , \tag{5}$$

where in the last inequality we used the fact that $\Delta_0 \leq |\bar{V}| = kn$. By Claim 3.4, for every $t \geq 1$ we have $\Delta_t \leq |C_{t-1}(I)\backslash C_t(I)|$, implying that the RHS of (5) is at most

$$\frac{\varepsilon}{2}n^2 + \frac{\varepsilon n}{4k}\sum_{t=1}^{4k/\varepsilon-1}|C_{t-1}(I)\backslash C_t(I)| \leq \frac{\varepsilon}{2}n^2 + \frac{\varepsilon n}{4k}\cdot|C_0(I)\backslash C_{4k/\varepsilon-1}(I)| < \frac{\varepsilon}{2}n^2 + \frac{\varepsilon n}{4k}\cdot kn < \varepsilon n^2\ ,$$

thus completing the proof. ◀

We now extract the following useful corollary. We remind the reader of the notation S_ϕ in Fact 3.7. If S_ϕ is such a subset of $\bar{V}$ then we will use F_ϕ in order to name subsets of S_ϕ (we mention this since we could call such subsets F without the subscript ϕ).

▶ **Corollary 3.11.** *Given a graph $G = (V, E)$ and an integer k let $H_{G,k} = (\bar{V}, \bar{E})$ be the graph from Definition 3.6. Suppose that for some $\varepsilon > 0$ the graph G is ε-far from being k-colorable. Suppose $S = \{v_1, \ldots, v_s\}$ is such that $G[S]$ is k-colorable with coloring $\phi : S \mapsto [k]$. Then there is $1 \leq t \leq 4k/\varepsilon$ and an $F_\phi \subseteq S_\phi$ of size $|F_\phi| = t$ so that*

- **(i)** *$C_t(F_\phi) = C_t(S_\phi)$.*
- **(ii)** *$|vert(C_t(F_\phi))| \leq \left(1 - \frac{\varepsilon t}{4k}\right)n$.*

Here, C_t refers to the containers produced by Algorithm-1.

Proof. By Fact 3.7 we know that S_ϕ is an independent set in $H_{G,k}$. By Lemma 3.10 we know that there is a $1 \leq t \leq 4k/\varepsilon$ so that $|\mathrm{vert}(C_t(S_\phi))| \leq \left(1 - \frac{\varepsilon t}{4k}\right)n$. Let $F_t \subseteq S_\phi$ be the fingerprint of $C_t(S_\phi)$. Then by Claim 3.2 we have $C_t(F_t) = C_t(S_\phi)$ so we also have $|\mathrm{vert}(C_t(F_t))| \leq \left(1 - \frac{\varepsilon t}{4k}\right)n$. Finally note that $|F_t| = t$ (by Algorithm-1) and thus we can take F_t as the set F_ϕ in the statement. ◀

3.4 Proof of Theorem 1.2

Suppose $G = (V, E)$ is a graph on n vertices and G is ε-far from being k-colorable. Let $S \subset V$ be a random set of vertices of size $s = C\frac{k}{\varepsilon}\ln(k/\varepsilon)$, drawn uniformly at random and without replacements, where C is a large enough constant to be determined below. We need to show that the probability that $G[S]$ is k-colorable is at most $1/3$. Denote the vertices of S by $\{u_1, \ldots, u_s\}$ so that $[s]$ is the set of indices of these vertices. Let $H_{G,k} = (\bar{V}, \bar{E})$ be the graph from Definition 3.6. If I is an independent set in $H_{G,k}$ then we say that a container $C_t(I) \subset \bar{V}$ is *small* if $|\mathrm{vert}(C_t(I))| \leq \left(1 - \frac{\varepsilon t}{4k}\right)n$.

For every subset of indices $R \subseteq [s]$ let $R^* = \{u_i : i \in R\}$ (so $R^* \subseteq S$). If R is as above and $\phi : R \mapsto [k]$ then we let $R^*_\phi = \{u_{i,\phi(i)} : i \in R\}$ (so $R^*_\phi \subseteq \bar{V}$ as in Fact 3.7). For every subset of indices $R \subseteq [s]$ of size $t = |R| \leq \frac{4k}{\varepsilon}$ and every coloring function $\phi : R \mapsto [k]$, let $X_{R,\phi}$ be the event that R^*_ϕ is an independent set in $H_{G,k}$, that $C_t(R^*_\phi)$ is a small container, and that ϕ can be extended to coloring of S so that $C_t(R^*_\phi) = C_t(S_\phi)$, where we refer to containers of Algorithm-1 running on $H_{G,k}$. Let $X = \bigcup_{R,\phi} X_{R,\phi}$.

We claim that if $G[S]$ is k-colorable, then event X must hold. Indeed, if ϕ is a k-coloring of $G[S]$ and $F_\phi \subseteq S_\phi$ is the set satisfying Corollary 3.11 then F_ϕ determines the set R and ϕ of one of the events $X_{R,\phi}$ that must hold. This means that if we let C denote the event that $G[S]$ is k-colorable then $\mathbb{P}[C] \leq \sum_{X_{R,\phi}} \mathbb{P}[C|X_{R,\phi}]$. We will now complete the proof by showing that this last expression is at most $1/3$.

Consider one of the events $X_{R,\phi}$ with $t = |R|$ and assume we first sampled the vertices R^* and then the remaining $s - t$ vertices. If event $X_{R,\phi}$ holds then $|\text{vert}(C_t(R^*_\phi))| \leq \left(1 - \frac{\varepsilon t}{4k}\right) n$ and the remaining $s - t$ vertices of S should be such that ϕ can be extended to all of S so that $C_t(R^*_\phi) = C_t(S_\phi)$. But this means in particular that these $s - t$ vertices should all belong to $\text{vert}(C_t(R^*_\phi))$. Indeed, if $s_i \in S$ does not belong to $\text{vert}(C_t(R^*_\phi))$, then for every color q, the vertex $v_{i,q} \notin C_t(R^*_\phi)$ implying that we cannot extend ϕ from R^* to S so that $S_\phi \subseteq C_t(R^*_\phi)$. But by the basic properties of containers $S_\phi \subseteq C_t(S_\phi)$ so we cannot have $C_t(R^*_\phi) = C_t(S_\phi)$. We thus conclude that

$$\mathbb{P}[C|X_{R,\phi}] \leq \left(\frac{|\text{vert}(C_t(R^*_\phi))|}{n}\right)^{s-t} \leq \left(1 - \frac{\varepsilon t}{4k}\right)^{s-t} .$$

Applying the union bound over all $1 \leq t \leq 4k/\varepsilon$, all possible choices of subsets $R \subseteq [s]$ of size $|R| = t$, and all the possible colorings[10] ϕ, we have

$$\mathbb{P}[C] \leq \sum_{X_{R,\phi}} \mathbb{P}[C|X_{R,\phi}] \leq \sum_{t=1}^{4k/\varepsilon} \binom{s}{t} \cdot k^t \cdot \left(1 - \frac{\varepsilon t}{4k}\right)^{s-t} \leq \sum_{t=1}^{4k/\varepsilon} \exp\left(t \ln(ks) - \frac{\varepsilon t s}{8k}\right) ,$$

where in the last inequality we use the fact that $s \geq 2t$. It is easy to see that if $s = C\frac{k}{\varepsilon}\log\frac{k}{\varepsilon} = O(\frac{k}{\varepsilon}\log\frac{1}{\varepsilon})$, for[11] a constant C large enough, then the above expression is bounded from above by $1/3$. We conclude that the probability that $G[S]$ is colorable, given that G itself is ε-far from being k-colorable, is at most $1/3$, thus completing the proof.

Distributed Gaussian Mean Testing Under Communication Constraints: Messages, Samples, and Coins

Clément L. Canonne
University of Sydney, Australia

Nimitt
IIT Gandhinagar, India

Abstract

We revisit the problem of Gaussian mean testing in a distributed, communication constrained setting, where each of n users independently observes samples from an unknown d-dimensional spherical Gaussian distribution $\mathcal{G}(\boldsymbol{\mu}, \mathbb{I}_d)$, and can communicate up to ℓ bits to a central referee. The referee's goal is then to distinguish between cases (i) $\|\boldsymbol{\mu}\|_2 = 0$ versus (ii) $\|\boldsymbol{\mu}\|_2 \geq \varepsilon$. This problem has been considered in the private- and public-coin settings, when each user holds exactly *one* sample, or more generally when each holds exactly m samples. In this work, we significantly generalize the question in three directions: when the users only share a small number s of random bits, when each user holds a different number of samples m_k, and when each user can send a different number of bits ℓ_k to the referee.

1 Introduction

You have been put in charge of a new program, to monitor underwater volcanic activity in a large sector of the ocean. To maximize coverage, you have identified a set of n locations where to deploy buoys equipped with high-tech measuring devices, strategically chosen to maximize coverage. Each of these sensors will measure the volcanic activity at regular intervals, and send hourly the result to the central station for processing and analysis, to detect any risk. But choosing the location of these buoys was only the first step: the ocean is a harsh and big place, and as a result these sensors are not only quite distant from the station, they also have strong limitations on how many good-quality measurements they can make and how much data they can accurately transmit before running out of energy for the day. The measurements they make are subject to significant background noise; and even broadcasting data *to* the network of buoys to synchronize them is complex, given how remote they all are. So you are left with a daunting, highly constrained task:

> *How to design a good detection protocol under heterogeneous constraints, where each sensor can make a different number of measurements, send a different amount of data back to the center, and they all only share a limited amount of coordination?*

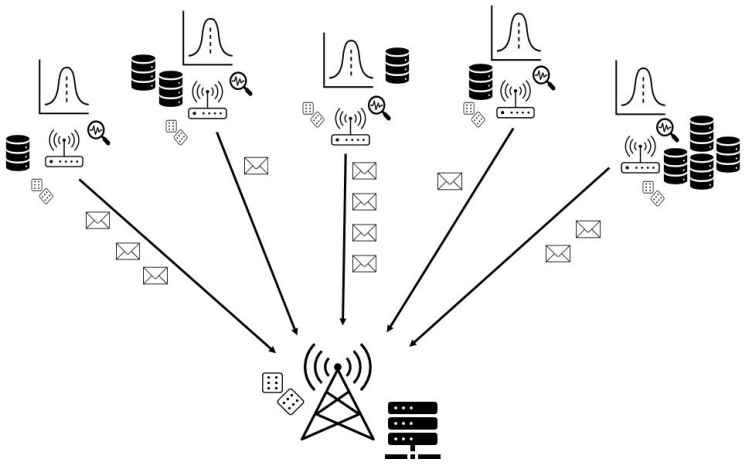

Figure 1 A depiction of the setting considered in this work: several distributed machines ("users") are measuring the same signal (vector $\boldsymbol{\mu} \in \mathbb{R}^d$) subject to white noise (spherical Gaussian). They all share a short random seed, and have different capabilities (amount of data collected, amount of communication they can send): by sending a message to a central server ("referee"), they must enable it to test whether the underlying signal measure exists ($\|\boldsymbol{\mu}\|_2 > \varepsilon$) or is pure noise ($\boldsymbol{\mu} = \mathbf{0}$).

Problem Statement

We formulate the problem as a composite hypothesis testing task. Let $\mathcal{G}(\boldsymbol{\mu}, \mathbb{I}_d)$ denote a d-dimensional Gaussian distribution with mean vector $\boldsymbol{\mu} \in \mathbb{R}^d$ and covariance $\mathbb{I}_d$. Define the following hypothesis classes for a pre-specified threshold $\varepsilon \in (0, 1]$:

$$\mathcal{H}_0 := \{\mathcal{G}(\mathbf{0}, \mathbb{I}_d)\} \quad \mathcal{H}_1 := \{\mathcal{G}(\boldsymbol{\mu}, \mathbb{I}_d) : \|\boldsymbol{\mu}\|_2 \geq \varepsilon\}$$

In a distributed setting, n users observe i.i.d. samples from an unknown distribution $G \in \mathcal{H}_0 \cup \mathcal{H}_1$ and transmit ℓ-bit messages to a central referee. Specifically, user $k \in [n]$ observes $m_k \geq 1$ independent samples from G:

$$X^{(k)} = \left(\boldsymbol{X}^{(k,1)}, \boldsymbol{X}^{(k,2)}, \cdots, \boldsymbol{X}^{(k,m_k)}\right), \quad \boldsymbol{X}^{(k,i)} \sim G.$$

and applies a (possibly randomized) encoding function $W^{(k)} \colon \mathbb{R}^{d \cdot m_k} \to \mathcal{Y}_k := \{0,1\}^{\ell_k}$ to it, before sending the resulting message $\boldsymbol{Y}^{(k)} = W^{(k)}\left(X^{(k)}\right)$ to the referee. The referee then applies a test $T \colon \mathcal{Y}_1 \times \cdots \times \mathcal{Y}_n \to \{0,1\}$ to the vector of received messages $Y^n = \left(\boldsymbol{Y}^{(1)}, \boldsymbol{Y}^{(2)}, \cdots, \boldsymbol{Y}^{(n)}\right)$, and accepts $\mathcal{H}_0$ if, and only if, $T(Y^n) = 0$.

We allow the users to share $s \geq 0$ bits of *public randomness*, which are used to jointly sample the tuple encoding functions $W^n = (W^{(1)}, W^{(2)}, \cdots, W^{(n)})$.[1] We define the *two-sided error* for protocol $\Pi := (W^n, T)$ as

$$\delta(\Pi) = \max\left(\sup_{G \in \mathcal{H}_0} \Pr\left[T(Y^n) = 1\right], \sup_{G \in \mathcal{H}_1} \Pr\left[T(Y^n) = 0\right]\right)$$

The goal is to find required amount of *resources* (amount of shared randomness s, numbers of samples $(m_k)_k$, individual communication budgets $(\ell_k)_k$) such that there exists a protocol Π with two-sided error bounded by a target error probability δ (unless specified otherwise, fixed as a small constant $1/10$). For simplicity, we decompose the problem into following three subproblems:

[1] That is, the encoding functions (or "channels") are randomized using both $s \geq 0$ bits of public randomness, and an arbitrary number of bits of private randomness (independent across users).

1. **Limited public coin**: Each user observes only one sample, and sends ℓ bits ($m_k = 1$, $\ell_k = \ell$ for all k); the users are allowed to share s bits of public randomness. What is the *sample complexity*, that is, the minimum $n = n(d, s, \ell, \varepsilon)$ such that $\inf_\Pi \delta(\Pi) \le 1/10$?
2. **Heterogeneous samples**: The users share $s = \Omega(\log(d/\ell))$ bits of public randomness, and each sends ℓ bits ($\ell_k = \ell$ for all k). What are sufficient conditions on $\boldsymbol{m} = (m_1, \dots, m_n)$ such that there exists a protocol Π with $\delta(\Pi) \le 1/10$?
3. **Heterogeneous communication**: The users share $s = \Omega(\log(d/\ell))$ bits of public randomness, and each observes one sample ($m_k = 1$ for all k). What are sufficient conditions on $\boldsymbol{\ell} = (\ell_1, \dots, \ell_n)$ such that there exists a protocol Π with $\delta(\Pi) \le 1/10$?

Our results

We now summarize our results for these three subproblems.

▶ **Theorem 1** (Limited public-coin). *For $\ell \in [d]$ and $s \ge 0$, there exists an s-public coin protocol for distributed Gaussian mean testing under ℓ-bit communication constraint with*

$$O\left(\frac{d}{\ell\varepsilon^2} \cdot \sqrt{\max\left(\frac{d}{2^{\Theta(s)}}, \ell\right)}\right)$$

users, each holding one sample.

Note that for $s = 0$ and $s = O(\log(d/\ell))$, this matches the *private-* and *public-coin* bounds of $O(d^{3/2}/(\ell\varepsilon^2))$ and $O(d/(\sqrt{\ell}\varepsilon^2))$ from [3], known to be tight [12].

▶ **Theorem 2** (Heterogeneous samples). *For $\ell \in [r, rd]$, $s = \Omega(\log(d/\ell))$, and $\boldsymbol{m} = (m_1, \dots, m_n) \in \mathbb{Z}_+^n$ satisfying $m_k \in [r, r\varepsilon^{-2}]$ for all $k \in [n]$, there exists a protocol for distributed Gaussian mean testing under ℓ-bit communication constraint with n users provided that*

$$\frac{\sum_{1 \le k_1 \ne k_2 \le n} \sqrt{m_{k_1} m_{k_2}}}{n} \ge C \cdot \frac{d}{\sqrt{\ell}\varepsilon^2}$$

where $C, r > 0$ are absolute constants.

To interpret this result, observe that, at one extreme, with $m_k = \Theta(1)$ for all k, the expression matches the *public-coin* bound. Moreover, we note that for a fixed "budget" of samples $m = \sum_{k=1}^n m_k$, a "balanced" allocation of samples across users maximizes the left-hand side, and hence is better (at least for our testing protocol).

▶ **Theorem 3** (Heterogeneous communication). *For $\boldsymbol{\ell} = (\ell_1, \dots, \ell_n) \in \mathbb{Z}_+^n$ and $s = \Omega(\log(d/\|\boldsymbol{\ell}\|_\infty))$, there exists a protocol for distributed Gaussian mean testing under $\boldsymbol{\ell}$-bit communication constraint with n users, where user k has one sample and can send ℓ_k bits to the referee, provided that*

$$\frac{\|\boldsymbol{\ell}\|_1}{\sqrt{\|\boldsymbol{\ell}\|_\infty}} \ge C \cdot \frac{d}{\varepsilon^2}$$

where $C > 0$ is an absolute constant.

Letting $\tilde{\ell} = \frac{1}{n}\sum_{k=1}^{n} \ell_k$ be the average communication budget, one can rephrase the sufficient condition as

$$n \cdot \frac{\tilde{\ell}}{\sqrt{\max_{1\le k\le n} \ell_k}} \ge C \cdot \frac{d}{\varepsilon^2}$$

which, for a fixed value of $\tilde{\ell}$, is easiest to satisfy when all communication constraints are the same ("balanced").

We emphasize that this separation in three subproblems is for clarity and simplicity of exposition: we also provide a protocol involving a "mix-and-match" of all parameters, where public randomness s, sample counts $\boldsymbol{m} = (m_1, \dots, m_n)$, and individual communication budgets $\boldsymbol{\ell} = (\ell_1, \dots, \ell_n)$ are all kept as free parameters. The guarantees of this protocol are summarized in the following theorem:

▶ **Theorem 4** (Everything, everywhere, all at once)**.** *For $s \ge 0$, $\boldsymbol{m} = (m_1, \dots, m_n) \in \mathbb{Z}_+^n$, and $\boldsymbol{\ell} = (\ell_1, \dots, \ell_n) \in \mathbb{Z}_+^n$, there exists a protocol for distributed Gaussian mean testing with n users sharing s bits of public randomness, where user k has m_k samples and can send ℓ_k bits to the referee, provided that there exists a partition $\mathcal{P} = \{P_1, \dots, P_K\}$ of the n users such that*

$$\frac{\sum_{j_1 \ne j_2 \in [K]} \sqrt{\min_{i_1 \in P_{j_1}}(m_{i_1}) \cdot \min_{i_2 \in P_{j_2}}(m_{i_2})}}{K} \ge C \cdot \frac{d}{\varepsilon^2 \sqrt{\max\left(\frac{d}{2^{\Theta(s)}}, \|\boldsymbol{\ell}\|_\infty\right)}}$$

and, for every $P \in \mathcal{P}$, $\sum_{i\in P} \ell_i \ge r \cdot \max\left(\frac{d}{2^{\Theta(s)}}, \|\boldsymbol{\ell}\|_\infty\right)$ and $\min_{i\in P}(m_i) \in [r, r\varepsilon^{-2}]$; where $C, r > 0$ are absolute constants.

Related work

In the centralized setting where all samples are fully available to the referee, the tight sample complexity of for Gaussian mean testing is known, and, while considered "folklore", can for instance be found in [7, 10] (as a special case of more general problem). Subsequent work has expanded on this foundation, exploring Gaussian mean testing under communication constraints [3] and truncation models [9]. [3] studied the problem in two variants of homogeneous regime (one sample and same communication budget ℓ for all users), namely the *private-coin* ($s = 0$) and *public-coin* ($s = \infty$), and showed sample complexities of

$$O\left(\frac{d^{3/2}}{\ell\varepsilon^2}\right) \quad (\textit{private coin}), \; O\left(\frac{d}{\sqrt{\ell}\varepsilon^2}\right) \quad (\textit{public coin})$$

While the authors only established upper bounds and (limited) lower bounds, follow-up work [11, 12] showed these two sample complexities to be tight. (Moreover, exploiting standard properties of the Gaussian distribution, the above easily generalizes to the case where each of the n users holds the same number of samples $m \ge 1$.[2])

The above works reveal a $\sqrt{d/\ell}$ gap between the private- and public-coin sample complexities, highlighting the value of shared randomness. However, the public-coin protocol of [3] (as well as the similar protocol of [12]) rely on jointly sampling a uniformly random rotation

[2] Namely, if $\boldsymbol{X}^{(k,1)}, \boldsymbol{X}^{(k,2)}, \cdots, \boldsymbol{X}^{(k,m_k)} \sim \mathcal{G}(\boldsymbol{\mu}, \mathbb{I}_d)$, then $\tilde{\boldsymbol{X}}^{(k)} := \frac{1}{\sqrt{m}}\sum_{i=1}^{m} \boldsymbol{X}^{(k,i)} \sim \mathcal{G}(\sqrt{m}\boldsymbol{\mu}, \mathbb{I}_d)$, so one can use the one-sample protocol with new distance parameter $\varepsilon' = \sqrt{m}\varepsilon$ and "single sample per user" $\tilde{\boldsymbol{X}}^{(k)}$.

of the space, which technically requires infinitely many shared random bits – even with adequate discretization, the amount of shared randomness necessary is still impractical. One can thus wonder what can be achieved with a *smaller* "shared randomness budget:" similarly, what happens if each user holds a different number of samples m_k, or can communicate a different number of bits ℓ_k. To the best of our knowledge, all of these remain essentially understudied and open in the context of Gaussian mean testing, and even distribution testing at large, with the two exceptions outlined below.

On the "limited randomness" side, our techniques and results for the s-public coin setting are reminiscent of the work of [1], which study the problem of *identity testing for discrete distributions* under communication constraints. They provide an optimal protocol for identity testing of distributions over a finite domain $[k]$ under ℓ-bit communication constraint with

$$n = \Theta\left(\frac{\sqrt{k}}{\varepsilon^2}\sqrt{\frac{d}{2^\ell}\vee 1}\sqrt{\frac{k}{2^{\ell+s}}\vee 1}\right)$$

users, giving clear interpolation between *private-* and *public-coin*. Our Blockwise Randomized Hadamard Transform (BRHT) primitive (see Section 3) for compression is similar to their technique "Domain Compression", showing an exponential saving (in the number of shared random bits) in the sample complexity of the problem. Interestingly, however, both the actual techniques used, and the resulting tradeoffs, are quite incomparable: the upshot of [1] was that "one bit of communication is equivalent to two bits of shared randomness" (in terms of sample complexity), which does no longer hold in the Gaussian mean testing setting.

On the "heterogeneous communication" side, while we are not aware of previous work for the case of Gaussian mean testing, we note that in the case of private-coin protocols for testing of discrete distributions, a baseline upper bound is hinted at in [6, Exercise 4.4], while *lower bounds* for *estimation* (not testing) are derived in [2].

We conclude by mentioning that, in the (as discussed above, analogous, yet orthogonal) setting of identity testing of discrete distributions, under local privacy constraints, the recent work [8] states that *"it is not at all obvious how this [heterogeneous sample sizes] could be handled neatly, and general results for this model could greatly help practical implementations."* While our results do not directly address their question (as we deal with mean testing and not discrete distributions, and communication instead of local privacy constraints), we hope that some of our ideas can help in this regard, especially given the observed similarities between communication and local privacy constraints [2].

2 Preliminaries

Notation

Throughout, we write $[n] := \{1, 2, \ldots, n\}$, and denote by $\boldsymbol{u}_d := (1/2, 1/2, \ldots, 1/2) \in \mathbb{R}^d$ the mean vector of a d-dimensional binary product uniform distribution over $\{0,1\}^d$, and by $\mathbb{I}_d$ the d-dimensional identity matrix. We use the standard asymptotic notations $O(\cdot), \Omega(\cdot)$ and $\Theta(\cdot)$.

Simplification

For clarity of exposition, we assume throughout that $d = 2^{k_1}$ and $\ell = 2^{k_2}$ for some integers $k_1, k_2 \geq 0$. This assumption is without loss of generality up to constant factors. Indeed, for arbitrary d, one can embed into dimension d' with

$$d \leq d' < 2d, \qquad d' = 2^{k_1}$$

via zero-padding. Similarly, for arbitrary ℓ, one can use ℓ' bits with

$$\ell/2 < \ell' \leq \ell, \qquad \ell' = 2^{k_2}.$$

We will heavily rely on the following tools and techniques from the literature, which we recall below.

▶ **Definition 5** (Normalized Sylvester Hadamard Matrix). *The* normalized Sylvester Hadamard matrix $H_d \in \mathbb{R}^{d\times d}$ *is recursively defined by*

$$H_1 := [1],$$

and for every integer $d \geq 1$

$$H_{2d} := \frac{1}{\sqrt{2}}\begin{bmatrix} H_d & H_d \\ H_d & -H_d \end{bmatrix}$$

▶ **Lemma 6** (Paley–Zygmund inequality). *For a non-negative random variable* Z *and* $0 \leq \theta \leq 1$

$$\Pr[Z > \theta\mathbb{E}[Z]] \geq (1-\theta)^2\frac{\mathbb{E}[Z]^2}{\mathbb{E}[Z^2]}$$

Binary product mean testing

Let P be an unknown d-dimensional binary product distribution over $\{0,1\}^d$ with mean vector $\boldsymbol{p} \in (0,1)^d$. Given i.i.d. samples from P and a threshold $\varepsilon > 0$, the binary product mean testing problem is to distinguish between cases $\boldsymbol{p} = \boldsymbol{u}_d$ versus $\|\boldsymbol{p} - \boldsymbol{u}_d\|_2 \geq \varepsilon$ with probability at least 99/100. It is known that the optimal sample complexity for this problem is $\Theta(\sqrt{d}/\varepsilon^2)$, and can be achieved by Algorithm 1 below. For completeness, we provide the analysis of Algorithm 1 in Appendix, Theorem 21.

Algorithm 1 Binary product mean testing.

Require: Samples $\boldsymbol{X}^{(1)}, \ldots, \boldsymbol{X}^{(n)} \in \{0,1\}^d$; threshold $\varepsilon > 0$.

$\tau \leftarrow \varepsilon^2/2$
for $i \in [d]$ **do**
  $T_i \leftarrow \sum_{k_1 \neq k_2 \in [n]} (X_i^{(k_1)} - 1/2)(X_i^{(k_2)} - 1/2)$
$T \leftarrow \frac{1}{n(n-1)} \sum_{i=1}^d T_i$
if $T > \tau$ **then**
  return reject
else
  return accept

Private-coin

As discussed above, the private-coin setting, which corresponds to $s = 0$ bits of shared randomness, was studied for Gaussian mean testing in [3]. We briefly describe their protocol, as we will use it later on, which uses two main ingredients: a reduction to the binary product case, and a simple private-coin algorithm to solve the latter.

▶ **Lemma 7** (Reduction to binary product mean testing). *Let* $\varepsilon \in (0,1)$. *If there exists an algorithm for a binary product mean testing with* $n(d,\varepsilon)$ *samples, there exists an algorithm for Gaussian mean testing with* $n(d, \varepsilon/\sqrt{8})$.

Proof. Let $\boldsymbol{X}^{(1)}, \dots, \boldsymbol{X}^{(n)}$ be i.i.d. samples from $\mathcal{G}(\boldsymbol{\mu}, \mathbb{I}_d)$. Define

$$\boldsymbol{Y}^{(k)} := \mathbb{I}(\boldsymbol{X}^{(k)} > 0) \in \{0,1\}^d.$$

Then the $\boldsymbol{Y}^{(k)}$ are i.i.d. samples from a binary product distribution P over $\{0,1\}^d$ with mean vector $\boldsymbol{p} \in (0,1)^d$. We distinguish the two cases,

Case 1: $\|\boldsymbol{\mu}\|_2 = 0$. Then, for all i, $p_i = \Pr[\boldsymbol{Y}_i^{(k)} = 1] = 1/2$. Thus, $\boldsymbol{p} = \boldsymbol{u}_d$.

Case 2: if $\|\boldsymbol{\mu}\|_2 \geq \varepsilon$. Then, for all i, $p_i = \Pr[\boldsymbol{Y}_i^{(k)} = 1] = \frac{1}{2}\operatorname{Erfc}\left(-\mu_i/\sqrt{2}\right)$. Using standard properties of Erfc, we have

$$\sum_{i=1}^{d}(p_i - 1/2)^2 \geq \frac{1}{8}\min\left(\sum_{i=1}^{d}\mu_i^2, d/2\right) = \frac{1}{8}\min\left(\|\boldsymbol{\mu}\|_2^2, d/2\right) \geq \frac{\varepsilon^2}{8}$$

Thus, $\|\boldsymbol{p} - \boldsymbol{u}_d\|_2 \geq \varepsilon/\sqrt{8}$.

Hence, to distinguish between the two cases, it is sufficient to test if $\boldsymbol{p} = \boldsymbol{u}_d$ versus $\|\boldsymbol{p} - \boldsymbol{u}_d\|_2 \geq \varepsilon/\sqrt{8}$, which is exactly the binary product mean testing problem. ◀

▶ **Theorem 8** ([3] Theorem 1). *For all $\ell \in [d]$, there exists a private-coin protocol for distributed Gaussian mean testing under ℓ-bit communication constraint with $O(d^{3/2}/\ell\varepsilon^2)$ users.*

Proof. Let $\boldsymbol{X}^{(1)}, \dots, \boldsymbol{X}^{(n)}$ be i.i.d. samples from $\mathcal{G}(\boldsymbol{\mu}, \mathbb{I}_d)$ where user k observes $\boldsymbol{X}^{(k)}$. Define $\boldsymbol{Y}^{(k)} := \mathbf{1}(\boldsymbol{X}^{(k)} > 0) \in \{0,1\}^d$. Then $\boldsymbol{Y}^{(k)}$ are i.i.d. samples from a binary product distribution P over $\{0,1\}^d$ with mean vector $\boldsymbol{p} \in (0,1)^d$. First, note that if $\ell = d$, each user can transmit the entire vector $\boldsymbol{Y}^{(k)}$, yielding a protocol with $\Theta(\sqrt{d}/\varepsilon^2)$ users using Lemma 7.

When $\ell < d$, we use the "*simulate and infer*" technique of [4]: d/ℓ users can simulate *one* sample of the d-dimensional product distribution, by having send (a different set of) ℓ coordinates. Combining this with the $\Theta(\sqrt{d}/\varepsilon^2)$ centralized sample complexity of binary product mean testing, this gives a protocol with sample complexity

$$\frac{d}{\ell} \cdot O\left(\frac{\sqrt{d}}{\varepsilon^2}\right) = O\left(\frac{d^{3/2}}{\ell\varepsilon^2}\right)$$

as claimed. ◀

3 Blockwise Randomized Hadamard Transform

In this section, we define and analyze the properties of a key primitive used throughout the paper, the *Blockwise Randomized Hadamard Transform (BRHT)*. At a high level, the idea is to replace a uniformly random rotation of $\mathbb{R}^d$ by a discrete analogue, which can be sampled using a *finite* number of random bits. An obvious candidate would be to use either a matrix of uniformly random ± 1; however, our aim is to preserve the ℓ_2 geometry, and this fails to do so. Indeed, we want an isometry, something which would play the same role as a uniformly random rotation, and in particular a transformation R which, when applied to a spherical Gaussian, would still result in a spherical Gaussian: which requires $R^\top R = \mathbb{I}_d$. This makes using a Hadamard matrix a very natural idea: however, with such a deterministic construction, we lack the randomness which enables more efficient testing protocols. To remedy this while still using a minimum amount of randomness, we consider a structured random orthogonal transform derived from the Hadamard matrix, which we define Blockwise Randomized Hadamard Transform (BRHT), and provides strong sketching guarantees with control over randomness requirement.

We note that structural randomized Hadamard transforms have previously been studied in areas such as fast dimensionality reduction and randomized linear algebra (e.g., the Fast Johnoson–Lindenstrauss Transform [5]). Our own primitive, BRHT, is tailored to the Gaussian mean testing setting, where the objective is not Johnson–Lindenstrauss embeddings but rather finite-randomness compression satisfying the block-wise energy preservation property established in Lemma 11. We formally define the BRHT below.

▶ **Definition 9** (Blockwise Randomized Hadamard Transform (BRHT))**.** *Let $d, L \in \mathbb{N}$ satisfy $L \mid d$, and define $b := d/L$. A (d, L)-*Blockwise Randomized Hadamard Transform (BRHT)* is the random matrix*

$$R := H_d D$$

where $H_d \in \mathbb{R}^{d\times d}$ is a normalized Sylvester Hadamard matrix and $D \in \mathbb{R}^{d\times d}$ is a blockwise diagonal matrix:

$$\mathrm{diag}(D) = \left(\boldsymbol{\delta}^{(1)}, \boldsymbol{\delta}^{(2)}, \cdots, \boldsymbol{\delta}^{(b)}\right)$$

where for every $i \in [b]$, $\boldsymbol{\delta}^{(i)} = (\delta_i, \delta_i, \cdots, \delta_i) \in \{-1, 1\}^L$ and $\delta_1, \ldots, \delta_b$ are 4-wise independent Rademacher random variables.

▶ **Lemma 10** (Orthogonality)**.** *Let R be a (d, L)-BRHT. Then $RR^\top = \mathbb{I}_d$.*

Proof. Since H_d is orthogonal and D is diagonal with entries in $\{\pm 1\}$, $RR^\top = (H_dD)(H_dD)^\top = H_dDD^\top H_d^\top = H_dH_d^\top = \mathbb{I}_d$. ◀

With this in hand, we are ready to state and prove the key property of BRHT our algorithms will hinge upon.

▶ **Lemma 11** ((d, L)-compression)**.** *Let R be a (d, L)-BRHT. Then, for every $\boldsymbol{\mu} \in \mathbb{R}^d$ and every $t \geq 1$,*

$$\Pr\left[\left\|(R\boldsymbol{\mu})_{[1:tL]}\right\|_2^2 \geq \frac{1}{100} \cdot \frac{tL}{d} \cdot \|\boldsymbol{\mu}\|_2^2\right] \geq \frac{8}{25},$$

where the probability is over the choice of R.

Proof. Let $b := d/L$ and $\rho := \|\boldsymbol{\mu}\|_2$. By Definition 9,

$$R = H_dD.$$

Define

$$Z := \left\|(R\boldsymbol{\mu})_{[1:tL]}\right\|_2^2.$$

Partition

$$\boldsymbol{\mu} = (\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_b), \qquad \boldsymbol{\mu}_i \in \mathbb{R}^L.$$

Using the Kronecker decomposition

$$H_d = H_b \otimes H_L,$$

the r-th block of $R\boldsymbol{\mu}$ satisfies

$$(R\boldsymbol{\mu})_{[(r-1)L+1:rL]} = \sum_{i=1}^{b} (H_b)_{r,i}\delta_i H_L \boldsymbol{\mu}_i.$$

Define

$$Z_r := \left\|(R\boldsymbol{\mu})_{[(r-1)L+1:rL]}\right\|_2^2,$$

so that

$$Z = \sum_{r=1}^{t} Z_r.$$

We first compute $\mathbb{E}[Z]$. Expanding Z_r gives

$$\begin{aligned} Z_r &= \left\| \sum_{i=1}^{b} (H_b)_{r,i}\delta_i H_L \boldsymbol{\mu}_i \right\|_2^2 \\ &= \sum_{i_1,i_2\in[b]} (H_b)_{r,i_1}(H_b)_{r,i_2}\delta_{i_1}\delta_{i_2} \left\langle H_L\boldsymbol{\mu}_{i_1}, H_L\boldsymbol{\mu}_{i_2}\right\rangle. \end{aligned}$$

Since H_L is orthogonal,

$$\langle H_L\boldsymbol{\mu}_{i_1}, H_L\boldsymbol{\mu}_{i_2}\rangle = \langle \boldsymbol{\mu}_{i_1}, \boldsymbol{\mu}_{i_2}\rangle.$$

Therefore,

$$Z_r = \sum_{i=1}^{b} (H_b)_{r,i}^2 \|\boldsymbol{\mu}_i\|_2^2 + \sum_{i_1\neq i_2} (H_b)_{r,i_1}(H_b)_{r,i_2}\delta_{i_1}\delta_{i_2}\langle \boldsymbol{\mu}_{i_1}, \boldsymbol{\mu}_{i_2}\rangle.$$

Since $(H_b)_{r,i}^2 = 1/b$,

$$Z_r = \frac{\rho^2}{b} + \sum_{i_1\neq i_2} (H_b)_{r,i_1}(H_b)_{r,i_2}\delta_{i_1}\delta_{i_2}\langle \boldsymbol{\mu}_{i_1}, \boldsymbol{\mu}_{i_2}\rangle.$$

By pairwise independence and symmetry of the Rademacher variables,

$$\mathbb{E}[\delta_{i_1}\delta_{i_2}] = 0 \qquad (i_1 \neq i_2),$$

and hence

$$\mathbb{E}[Z_r] = \frac{\rho^2}{b}.$$

Summing over $r \in [t]$,

$$\mathbb{E}[Z] = \frac{t\rho^2}{b}.$$

We now bound $\mathbb{E}[Z^2]$. For $r_1, r_2 \in [t]$,

$$\mathbb{E}[Z_{r_1}Z_{r_2}] = \frac{\rho^4}{b^2} + \sum_{\substack{i_1\neq i_2\\ j_1\neq j_2}} (H_b)_{r_1,i_1}(H_b)_{r_1,i_2}(H_b)_{r_2,j_1}(H_b)_{r_2,j_2} \cdot \mathbb{E}[\delta_{i_1}\delta_{i_2}\delta_{j_1}\delta_{j_2}]\langle \boldsymbol{\mu}_{i_1}, \boldsymbol{\mu}_{i_2}\rangle\langle \boldsymbol{\mu}_{j_1}, \boldsymbol{\mu}_{j_2}\rangle.$$

By 4-wise independence and symmetry of the Rademacher variables, only terms in which every δ_i appears with even multiplicity contribute to the expectation. Thus,

$$\mathbb{E}[Z_{r_1}Z_{r_2}] = \frac{\rho^4}{b^2} + 2\sum_{i_1\neq i_2} (H_b)_{r_1,i_1}(H_b)_{r_1,i_2}(H_b)_{r_2,i_1}(H_b)_{r_2,i_2}\langle \boldsymbol{\mu}_{i_1}, \boldsymbol{\mu}_{i_2}\rangle^2.$$

Using

$$(H_b)_{r,i} = \pm\frac{1}{\sqrt{b}}$$

and Cauchy–Schwarz,

$$\begin{aligned}\mathbb{E}[Z_{r_1}Z_{r_2}] &\le \frac{\rho^4}{b^2} + \frac{2}{b^2}\sum_{i_1\neq i_2}\|\boldsymbol{\mu}_{i_1}\|_2^2\|\boldsymbol{\mu}_{i_2}\|_2^2 \\ &\le \frac{3\rho^4}{b^2},\end{aligned}$$

where we used

$$\sum_{i=1}^{b}\|\boldsymbol{\mu}_i\|_2^2 = \rho^2.$$

Summing over $r_1, r_2 \in [t]$ yields

$$\mathbb{E}[Z^2] \le \frac{3t^2\rho^4}{b^2}.$$

Applying the Paley–Zygmund (Lemma 6),

$$\Pr[Z > \theta\mathbb{E}[Z]] \ge (1-\theta)^2\frac{\mathbb{E}[Z]^2}{\mathbb{E}[Z^2]} \ge \frac{(1-\theta)^2}{3}.$$

Choosing $\theta = 1/100$ gives

$$\Pr\left[Z > \frac{t\rho^2}{100b}\right] \ge \frac{8}{25}.$$

Since

$$b = \frac{d}{L},$$

the claim follows. ◀

The compression guarantees established in Lemma 11 are the key property of BRHT used throughout the remainder of the paper. Roughly speaking, this guarantees that, with constant probability, the retained block preserves $\Omega(L/d)$ fraction of the signal energy, allowing the original Gaussian mean testing problem to be compressed while retaining sufficient signal for testing. To conclude, we analyze the amount of randomness required to sample a BRHT.

▶ Remark 12. A (d, L)-BRHT requires at most $4\log(d/L)$ bits of randomness as (d/L) 4-wise Rademacher random variables can be generated using a standard construction involving a degree-3 polynomial over an appropriate field (see, e.g., [13, Corollary 3.34]).

▶ Remark 13 (Computational complexity). For $\boldsymbol{v} \in \mathbb{R}^d$, $H_d\boldsymbol{v}$ can be computed in $O(d\log d)$ time via the Fast Walsh–Hadamard transform. This computation dominates the running time of our protocols.

4 Limited randomness

In this section, we prove Theorem 1, by providing and analyzing an explicit protocol for the problem. This protocol is quite simple: it first uses the shared randomness to jointly sample a BRHT R with suitable parameters; each user then applies R to their samples to obtain an instance of Gaussian mean testing in a lower-dimensional space. Having used all the shared randomness available, they then run the private-coin protocol of Theorem 8 on this lower-dimensional problem.

▶ **Theorem 14** (Theorem 1, restated). *For $\ell \in [d]$ and $s \geq 0$, there exists an s-public coin protocol for distributed Gaussian mean testing under ℓ-bit communication constraint with*

$$O\left(\frac{d}{\ell\varepsilon^2} \cdot \sqrt{\max\left(\frac{d}{2^{\Theta(s)}}, \ell\right)}\right)$$

users, each holding one sample.

Proof. The users use $s/7$ bits of shared randomness to sample a (d, d_s)-BRHT R, where

$$d_s := d/2^{\lfloor s/28 \rfloor}\,.$$

This is possible by Remark 12, as sampling R requires at most $4\log(d/d_s)$ random bits. (We will explain the reason for the factor 7 in $s/7$ momentarily.)

Let $\boldsymbol{\mu} \in \mathbb{R}^d$ be an unknown mean vector and for all $k \in [n]$, $\boldsymbol{X}^{(k)} \sim \mathcal{G}(\boldsymbol{\mu}, \mathbb{I}_d)$ be the sample observed by user k. Define $L := d_s \vee \ell$ and $\tilde{\boldsymbol{\mu}} = (R\boldsymbol{\mu})_{[1:L]}$. Each user applies R to its sample to get $\tilde{\boldsymbol{X}}^{(k)} := (R\boldsymbol{X}^{(k)})_{[1:L]}$, so that $\tilde{\boldsymbol{X}}^{(k)} \sim \mathcal{G}\left(\tilde{\boldsymbol{\mu}}, \mathbb{I}_L\right)$. By Lemma 11, with probability at least $8/25$,

$$\|\tilde{\boldsymbol{\mu}}\|_2^2 \geq \frac{1}{100} \cdot \frac{L}{d} \cdot \|\boldsymbol{\mu}\|_2^2$$

Thus, if $\boldsymbol{\mu} = \mathbf{0}$, $\tilde{\boldsymbol{\mu}} = \mathbf{0}$ and otherwise $\|\boldsymbol{\mu}\|_2 \geq \varepsilon$ and with probability at least $8/25$, $\|\tilde{\boldsymbol{\mu}}\|_2^2 \geq \frac{L\varepsilon^2}{100d}$. The users and referee then use the private-coin protocol of Theorem 8 with $\tilde{\boldsymbol{X}}^{(k)}$ to distinguish between the two cases with

$$O\left(\frac{(L)^{3/2}}{\ell\left(\frac{L}{d}\varepsilon^2\right)}\right) = O\left(\frac{d\sqrt{L}}{\ell\varepsilon^2}\right)$$

users, (almost) proving the theorem. It remains to amplify the success probability.

Thus, with $O\left(\frac{d\sqrt{L}}{\ell\varepsilon^2}\right)$ users, if $\boldsymbol{\mu} = \mathbf{0}$, the referee accepts with probability at least $99/100$ (which is the failure probability from Theorem 8). But when $\|\boldsymbol{\mu}\|_2 \geq \varepsilon$, all we can say is that, by a union bound, the referee rejects with probability at least $1 - (\frac{17}{25} + \frac{8}{25} \cdot \frac{1}{100}) > 3/10$, as now the failure probability comes both from the choice of R and that of Theorem 8. Repeating the protocol 7 independent times, each time with new R, and accepting only if all repetitions output accept reduces the error probability below $1/10$. This increases the number of users only by a constant factor. Since $L = \max(d/2^{\lfloor s/28 \rfloor}, \ell)$, the theorem follows. ◀

With $s = O(\log(d/\ell))$, Theorem 1 yields sample complexity $O(d/\sqrt{\ell}\varepsilon^2)$, which matches the public-coin sample complexity in [3] when users must share an infinite amount of randomness.

▶ **Corollary 15** (Randomness-efficient optimal public-coin protocol). *There exists a protocol for distributed Gaussian mean testing under ℓ-bit communication constraints with $O(d/(\sqrt{\ell}\varepsilon^2))$ users, each holding one sample, and sharing $O(\log(d/\ell))$ bits of randomness.*

5 Heterogeneous samples

In this section, we prove Theorem 2. The core idea, which we refer to as *Signal Aggregation*, is to generalize the "naive strategy" previously discussed (see Footnote 2) where all users have the same number m of samples and aggregate them into a single "aggregated sample":

$$\boldsymbol{X}^{(k,1)}, \boldsymbol{X}^{(k,2)}, \cdots, \boldsymbol{X}^{(k,m_k)} \sim \mathcal{G}(\boldsymbol{\mu}, \mathbb{I}_d) \quad \rightsquigarrow \quad \tilde{\boldsymbol{X}}^{(k)} := \frac{1}{\sqrt{m}} \sum_{i=1}^{m} \boldsymbol{X}^{(k,i)} \sim \mathcal{G}(\sqrt{m}\boldsymbol{\mu}, \mathbb{I}_d)$$

Doing so effectively amplifies the signal, which means that one can then use a protocol designed for *one* sample per user, but with better distance parameter $\varepsilon' := \sqrt{m}\varepsilon$.

In the heterogeneous sample case, one can attempt to do the same thing, but now (since user k has m_k samples, while user k' has a possible different number of samples $m_{k'}$) the resulting aggregated samples no longer have the same distribution in the no-case (when $\boldsymbol{\mu} \neq \mathbf{0}$). Dealing with the fact that samples are no longer i.i.d. is the key technical difficulty in proving Theorem 2.

▶ **Theorem 16** (Theorem 2, restated). *For $\ell \in [r, rd]$, $s = \Omega(\log(d/\ell))$, and $\boldsymbol{m} = (m_1, \ldots, m_n) \in \mathbb{Z}_+^n$ satisfying $m_k \in [r, r\varepsilon^{-2}]$ for all $k \in [n]$, there exists a protocol (Algorithm 2) for distributed Gaussian mean testing under ℓ-bit communication constraint with n users provided that*

$$\frac{\sum_{1 \leq k_1 \neq k_2 \leq n} \sqrt{m_{k_1} m_{k_2}}}{n} \geq C \cdot \frac{d}{\sqrt{\ell}\varepsilon^2}$$

where $C, r > 0$ are absolute constants.

Proof. We first describe the protocol in Algorithm 2 and then analyze its correctness.

Algorithm 2 ℓ-bit, $\boldsymbol{m}$-sample distributed Gaussian mean testing.

User k, for every $k \in [n]$:

Require: $\forall j \in [m_k]$, $\boldsymbol{X}^{(k,j)} \sim \mathcal{G}(\boldsymbol{\mu}, \mathbb{I}_d)$; communication budget $\ell \in [7, 7d]$; $\forall t \in [7]$, R_t: $(d, 7d/\ell)$-BRHT

for $t \in [7]$ **do**
  Samples $\boldsymbol{X}^{(k,t)} \leftarrow \frac{1}{\sqrt{\lfloor m_k/7 \rfloor}} \sum_{j=(t-1)\lfloor m_k/7 \rfloor + 1}^{t\lfloor m_k/7 \rfloor} \boldsymbol{X}^{(k,j)}$
  $\tilde{\boldsymbol{X}}^{(k,t)} \leftarrow R_t \boldsymbol{X}^{(k,t)}$
  $\boldsymbol{y}^{(k,t)} \leftarrow \mathbf{1}\left(\tilde{\boldsymbol{X}}^{(k,t)}_{[1:\lfloor \ell/7 \rfloor]} > 0\right)$
Send $\boldsymbol{Y}^{(k)} = (\boldsymbol{y}^{(k,1)}, \ldots, \boldsymbol{y}^{(k,7)})$

Referee:

Require: Messages $\forall k \in [n]$, $\boldsymbol{Y}^{(k)} \in \{0,1\}^\ell$, threshold ε

$N \leftarrow \sum_{k_1 \neq k_2} \sqrt{\lfloor m_{k_1}/7 \rfloor \lfloor m_{k_2}/7 \rfloor}$
for $t \in [7]$ **do**
  Run Algorithm 1 on samples $\boldsymbol{y}^{(1,t)}, \ldots, \boldsymbol{y}^{(n,t)}$ with
    threshold $\varepsilon' = \frac{\varepsilon}{80}\sqrt{\frac{\ell N}{7dn(n-1)}}$ ▷ $\tau \leftarrow (\varepsilon')^2/2$
  if output is reject **then**
    return reject
return accept

The protocol performs 7 independent repetitions for probability amplification. We analyze a single repetition and omit the superscript (t) throughout. For simplicity, we also ignore flooring operations, as they affect the bounds only up to constant factors. Fix one repetition, and let R denote the corresponding $(d, 7d/\ell)$-BRHT. Define

$$\tilde{\boldsymbol{\mu}} := (R\boldsymbol{\mu})_{[1:\ell/7]}.$$

For every user k,

$$\boldsymbol{X}^{(k)} = \frac{1}{\sqrt{m_k/7}} \sum_{j=1}^{m_k/7} \boldsymbol{X}^{(k,j)} \sim \mathcal{G}\left(\sqrt{m_k/7}\,\boldsymbol{\mu}, \mathbb{I}_d\right).$$

Since R is orthogonal,

$$\tilde{\boldsymbol{X}}^{(k)} := (R\boldsymbol{X}^{(k)})_{[1:\ell/7]} \sim \mathcal{G}\left(\sqrt{m_k/7}\,\tilde{\boldsymbol{\mu}}, \mathbb{I}_{\ell/7}\right).$$

Define

$$\boldsymbol{y}^{(k)} = \mathbf{1}(\tilde{\boldsymbol{X}}^{(k)} > 0) \in \{0,1\}^{\ell/7}.$$

The vectors $\boldsymbol{y}^{(1)}, \ldots, \boldsymbol{y}^{(n)}$ are independent, though generally not identically distributed. For every coordinate $i \in [\ell/7]$, define

$$p_i^{(k)} := \Pr[y_i^{(k)} = 1], \qquad \tilde{p}_i^{(k)} := p_i^{(k)} - \frac{1}{2}.$$

The referee computes

$$T_i := \sum_{k_1 \neq k_2} (y_i^{(k_1)} - 1/2)(y_i^{(k_2)} - 1/2).$$

Since for all $k_1 \neq k_2$, $\tilde{p}_i^{(k_1)} \tilde{p}_i^{(k_2)} \geq 0$, applying Lemma 20 coordinate-wise yields

$$\mathbb{E}[T_i] = \sum_{k_1 \neq k_2} \tilde{p}_i^{(k_1)} \tilde{p}_i^{(k_2)},$$

and

$$\mathrm{Var}(T_i) \leq \frac{n(n-1)}{8} + (n-2)\mathbb{E}[T_i].$$

Define

$$T := \frac{1}{n(n-1)} \sum_{i=1}^{\ell/7} T_i.$$

Then

$$\begin{aligned}
\mathbb{E}[T] &= \frac{1}{n(n-1)} \sum_{i=1}^{\ell/7} \sum_{k_1 \neq k_2} \tilde{p}_i^{(k_1)} \tilde{p}_i^{(k_2)}, \\
\mathrm{Var}(T) &= \frac{1}{n^2(n-1)^2} \sum_{i=1}^{\ell/7} \mathrm{Var}(T_i) \\
&\leq \frac{\ell}{56\, n(n-1)} + \frac{(n-2)\mathbb{E}[T]}{n(n-1)}.
\end{aligned}$$

We now analyze the two cases:

Case 1: $\mu = 0$. In this case, $p_i^{(k)} = 1/2$ for all i, k, and hence $\tilde{p}_i^{(k)} = 0$. Therefore,

$$\mathbb{E}[T] = 0.$$

Applying Chebyshev's inequality,

$$\Pr[T \geq \tau] \leq \frac{\mathrm{Var}(T)}{\tau^2} \leq \frac{\ell}{56\, n(n-1)\tau^2}.$$

Using the threshold

$$\tau = \frac{1}{2} \cdot \frac{1}{6400} \cdot \frac{N}{n(n-1)} \cdot \frac{\ell\varepsilon^2}{7d},$$

we obtain

$$\Pr[T \geq \tau] = O\left(\frac{d^2 n(n-1)}{N^2 \ell \varepsilon^4}\right) < \frac{1}{100},$$

whenever

$$\frac{N}{n} > C_1 \cdot \frac{d}{\sqrt{\ell}\varepsilon^2}$$

for a sufficiently large absolute constant $C_1 > 0$.

Case 2: $\|\mu\|_2 \geq \varepsilon$. Using standard properties of Erfc,

$$|\tilde{p}_i^{(k)}| \geq \frac{1}{8}\sqrt{\frac{m_k}{7}}\,|\tilde{\mu}_i|,$$

Therefore,

$$\begin{aligned}
\mathbb{E}[T] &= \frac{1}{n(n-1)} \sum_{i=1}^{\ell/7} \sum_{k_1 \neq k_2} \tilde{p}_i^{(k_1)} \tilde{p}_i^{(k_2)} \\
&\geq \frac{1}{64\, n(n-1)} \sum_{i=1}^{\ell/7} \sum_{k_1 \neq k_2} \sqrt{\frac{m_{k_1}}{7}}\sqrt{\frac{m_{k_2}}{7}}\,\tilde{\mu}_i^2 \\
&= \frac{N}{64\, n(n-1)} \|\tilde{\boldsymbol{\mu}}\|_2^2.
\end{aligned}$$

By Lemma 11, with probability at least $8/25$,

$$\|\tilde{\boldsymbol{\mu}}\|_2^2 \geq \frac{1}{100} \cdot \frac{\ell}{7d} \cdot \varepsilon^2.$$

Hence, with probability at least $8/25$,

$$\mathbb{E}[T] \geq \frac{1}{6400} \cdot \frac{N}{n(n-1)} \cdot \frac{\ell\varepsilon^2}{7d}.$$

Conditioned on this event, applying Chebyshev's inequality,

$$\begin{aligned}
\Pr[T \leq \tau] &= \Pr\left(\mathbb{E}[T] - T \geq \frac{\mathbb{E}[T]}{2}\right) \\
&\leq \frac{4\,\mathrm{Var}(T)}{\mathbb{E}[T]^2} \\
&= O\left(\frac{d^2 n^2}{N^2 \ell \varepsilon^4} + \frac{nd}{N\ell\varepsilon^2}\right).
\end{aligned}$$

Thus,

$$\Pr[T \le \tau] < \frac{1}{100},$$

provided

$$\frac{N}{n} > C_2 \cdot \frac{d}{\sqrt{\ell}\varepsilon^2}$$

for a sufficiently large absolute constant $C_2 > 0$.

Therefore, a single repetition accepts with probability at least 99/100, if $\|\boldsymbol{\mu}\|_2 = 0$ and rejects with probability at least $1 - \left(\frac{17}{25} + \frac{8}{25} \cdot \frac{1}{100}\right) > \frac{3}{10}$, if $\|\boldsymbol{\mu}\|_2 \ge \varepsilon$. Repeating independently 7 times and accepting only if all repetitions output accept reduces the error probability below 1/10. Finally, by Remark 12, the 7 independent BRHTs require only $O(\log(d/\ell))$ shared random bits. ◀

▶ Remark 17. Note that for a fixed sampling budget $m = \sum_{k\in[n]} m_k$, $\sum_{k_1\neq k_2\in[n]} \sqrt{m_{k_1}}\sqrt{m_{k_2}}$ is maximized when $m_{k_1} = m_{k_2} = m/n$ for all $k_1, k_2 \in [n]$. Then, we need $m = O(d/\sqrt{\ell}\varepsilon^2)$.

6 Heterogeneous communication

Having addressed limited (public) randomness and heterogeneous sample sizes in the previous two sections, we now turn to the last generalization considered in this work, heterogeneous communication budgets. Specifically, we will establish Theorem 3, restated below:

▶ **Theorem 18** (Theorem 3, restated). *For $\boldsymbol{\ell} = (\ell_1, \dots, \ell_n) \in \mathbb{Z}_+^n$ and $s = \Omega(\log(d/\|\boldsymbol{\ell}\|_\infty))$, there exists a protocol for distributed Gaussian mean testing under $\boldsymbol{\ell}$-bit communication constraint with n users, where user k has one sample and can send ℓ_k bits to the referee, provided that*

$$\frac{\|\boldsymbol{\ell}\|_1}{\sqrt{\|\boldsymbol{\ell}\|_\infty}} \ge C \cdot \frac{d}{\varepsilon^2}$$

where $C > 0$ is an absolute constant.

Proof. In view of the previous protocols, the idea is relatively straightforward: the users use $s/7$ bits of shared randomness to sample a (d, d_s)-BRHT R, for

$$d_s := d/2^{\lfloor s/28 \rfloor}.$$

Let $L := d_s \vee \max_{1\le k\le n} \ell_k = \Theta(\max_{1\le k\le n} \ell_k)$ (the last equality by our assumption on s) and $\tilde{\boldsymbol{\mu}} = (R\boldsymbol{\mu})_{[1:L]}$. As in the proof of Theorem 1, each user applies R to its sample to get $\tilde{\boldsymbol{X}}^{(k)} = (R\boldsymbol{X}^{(k)})_{[1:L]}$, so that $\tilde{\boldsymbol{X}}^{(k)} \sim \mathcal{G}(\tilde{\boldsymbol{\mu}}, \mathbb{I}_L)$. Using Lemma 11, with probability at least 8/25,

$$\|\tilde{\boldsymbol{\mu}}\|_2^2 \ge \frac{1}{100} \cdot \frac{L}{d} \cdot \|\boldsymbol{\mu}\|_2^2$$

so that in one case $\tilde{\boldsymbol{\mu}} = \mathbf{0}$ and in the other $\|\tilde{\boldsymbol{\mu}}\|_2^2 = \Omega(\frac{L\varepsilon^2}{d})$ with constant probability. This is where we depart from Theorem 1. The users and referee will now use the same idea of distributed simulation, but in a slightly different fashion: recall that all parameters are known to all parties, and that by choice of L we have $\ell_k \le L$ for all k. Then, user 1 sends the first ℓ_1 bits of their resulting L-dimensional sample; user 2 sends the following ℓ_2 bits,

wrapping around (i.e., the bits $\ell_1+1, \ell_1+2, \ldots, \ell_1+\ell_2 \bmod L$), and so on. Overall, the $\ell_1+\cdots+\ell_n = \|\boldsymbol{\ell}\|_1$ bits sent allow the referee to reconstruct exactly $n' := \lfloor \|\boldsymbol{\ell}\|_1/L \rfloor$ binary samples $\boldsymbol{Y}_1, \ldots, \boldsymbol{Y}_{n'}$ as in the proof of Theorem 8, which leads to a successful protocol whenever

$$n' \geq C \cdot \frac{\sqrt{d_s}}{\varepsilon^2(d_s/d)}$$

i.e.,

$$\frac{\|\boldsymbol{\ell}\|_1}{\|\boldsymbol{\ell}\|_\infty} \geq C \cdot \frac{d}{\varepsilon^2\sqrt{\|\boldsymbol{\ell}\|_\infty}}$$

from our settings of L and d_s (after, as before, including the probability amplification over 7 independent repetitions). ◀

7 Putting it all together: Theorem 4

With protocols for the three settings, we conclude by providing a protocol for the general setting where shared randomness, sample counts and communication budgets are all free parameters. The protocol is relatively straightforward as it combines the protocols for the three settings.

▶ **Theorem 19** (Theorem 4, restated). *For $s \geq 0$, $\boldsymbol{m} = (m_1, \ldots, m_n) \in \mathbb{Z}_+^n$, and $\boldsymbol{\ell} = (\ell_1, \ldots, \ell_n) \in \mathbb{Z}_+^n$, there exists a protocol for distributed Gaussian mean testing with n users sharing s bits of public randomness, where user k has m_k samples and can send ℓ_k bits to the referee, provided that there exists a partition $\mathcal{P} = \{P_1, \ldots, P_K\}$ of the n users such that*

$$\frac{\sum_{j_1 \neq j_2 \in [K]} \sqrt{\min_{i_1 \in P_{j_1}}(m_{i_1}) \cdot \min_{i_2 \in P_{j_2}}(m_{i_2})}}{K} \geq C \cdot \frac{d}{\varepsilon^2\sqrt{\max\left(\frac{d}{2^{\Theta(s)}}, \|\boldsymbol{\ell}\|_\infty\right)}}$$

and, for every $P \in \mathcal{P}$, $\sum_{i \in P} \ell_i \geq r \cdot \max\left(\frac{d}{2^{\Theta(s)}}, \|\boldsymbol{\ell}\|_\infty\right)$ and $\min_{i \in P}(m_i) \in [r, r\varepsilon^{-2}]$; where $C, r > 0$ are absolute constants.

Proof. Let $\mathcal{P} = \{P_1, \ldots, P_K\}$ be a partition of users (for all j_1, j_2 $P_{j_1} \cap P_{j_2} = \emptyset$, $\bigcup_j P_j = [n]$) such that for all j, $\sum_{i \in P_j} \ell_i \geq 7 \cdot \max\left(\frac{d}{2^{\lfloor s/28 \rfloor}}, \|\boldsymbol{\ell}\|_\infty\right)$. Define

$$L := \max\left(\frac{d}{2^{\lfloor s/28 \rfloor}}, \|\boldsymbol{\ell}\|_\infty\right)$$

Using the distributed simulation idea in Theorem 18, users in each $P_j \in \mathcal{P}$ can simulate *one* L-dimensional binary sample. But, users in P_j hold $(m_i)_{i \in P_j}$ samples. Thus, the setting can be reduced to $K = |\mathcal{P}|$ users holding $(\min_{i \in P_1}(m_i), \ldots, \min_{i \in P_K}(m_i))$ samples under L-bit communication constraints, for which we invoke the protocol of Algorithm 2. ◀

A Deferred Proofs

▶ **Lemma 20.** *Let $Z_1, \dots, Z_n$ be independent random variables such that $Z_k \in \{-1/2, 1/2\}$ and $\mathbb{E}[Z_k] = p_k$. Assume furthermore $p_{k_1} p_{k_2} \geq 0$ for all $k_1 \neq k_2$ and define*

$$T := \sum_{k_1 \neq k_2} Z_{k_1} Z_{k_2}.$$

Then the following holds:

1. $\mathbb{E}[T] = \sum_{k_1 \neq k_2} p_{k_1} p_{k_2}$
2. $\mathrm{Var}(T) \leq \frac{n(n-1)}{8} + (n-2)\mathbb{E}[T]$

Proof. Define

$$S := \sum_{k \in [n]} Z_k.$$

Since $Z_k^2 = 1/4$, we have

$$T = \sum_{k_1 \neq k_2} Z_{k_1} Z_{k_2} = \left(\sum_{k \in [n]} Z_k \right)^2 - \sum_{k \in [n]} Z_k^2 = S^2 - \frac{n}{4}.$$

1. $\mathbb{E}[\boldsymbol{T}]$**.** Using independence,

$$\mathbb{E}[S] = \sum_{k \in [n]} p_k$$

and

$$\mathrm{Var}(S) = \sum_{k \in [n]} \left(\frac{1}{4} - p_k^2 \right).$$

Hence,

$$\begin{aligned} \mathbb{E}[S^2] &= \mathrm{Var}(S) + \mathbb{E}[S]^2 \\ &= \sum_{k \in [n]} \left(\frac{1}{4} - p_k^2 \right) + \left(\sum_{k \in [n]} p_k \right)^2 \\ &= \frac{n}{4} + \sum_{k_1 \neq k_2} p_{k_1} p_{k_2}. \end{aligned}$$

Therefore,

$$\mathbb{E}[T] = \mathbb{E}[S^2] - \frac{n}{4} = \sum_{k_1 \neq k_2} p_{k_1} p_{k_2}.$$

2. $\mathbf{Var}[\boldsymbol{T}]$**.** Since $T = S^2 - n/4$,

$$\mathrm{Var}(T) = \mathrm{Var}(S^2) = \mathbb{E}[S^4] - \mathbb{E}[S^2]^2.$$

Expanding S^4 and using independence together with

$$\mathbb{E}[Z_k] = p_k, \qquad Z_k^2 = \frac{1}{4}, \qquad \mathbb{E}[Z_k^3] = \frac{p_k}{4}, \qquad Z_k^4 = \frac{1}{16},$$

we obtain

$$\begin{aligned} \mathbb{E}[S^4] = \frac{n}{16} &+ \frac{3n(n-1)}{16} \\ &+ \sum_{k_1 \neq k_2} p_{k_1} p_{k_2} + \frac{3(n-2)}{2} \sum_{k_1 \neq k_2} p_{k_1} p_{k_2} \\ &+ \sum_{k_1 \neq k_2 \neq k_3 \neq k_4} p_{k_1} p_{k_2} p_{k_3} p_{k_4}. \end{aligned}$$

On the other hand,

$$\mathbb{E}[S^2]^2 = \frac{n^2}{16} + \frac{n}{2} \sum_{k_1 \neq k_2} p_{k_1} p_{k_2} + \left(\sum_{k_1 \neq k_2} p_{k_1} p_{k_2} \right)^2.$$

Subtracting,

$$\mathrm{Var}(T) = \mathbb{E}[S^4] - \mathbb{E}[S^2]^2 = \frac{n(n-1)}{8} + (n-2)\sum_{k_1 \neq k_2} p_{k_1} p_{k_2} - 4\sum_{k_1 \neq k_2 \neq k_3} p_{k_1}^2 p_{k_2} p_{k_3} - 2\sum_{k_1 \neq k_2} p_{k_1}^2 p_{k_2}^2.$$

Since $p_{k_1} p_{k_2} \geq 0$ for all $k_1 \neq k_2$ and

$$\mathbb{E}[T] = \sum_{k_1 \neq k_2} p_{k_1} p_{k_2},$$

the result follows. ◀

▶ **Theorem 21.** *Algorithm 1 achieves sample complexity $\Theta(\sqrt{d}/\varepsilon^2)$ for testing whether $\boldsymbol{p} = \boldsymbol{u}_d$ versus $\|\boldsymbol{p} - \boldsymbol{u}_d\|_2 \geq \varepsilon$ for a d-dimensional binary product distribution with mean vector $\boldsymbol{p}$.*

Proof. Let $\tilde{\boldsymbol{p}} := \boldsymbol{p} - \boldsymbol{u}_d$. For each coordinate $i \in [d]$, define

$$T_i := \sum_{k_1 \neq k_2 \in [n]} \left(X_i^{(k_1)} - \frac{1}{2}\right)\left(X_i^{(k_2)} - \frac{1}{2}\right),$$

and

$$T := \frac{1}{n(n-1)} \sum_{i=1}^{d} T_i.$$

Fix $i \in [d]$, and define

$$Z_k := X_i^{(k)} - \frac{1}{2}.$$

Then $Z_1, \ldots, Z_n$ are independent random variables taking values in $\{-1/2, 1/2\}$, with $\mathbb{E}[Z_k] = \tilde{p}_i$. Applying Lemma 20,

$$\mathbb{E}[T_i] = n(n-1)\tilde{p}_i^2$$

and

$$\mathrm{Var}(T_i) \leq \frac{n(n-1)}{8} + n(n-1)(n-2)\tilde{p}_i^2.$$

Summing over coordinates,

$$\mathbb{E}[T] = \|\tilde{\boldsymbol{p}}\|_2^2 = \|\boldsymbol{p} - \boldsymbol{u}_d\|_2^2,$$

and

$$\begin{aligned}\mathrm{Var}(T) &= \frac{1}{n^2(n-1)^2} \sum_{i=1}^{d} \mathrm{Var}(T_i) \\ &\leq \frac{d}{8n(n-1)} + \frac{n-2}{n(n-1)} \|\tilde{\boldsymbol{p}}\|_2^2.\end{aligned}$$

We now analyze the two cases:

Case 1: $p = u_d$. In this case, $\mathbb{E}[T] = 0$ and therefore

$$\mathrm{Var}(T) \leq \frac{d}{8n(n-1)}.$$

By Chebyshev's inequality,

$$\Pr\left(T > \frac{\varepsilon^2}{2}\right) \leq \frac{4\,\mathrm{Var}(T)}{\varepsilon^4} \leq O\left(\frac{d}{n^2\varepsilon^4}\right).$$

Case 2: $\|p - u_d\|_2 \geq \varepsilon$. In this case,

$$\mathbb{E}[T] = \|\boldsymbol{p} - \boldsymbol{u}_d\|_2^2 \geq \varepsilon^2.$$

Again by Chebyshev's inequality,

$$\begin{aligned}\Pr\left(T \leq \frac{\varepsilon^2}{2}\right) &= \Pr\left(\mathbb{E}[T] - T \geq \frac{\mathbb{E}[T]}{2}\right)\\ &\leq \frac{4\,\mathrm{Var}(T)}{\mathbb{E}[T]^2}\\ &\leq O\left(\frac{d}{n^2\varepsilon^4} + \frac{1}{n\varepsilon^2}\right).\end{aligned}$$

Thus, choosing

$$n > C \cdot (\sqrt{d}/\varepsilon^2)$$

for some absolute constant $C > 0$, makes both error probabilities smaller than $1/100$. ◀

Hard-To-Sample Distributions from Robust Extractors

Abstract

We provide a unified method for constructing explicit distributions which are difficult for restricted models of computation to generate. Our constructions are based on a new notion of *robust extractors*, which are extractors that remain sound even when a small number of points violate the min-entropy constraint. Using such objects, we show that for a broad range of sampling models (e.g., low-depth circuits, small-space sources, etc.), every output of the model has distance $1 - o(1)$ from our target distribution, qualitatively recovering essentially all previously known hardness results. Our work extends that of Viola (SICOMP '14), who developed an earlier unified framework based on traditional extractors to rule out sampling with very small error.

As a further application of our technique, we leverage a recent extractor construction of Chattopadhyay, Goodman, and Gurumukhani (ITCS '24) to present the first explicit distribution with distance $1 - o(1)$ from the output of any low-degree $\mathbb{F}_2$-polynomial source. We note that a similar bound was obtained concurrently and independently by Khodabandeh and Shinkar (ECCC '26). We also describe a potential avenue toward proving a similar hardness result for $\mathsf{AC}^0[\oplus]$ circuits.

In particular, we are grateful for the suggestion of and discussion about "smooth extractors" as mentioned in Subsection 3.2. We also thank anonymous reviewers for their useful feedback.

1 Introduction

The quest to prove unconditional hardness results for restricted models of computation (e.g., low-depth circuits) is one of the major programs of complexity theory. This program saw a number of major successes in the 1980s when researchers exposed the limitations of AC^0 and $\mathsf{AC}^0[p]$ circuits with simple and explicit hard-to-compute functions [19, 1, 50, 24, 25, 41, 37].

Unfortunately, the current state of affairs on this front remains rather humble: even four decades later we still cannot rule out the preposterous claim that all of PSPACE can be computed by polynomially-sized AC^0 circuits with mod 6 gates.

It would be disingenuous, however, to suggest that no modern progress has occurred. Even just the past few years have seen impressive developments in understanding the limitations of these models through the lens of pseudorandom generators [16, 17, 27, 32, 33] (see also the survey [26]), extractors [13, 20, 3], and quantum analogs [36, 5, 28, 18, 23].[1]

One particularly exciting line of inquiry is understanding the capabilities of these weak models to generate specific distributions (when taking random bits as input). The landscape here is dramatically different from the traditional task of computing specific functions. For example, if a circuit can compute a function $f\colon \{0,1\}^n \to \{0,1\}$, then it can output the uniform distribution over $(x, f(x))$ by simply computing f on each random input. The converse, however, is not true. While PARITY has long been known to be difficult for AC^0 circuits to compute [19, 1, 50, 24, 25, 41, 37], one can produce the uniform distribution over input-output pairs by simply mapping the uniformly random bits $(x_1, x_2, \ldots, x_{n+1})$ to $(x_1 \oplus x_2, x_2 \oplus x_3, \ldots, x_n \oplus x_{n+1}, x_{n+1} \oplus x_1)$ [6, 11].

Even still, for many common models including small AC^0 circuits [35, 8], small-space sources [14], and communication protocols [4, 21, 14, 52], researchers have discovered explicit distributions which have total variation distance $1 - o(1)$ from any distribution produced by the model. In comparison to our knowledge of computation, the glaring shortcoming in our understanding of sampling is that we do not know of any explicit distribution which cannot be (approximately) produced by polynomially-sized AC^0 circuits with mod p gates for any prime p.

Beyond its inherent intrigue, the complexity of distributions has intimate connections with data structure lower bounds [44, 35, 8, 48, 14, 49, 52, 29, 2], quantum supremacy [10, 29, 22], explicit codes [40], and learning theory [30]. Moreover, the field has had a fruitful relationship with the study of *extractors* [42, 45, 15, 46, 7, 39], which are objects that convert particular sources of randomness into approximately uniform ones.

This work further develops the latter connection by introducing a general paradigm based on *robust extractors* to prove sampling lower bounds. Intuitively, one can view robust extractors as extractors which remain sound even when a small number of points violate the min-entropy condition. There are several ways to formalize this notion, and we defer our exact definition and discussion of alternatives to Subsection 3.2. For now, we will say a robust extractor $\mathsf{rExt}\colon \{0,1\}^n \to \{0,1\}^m$ for a class of distributions $\mathcal{X}$ satisfies the following two conditions:

1. (Extractor Property) For every source $\mathbf{X} \in \mathcal{X}$ with sufficient min-entropy, the output of rExt on $\mathbf{X}$ is close in total variation (TV) distance to the uniform distribution over $\{0,1\}^m$, and
2. (Robustness Property) For every source $\mathbf{X} \in \mathcal{X}$, the probability that $\mathbf{x} \sim \mathbf{X}$ lands in the set of $\mathbf{X}$'s low probability points and $\mathsf{rExt}(\mathbf{x}) = 0^m$ is not much more than 2^{-m}.

With these objects in hand, we can generically prove strong sampling lower bounds. This result further advances a similar approach based on traditional extractors [46], which we discuss in greater detail in Section 2. Below, $\mathbf{U}^n$ denotes the uniform distribution over $\{0,1\}^n$, and for a function $f\colon \{0,1\}^n \to \{0,1\}^m$, $f(\mathbf{U}^n)$ denotes the output distribution of f with n uniformly random bits as input.

[1] This is only a minute fraction of contemporary work, and we encourage the interested reader to consult references within those cited.

▶ **Theorem 1** (Informal version of Theorem 8). *Let $\mathcal{X}$ be a class of distributions over $\{0,1\}^{t(n+1)}$, and let $\mathcal{Y}$ be the class of distributions over $\{0,1\}^n$ obtained from "low complexity" functions of $\mathcal{X}$. Suppose $\mathsf{rExt}\colon \{0,1\}^n \to \{0,1\}^m$ is a sufficiently good robust extractor for $\mathcal{Y}$, and define the function $f\colon \{0,1\}^n \to \{0,1\}$ by $f(x) = \mathbf{1}(\mathsf{rExt}(x) = 0^m)$. If we consider the distribution*

$$\mathbf{D} = (\mathbf{U}_1, \mathbf{U}_2, \dots, \mathbf{U}_t, f(\mathbf{U}_1), f(\mathbf{U}_2), \dots, f(\mathbf{U}_t)),$$

where $\mathbf{U}_1, \dots, \mathbf{U}_t$ are independent copies of $\mathbf{U}^n$, then every source $\mathbf{X} \in \mathcal{X}$ has TV distance

$$\|\mathbf{X} - \mathbf{D}\|_{\mathsf{TV}} \geq 1 - o_{t,n}(1),$$

where $o_{t,n}(1) \to 0$ as $t, n \to \infty$.

Moreover, if $\widetilde{\mathsf{rExt}}\colon \{0,1\}^n \to \{0,1\}$ is a sufficiently good robust extractor (in a different parameter regime) for $\mathcal{Y}$, then $\left\|\mathbf{X} - (\mathbf{U}^n, \widetilde{\mathsf{rExt}}(\mathbf{U}^n))\right\|_{\mathsf{TV}} \geq \frac{1}{4} - o_n(1)$.

▶ Remark 2. Robust extractors are the motivating object behind our approach, but actually a weaker one-sided notion in place of the typical extractor guarantee (1) suffices for our purposes. In particular, Theorem 1 holds as long as rExt on the uniform distribution assigns decent probability to 0^m. The details can be found in Section 2.

We highlight that the "moreover" part of Theorem 1 can be viewed as a stronger type of lower bound than those for approximate computation. If, for example, the functions $f, g\colon \{0,1\}^n \to \{0,1\}$ agree on a $(1-\delta)$-fraction of their inputs, then it is easy to generate the uniform distribution over $(\mathbf{U}^n, g(\mathbf{U}^n))$ to TV distance at most δ by simply computing f on each random input.

Using Theorem 1, we can recover unconditional hardness results for sampling in essentially every model where they are currently known (albeit with weaker decay rates). We are also able to provide the first explicit[2] distribution which has distance $1 - o(1)$ from the output of any low-degree $\mathbb{F}_2$-polynomial source, making progress toward a similar result for $\mathsf{AC}^0[\oplus]$ circuits.[3] Previous arguments [46, 13] only forbade distance $2^{-\Omega(n)}$.

▶ **Theorem 3** (Informal instantiations of Theorem 1). *Let $\mathcal{X}$ be one of the following classes of sources over $\{0,1\}^N$:*

- *low-degree $\mathbb{F}_2$-polynomial,*
- *local (NC^0),*
- *circuit (AC^0) ,*
- *communication,*
- *small-space,*
- *Turing machine.*

Then every source $\mathbf{X} \in \mathcal{X}$ satisfies

$$\|\mathbf{X} - \mathbf{D}\|_{\mathsf{TV}} \geq 1 - o(1),$$

where $\mathbf{D}$ is defined by taking many independent copies of $(\mathbf{U}^n, \mathbf{1}(\mathsf{rExt}(\mathbf{U}^n) = 0^m))$ for an explicit robust extractor $\mathsf{rExt}\colon \{0,1\}^n \to \{0,1\}^m$ (depending on the choice of $\mathcal{X}$).

[2] One can essentially use a standard counting argument to show such a distribution exists; see the appendix in the full version.

[3] Recall these are AC^0 circuits with mod 2 gates.

Moreover, there exists an explicit robust extractor $\widetilde{\mathsf{rExt}}\colon \{0,1\}^{N-1} \to \{0,1\}$ *(in a different parameter regime) such that every source* $\mathbf{X} \in \mathcal{X}$ *satisfies*

$$\left\|\mathbf{X} - (\mathbf{U}^{N-1}, \widetilde{\mathsf{rExt}}(\mathbf{U}^{N-1}))\right\|_{\mathsf{TV}} \geq \frac{1}{4} - o(1).$$

We emphasize that bounds of this form were already known (with better quantitative behavior) for local and circuit [35, 8], communication [4, 21, 14, 52], small-space [14], and Turing-machine sources [45, 14]. Our novel contribution is obtaining these bounds in a *unified* way, as well as providing strong bounds for low-degree $\mathbb{F}_2$-polynomial sources.

Concurrent Work

In independent and concurrent work, Khodabandeh and Shinkar also investigate the complexity of sampling with low-degree $\mathbb{F}_2$-polynomials [31]. Using very different techniques from our own, they prove that the output of any such polynomial sampler has TV distance $1 - o(1)$ from the $(1/3)$-biased product distribution. As in the present work, the $o(1)$ term has suboptimal decay, but in the case of degrees 1, 2, and 3, they prove it can be taken to be $\exp(-\Omega(N))$, $\exp(-\Omega(\log(N)/\log\log(N)))$, and $\exp(-\Omega(\sqrt{\log\log(N)}))$, respectively, which is stronger than we are able to obtain via our robust extractor framework. (Note, however, that an extractor-based approach can match their bound for degree-1 polynomials – see Section 5.)

Paper Organization

We state and prove Theorem 8, the precise version of Theorem 1, in Section 2, along with additional background and context. We then review some preliminary material in Section 3 before instantiating Theorem 8 in Section 4 to obtain Theorem 3 for polynomial sources. We address the other classes (local, circuit, communication, small-space, and Turing-machine sources) in the full version. We conclude with some open problems in Section 5. Supplementary material on non-explicit constructions can be found in the appendix of the full version.

2 Background and Main Result

In this section, we state and prove our main result, Theorem 8. Before doing so, it will be instructive to review existing arguments and their limitations to develop intuition for our approach. For concreteness, we will focus our discussion on distributions generated by low-degree $\mathbb{F}_2$-polynomials, but essentially all of the analysis holds more generally. The meaning of any unfamiliar terminology or notation in this section can be found in Section 3.

Let $P\colon \mathbb{F}_2^r \to \mathbb{F}_2^n$ be a polynomial map defined by n arbitrary degree-d polynomials $\{p_i\colon \mathbb{F}_2^r \to \mathbb{F}_2\}_{i=1}^n$ acting on the same r input bits, where we view r as some arbitrarily large integer. Our goal is to construct an explicit distribution $\mathbf{D}$ over $\{0,1\}^n$ such that regardless of how the p_i's are defined, the output distribution of P on r uniformly random bits, denoted $P(\mathbf{U}^r)$, has total variation distance at least $1 - o(1)$ from $\mathbf{D}$. (Here, we identify $\mathbb{F}_2^n$ with $\{0,1\}^n$.)

2.1 A Nonzero Lower Bound

We begin with the more modest goal of showing that P cannot *exactly* generate some explicit distribution $\mathbf{D}$. Here, we may invoke an argument of Viola [46, 47] based on extractors, whose formal definition we now recall.

▶ **Definition 4** (Extractor). *A function* $\mathsf{Ext}\colon \{0,1\}^n \to \{0,1\}$ *is an* (ε, k)-extractor *for a class* $\mathcal{X}$ *of distributions over* $\{0,1\}^n$ *if for every source* $\mathbf{X} \in \mathcal{X}$ *with min-entropy at least* k*, we have*

$$\mathbf{Pr}[\mathsf{Ext}(\mathbf{X}) = 1] = \frac{1}{2} \pm \varepsilon.$$

We will take the hard distribution to be uniform over input-output pairs of an explicit (ε, k)-extractor $\mathsf{Ext}\colon \{0,1\}^{n-1} \to \{0,1\}$ for polynomial sources of degree $2d$, where ε is some small constant and $k = n - O(1)$. That is, $\mathbf{D} = (\mathbf{U}^{n-1}, \mathsf{Ext}(\mathbf{U}^{n-1}))$. Such extractors which are computable in time $\mathsf{poly}(n)$ are known [13]. For clarity, we express $P(\mathbf{U}^r)$ similarly as $(Q(\mathbf{U}^r), q(\mathbf{U}^r))$, where $Q\colon \{0,1\}^r \to \{0,1\}^{n-1}$ and $q\colon \{0,1\}^r \to \{0,1\}$ are degree-d polynomials acting on the same set of input bits, corresponding to the first $n-1$ output bits and last output bit of P, respectively.

Suppose for contradiction that $P(\mathbf{U}^r)$ exactly generates $\mathbf{D}$. Viola's argument considers the random variable $\mathbf{M}$ over $\{0,1\}^{n-1}$ defined by sampling $\mathbf{u} \sim \mathbf{U}^r$ and outputting $Q(\mathbf{u})$ if $q(\mathbf{u}) = 1$, and otherwise $n-1$ uniformly random bits independent of $\mathbf{U}^r$, which we denote by $\widetilde{\mathbf{U}}^{n-1}$. Written suggestively similar to a polynomial, we have

$$\mathbf{M} = q(\mathbf{U}^r)Q(\mathbf{U}^r) + (1 - q(\mathbf{U}^r))\widetilde{\mathbf{U}}^{n-1}, \tag{1}$$

or equivalently by our assumption,

$$\mathbf{M} = \mathsf{Ext}(\mathbf{U}^{n-1})\mathbf{U}^{n-1} + (1 - \mathsf{Ext}(\mathbf{U}^{n-1}))\widetilde{\mathbf{U}}^{n-1}. \tag{2}$$

Now consider the effect of applying Ext to $\mathbf{M}$. By (1), $\mathbf{M}$ can be generated by a degree-$(2d)$ $\mathbb{F}_2$-polynomial source with $n - O(1)$ bits of min-entropy (recall $Q(\mathbf{U}^r)$ is assumed to be uniform), so $\mathbf{Pr}[\mathsf{Ext}(\mathbf{M}) = 1] \le \frac{1}{2} + \varepsilon$. By contrast, whenever the sample $\mathbf{u} \sim \mathbf{U}^{n-1}$ satisfies $\mathsf{Ext}(\mathbf{u}) = 1$, we must have $\mathsf{Ext}(\mathbf{M}) = 1$ by (2), so

$$\begin{aligned}
\mathbf{Pr}[\mathsf{Ext}(\mathbf{M}) = 1] &= \mathbf{Pr}\left[\mathsf{Ext}(\mathbf{M}) = 1 \,\middle|\, \mathsf{Ext}(\mathbf{U}^{n-1}) = 1\right] \cdot \mathbf{Pr}[\mathsf{Ext}(\mathbf{U}^{n-1}) = 1] \\
&\quad + \mathbf{Pr}\left[\mathsf{Ext}(\mathbf{M}) = 1 \,\middle|\, \mathsf{Ext}(\mathbf{U}^{n-1}) = 0\right] \cdot \mathbf{Pr}[\mathsf{Ext}(\mathbf{U}^{n-1}) = 0] \\
&= 1 \cdot \mathbf{Pr}[\mathsf{Ext}(\mathbf{U}^{n-1}) = 1] + \mathbf{Pr}[\mathsf{Ext}(\widetilde{\mathbf{U}}^{n-1}) = 1] \cdot \mathbf{Pr}[\mathsf{Ext}(\mathbf{U}^{n-1}) = 0] \\
&\approx \frac{1}{2} + \frac{1}{4} \gg \frac{1}{2} + \varepsilon,
\end{aligned}$$

a contradiction. That is, no low-degree polynomial can exactly sample $\mathbf{D}$. In fact, a more careful analysis forbids P from sampling $\mathbf{D}$ to distance better than $2^{-\Omega(k)}$ (which is $2^{-\Omega(n)}$ for known explicit constructions of such extractors [13]).

2.2 A Constant Lower Bound

It is initially unclear how to strengthen the previous argument to obtain even some constant distance lower bound. The primary issue is that even if $\mathbf{D}$ has large min-entropy, it might be reasonably close to some distribution $P(\mathbf{U}^n)$ with small min-entropy, so we do not have any guarantees on the output of the extractor on $\mathbf{M}$.

2.2.1 Min-Entropy Polarization

One approach that was successful in the analysis of distributions generated by low-depth circuits is *min-entropy polarization* [48]. Using random restrictions and hypercontractivity, Viola proved that any distribution $C(\mathbf{U}^r)$ produced by a small circuit $C\colon \{0,1\}^r \to \{0,1\}^n$

could be approximated by a not-too-large collection of restrictions of C whose output was either constant or had large min-entropy, in which case an extractor Ext could be meaningfully applied (see Section 4.2 in the full version for additional details). The event witnessing the total variation distance can then be defined as the union of a small set of outputs, corresponding to restrictions under which the circuit is constant, and pairs (x, b) where $\mathsf{Ext}(x) \neq b$.

Unfortunately, one cannot always polarize the output distribution of an arbitrary sampler in this fashion; consider the following example from [48].

▶ **Example 5.** Let $\mathbf{G}$ be the distribution over $\{0,1\}^n$ obtained by sampling a random string $\mathbf{u} \sim \mathbf{U}^n$, and outputting $\mathbf{u}$ if $|\mathbf{u}| \bmod 2 = 1$ and otherwise outputting 0^n. This sampler cannot have its min-entropy polarized via restrictions for the following reason. For any restriction which leaves some variable free, the min-entropy remains 1. This means that every restriction in a polarizing collection must fix every variable, but then $\Omega(2^n)$ many such restrictions are needed to approximate the distribution.

Note, however, that this sampling procedure *can* be implemented by the degree-2 $\mathbb{F}_2$-polynomial map

$$P(y) = \left(\sum_{i=1}^{n} y_i\right) \cdot (y_1, \ldots, y_n) + \left(1 - \sum_{i=1}^{n} y_i\right) \cdot 0^n$$

to express $\mathbf{G}$ as $P(\mathbf{U}^n)$. Hence, we are not able to apply this framework for our purposes.

2.2.2 Discarding Heavy Points

An alternative approach, still somewhat in the spirit of [48], was taken by Chattopadhyay, Goodman, and Zuckerman [14] when considering communication sources (see Section 4.3.1 in the full version for a formal definition). They also defined their witness event to be the union of a small "bad" set and input-output pairs which contradict a particular extractor's definition. Unlike Viola, however, they define their bad set to be strings which are assigned substantial probability by the sampler (excluding the last bit). Since there cannot be many "heavy" strings, this set is indeed small.

The downside to this approach is that the extractor one requires does not necessarily correspond to an extractor for the class of sources being considered. In particular, the argument requires an extractor that works on the source after conditioning on membership in some set. For communication sources, one can reduce to the case of being able to apply a two-source extractor, but it is unclear how to generically perform a similar reduction to known extractors in the case of other sources, such as those generated by low-degree polynomials.

2.2.3 Robust Extractors

To overcome the previous two obstacles, we ask for more from the *extractor* rather than from the *source*. Recall that the issue with trying to strengthen the argument from Subsection 2.1 is that the generated distribution $P(\mathbf{U}^r) = (Q(\mathbf{U}^r), q(\mathbf{U}^r))$ might assign too much mass to a small set of "bad" points, so the auxiliary distribution of $\mathbf{M}$ does not have enough min-entropy to apply an extractor. Our solution is to simply ask for an extractor whose soundness holds on the light (i.e., low probability) points, rather than the entire domain. In other words, we seek an extractor which is robust to a small number of points violating the min-entropy constraint.

To be a bit more precise, suppose that the (ε, k)-extractor $\mathsf{Ext}\colon \{0,1\}^{n-1} \to \{0,1\}$ we have been considering had the property that every degree-$(2d)$ $\mathbb{F}_2$-polynomial source $\mathbf{X}$ satisfies

$$\mathbf{Pr}[\mathbf{X} \in L \text{ and } \mathsf{Ext}(\mathbf{X}) = 1] \leq \frac{1}{2} + \varepsilon, \tag{3}$$

where $L = \{x \in \{0,1\}^{n-1} : \mathbf{Pr}[\mathbf{X} = x] \leq 2^{-k}\}$ is the set of light points.[4] (Recall that a "traditional" extractor is only guaranteed to satisfy (3) when $L = \{0,1\}^{n-1}$.) A priori, it is not obvious that these objects even exist, but it turns out that a straightforward modification to the extractor construction of [13] yields such an object.

In general, we believe that essentially any natural class of distributions should have extractors with a similar guarantee, and much of the present work is devoted to showing that existing extractor constructions (or simple modifications of them) are robust. In fact, one can interpret the aforementioned min-entropy polarization results in [48] as saying that any extractor for circuit sources enjoys the robustness property (see Section 4.2.1 in the full version).

Now that we have a *robust extractor*, we can run a version of our earlier argument. Once again, let $\mathbf{M}$ be the random variable over $\{0,1\}^{n-1}$ defined by sampling $\mathbf{u} \sim \mathbf{U}^r$ and outputting $Q(\mathbf{u})$ if $q(\mathbf{u}) = 1$, and otherwise $n-1$ random bits using fresh randomness. We also define $\widetilde{\mathbf{M}}$ similarly, but with $\mathbf{D} = (\mathbf{U}^{n-1}, \mathsf{Ext}(\mathbf{U}^{n-1}))$ in place of $P(\mathbf{U}^r)$. By (3), we morally have that $\mathsf{Ext}(\mathbf{M})$ is near balanced on its light points, whereas by construction, $\mathsf{Ext}(\widetilde{\mathbf{M}})$ is likely to output 1 on such points. Working out the details (see Subsection 2.4), one finds that $P(\mathbf{U}^r)$ must be $\Omega(1)$-far from $\mathbf{D}$, as desired.

2.3 A $1 - o(1)$ Lower Bound

It remains to amplify the total variation distance lower bound from constant to $1 - o(1)$. Toward this end, we will take many independent copies of the distribution above, and prove that generating this product of distributions is much harder than generating any individual distribution. We note that such *direct product theorems* have been examined previously in the sampling context [14, 22].

Proceeding more formally, we redefine the distribution $\mathbf{D}$ to be

$$\mathbf{D} = (\mathbf{U}_1, \mathbf{U}_2, \ldots, \mathbf{U}_t, \mathsf{Ext}(\mathbf{U}_1), \mathsf{Ext}(\mathbf{U}_2), \ldots, \mathsf{Ext}(\mathbf{U}_t)),$$

where the $\mathbf{U}_i$'s are independent copies of $\mathbf{U}^{n-1}$ and $t \geq 1$ is an integer to be chosen later. Observe that now $\mathbf{D}$ is over $\{0,1\}^N$ for $N \coloneqq tn$, so we must redefine our polynomial map P to also be on N output bits. We emulate much of our previous analysis with the auxiliary random variable $\widetilde{\mathbf{M}}$ generalized to output $\mathbf{u}_i$ if $\mathsf{Ext}(\mathbf{u}_i) = 1$ for any $i \in \{1, \ldots, t\}$ (and $\mathbf{M}$ similarly generalized with respect to $P(\mathbf{U}^r)$). This greatly increases the probability that $\mathsf{Ext}(\widetilde{\mathbf{M}}) = 1$, which further improves our distance bound.

Unfortunately, the approach as written does not provide distance approaching 1. The problem can essentially be traced back to a loss of $\mathbf{Pr}[\mathbf{X} \in L \text{ and } \mathsf{Ext}(\mathbf{X}) = 1]$ coming from our test event. Since the set of low probability points L might be the entire domain, we cannot upper bound this quantity by anything appreciably better than $1/2$ without violating the extractor guarantee. In order to make further progress, we extend our extractor to have multiple output bits.

[4] There are other ways to capture a similar notion of robustness, but this definition seems to be particularly advantageous; see the discussion in Subsection 3.2.

This multi-output extractor $\mathsf{Ext}\colon \{0,1\}^{n-1} \to \{0,1\}^m$ is defined similarly to the single-output version (Definition 4), only now with the pseudorandomness condition being a bound on the total variation distance $\|\mathsf{Ext}(\mathbf{X}) - \mathbf{U}^m\|_{\mathsf{TV}} \leq \varepsilon$. One can again obtain a robust version (with $m = \Omega(\log \log n)$) by modifying the construction of [13]; we defer the formal definition to Subsection 3.2.

The upshot is that now we can replace the bottleneck of the previous argument with an analysis of $\mathbf{Pr}[\mathbf{X} \in L \text{ and } \mathsf{Ext}(\mathbf{X}) = 0^m]$. This, in turn, can be more tightly bounded by $2^{-m} + \varepsilon$. In our construction, ε will tend to 0 as m grows,[5] so working out the calculations, we obtain a bound roughly of the form

$$1 - \exp(-2^{-m} \cdot t) - 2^{-\Omega(n)} \cdot \mathsf{poly}(t)$$

for sufficiently large n. Setting t to be slightly larger than 2^m, we can finally obtain our desired $1 - o(1)$ bound. The full details can be found in the subsequent subsection.

2.3.1 Isolators

Before formalizing our discussion into a theorem, it is worth reflecting on exactly what properties of the robust extractor we used. (These properties may be further illuminated by consulting the proof of Theorem 8.) In analyzing our target distribution $\mathbf{D}$, all that we truly needed is for some output $y \in \{0,1\}^m$ to be assigned substantial mass by $\mathsf{Ext}(\mathbf{U}^{n-1})$. By contrast, our analysis of the generated distribution $P(\mathbf{U}^r)$ only required that the extractor did not map too many of the light points to the same output y. In other words, our argument does not require the full power of robust extractors. We distill the properties we need into the following weaker object, which we call an *isolator*, since it in some sense controls the isolated light points.

▶ **Definition 6** (Isolator). *A function* $\mathsf{Iso}\colon \{0,1\}^n \to \{0,1\}$ *is an* (α, β, k)-isolator *for a class* $\mathcal{X}$ *of distributions over* $\{0,1\}^n$ *if*

1. $\mathbf{Pr}[\mathsf{Iso}(\mathbf{U}^n) = 1] \geq \alpha$, *and*
2. *Every source* $\mathbf{X} \in \mathcal{X}$ *satisfies* $\mathbf{Pr}_{x \sim \mathbf{X}}[x \in L \text{ and } \mathsf{Iso}(x) = 1] \leq \beta$, *where* $L = \{x \in \{0,1\}^n : \mathbf{Pr}[\mathbf{X} = x] \leq 2^{-k}\}$.

It is perhaps worth highlighting that although all our constructions of isolators essentially work by "robustifying" existing extractor constructions, this is not strictly necessary to satisfy Definition 6. It is plausible one could explicitly construct an isolator for $\mathsf{AC}^0[\oplus]$ sources, for example, without first explicitly constructing seemingly elusive extractors for that class.

2.4 Main Result

We conclude Section 2 by stating our main result, Theorem 8, and its proof. Below, the following notation will be convenient for generalizing the random variable $\mathbf{M}$ considered above.

[5] We had previously defined ε to be a small constant, but our construction of robust extractors allows for this smaller setting.

▶ **Definition 7** (Randomized Addressing). *For positive integers t and n, we define the randomized function* $\mathsf{addr}\colon (\{0,1\}^n)^t \times \{0,1\}^t \to \{0,1\}^n$ *as*

$$\mathsf{addr}(A_1, A_2, \ldots, A_t, b_1, b_2, \ldots, b_t) = \begin{cases} A_1 & \text{if } b_1 = 1, \\ A_2 & \text{if } b_1 = 0, b_2 = 1, \\ A_3 & \text{if } b_1 = b_2 = 0, b_3 = 1, \\ \quad\vdots & \\ A_t & \text{if } b_1 = b_2 = \cdots = b_{t-1} = 0, b_t = 1, \\ \mathbf{U}^n & \text{if } b_1 = b_2 = \cdots = b_t = 0. \end{cases}$$

Though the parameters n and t will mostly be clear from context, we will sometimes write $\mathsf{addr}_{n,t}$ for clarity.

We can now finally present our main result.

▶ **Theorem 8.** *Let $\alpha, \beta \in [0,1]$ and t, k, n be positive integers where $k \le n-1$. Let $\mathcal{X}$ be a class of distributions over $\{0,1\}^{t(n+1)}$, and let $\mathcal{Y}$ be the class of distributions over $\{0,1\}^n$ of the form $\mathsf{addr}_{n,t}(\mathbf{X})$ for some $\mathbf{X} \in \mathcal{X}$. Suppose $\mathsf{Iso}\colon \{0,1\}^n \to \{0,1\}$ is an (α, β, k)-isolator for $\mathcal{Y}$, and define the distribution*

$$\mathbf{D} = (\mathbf{U}_1, \mathbf{U}_2, \ldots, \mathbf{U}_t, \mathsf{Iso}(\mathbf{U}_1), \mathsf{Iso}(\mathbf{U}_2), \ldots, \mathsf{Iso}(\mathbf{U}_t)),$$

where $\mathbf{U}_1, \ldots, \mathbf{U}_t$ are independent copies of $\mathbf{U}^n$. Then every source $\mathbf{X} \in \mathcal{X}$ satisfies

$$\|\mathbf{X} - \mathbf{D}\|_{\mathsf{TV}} \ge 1 - (1-\alpha)^{t+1} - 2^{-(n-k)}\left(2t^3 + 1\right) - \beta.$$

In particular, $\|\mathbf{X} - (\mathbf{U}^n, \mathsf{Iso}(\mathbf{U}^n))\|_{\mathsf{TV}} \ge 2\alpha - \alpha^2 - 2^{-(n-k-2)} - \beta$.

▶ Remark 9. Depending on the sampling model and particular goal, the precise ordering of the coordinates in a target distribution may affect whether or not that distribution can be sampled (e.g., [45]). In the case of Theorem 8, the proof goes through for any permutation of the coordinates of addr and $\mathbf{D}$, although the order may affect whether $\mathsf{addr}(\mathbf{X})$ lies in a particular class.

Proof of Theorem 8. Let $\mathbf{X}$ be any source in $\mathcal{X}$. Viewing $\mathbf{X}$ as $(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_t, \mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_t)$ with the $\mathbf{X}_i$'s and $\mathbf{x}_j$'s over $\{0,1\}^n$ and $\{0,1\}$, respectively, we may apply $\mathsf{addr}_{n,t}$ to $\mathbf{X}$ to obtain the source $\mathbf{Y} = \mathsf{addr}(\mathbf{X}) \in \mathcal{Y}$. Next, define the sets of light points in $\mathbf{X}_i$ for $i = 1, 2, \ldots, t$ and $\mathbf{Y}$ by

$$L_{\mathbf{X}_i} = \{x \in \{0,1\}^n : \mathbf{Pr}[\mathbf{X}_i = x] \le 2^{-(\log(t)+k+1)}\} \text{ and } L_{\mathbf{Y}} = \{y \in \{0,1\}^n : \mathbf{Pr}[\mathbf{Y} = y] \le 2^{-k}\}.$$

Observe that $\bigcap_i L_{\mathbf{X}_i} \subseteq L_{\mathbf{Y}}$, since any string $z \in \bigcap_i L_{\mathbf{X}_i}$ satisfies

$$\begin{aligned} \mathbf{Pr}[\mathbf{Y} = z] = \Pr_{\mathbf{X}}[\mathsf{addr}(\mathbf{X}) = z] &\le \mathbf{Pr}[\mathbf{U}^n = z] + \sum_{i=1}^{t} \mathbf{Pr}[\mathbf{X}_i = z] \qquad \text{(by union bound)} \\ &\le 2^{-n} + t \cdot 2^{-(\log(t)+k+1)} \le 2^{-k}. \end{aligned}$$

Thus, the isolator property of Iso guarantees that

$$\begin{aligned} \mathcal{E}(\mathbf{X}) &\coloneqq \Pr_{\mathbf{X}}\left[\bigcap_i \left(\mathbf{X}_i \in \bigcap_j L_{\mathbf{X}_j}\right) \text{ and } \mathsf{Iso}(\mathsf{addr}(\mathbf{X})) = 1\right] \\ &\le \Pr_{\mathbf{X}}[\mathsf{addr}(\mathbf{X}) \in L_{\mathbf{Y}} \text{ and } \mathsf{Iso}(\mathsf{addr}(\mathbf{X})) = 1] + \Pr_{\mathbf{X}}\left[\mathsf{addr}(\mathbf{X}) \notin L_{\mathbf{Y}} \,\middle|\, \bigcap_i \left(\mathbf{X}_i \in \bigcap_j L_{\mathbf{X}_j}\right)\right] \\ &\le \beta + \mathbf{Pr}[\mathbf{U}^n \notin L_{\mathbf{Y}}] \le \beta + 2^{-(n-k)}, \end{aligned} \tag{4}$$

where the final inequality follows from the fact that $\mathbf{Y}$ can assign 2^{-k} probability mass to at most 2^k points.

We will choose $\mathcal{E}$ to be the test witnessing the claimed TVD between $\mathbf{X}$ and $\mathbf{D}$, although it will be slightly more convenient in this part of the analysis to consider the complement event. In a similar fashion to $\mathbf{X}$, we view $\mathbf{D}$ as $(\mathbf{D}_1, \mathbf{D}_2, \ldots, \mathbf{D}_t, \mathbf{d}_1, \mathbf{d}_2, \ldots, \mathbf{d}_t)$, where recall each $\mathbf{D}_i$ is an independent copy of the uniform distribution $\mathbf{U}^n$. By the union bound, we have

$$\begin{aligned}
&\Pr_{\mathbf{D}}\left[\bigcup_i \left(\mathbf{D}_i \notin \bigcap_j L_{\mathbf{X}_j}\right) \text{ or } \mathsf{Iso}(\mathsf{addr}(\mathbf{D})) = 0\right] \\
&\leq \sum_i \Pr_{\mathbf{D}}\left[\mathbf{D}_i \notin \bigcap_j L_{\mathbf{X}_j}\right] + \Pr_{\mathbf{D}}[\mathsf{Iso}(\mathsf{addr}(\mathbf{D})) = 0] \\
&\leq \sum_{i,j} \Pr_{\mathbf{D}}\left[\mathbf{D}_i \notin L_{\mathbf{X}_j}\right] + \Pr_{\mathbf{D}}[\mathsf{Iso}(\mathsf{addr}(\mathbf{D})) = 0]. \qquad (5)
\end{aligned}$$

Note that the first term is at most $t^2 \cdot 2^{-(n-(\log(t)+k+1))}$, since no $\mathbf{X}_j$ can assign $2^{-(\log(t)+k+1)}$ probability mass to more than $2^{\log(t)+k+1}$ points. To address the second term, let us consider the effect of applying addr to $\mathbf{D}$. Whenever any $\mathbf{D}_i$ satisfies $\mathsf{Iso}(\mathbf{D}_i) = 1$, we have $\mathsf{Iso}(\mathsf{addr}(\mathbf{D})) = \mathsf{Iso}(\mathbf{D}_i) = 1$. Otherwise, $\mathsf{Iso}(\mathbf{D}_i) = 0$ for all i, and we have $\mathsf{Iso}(\mathsf{addr}(\mathbf{D})) = \mathsf{Iso}(\mathbf{U}^n)$. Thus,

$$\begin{aligned}
\mathbf{Pr}[\mathsf{Iso}(\mathsf{addr}(\mathbf{D})) = 0] &= \Pr_{\mathbf{D}}\left[\mathsf{Iso}(\mathbf{U}^n) = 0 \text{ and } \bigcap_i (\mathsf{Iso}(\mathbf{D}_i) = 0)\right] \\
&= \mathbf{Pr}[\mathsf{Iso}(\mathbf{U}^n) = 0]^{t+1} \leq (1-\alpha)^{t+1}.
\end{aligned}$$

Plugging these two bounds back into (5) yields

$$\Pr_{\mathbf{D}}\left[\bigcap_i \left(\mathbf{D}_i \in \bigcap_j L_{\mathbf{X}_j}\right) \text{ and } \mathsf{Iso}(\mathsf{addr}(\mathbf{D})) = 1\right] \geq 1 - (1-\alpha)^{t+1} - t^2 \cdot 2^{-(n-(\log(t)+k+1))}.$$

Recalling the upper bound from (4), we conclude

$$\|\mathbf{X} - \mathbf{D}\|_{\mathsf{TV}} \geq 1 - (1-\alpha)^{t+1} - 2^{-(n-k)}\left(2t^3+1\right) - \beta. \qquad \blacktriangleleft$$

3 Preliminaries

We now briefly review some notation and formal definitions used throughout the work.

3.1 The Basics

For a positive integer n, we use $[n]$ to denote the set $\{1, 2, \ldots, n\}$. For a binary string x, we use $|x|$ to denote the Hamming weight of x. All logarithms given in the paper are base 2. For two real numbers a and b, we write $a \pm b$ to denote a value in the range $[a-b, a+b]$. The indicator function is denoted by $\mathbf{1}(\cdot)$. The notation $\binom{n}{\leq k}$ is shorthand for $\sum_{i=0}^{k}\binom{n}{i}$. We use $\mathbb{F}_2$ to denote the finite field of two elements; we often identify it with $\{0,1\}$. The concatenation of two strings x and y is denoted $x \circ y$.

3.1.1 Asymptotics

We use the standard $\Omega(\cdot), O(\cdot), \Theta(\cdot)$ asymptotic notation to hide universal positive constants, although we will sometimes use $\gg$ and $\ll$ in more informal contexts. Occasionally, we will use subscripts to indicate an unspecified dependence on a particular parameter (e.g., $\Omega_d(n)$). Additionally, we write $o_t(1)$ to denote a positive quantity tending to 0 as t tends to infinity; we often omit the subscript when t is clear from context. The shorthand $\mathsf{poly}(n)$ corresponds to a polynomial in n of some fixed, but unspecified, degree.

3.1.2 Probability

We endeavor to use bold capital letters to denote probability distributions, and use bold lowercase letters to denote randomly drawn samples. That is, $\mathbf{x} \sim \mathbf{X}$ denotes a sample $\mathbf{x}$ drawn from the distribution $\mathbf{X}$. Oftentimes, we will refer to a distribution as a *source* if it is being fed into an extractor-like object. We reserve $\mathbf{U}$ for the uniform distribution over $\{0,1\}$. We use calligraphic letters, such as $\mathcal{X}$, for classes of distributions. For an event $\mathcal{E}$, we define $\mathbf{X}(\mathcal{E})$ to be the probability mass assigned to $\mathcal{E}$ by $\mathbf{X}$. For a function f, we use $f(\mathbf{X})$ to denote the output distribution of $f(\mathbf{x})$ on randomly drawn $\mathbf{x} \sim \mathbf{X}$. The *min-entropy* of a distribution $\mathbf{X}$, denoted $H_\infty(\mathbf{X})$, is given by $-\log \max_{x \in \mathsf{supp}(\mathbf{X})} \mathbf{Pr}[\mathbf{X} = x]$, where the support $\mathsf{supp}\,(\mathbf{X}) = \{x : \mathbf{Pr}[\mathbf{X} = x] > 0\}$.

Given a distribution $\mathbf{X}$ and positive integer t, we use $\mathbf{X}^t$ to denote the t-fold product distribution $\mathbf{X} \times \cdots \times \mathbf{X}$. If s is a finite set, we write $\mathbf{X}^s$ to emphasize that the coordinates of $\mathbf{X}^{|s|}$ are indexed by s. We refer to $\mathbf{X}$ as a mixture if it can be written as a convex combination of other distributions. That is, there exists $c_1, \ldots, c_k \in [0,1]$ and distributions $\mathbf{X}_1, \ldots, \mathbf{X}_k$ such that $\mathbf{X}(\mathcal{E}) = \sum_{i=1}^k c_i \cdot \mathbf{X}_i(\mathcal{E})$ for every event $\mathcal{E}$. Occasionally, we write this more concisely as $\mathbf{X} = \sum_{i=1}^k c_i \mathbf{X}_i$.

We measure the similarity of two (discrete) distributions $\mathbf{P}$ and $\mathbf{Q}$ by the *total variation (TV) distance*

$$\|\mathbf{P} - \mathbf{Q}\|_{\mathsf{TV}} = \max_{\text{event } \mathcal{E}} \mathbf{P}(\mathcal{E}) - \mathbf{Q}(\mathcal{E}) = \frac{1}{2} \sum_x |\mathbf{P}(x) - \mathbf{Q}(x)| \,.$$

We say $\mathbf{P}$ is ε-*close* to $\mathbf{Q}$ if $\|\mathbf{P} - \mathbf{Q}\|_{\mathsf{TV}} \leq \varepsilon$, and ε-*far* otherwise.

3.1.3 Explicit Constructions

The focus of this work is on *explicitly* constructing distributions with certain properties, by which we mean $\mathbf{D}$ can be sampled in $\mathsf{poly}(n)$ time. Note that as in the computational world, it is straightforward to non-constructively prove strong hardness results via a counting argument. More precisely, for any class $\mathcal{X}$ of distributions over $\{0,1\}^n$ of size $2^{2^{cn}}$ for a constant $c < 1$, there exists a uniform distribution $\mathbf{D}$ with distance $1 - 2^{-\Omega(n)}$ from every distribution in $\mathcal{X}$ (see the full version for details).

There is a small subtlety, however, in that the sampling models we consider have unbounded input length, so one cannot naively apply the above claim. Fortunately, the classes of interest can typically be approximated by a subset of the class where the input length is bounded (e.g., [14]), which allows the argument to go through. We are unaware of any work formally describing these counting arguments giving hard distributions for low-degree polynomial sources and $\mathsf{AC}^0[\oplus]$ sources, so we record the details in the appendix of the full version.

3.2 Extractors, Robust Extractors, and Isolators

There are three pseudorandom objects at the core of our work: extractors, robust extractors, and isolators. We state the formal definitions of the first two below.

▶ **Definition 10** ((Robust) Extractor). *A function* $\mathsf{Ext}\colon \{0,1\}^n \to \{0,1\}^m$ *is an* (ε, k)-extractor *for a class* $\mathcal{X}$ *of distributions over* $\{0,1\}^n$ *if for every source* $\mathbf{X} \in \mathcal{X}$ *with min-entropy at least* k*, we have*

$$\|\mathsf{Ext}(\mathbf{X}) - \mathbf{U}^m\|_{\mathsf{TV}} \leq \varepsilon.$$

If additionally, there exists some $z \in \{0,1\}^m$ *such that every source* $\mathbf{X} \in \mathcal{X}$ *satisfies*

$$\mathbf{Pr}[\mathbf{X} \in L \text{ and } \mathsf{Ext}(\mathbf{X}) = z] \leq \frac{1}{2^m} + \delta,$$

where $L = \{x \in \{0,1\}^n : \mathbf{Pr}[\mathbf{X} = x] \leq 2^{-k}\}$*, then we call* Ext *an* (ε, δ, k)-robust extractor.

It is worth mentioning that there are other ways to formalize this notion of robustness. For example, one could ask for an extractor which works for a source $\mathbf{X}$, as long as $\mathbf{X}$ has TV distance no more than some parameter γ to a high min-entropy source $\mathbf{X}'$ (i.e., an extractor for sources of high smooth min-entropy [38]). Assuming such extractors existed for the classes of distributions we consider, it would be possible to obtain a constant distance lower bound as in the second part of Theorem 8.

Unfortunately, it does not seem feasible to get distance approaching 1. Fix some choice of γ and a sampler $f(\mathbf{U}^r)$ for the hard distribution $\mathbf{D}$ considered in Theorem 8. If $f(\mathbf{U}^r)$ is γ-far from $\mathbf{D}$, we trivially have a lower bound of γ, so assume this is not the case. Note that we cannot expect a "smooth extractor" to have a better upper bound probability guarantee than $2^{-m} + \gamma$, since it has to apply to distributions which are a point mass with probability γ and uniform otherwise. Tracing through the remainder of the argument, one finds that $f(\mathbf{U}^r)$ has distance roughly $1 - \varepsilon - \gamma$ from $\mathbf{D}$ for some small ε. In other words, we can only guarantee a bound around $\min(\gamma, 1 - \varepsilon - \gamma) \ll 1$.

One of the benefits of Definition 10 is that we can obtain tighter distance guarantees, because we do not need to consider the behavior of the extractor on heavy points. Hence, we can avoid the above issue. Returning back to our selected formalizations, we restate the definition of an isolator for the reader's convenience.

▶ **Definition 6** (Isolator). *A function* $\mathsf{Iso}\colon \{0,1\}^n \to \{0,1\}$ *is an* (α, β, k)-isolator *for a class* $\mathcal{X}$ *of distributions over* $\{0,1\}^n$ *if*

1. $\mathbf{Pr}[\mathsf{Iso}(\mathbf{U}^n) = 1] \geq \alpha$*, and*
2. *Every source* $\mathbf{X} \in \mathcal{X}$ *satisfies* $\mathbf{Pr}_{x \sim \mathbf{X}}[x \in L \text{ and } \mathsf{Iso}(x) = 1] \leq \beta$*, where* $L = \{x \in \{0,1\}^n : \mathbf{Pr}[\mathbf{X} = x] \leq 2^{-k}\}$.

The role of robust extractors in the present work is primarily as a convenient device for constructing isolators.

▶ **Fact 11.** *Let* $\mathcal{X}$ *be a class of distributions over* $\{0,1\}^n$ *which includes the uniform distribution* $\mathbf{U}^n$*. If* $\mathsf{rExt}\colon \{0,1\}^n \to \{0,1\}^m$ *is an* (ε, δ, k)*-robust extractor for* $\mathcal{X}$*, then the function* $\mathsf{Iso}(x) \coloneqq \mathbf{1}(\mathsf{rExt}(x) = z)$ *is a* $(2^{-m} - \varepsilon, 2^{-m} + \delta, k)$*-isolator for* $\mathcal{X}$ *(where* z *is the same string as in Definition 10).*

Of course, one still has to construct a robust extractor to apply Fact 11. Typically, this is not much more difficult than constructing a traditional extractor, and in the following section, we illustrate such a modification with a number of natural examples. We note that in certain cases, the robustness can even be obtained for free.

▷ Claim 12. Let $\mathcal{X}$ be a class of distributions over $\{0,1\}^n$ such that each $\mathbf{X} \in \mathcal{X}$ is the uniform distribution on some set $S_{\mathbf{X}} \subseteq \{0,1\}^n$ (i.e., $\mathcal{X}$ is a family of *flat* sources). If $\mathsf{Ext}\colon \{0,1\}^n \to \{0,1\}^m$ is an (ε, k)-extractor for $\mathcal{X}$, then Ext is also an $(\varepsilon, \varepsilon, k)$-robust extractor for $\mathcal{X}$.

Proof. Consider any source $\mathbf{X} \in \mathcal{X}$, which is uniform over a set $S_{\mathbf{X}}$. If $|S_{\mathbf{X}}| \geq 2^k$, then $\mathbf{X}$ has min-entropy at least k and the set

$$L \coloneqq \{x \in \{0,1\}^n : \mathbf{Pr}[\mathbf{X} = x] \leq 2^{-k}\} = \{0,1\}^n.$$

Thus, the extractor guarantee implies

$$\mathop{\mathbf{Pr}}_{x\sim\mathbf{X}}[x \in L \text{ and } \mathsf{Ext}(x) = 0^m] = \mathop{\mathbf{Pr}}_{x\sim\mathbf{X}}[\mathsf{Ext}(x) = 0^m] \leq 2^{-m} + \varepsilon.$$

Otherwise $|S_{\mathbf{X}}| < 2^k$, and $\mathbf{Pr}[\mathbf{X} = x] = 0$ for every $x \in L$. Hence,

$$\mathop{\mathbf{Pr}}_{x\sim\mathbf{X}}[x \in L \text{ and } \mathsf{Ext}(x) = 0^m] \leq \mathop{\mathbf{Pr}}_{x\sim\mathbf{X}}[x \in L] = 0. \qquad \triangleleft$$

4 Hard-to-Sample Distributions for Polynomial Sources

In this section, we instantiate Theorem 8 for polynomial sources.

▶ **Definition 13** (Polynomial Source). *A degree-d* polynomial source $\mathbf{X}$ *is defined by a polynomial map $P\colon \mathbb{F}_2^m \to \mathbb{F}_2^n$, where $P = (p_1, p_2, \ldots, p_n)$ and each p_i is an $\mathbb{F}_2$-polynomial of degree at most d, such that $\mathbf{X} = P(\mathbf{U}^m)$.*

Prior to our work, the best explicit distribution was only known to have distance $2^{-\Omega(n)}$ from any low-degree polynomial map; this is achieved by combining an argument of [46] (described in Subsection 2.1) with an extractor construction of [13]. We improve this distance bound to $1 - o(1)$.

▶ **Theorem 14.** *There exists a constant $\delta > 0$ such that the following holds. Let N and Δ be positive integers satisfying $\Delta \leq \delta \log\log N$. There exist positive integers n, t, d with $(n+1)t \leq N$ and an isolator $\mathsf{Iso}\colon \{0,1\}^n \to \{0,1\}$ with suitable parameters for the class of polynomial sources on $\{0,1\}^n$ of degree d such that the following holds.*

Define the distribution

$$\mathbf{D} = (\mathbf{U}_1, \mathbf{U}_2, \ldots, \mathbf{U}_t, \mathsf{Iso}(\mathbf{U}_1), \mathsf{Iso}(\mathbf{U}_2), \ldots, \mathsf{Iso}(\mathbf{U}_t)),$$

where $\mathbf{U}_1, \mathbf{U}_2, \ldots, \mathbf{U}_t$ are independent copies of $\mathbf{U}^n$. Let $\mathcal{X}$ be the class of all polynomial sources $\mathbf{X}$ on $\{0,1\}^{(n+1)t}$ of degree Δ. Then for any $\mathbf{X} \in \mathcal{X}$,

$$\|\mathbf{D} - \mathbf{X}\|_{\mathsf{TV}} \geq 1 - O\left(\frac{\Delta}{\log\log N} \log\left(\frac{\log\log N}{\Delta}\right)\right).$$

Moreover, the distribution $\mathbf{D}$ can be sampled in $\mathsf{poly}(N)$ time.

Additionally, there exists an isolator $\widetilde{\mathsf{Iso}}\colon \{0,1\}^n \to \{0,1\}$ (with possibly different parameters) such that the distribution $\widetilde{\mathbf{D}} = (\mathbf{U}^n, \widetilde{\mathsf{Iso}}(\mathbf{U}^n))$ satisfies $\left\|\widetilde{\mathbf{D}} - \mathbf{Y}\right\|_{\mathsf{TV}} \geq 1/4 - n^{-\Omega(1)}$ for all degree-Δ polynomial sources $\mathbf{Y}$ on $\{0,1\}^{n+1}$. $\widetilde{\mathbf{D}}$, too, can be sampled in $\mathsf{poly}(N)$ time.

We prove Theorem 14 by modifying the construction of an explicit extractor from [13] to create an isolator Iso for low-degree polynomial sources, and invoke Theorem 8 using Iso.

The extractor from [13] is constructed by brute-forcing over many possible extractors on a small number of input bits. The existence of such an extractor is guaranteed by the probabilistic method (as is standard), but what makes their argument not straightforward is that the number of polynomial sources is not bounded, since a polynomial source can have any number of input bits. Their key ingredient is an input reduction technique [13, Theorem 4.1], which shows that it is enough to consider only sources where the number of input bits is at most a constant factor times the min-entropy.

We observe below that a variant of their input reduction argument also works for isolators. We first prove a variant of their simple entropy smoothing claim [13, Claim 4.3].

▷ Claim 15. For any random variable $\mathbf{X}$ over $\{0,1\}^n$ and positive integer k, there exists a function $S\colon \{0,1\}^n \to \{0,1\}^{k+1}$ with the following property. For every $x \in \{0,1\}^n$ such that $\mathbf{Pr}[\mathbf{X} = x] \le 2^{-k}$, we have $\mathbf{Pr}[S(\mathbf{X}) = S(x)] \le 2^{-k}$.

Proof. We perform the following merging operation. Start with each string in $\{0,1\}^n$ in its own bucket. If there are two buckets whose combined probability mass under $\mathbf{X}$ is at most 2^{-k}, then merge the two buckets. This operation is repeated for as long as possible. (This process necessarily terminates since the number of buckets decreases in each step.)

At the end, there can be at most one bucket whose corresponding probability is at most $2^{-(k+1)}$, since otherwise we could merge two such buckets. This implies that there are at most 2^{k+1} buckets in total, and we can define S to simply map each string $x \in \{0,1\}^n$ to the bucket containing it (where we associate each bucket with a distinct string in $\{0,1\}^{k+1}$).

To verify the desired property of S, first observe that since any bucket containing two or more elements is the result of some merge operation, it must have total probability at most 2^{-k}. This handles all x such that $|S(x)| \ge 2$. On the other hand, if $\mathbf{Pr}[\mathbf{X} = x] \le 2^{-k}$ and $|S(x)| = 1$, then clearly $\mathbf{Pr}[S(\mathbf{X}) = S(x)] = \mathbf{Pr}[\mathbf{X} = x] \le 2^{-k}$. ◁

We also need the following general lemma, which is implicit [13]. We sketch the proof for completeness.

▶ **Lemma 16.** *Let $f\colon \mathbb{F}_2^r \to \mathbb{F}_2^n$ be a function and $0 < \varepsilon < 1/4$. Let $\ell = \lceil n + 3\log(1/\varepsilon) \rceil$. If $r > \ell$, there exist $A \in \mathbb{F}_2^{r \times \ell}$ and $b \in \mathbb{F}_2^r$ such that if we define $h\colon \mathbb{F}_2^\ell \to \mathbb{F}_2^n$ by $h(x) = f(Ax+b)$, we have $\left\| f(\mathbf{U}^r) - h(\mathbf{U}^\ell) \right\|_{\mathsf{TV}} \le 2\varepsilon$.*

Proof. Lemma 4.2 in [13] gives a full rank[6] linear map $M\colon \mathbb{F}_2^r \to \mathbb{F}_2^{r-\ell}$ such that

$$\left\| f(\mathbf{U}^r) \circ M(\mathbf{U}^r) - f(\mathbf{U}^r) \circ \mathbf{U}^{r-\ell} \right\|_{\mathsf{TV}} \le 2\varepsilon. \tag{6}$$

We start by observing that

$$\left\| f(\mathbf{U}^r) \circ M(\mathbf{U}^r) - f(\mathbf{U}^r) \circ \mathbf{U}^{r-\ell} \right\|_{\mathsf{TV}} = \mathop{\mathbb{E}}_{v \sim M(\mathbf{U}^r)} \Big[\left\| (f(\mathbf{U}^r) \,|\, M(\mathbf{U}^r) = v) - f(\mathbf{U}^r) \right\|_{\mathsf{TV}} \Big],$$

where we have used that M has full rank, so $M(\mathbf{U}^r)$ is $\mathbf{U}^{r-\ell}$. Combining with (6), there must exist some $v \in \mathbb{F}_2^{r-\ell}$ such that

$$\left\| (f(\mathbf{U}^r) \,|\, M(\mathbf{U}^r) = v) - f(\mathbf{U}^r) \right\|_{\mathsf{TV}} \le 2\varepsilon.$$

Now $(f(\mathbf{U}^r) \,|\, M(\mathbf{U}^r) = v)$ can be expressed as $h(\mathbf{U}^\ell)$ for a function h on ℓ inputs of the desired form $h(x) = f(Ax + b)$, since conditioning on $M(\mathbf{U}^r) = v$ (where M has full rank) is equivalent to replacing $r - \ell$ of the r input bits for f by affine functions of the other ℓ inputs. Thus, we have $\left\| h(\mathbf{U}^\ell) - f(\mathbf{U}^r) \right\|_{\mathsf{TV}} \le 2\varepsilon$ as desired. ◀

[6] The conference version of [13] does not explicit state that M is full rank, but this can be found in the updated arXiv version: `https://arxiv.org/abs/2309.11019`.

We now proceed to the input reduction lemma.

▶ **Lemma 17.** *Suppose* $\mathsf{Iso}\colon \mathbb{F}_2^n \to \mathbb{F}_2$ *is an* $(\alpha, \beta, k-1)$*-isolator for the class of degree-*d *polynomial sources with at most* $4(k+1)$ *inputs. Then* Iso *is also an* $(\alpha, \beta + 2^{-k}, k)$*-isolator for the class of all degree-*d *polynomial sources.*

Proof. We clearly have $\mathbf{Pr}[\mathsf{Iso}(\mathbf{U}^n) = 1] \geq \alpha$ since Iso is an $(\alpha, \beta, k-1)$-isolator, so it remains to verify that Iso satisfies the second condition in the definition of an $(\alpha, \beta + 2^{-k}, k)$-isolator for the class of all degree-d polynomial sources.

Let $f\colon \mathbb{F}_2^r \to \mathbb{F}_2^n$ be a degree-d polynomial map with light points $L_f \coloneqq \{x : \mathbf{Pr}[f(\mathbf{U}^r) = x] \leq 1/2^k\}$. Let $\ell = 4(k+1)$, and let $S\colon \{0,1\}^n \to \{0,1\}^{k+1}$ be the map given by Claim 15 applied to $f(\mathbf{U}^r)$ and k. Apply Lemma 16 to the function $S(f(\cdot))$ with $\varepsilon = 2^{-(k+1)}$ to get $A \in \mathbb{F}_2^{r \times \ell}, b \in \mathbb{F}_2^r$ such that

$$\left\| S(f(A \cdot \mathbf{U}^\ell + b)) - S(f(\mathbf{U}^r)) \right\|_{\mathsf{TV}} \leq 2^{-k}. \tag{7}$$

Let $g\colon \mathbb{F}_2^\ell \to \mathbb{F}_2^n$ be defined by $g(x) = f(Ax + b)$. Observe that g is a degree-d polynomial since we have only substituted linear polynomials for the inputs of f.

Define $L_g = \{x : \mathbf{Pr}[g(\mathbf{U}^\ell) = x] \leq 2^{-(k-1)}\}$. Observe that $L_f \subseteq L_g$, since (7) implies every $x \in L_f$ satisfies

$$\mathbf{Pr}[g(\mathbf{U}^\ell) = x] \leq \mathbf{Pr}[S(g(\mathbf{U}^\ell)) = S(x)] \leq \mathbf{Pr}[S(f(\mathbf{U}^r)) = S(x)] + 2^{-k} \leq 2^{-(k-1)}.$$

Therefore, we conclude

$$\begin{aligned}
\mathop{\mathbf{Pr}}_{\mathbf{x} \sim f(\mathbf{U}^r)}[\mathbf{x} \in L_f \text{ and } \mathsf{Iso}(\mathbf{x}) = 1] &\leq \mathop{\mathbf{Pr}}_{\mathbf{x} \sim g(\mathbf{U}^\ell)}[\mathbf{x} \in L_f \text{ and } \mathsf{Iso}(\mathbf{x}) = 1] + 2^{-k} && \text{(by (7))} \\
&\leq \mathop{\mathbf{Pr}}_{\mathbf{x} \sim g(\mathbf{U}^\ell)}[\mathbf{x} \in L_g \text{ and } \mathsf{Iso}(\mathbf{x}) = 1] + 2^{-k} && \text{(since } L_f \subseteq L_g\text{)} \\
&\leq \beta + 2^{-k}.
\end{aligned}$$

The last inequality above uses the isolator guarantee for $g(\mathbf{U}^\ell)$. This finishes the proof. ◀

To apply Lemma 17, we need to construct an isolator for the class of polynomial sources with bounded input length. The following lemma will allow us to find such an object more efficiently than a naive brute force. Below, recall that a family $\{f_i\colon \{0,1\}^n \to \{0,1\}^m\}_i$ of t-wise uniform hash functions is defined by the property that for any string $(y_1, y_2, \ldots, y_t) \in (\{0,1\}^m)^t$ and all distinct strings $x_1, x_2, \ldots, x_t \in \{0,1\}^n$, a function $\mathbf{f}$ chosen uniformly at random from the family satisfies $(\mathbf{f}(x_1), \mathbf{f}(x_2), \ldots, \mathbf{f}(x_t)) = (y_1, y_2, \ldots, y_t)$ with probability 2^{-mt}.

▶ **Lemma 18.** *Let* $0 < \alpha < \beta < 1$*. Let* k, n, ℓ*, and* d *be positive integers. Set* $K = 2^k$ *and* $N = 2^n$*. Let* $t \geq 4$ *be an even integer. Suppose there exists an integer* m *such that* $p \coloneqq 2^{-m}$ *satisfies* $\alpha < p < \beta$ *and the following inequality holds:*

$$\left(\frac{Npt + t^2}{N^2(p-\alpha)^2}\right)^{t/2} + 2^{\binom{\ell}{\leq d}n}\left(\frac{Kpt + t^2}{K^2(\beta - p)^2}\right)^{t/2} < 1/8.$$

Additionally, let $\mathcal{H}$ *be a family of* t*-wise uniform hash functions from* $\{0,1\}^n$ *to* $\{0,1\}^m$*. Then there exists a function* $h \in \mathcal{H}$ *such that the function* g *defined by* $g(x) = \mathbf{1}(h(x) = 0^m)$ *is an* (α, β, k)*-isolator for the class of degree-*d *polynomial sources with* ℓ *inputs and* n *outputs.*

Proof. Let $\mathbf{h}$ be a function drawn uniformly at random from $\mathcal{H}$, and define $\mathbf{g}\colon \{0,1\}^n \to \{0,1\}$ by $\mathbf{g}(x) = \mathbf{1}(\mathbf{h}(x) = 0^m)$. By the assumption on $\mathcal{H}$, $\{\mathbf{g}(x)\}_{x\in\{0,1\}^n}$ is a collection of t-wise independent random variables, and for each x, $\mathbf{Pr}[\mathbf{g}(x) = 1] = 2^{-m}$. By using a tail inequality for sums of t-wise independent random variables (see [9, Lemma 2.3]), we have

$$\mathop{\mathbf{Pr}}_{\mathbf{g}}[\mathbf{Pr}[\mathbf{g}(\mathbf{U}^n) = 1] \le \alpha] \le 8\left(\frac{Npt + t^2}{N^2(p-\alpha)^2}\right)^{t/2}.$$

This is the probability that $\mathbf{g}$ fails to satisfy the first condition for being an (α, β, k)-isolator.

We will now estimate the probability that for some source, the second condition for being an (α, β, k)-isolator is not satisfied. Fix any source $\mathbf{X}$ on $\{0,1\}^n$, and define $L = \{x : \mathbf{Pr}[\mathbf{X} = x] \le 2^{-k}\}$. We wish to show that with high probability over $\mathbf{g}$, $\mathbf{Pr}[\mathbf{g}(\mathbf{X}) = 1 \text{ and } \mathbf{X} \in L] \le \beta$. Let $\mathbf{Z} = \mathbf{Pr}[\mathbf{g}(\mathbf{X}) = 1 \text{ and } \mathbf{X} \in L]$ be the random variable of interest. For each $x \in L$, define the indicator random variable $\mathbf{Z}_x = \mathbf{1}(\mathbf{g}(x) = 1)$, each of which is a Bernoulli random variable with probability p of being 1. Then $\mathbf{Z} = \sum_{x\in L} \mathbf{Pr}[\mathbf{X} = x]\mathbf{Z}_x$ and $\mathbb{E}[\mathbf{Z}] = \mathbf{Pr}[\mathbf{X} \in L] \cdot p \le p$.

By a tail inequality for t-wise independent random variables as above and using that $\mathbf{Pr}[\mathbf{X} = x] \le 2^{-k}$ for all $x \in L$, we obtain

$$\begin{aligned}\mathbf{Pr}[\mathbf{Z} \ge \beta] &= \mathbf{Pr}[\mathbf{Z} \ge \mathbb{E}[\mathbf{Z}] + \beta - \mathbf{Pr}[\mathbf{X} \in L] \cdot p] \\ &\le \mathbf{Pr}[\mathbf{Z} \ge \mathbb{E}[\mathbf{Z}] + \beta - p] \\ &\le 8\left(\frac{Kpt + t^2}{K^2(\beta-p)^2}\right)^{t/2}.\end{aligned}$$

Now a union bound over the $2^{\binom{\ell}{\le d}n}$ many degree-d polynomial sources with ℓ inputs and n outputs gives that the second condition for being an (α, β, k)-isolator for such sources does not hold with probability at most $8 \cdot 2^{\binom{\ell}{\le d}n} \cdot \left(\frac{Kpt+t^2}{K^2(\beta-p)^2}\right)^{t/2}$. Combining this with the failure probability for the first condition shows that g fails to be an (α, β, k)-isolator for such sources with probability at most

$$8\left(\left(\frac{Npt + t^2}{N^2(\alpha-p)^2}\right)^{t/2} + 2^{\binom{\ell}{\le d}n}\left(\frac{Kpt + t^2}{K^2(\beta-p)^2}\right)^{t/2}\right) < 1$$

by assumption. Hence there exists some $\mathbf{g}$ which is an (α, β, k)-isolator, as desired. ◀

By iterating through a t-wise uniform family of hash functions, we must find an isolator in a reasonable amount of time.

▶ **Corollary 19.** *Let k, n, d, and m be positive integers. Suppose $k \ge 10(d + \log n)$, $k \le n$, and $m \le 0.01k$. For $p = 2^{-m}$, there exist $\alpha = p - 2^{-\Omega(n)}$ and $\beta = p + 2^{-\Omega(k)}$ such that there exists an (α, β, k)-isolator* Iso *for the class of degree-d polynomials with n outputs, which can be computed in time $2^{O(\binom{\Theta(k)}{\le d}n^2)}$.*

Proof. Set $\ell = 5k$, $K = 2^k$, and $t = 2\left(\binom{\ell}{\le d}n + 4\right)$; note that $K^{0.99} \ge 4t$. By using Lemma 18 under the conditions on k, d in the statement, there exists a function Iso which is an $(\alpha', \beta', k-1)$-isolator for the class of degree-d polynomial sources with $4(k+1) \le 5k$ inputs and n outputs, where $\alpha' = p - 2^{-\Omega(n)}$ and $\beta' = p + 2^{-\Omega(k)}$. Furthermore by Lemma 17, Iso is an (α, β, k)-isolator for the class of degree-d polynomial sources with n outputs, where $\alpha = \alpha' = p - 2^{-\Omega(n)}$ and $\beta = \beta' + 2^{-k} = p + 2^{-\Omega(k)}$.

We compute such a function by going over any fixed t-wise uniform family of hash functions from $\{0,1\}^n$ to $\{0,1\}^m$ until we find a function that lets us construct an isolator as described in Lemma 18. It is well known that there is such a family $\mathcal{H}$ of size 2^{tn} where each

function in the family can be evaluated in $\mathsf{poly}(n, m, t)$ time (see, for instance, [43, Corollary 3.34]). For any such fixed function $h \in \mathcal{H}$, we check whether g defined by $g(x) = \mathbf{1}(h(x) = 0^m)$ is an (α, β, k)-isolator. This can be done in time $2^{O(\binom{\ell}{\leq d} n)}$. ◀

By invoking Theorem 8 with the above isolator, we obtain an explicit hard distribution for polynomial sources, proving Theorem 14. We restate the theorem below for the reader's convenience.

▶ **Theorem 14.** *There exists a constant $\delta > 0$ such that the following holds. Let N and Δ be positive integers satisfying $\Delta \leq \delta \log\log N$. There exist positive integers n, t, d with $(n+1)t \leq N$ and an isolator $\mathsf{Iso}\colon \{0,1\}^n \to \{0,1\}$ with suitable parameters for the class of polynomial sources on $\{0,1\}^n$ of degree d such that the following holds.*

Define the distribution

$$\mathbf{D} = (\mathbf{U}_1, \mathbf{U}_2, \ldots, \mathbf{U}_t, \mathsf{Iso}(\mathbf{U}_1), \mathsf{Iso}(\mathbf{U}_2), \ldots, \mathsf{Iso}(\mathbf{U}_t)),$$

where $\mathbf{U}_1, \mathbf{U}_2, \ldots, \mathbf{U}_t$ are independent copies of $\mathbf{U}^n$. Let $\mathcal{X}$ be the class of all polynomial sources $\mathbf{X}$ on $\{0,1\}^{(n+1)t}$ of degree Δ. Then for any $\mathbf{X} \in \mathcal{X}$,

$$\|\mathbf{D} - \mathbf{X}\|_{\mathsf{TV}} \geq 1 - O\left(\frac{\Delta}{\log\log N} \log\left(\frac{\log\log N}{\Delta}\right)\right).$$

Moreover, the distribution $\mathbf{D}$ can be sampled in $\mathsf{poly}(N)$ time.

Additionally, there exists an isolator $\widetilde{\mathsf{Iso}}\colon \{0,1\}^n \to \{0,1\}$ (with possibly different parameters) such that the distribution $\widetilde{\mathbf{D}} = (\mathbf{U}^n, \widetilde{\mathsf{Iso}}(\mathbf{U}^n))$ satisfies $\left\|\widetilde{\mathbf{D}} - \mathbf{Y}\right\|_{\mathsf{TV}} \geq 1/4 - n^{-\Omega(1)}$ for all degree-Δ polynomial sources $\mathbf{Y}$ on $\{0,1\}^{n+1}$. $\widetilde{\mathbf{D}}$, too, can be sampled in $\mathsf{poly}(N)$ time.

Proof. We choose parameters to optimize the final distance with respect to the distribution length $(n+1)t$ while ensuring the construction takes only $\mathsf{poly}(N)$ time. Set $n = \lfloor (\log N)^{1/(2+\lambda)} \rfloor$ for a constant $\lambda > 0$ to be determined later. Let $d = \log n$ and $t = \lfloor d/\Delta \rfloor - 1$ so that $\Delta(t+1) \leq d$. By picking δ to be small enough, we have $t \geq 1$. Let $k = \lceil 20 \log n \rceil$ so that the condition $k \geq 10(\log n + d)$ in Corollary 19 is satisfied. Let m be the largest integer such that for $p = 2^{-m}$, we have $t \geq \frac{1}{p} \log \frac{1}{p}$. Since $t \leq d = \log n$ and $m \leq \log t$, we have $m \leq 0.01k$. Now let Iso be the (α, β, k)-isolator given by Corollary 19 with the chosen parameters and $\alpha = p - 2^{-\Omega(n)}, \beta = p + 2^{-\Omega(k)}$.

Let $\mathbf{X} \in \mathcal{X}$. Note that $\mathsf{addr}_{n,t}(\mathbf{X})$ can be computed by a degree $\Delta(t+1) \leq d$ polynomial source since $\mathsf{addr}_{n,t}$ can be computed by a degree-$(t+1)$ polynomial. By Theorem 8, we have

$$\begin{aligned}
1 - \|\mathbf{D} - \mathbf{X}\|_{\mathsf{TV}} &\leq (1-\alpha)^t + \beta + (2t^3+1)2^{-(n-k)} \\
&\leq (1 - p + 2^{-\Omega(n)})^t + p + 2^{-\Omega(k)} + (2t^3+1) \cdot 2^{-\Omega(n)} \\
&\leq (1-p)^t + t \cdot 2^{-\Omega(n)} + p + 2^{-\Omega(k)} + 2^{-\Omega(n)} \\
&\leq \exp(-pt) + p + n^{-\Omega(1)} \\
&\leq O(p) \leq O\left(\frac{\log t}{t}\right) \\
&\leq O\left(\frac{\Delta}{\log\log N} \log\left(\frac{\log\log N}{\Delta}\right)\right).
\end{aligned}$$

Finally, we show that $\mathbf{D}$ can be sampled in time $\mathsf{poly}(N)$. The isolator Iso can be computed in time $2^{O(\binom{\Theta(k)}{\leq d} n^2)}$. We have

$$\binom{\Theta(k)}{\leq d} \leq \left(\frac{e \cdot \Theta(k)}{d}\right)^d \leq C_0^{\log n} = n^{\log C_0}$$

for some constant $C_0 > 1$. Set $\lambda = \log C_0$, so Iso can be computed in time $2^{O(n^{2+\lambda})} = \mathsf{poly}(N)$. Given that Iso is computable in $\mathsf{poly}(N)$ time, it is straightforward to see that $\mathbf{D}$ can be sampled in $\mathsf{poly}(N)$ time.

We now specialize to the case of $t = 1$ and $\widetilde{\mathbf{D}} = (\mathbf{U}^n, \widetilde{\mathsf{Iso}}(\mathbf{U}^n))$, where $\widetilde{\mathsf{Iso}}$ is an $(1/2 - 2^{-\Omega(n)}, 1/2 + n^{-\Omega(1)}, 20\log n)$-isolator. Invoking Theorem 8, we obtain

$$\left\|\widetilde{\mathbf{D}} - \mathbf{Y}\right\|_{\mathsf{TV}} \geq 1 - (1/2 + 2^{-\Omega(n)})^2 - (1/2 + n^{-\Omega(1)}) - 2^{-\Omega(n)} \geq 1/4 - n^{-\Omega(1)}. \quad \blacktriangleleft$$

Note that our hard distribution above has at most N bits instead of exactly N bits. To obtain a distribution with exactly N bits, one can pad with some bits that are fixed to, say, 0. It is clear that the padded distribution does not become easier for polynomial sources of degree Δ since TV distance cannot increase by applying a projection. It is also easy to see that the padded distribution is computable in $\mathsf{poly}(N)$ time if the original distribution is computable in $\mathsf{poly}(N)$ time.

5 Open Problems

We conclude by highlighting several directions for future research. One notable goal is to bring our understanding of sampling by small circuits with parity gates (i.e., $\mathsf{AC}^0[\oplus]$) up to the frontier of what is known in the computational setting.

1. Provide an explicit distribution over $\{0,1\}^n$ which has distance $1 - o(1)$ from the output of any $\mathsf{AC}^0[\oplus]$ circuit with n outputs, $\mathsf{poly}(n)$ many gates, and arbitrarily many random input bits.

Even obtaining a much weaker bound would be novel; to the best of our knowledge, no hardness results for explicit[7] distributions exist beyond the trivial arguments of finding a hard distribution for extremely small circuits via brute force, or appealing to the limitations posed by binary precision. For example, the $(1/3)$-biased distribution over $\{0,1\}$ cannot be exactly generated by a circuit with r random bits as input, since each output occurs with probability that is an integer multiple of 2^{-r}. Of course, one could also ask for a similarly hard distribution in the case of circuits with mod p gates for any other prime p. Without these more powerful gates, it is known that such circuits cannot accurately generate the uniform distribution over the codewords of a good code [35, 8]. Unfortunately, the arguments do not seem to generalize.

In light of Theorem 14, a reasonable approach to Question 1 is to construct an isolator for $\mathbb{F}_2$-polynomial sources of polylogarithmic degree, and then appeal to classical results on polynomial approximations of circuits [37, 41]. This is a more general degree constraint than the best-known explicit extractors can handle [13], but we are optimistic further improvements in these extractors will be flexible enough for our techniques to apply. It is also worth emphasizing that extractors and isolators are incomparable objects, and it is plausible that the latter may be easier to construct in certain settings.

An alternative strengthening of Theorem 14 is to improve the quantitative behavior; while we can prove a $1 - o(1)$ bound, the specific decay rate of the $o(1)$ term is suboptimal.

2. Provide an explicit distribution over $\{0,1\}^n$ which has distance $1 - \exp(-n^{\Omega_d(1)})$ from the output of any degree-d $\mathbb{F}_2$-polynomial source.

[7] Existential results can be found in the appendix of the full version.

We note that one can prove such a bound in the case of $d = 1$, where the source $P(\mathbf{U}^r)$ is uniform over an affine subspace. Letting $\mathsf{Ext}\colon \{0,1\}^n \to \{0,1\}^m$ be an (ε, k)-extractor for affine sources, we can set the hard distribution $\mathbf{D}$ to be uniform over the preimage $\mathsf{Ext}^{-1}(0^m)$. If $P(\mathbf{U}^r)$ has min-entropy at least k, then it has distance at least $1 - 2^{-m} - \varepsilon$ from $\mathbf{D}$. Otherwise, $P(\mathbf{U}^r)$ is uniform over a set of size less than 2^k, so it has distance at least $1 - 2^{-(n-k)}/(2^{-m} - \varepsilon)$ from $\mathbf{D}$. By known explicit constructions of such objects [12, 51, 34], we can take $k = \Omega(n)$, $\varepsilon = 2^{-\Omega(n)}$, and $m = \Omega(n)$ with a sufficiently small implicit constant to conclude $\|P(\mathbf{U}^r) - \mathbf{D}\|_{\mathsf{TV}} \geq 1 - \exp(-\Omega(n))$.

Sadly, this argument already breaks down for $d = 2$, since we no longer get meaningful information about $\mathsf{supp}\,(P(\mathbf{U}^r))$ in the low min-entropy case. Moreover, our current framework does not appear strong enough to address Question 2, and it would be interesting to determine whether the framework itself can be strengthened.

3. Prove a quantitatively stronger version of Theorem 8.

More specifically, it would be desirable to have the β term in Theorem 8 decrease as t increases. It also seems worthwhile to try to improve the $t = 1$ setting to be able to obtain the optimal form $\frac{1}{2} - o(1)$, rather than our current $\frac{1}{4} - o(1)$. In both cases, one may wish to consider a variant of extractors even beyond robust extractors or isolators.

Abstract

Answering a question of Claudet, we prove that the uniformly random graph $G \sim \mathbb{G}(n, 1/2)$ is $\Omega(\sqrt{n})$-vertex-minor universal with high probability. That is, for some constant $\alpha \approx 0.911$, any graph on any $\alpha\sqrt{n}$ specified vertices of G can be obtained as a vertex-minor of G. This has direct implications for quantum communications networks: an n-vertex k-vertex-minor universal graph corresponds to an n-qubit k-stabilizer universal graph state, which has the property that one can induce any stabilizer state on any k qubits using only local operations and classical communications.

We further employ our methods in two other contexts. We obtain a bipartite pivot-minor version of our main result, and we use it to derive a universality statement for minors in random binary matroids. We also introduce the *vertex-minor Ramsey number* $R_{\mathrm{vm}}(k)$ to be the smallest value n such that every n-vertex graph contains an independent set of size k as a vertex-minor. Supported by our main result, we conjecture that $R_{\mathrm{vm}}(k)$ is polynomial in k. We prove $\Omega(k^2) \leq R_{\mathrm{vm}}(k) \leq 2^k - 1$.

1 Background and main results

Vertex-minors have been the star of numerous fascinating problems in graph theory since the 1980s. They often serve as a dense analogue of the usual minor relation, and so similarly have many deep applications to width parameters, algorithms, and logic [30, 22, 15, 5]. For more background on vertex-minors and their applications, see the recent survey on vertex-minors by Kim and Oum [28]. We begin with their definition.

▶ **Definition 1.** *Given a graph G and a vertex $v \in V(G)$, a* local complementation *at v is an operation which replaces $G[N(v)]$, the subgraph of G induced on the neighborhood of v, by its complement. The resulting graph is denoted $G * v$ and has the same vertex set as G. A graph H with $V(H) \subseteq V(G)$ is a* vertex-minor *of G if it can be obtained from G through a sequence of local complementations and vertex deletions.*

Vertex-minors also have fascinating connections to quantum information theory, on which we elaborate in Section 1.1. The following definition, introduced by Claudet et al. [12] and further studied by Cautrès et al. [8], provides a bridge between the purely graph-theoretic concept of vertex-minors and the quantum-theoretic notion of k-stabilizer universal states.

▶ **Definition 2.** *A graph G is* k-vertex-minor universal *on $V(G)$ if for every vertex subset $U \subseteq V(G)$ with $|U| = k$, every graph H on U is a vertex-minor of G.*

We emphasize that we require each H to be obtained exactly on each specified vertex set U. In particular, there are $\binom{|V(G)|}{k}2^{\binom{k}{2}}$ total choices of pairs U and H.

Our main result, resolving a question of Claudet [11], is that for some constant C, *almost all* graphs on Ck^2 vertices are k-vertex-minor universal. That is, a uniformly random graph on Ck^2 vertices is k-vertex-minor universal with probability tending exponentially fast to 1 as k increases. The quadratic dependence is best possible up to the constant factor C [12]. We use the notation $\mathbb{G}(n,p)$ for the Erdős-Renyi distribution on graphs on n vertices where each edge is included independently with probability p; in particular, $\mathbb{G}(n,1/2)$ is the uniform distribution on graphs on n vertices.

▶ **Theorem 3.** *For all $c > 0$, if $G \sim \mathbb{G}(n,1/2)$ with $n \geq (1+c)\frac{1}{2\log_2(4/3)}k^2$, then G is k-vertex-minor universal with probability at least $1 - 2^{-(1+o(1))ck^2/2}$.*

On the practical side, our explicit bound on the probability of success converges exponentially quickly beyond the threshold value. Thus we have a probabilistic algorithm to produce a k-vertex-minor universal graph on $O(k^2)$ vertices. Explicitly, letting $C = \frac{1}{2\log_2(4/3)} \approx 1.205$, we have that for any $\varepsilon > 0$ and $k \geq 3$, a uniformly random graph on $n = \lceil Ck^2 + 16k\log k + 4\log(1/\varepsilon)\rceil$ vertices is k-vertex-minor universal with probability at least $1-\varepsilon$. This follows from keeping track of the error terms in the union bound (see (3)).

The proof of Theorem 3 is non-constructive, and we do not obtain an algorithm for finding a desired vertex-minor in $\mathbb{G}(n,1/2)$. We note that this problem is NP-hard in general [17, 16], but this does not preclude the possibility of an efficient algorithm which succeeds with high probability when the input is a random graph.

▶ **Question.** *Does there exist a polynomial-time algorithm which takes as input $G \sim \mathbb{G}(n,1/2)$ and a graph H on $O(\sqrt{n})$ vertices, and with high probability outputs a sequence of local complementations verifying that H is a vertex-minor of G?*

For comparison to known results regarding k-vertex-minor universal graphs, Claudet et al. [12] showed that there exist k-vertex-minor universal graphs with $O(k^4 \log k)$ vertices, while any k-vertex-minor universal graph must have at least $(k-2)^2/(2\log_2 3)$ vertices. Cautrès et al. [8] improved the existence result to match the lower bound up to a constant factor, establishing the existence of k-vertex-minor universal graphs on $(2+o(1))k^2$ vertices. Their construction is based on a random unbalanced bipartite graph G where one side has $\Theta(k^2)$ vertices and the other has $\Theta(k \log k)$ vertices, with edges between the two sides included independently with probability $1/2$. This yields a graph with $\Theta(k^3 \log k)$ edges with high probability, which is less than a constant proportion of possible edges. They also give a polynomial time algorithm to find a k-vertex graph H as a vertex-minor in G with high probability.

Our Theorem 3 improves the constant factor 2 from Cautrès et al. [8] to $\frac{1}{2\log_2(4/3)} \approx 1.205$, progressing closer to the lower bound [12] of $1/(2\log_2 3) \approx 0.315$. More conceptually important, however, is that our result states that almost all graphs – including dense and non-bipartite graphs – also have the vertex-minor universality property. This is perhaps surprising in the context of a paper of Gross, Flammia, and Eisert [24], which shows that all but an exponentially small fraction of quantum states are too entangled to be computationally useful. Our theorem, in contrast, shows that all but an exponentially small fraction of $O(k^2)$-qubit *graph* states are in fact k-stabilizer universal. We elaborate more on the quantum perspective in Section 1.1.

Although the vertex-minor problem addressed by Theorem 3 is most relevant to quantum information theory, our methods extend to a stronger notion of universality. The following definition plays a key role.

▶ **Definition 4.** *Given a graph G and an edge $uv \in E(G)$, a pivot at the edge uv is the operation which replaces G by $G \times uv := G * u * v * u$. It is easy to verify that $G*u*v*u = G*v*u*v$, so the operation is well-defined. A graph H with $V(H) \subseteq V(G)$ is a* pivot-minor *of G if it can be obtained from G through a sequence of pivots and vertex deletions. A graph G is* k-pivot-minor universal *on $V(G)$ if for every vertex subset $U \subseteq V(G)$ with $|U| = k$, every graph H on U is a pivot-minor of G.*

Our techniques naturally extend to pivot-minors. Pivot-minors in bipartite graphs are essentially equivalent to minors in binary matroids, and thus we also obtain the following two results. For brevity, we omit proofs of these results and precise definitions for matroid minor universality, but we include them in the full version of this manuscript [1].

▶ **Theorem 5.** *For all $c > 0$, if $G \sim \mathbb{G}(n, 1/2)$ with $n \geq (1+c)\frac{2}{\log_2(16/13)}k^2 \approx (1+c)6.68k^2$, then G is k-pivot-minor universal with probability at least $1 - 2^{-(1+o(1))ck^2}$.*

▶ **Theorem 6.** *Let $C = \frac{1}{2\log_2(8/7)} + \frac{1}{4} \approx 2.85$. For all $c > 0$, if M is a uniformly random binary matroid on ground set $[n]$ and $n \geq (1+c)2Ck^2$, then M is k-minor universal with probability at least $1 - 2^{-(1+o(1))ck^2/4}$.*

For G to be k-vertex-minor universal requires that we can obtain every graph on every k-subset of vertices of G as a vertex-minor. We can also ask a related question: how big does n need to be to ensure that *every* graph on n vertices contains a *particular* graph H as a vertex-minor on some k vertices? The answer is only finite if the graph H has no edges, or is an *independent set*; indeed, otherwise, a graph of any size n with no edges does not contain H as a vertex-minor.

▶ **Definition 7.** *Let $R_{\mathrm{vm}}(k)$ be the minimum n such that any n-vertex graph contains the independent set of size k as a vertex-minor.*

Recall the classical Ramsey number $R(s,t)$ which is the smallest n such that any n-vertex graph contains either an independent set of size s or a clique of size t. As observed in [6], we have $R_{\mathrm{vm}}(k) \leq R(k,k+1)$, since if a graph contains a clique of size $k+1$, locally complementing at one vertex forms an independent set on the remaining k vertices. The current best upper bound on $R(k,k+1)$ is roughly 3.8^k, due to Gupta, Ndiaye, Norin, and Wei [25] following the breakthrough work of Campos, Griffiths, Morris, and Sahasrabudhe [7]. Here we provide a nontrivial, but still exponential upper bound for $R_{\mathrm{vm}}(k)$, as well as a quadratic lower bound obtained from the random graph.

▶ **Theorem 8.** *For all $k \geq 0$,*

$$(1+o(1))\frac{1}{2\log_2 3}k^2 \leq R_{\mathrm{vm}}(k) \leq 2^k - 1.$$

The lower bound comes from showing that with high probability, the uniformly random graph $G \sim \mathbb{G}(n,1/2)$ does not contain an independent set of size k as a vertex-minor if $k \geq (1+\varepsilon)\sqrt{2\log_2(3)n}$, for any $\varepsilon > 0$. Due to Theorem 3, this is best possible up to the constant factor, and we believe the lower bound is closer to the true answer.

▶ **Conjecture 9.** $R_{\mathrm{vm}}(k) \leq \mathsf{poly}(k)$.

Paper organization. We conclude this section by discussing the connection between vertex-minor universality and quantum information theory. Then, in Section 2, we provide the technical graph-theoretic and probabilistic tools we need for the proof of Theorem 3, state some preliminary lemmas, and give a detailed overview of the proof. In Section 3, we carry out our proof strategy for Theorem 3. Finally, in Section 4, we prove Theorem 8 about the vertex-minor Ramsey number and conclude with some remaining open questions.

1.1 Motivation from quantum information theory

Although the study of k-vertex-minor universal graphs has only taken off in recent years, the relationship between quantum graph states and vertex-minors dates back to 2004 with the pioneering work of Van den Nest, Dehaene, and De Moor [31]. In the years since, many authors have studied various models of random graph states and their algorithmic and quantum entanglement properties; see e.g. [32, 16, 27, 23] and the references therein for non-exhaustive coverage of the subject.

Recent work in quantum information theory has emphasized the role of entangled multipartite states as reusable resources for large-scale quantum communication networks. In such networks, separate parties are restricted to Local Operations and Classical Communication (LOCC), with no ability to perform joint quantum operations once the resource state has been distributed. A central question in this setting is to understand which global entangled states allow pairs of parties to generate entangled EPR pairs.

Motivated by this perspective, Bravyi, Sharma, Szegedy, and de Wolf [4] introduced the notion of k-pairable quantum states. An n-party state $|\psi\rangle$ is k-pairable if, for any choice of k disjoint pairs of parties, there exists a LOCC protocol that starts with $|\psi\rangle$ and ends in a

state such that each of those pairs of parties share an EPR pair. This definition reflects a worst-case notion of network universality: a single fixed resource state must, under LOCC, generate EPR pairs for any choice of k disjoint pairs of parties. Bravyi et al. [4] established upper and lower bounds on the achievable value of k in terms of the number of parties and number of qubits per party.

Subsequently, Claudet, Mhalla, and Perdrix [12] and Cautrès, Claudet, Mhalla, Perdrix, Savin, and Thomassé [8] elaborated on the ideas of Bravyi et al. [4], focusing on the case where each party has just one qubit and studying a generalization of k-pairable states which Cautrés et al. [8] call *k-stabilizer universal* states. A state is k-stabilizer universal if any stabilizer state on any subset of k qubits can be obtained through LOCC protocols. Stabilizer universality is a stronger notion than k-pairability: EPR pairs are stabilizer states, so any $2k$-stabilizer universal state is also k-pairable. For more background on stabilizer states, see for example [26].

The quantum-theoretic contributions of [12] and [8], as well as those of this article, rely on the connection between quantum states and graph theory. Vertex-minors capture an important sequence of operations on quantum states: if H can be obtained as a vertex-minor of G, then the quantum graph state corresponding to H can be obtained from the graph state corresponding to G through just local Clifford operations, local Pauli measurements, and classical communications. (The converse also holds if H has no isolated vertices [18].) It follows that if G is a k-vertex-minor universal graph then the quantum graph state corresponding to G is k-stabilizer universal. This enables explicit constructions of universal resource states for quantum communication protocols [12, 8].

2 Preliminaries and proof overview

We denote the symmetric difference of sets by $A \triangle B = (A \setminus B) \cup (B \setminus A)$. For a graph G, we use $V(G)$ and $E(G)$ to denote its vertex set and edge set respectively. For $U \subseteq V(G)$, we use $G[U]$ to denote the graph induced on U, and $G - U$ to denote the graph obtained by deleting U. The *adjacency matrix* of a graph G (over $\mathbb{F}_2$) is the symmetric matrix $A \in \mathbb{F}_2^{V(G)\times V(G)}$ such that $A_{u,v} = 1$ if $uv \in E(G)$ and $A_{u,v} = 0$ otherwise. Note that as we assume graphs to be simple, A has 0 along the diagonal. For disjoint sets X, Y, we define the set $[X, Y] \coloneqq \{\{x, y\} \mid x \in X, y \in Y\}$ and let $G[X, Y]$ be the induced bipartite subgraph with edge set $E(G) \cap [X, Y]$.

2.1 Vertex-minor preliminaries

Throughout the paper it will be convenient to have notation which represents both the local complementation and pivot operations. To that end we define the following. Let $x \in \{\varnothing, \{v\}, \{u, v\}\}$. Then

$$G \circ x = \begin{cases} G & x = \varnothing \\ G * v & x = \{v\} \\ G \times uv & x = \{u, v\}. \end{cases}$$

Implicitly we assume that if $x = \{u, v\}$, then $uv \in E(G)$, otherwise the operation is not defined. If $(x_i)_{i=1}^{\ell}$ is a sequence of such x, then we often use $G \circ (x_i)_{i=1}^{\ell}$ as shorthand for $G \circ x_1 \circ x_2 \circ \cdots \circ x_n$. We similarly write $G * (v_i)_{i=1}^{\ell}$ as shorthand for $G * v_1 * \cdots * v_\ell$.

Observe that an equivalent way to view the pivot operation is that for $vu \in E(G)$, $G \times vu$ is the graph obtained from G by taking the symmetric difference of G with the complete tripartite graph with parts $N(v) \cap N(u)$, $N(v) \setminus (N(u) \cup \{u\})$, $N(u) \setminus (N(v) \cup \{v\})$, and then swapping the labels of u and v.

We now discuss some well-known facts about vertex-minors and pivot-minors. We say two graphs are *locally equivalent* if one can be obtained from the other by a sequence of local complementations. Similarly we say that two graphs are *pivot equivalent* if one can be obtained from the other by a sequence of pivots. It is easy to see that if H is a vertex-(pivot-) minor of G, then $H \subseteq G'$ for some graph G' which is locally (pivot) equivalent to G. The following fact is well-known.

▶ **Lemma 10** ([30, Proposition 2.5])**.** *If $vu \in E(G)$, then $uw \in E(G \times vu)$ if and only if $vw \in E(G)$. Furthermore, if both edges exist, we have*

$$G \times vu \times uw = G \times vw.$$

The following result, proven independently by Bouchet [3] and Fon-Der-Flaass [21], will be crucial in reordering the operations when finding a vertex-minor.

▶ **Theorem 11** ([3, 21])**.** *Suppose H is a vertex-minor of G and $v \in V(G) \setminus V(H)$. Then H is a vertex-minor of*

1. *$G - v$,*
2. *$G * v - v$, or*
3. *$G \times vu - v$ for some $u \in N(v)$.*

We note that Lemma 10 implies that the choice of u does not matter up to pivot-equivalence. That is, if H is a vertex-minor of $G \times vu - v$ for some $u \in N(v)$, then H is a vertex-minor of $G \times vu' - v$ for every $u' \in N(v)$. This helps us prove our key structural lemma below. We call this our "reordering lemma," because it allows us to reorganize a sequence of local complementations in a convenient way.

▶ **Lemma 12.** *Fix a set $\hat{V}$. Let $v_1, \dots, v_\ell \in \hat{V}$ be a (possibly repeating) sequence and let $\hat{G}$ be a graph with $V(\hat{G}) = \hat{V}$. Then there is a sequence $x_1, \dots, x_r$ of singletons and pairs from $\hat{V}$ such that for any graph G with $\hat{V} \subseteq V(G)$ and $G[\hat{V}] = \hat{G}$, we have*

- **(I)** *$G * v_1 * v_2 \cdots * v_\ell - \hat{V} = G \circ x_1 \cdots \circ x_r - \hat{V}$.*
- **(II)** *The sets $x_1, \dots, x_r$ are pairwise disjoint.*
- **(III)** *If $v \in \hat{V}$ appears exactly once in $(v_i)_{i=1}^{\ell}$, then $v \in x_j$ for some $j \in [r]$.*

Moreover, any choice of $(x_i)_i$ satisfying (I) and (II) for all G also satisfies (III).

We emphasize that the sequence $(x_i)_i$ depends *only* on the subgraph $\hat{G} = G[\hat{V}]$, and is independent of the edges between $\hat{V}$ and $V(G) \setminus \hat{V}$. Without this careful tracking of the dependency, this lemma would be implied by known results, (see [14, Proposition 6] or [13, Proposition 7]). In Section 3.3, we give a short proof by induction using Theorem 11.

Because of the dependence only on $\hat{G}$, if $G \sim \mathbb{G}(n, 1/2)$, then by revealing only the edges of $\hat{G}$ we can rewrite any arbitrary sequence of local complementations $*(v_i)_i$ in the desired form $\circ(x_j)_j$, and then study the statistics of the resulting graph.

2.2 Probability preliminaries

We use $\mathbb{G}(n,p)$ to denote the Erdős-Rényi random graph distribution on vertex set $[n]$, where each edge is present independently with probability p. We let $\mathcal{G}_n$ denote the set of all labeled graphs on vertex set $[n]$. The following simple proposition is crucial for our proof.

▶ **Proposition 13.** *If $G \sim \mathbb{G}(n,1/2)$ and $v \in [n]$, then $G * v \sim \mathbb{G}(n,1/2)$.*

Proof. Since the map $G \mapsto G*v$ is an involution on $\mathcal{G}_n$, it preserves the uniform distribution. Indeed, for any graph $G' \in \mathcal{G}_n$, we have $\mathbb{P}[G*v = G'] = \mathbb{P}[G = G'*v] = \frac{1}{|\mathcal{G}_n|}$. ◀

The basic probabilistic tool we rely on is Chebyshev's inequality, which we use in the following form.

▶ **Lemma 14** (Chebyshev's inequality). *For a random variable X and $\alpha > 0$, we have*

$$\mathbb{P}[|X - \mathbb{E}[X]| \geq \alpha] \leq \frac{\mathrm{Var}[X]}{\alpha^2}.$$

In particular, setting $\alpha = \mathbb{E}[X]$ gives $\mathbb{P}[X = 0] \leq \frac{\mathrm{Var}[X]}{\mathbb{E}[X]^2}$.

2.3 Proof overview

Before the complete proof in Section 3, we outline the argument for Theorem 3. Let $G \sim \mathbb{G}(n+k,1/2)$. Fix a vertex set $U \subseteq V(G)$ of size $|U| = k$, and fix a graph H on U. Denote the vertices of G by $V = \{v_1, \ldots, v_n\} \sqcup U$. To form a copy of H on vertex set U, we locally complement on some subset of the vertices in $\{v_1, \ldots, v_n\}$, given by index set J. Complementing on this subset J produces a random graph on U, which we denote by $G_J[U]$. If two choices for the subset J are sufficiently different, then the resulting graphs $G_J[U]$ will likely also be different. There are 2^n choices for J and $2^{\binom{k}{2}}$ choices for the graph H. Hence for $k = \Theta(\sqrt{n})$, we are likely to find a choice of J for which the graph $G_J[U]$ is equal to H. The core difficulty of the proof is analyzing the difference, or more precisely the correlation, between G_J and $G_{J'}$ for different subsets J, J'.

We now proceed with a more technical overview of our proof. For each subset $J \subseteq [n]$, where $J = \{i_1 < i_2 < \ldots < i_{|J|}\}$ we define

$$G_J := G * v_{i_1} * v_{i_2} * \cdots * v_{i_{|J|}}, \tag{1}$$

so we can track 2^n distinct procedures for locally complementing on G. For example, $G_\emptyset = G$ and $G_{[n]} = G * v_1 * \cdots * v_n$. Let X be the number of "successful" procedures, i.e. $X = \sum_{J \subseteq [n]} X_J$ where X_J the indicator that $G_J[U] = H$. We want to show that $X > 0$, and hence H is a vertex-minor of G, with high probability. By Proposition 13, for each J we have $G_J \sim \mathbb{G}(n,1/2)$, so each X_J equals 1 with probability $2^{-\binom{k}{2}}$. Thus $\mathbb{E}[X] = 2^n 2^{-\binom{k}{2}} \to \infty$, and we upper bound $\mathbb{P}[X = 0]$ using Chebyshev's inequality. Finally, we apply a union bound over all choices of U and H to show that G is k-vertex-minor universal.

The central challenge for this argument is to control $\mathrm{Var}[X]$, and therefore to show that the various $G_J, G_{J'}$ are not too correlated. For example, comparing $G_\emptyset = G$ and $G_{[n]}$, we find that each time we locally complement at a vertex v_i, a random subset of the edges in U are flipped. Hence, we expect that after sufficiently many flips, the distributions of $G[U]$ and $G_{[n]}[U]$ will be almost entirely uncorrelated.

To make this precise, we define two random walks on the space of graphs with vertex set U (see Section 3.1). The first random walk chooses a uniformly random subset of U and complements the edges with both ends in that subset. This corresponds to locally complementing at a vertex outside of U that has a random neighborhood. The second random walk chooses two uniformly random subsets $S, T \subseteq U$ and toggles adjacency between pairs of vertices which lie in two different sets among $S \setminus T, T \setminus S$, and $S \cap T$. This corresponds to pivoting on an edge outside U where each end has a random neighborhood in U.

We view these random walks as linear transformations over the space of all graphs, and we compute their eigenvectors and eigenvalues exactly (see Lemma 16). We use this spectral calculation to conclude that both random walks quickly approach the uniform distribution (Lemma 20).

We then use these random walks to study $G_J[U] \triangle G_{J'}[U]$ when J and J' differ. Specifically, we argue that if $|J \triangle J'|$ is large, then $G_J[U] \triangle G_{J'}[U]$ is close to uniformly random, and thus the covariance between X_J and $X_{J'}$ is very small (see Lemma 24). Suppose $J = \{i_1 < i_2 < \cdots < i_{|J|}\}$ and $J' = \{j_1 < j_2 < \cdots < j_{|J'|}\}$. Because local complementation is an involution, we have

$$G_{J'} = G_J * v_{i_{|J|}} * \cdots * v_{i_1} * v_{j_1} * \cdots * v_{j_{|J'|}},$$

meaning that $G_{J'}[U]$ is formed from $G_J[U]$ by locally complementing on vertices outside of U. This sounds like our random walk, but as stated, the same vertex could be locally complemented on multiple times, and thus the steps in the corresponding random walk may be correlated. To combat this, we apply our reordering Lemma 12 to obtain a sequence $(x_i)_{i=1}^{\ell}$ where

$$G_{J'}[U] = G_J \circ (x_i)_{i=1}^{\ell}[U]$$

such that the x_i are pairwise disjoint. Then we may consider $G_J[U] \triangle (G_J \circ (x_i)_{i=1}^{t})[U]$ as a random walk starting at $t = 0$ with the empty graph and ending at $t = \ell$ with $G_J[U] \triangle G_{J'}[U]$. Property (III) of Lemma 12 implies that $|\bigcup_{i=1}^{\ell} x_i| \geq |J \triangle J'|$, so if $|J \triangle J'|$ is sufficiently large, then this random walk mixed for many steps, implying that $G_J[U] \triangle G_{J'}[U]$ is approximately uniformly random. Since typical sets J, J' differ in $n/2$ many indices, this gives the desired correlation bounds, implying that the variance of X is small and hence the probability that H is a vertex-minor of G is large (Lemma 26).

We note some subtlety in the sets of edges which must stay independent in this approach. In order to apply Lemma 12, we first reveal the edges of $G \setminus U$. Then we reveal the edges between x_i and U one at a time so that at each step, each vertex in x_i has a uniformly random neighborhood in U. We use Lemma 21 to argue that conditional on all previous steps, the unexposed edges remain uniformly random throughout the process. This guarantees that each step of the random walk is independent of the previous steps, and so each step brings us closer to the uniform distribution.

3 Proof of vertex-minor universality of the random graph

3.1 Random walks on the space of graphs

We first define and consider two random walks Com and Piv on the space of graphs with vertex set $U = [k]$. We begin with a graph Γ drawn from some starting distribution μ_0 on all graphs with vertex set U. Then at each time t, the Com walk simulates locally complementing

(and deleting) at vertex v outside of U with a uniformly random neighborhood. Similarly, the Piv walk simulates pivoting on an edge outside U with uniformly random neighborhoods. Formally, we define the random walks as follows.

▶ **Definition 15.** *Suppose μ is a probability distribution on $\mathcal{G}_k$, the set of labeled graphs with vertex set $[k]$. Identify μ with a vector in $[0,1]^{\mathcal{G}_k}$, and we write $\mu(H)$ to be the probability of the graph $H \in \mathcal{G}_k$. First, let $\mathrm{Com}(\mu)$ be the distribution of the graph $\Gamma \triangle K_S$, where $\Gamma \sim \mu$, and $S \subseteq [k]$ is a uniformly random subset independent of Γ. Next, for $S, T \subseteq [k]$ we let $K^{\triangle}_{S,T}$ be the complete tripartite graph with tripartition $\{S \setminus T, T \setminus S, S \cap T\}$. Then let $\mathrm{Piv}(\mu)$ be the distribution of $\Gamma \triangle K^{\triangle}_{S,T}$ where $\Gamma \sim \mu$ and $S, T \subseteq [k]$ are uniformly random and independent of Γ. Finally, let μ_{unif} be the uniform distribution on $\mathcal{G}_k$.*

It is easy to see that the uniform distribution μ_{unif} is stationary under both the Com and Piv operators, and we will be interested in how fast the distribution μ_0 approaches μ_{unif} under these operators. It is helpful to think of these as steps in a random walk on a Cayley graph of the additive group $\mathbb{F}_2^{E(K_k)}$. For example, if we construct the Cayley graph with multiset of generators $\{\mathbb{1}_{E(K_S)} : S \subseteq [k]\}$, then one step in this walk gives the convolution $\mu \mapsto \mathrm{Com}(\mu)$. A nice survey of random walks on groups is given by Diaconis [20]. As symmetric random walks, both $\mathrm{Com}, \mathrm{Piv} : \mathbb{R}^{\mathcal{G}_n} \to \mathbb{R}^{\mathcal{G}_n}$ are symmetric linear transformations over $\mathbb{R}$. Because they are walks on a Cayley graph, we can explicitly compute their eigenvectors.

▶ **Lemma 16.** *The eigenvectors of* Com *and* Piv *are given by $\{\chi_G \mid G \in \mathcal{G}_k\}$ where $\chi_G \in \mathbb{R}^{\mathcal{G}_k}$ is defined as $\chi_G(H) = (-1)^{|E(G) \cap E(H)|}$. For each $G \in \mathcal{G}_k$, let $\lambda_G^{\mathrm{Com}}, \lambda_G^{\mathrm{Piv}}$ denote the eigenvalues of χ_G under* Com, Piv *respectively. Then we have*

$$\lambda_G^{\mathrm{Com}} = \mathbb{E}_S\left[(-1)^{|E(G)\cap E(K_S)|}\right]$$
$$\lambda_G^{\mathrm{Piv}} = \mathbb{E}_{S,T}\left[(-1)^{|E(G)\cap E(K^{\triangle}_{S,T})|}\right]$$

where the expectation is over $S, T \subseteq [k]$ drawn uniformly at random.

Proof. The statement for Com follows from a simple calculation:

$$\begin{aligned}
\mathrm{Com}(\chi_G)(H) &= 2^{-k} \sum_{S \subseteq [k]} \chi_G(H \triangle K_S) \\
&= 2^{-k} \sum_{S \subseteq [k]} (-1)^{|E(G)\cap E(H)|}(-1)^{|E(G)\cap E(K_S)|} \\
&= \chi_G(H) \cdot 2^{-k} \sum_{S \subseteq [k]} (-1)^{|E(G)\cap E(K_S)|} \\
&= \chi_G(H) \cdot \mathbb{E}_S\left[(-1)^{|E(G)\cap E(K_S)|}\right].
\end{aligned}$$

The proof for Piv is similar. ◀

We can now bound the eigenvalues as follows.

▶ **Lemma 17.** *Let $G \in \mathcal{G}_k$ have adjacency matrix $A \in \mathbb{F}_2^{k\times k}$. Then*

$$(\lambda_G^{\mathrm{Com}})^2 \le \lambda_G^{\mathrm{Piv}} = 2^{-\mathrm{rank}_{\mathbb{F}_2}(A)}.$$

Proof. We first compute λ_G^{Piv}. Recall that for $S, T \subseteq [k]$, if x_S and x_T are the indicator vectors of S and T, then $x_S^\top A x_T = |\{(u,v) \mid u \in S, v \in T, uv \in E(G)\}|$ over $\mathbb{R}$. For example, $x_S^\top A x_S = 2|E(G) \cap E(K_S)|$. We observe that $|E(G) \cap E(K_{S,T}^\triangle)| \equiv x_S^\top A x_T \pmod 2$. This is because every edge from S to T is counted, with edges in $S \cap T$ counted twice. Using this and Lemma 16,

$$\lambda_G^{\mathrm{Piv}} = \mathbb{E}\left[(-1)^{|E(G \cap K_{S,T}^\triangle)|}\right] = 2^{-2k} \sum_{S,T \subseteq [k]} (-1)^{x_T^\top A x_S} = 2^{-2k} \sum_{u \in \mathbb{F}_2^k} \left(\sum_{v \in \mathbb{F}_2^k} (-1)^{v^\top A u} \right).$$

Consider the inner sum. If $u \in \mathrm{Null}_{\mathbb{F}_2}(A)$, then (over $\mathbb{F}_2$) we have $Au = 0$, so the inner sum is 2^k. Otherwise, Au is a nonzero vector, so exactly half of vectors $v \in \mathbb{F}_2^k$ have $v^\top A u = 0$, and hence the inner sum is 0. Thus,

$$\lambda_G^{\mathrm{Piv}} = 2^{-2k}\Big(2^k |\mathrm{Null}(A)|\Big) = 2^{-k} \cdot 2^{k - \mathrm{rank}(A)} = 2^{-\mathrm{rank}(A)}.$$

Next, we use this to bound λ_G^{Com}. For subsets $S, T \subseteq [k]$, let $R = S \triangle T$. Observe the following two identities:

$$\begin{aligned} |E(G) \cap E(K_S)| + |E(G) \cap E(K_T)| &\equiv |E(G) \cap E(K_{S \triangle T})| + |E(G) \cap E(K_{S,T}^\triangle)| \pmod 2 \\ &\equiv |E(G) \cap E(K_R)| + |E(G) \cap E(K_{S,R}^\triangle)| \pmod 2. \end{aligned}$$

The first can be checked combinatorially, or using linear algebra (over $\mathbb{R}$):

$$\frac{x_S^\top A x_S}{2} + \frac{x_T^\top A x_T}{2} = \frac{(x_S + x_T)^\top A (x_S + x_T)}{2} - x_T^\top A x_S.$$

Evaluating each side mod 2 yields the first identity. For the second, note that by definition $K_{S,T}^\triangle = K_{S,R}^\triangle$, or using algebra $x_T^\top A x_S \equiv (x_T + x_S)^\top A x_S \pmod 2$. As a result, we have the following change of variables (where again we use Lemma 16):

$$\begin{aligned} (\lambda_G^{\mathrm{Com}})^2 = \mathbb{E}\big[(-1)^{|E(G) \cap E(K_S)|}\big]^2 &= 2^{-2k} \sum_{S \subseteq [k]} (-1)^{|E(G) \cap E(K_S)|} \sum_{T \subseteq [k]} (-1)^{|E(G) \cap E(K_T)|} \\ &= 2^{-2k} \sum_{S,T \subseteq [k]} (-1)^{|E(G) \cap E(K_{S \triangle T})|} (-1)^{|E(G) \cap E(K_{S,T}^\triangle)|} \\ &= 2^{-2k} \sum_{R \subseteq [k]} (-1)^{|E(G) \cap E(K_R)|} \sum_{S \subseteq [k]} (-1)^{|E(G \cap K_{S,R}^\triangle)|} \\ &\leq 2^{-2k} \sum_{R \subseteq [k]} \left| \sum_{S \subseteq [k]} (-1)^{x_S^\top A x_R} \right| = \lambda_G^{\mathrm{Piv}}. \end{aligned}$$

In the last line, we used the fact again that the inner sum is either 2^k or 0. Thus, we conclude that $(\lambda_G^{\mathrm{Com}})^2 \leq \lambda_G^{\mathrm{Piv}} = 2^{-\mathrm{rank}(A)}$, as desired. ◀

▶ Remark 18. We note that A is an alternating matrix over $\mathbb{F}_2$, and so the rank of A is even. Thus in particular, if $G = I_k$, $\lambda_G^{\mathrm{Com}} = \lambda_G^{\mathrm{Piv}} = 1$, and for every other $G \in \mathcal{G}_k$, $\lambda_G^{\mathrm{Com}} \leq 1/2$ and $\lambda_G^{\mathrm{Piv}} \leq 1/4$.

We note that μ_{unif} is a multiple of χ_{I_k}, and so the crude bound of $1/2$ is enough to get exponential convergence to the uniform distribution. To get even sharper bounds, we count the number of graphs whose adjacency matrix has a given rank. This is explicitly enumerated by MacWilliams [29], but we only require the following bound.

▶ **Theorem 19** ([29, Theorem 3]). *Let $\mathcal{G}_{k,r}$ denote the set of labeled graphs whose adjacency matrix (a symmetric matrix in $\mathbb{F}_2^{k\times k}$ with 0 diagonal) has rank r. Then if $r \geq 1$ is even,*

$$|\mathcal{G}_{k,r}| \leq 2^{rk-2}$$

and if r is odd, $|\mathcal{G}_{k,r}| = 0$.

We are now ready to show that the two random walks (or any combination of the two) converge exponentially fast to the uniform distribution.

▶ **Lemma 20.** *Let $\mu_0 = \delta_{I_k}$ be the point mass distribution on the independent graph $I_k \in \mathcal{G}_k$. Then for $t = 1, \ldots, \ell$, define either $\mu_t = \mathrm{Com}(\mu_{t-1})$ or $\mu_t = \mathrm{Piv}(\mu_{t-1})$. Suppose that the* Com *transformation is applied m_1 times and the* Piv *transformation is applied m_2 times, and let $m = m_1 + 2m_2$. Then if $m > 2k$, we have*

$$|\mu_\ell(H) - \mu_{\mathrm{unif}}(H)| \leq 2^{2k-\binom{k}{2}-m}$$

for every graph $H \in \mathcal{G}_k$.

Proof. Note that $\{\chi_G \mid G \in \mathcal{G}_k\}$ is an orthogonal basis of $\mathbb{R}^{\mathcal{G}_k}$. Because $\mu_0 = \delta_{I_k}$ has the same inner product with each eigenvector, we have exactly $\mu_0 = 2^{-\binom{k}{2}} \sum_{G\in\mathcal{G}_k} \chi_G$. By induction on t, we compute

$$\mu_\ell = 2^{-\binom{k}{2}} \sum_{G\in\mathcal{G}_k} (\lambda_G^{\mathrm{Com}})^{m_1} (\lambda_G^{\mathrm{Piv}})^{m_2} \chi_G.$$

We note that $2^{-\binom{k}{2}}\chi_{I_k} = \mu_{\mathrm{unif}}$ and $\lambda_{I_k}^{\mathrm{Com}} = \lambda_{I_k}^{\mathrm{Piv}} = 1$, so

$$\mu_\ell - \mu_{\mathrm{unif}} = 2^{-\binom{k}{2}} \sum_{G\neq I_k} (\lambda_G^{\mathrm{Com}})^{m_1} (\lambda_G^{\mathrm{Piv}})^{m_2} \chi_G.$$

We now decompose the sum into the families $\mathcal{G}_{k,2r}$ for all $r \geq 0$, noting that $\mathcal{G}_{k,0} = \{I_k\}$. Using the eigenvalue bounds in Lemma 17 and the counting bounds of Theorem 19, we have the following for any $H \in \mathcal{G}_k$:

$$\begin{aligned}
|\mu_\ell(H) - \mu_{\mathrm{unif}}(H)| &\leq 2^{-\binom{k}{2}} \sum_{G\neq I_k} |\lambda_G^{\mathrm{Com}}|^{m_1} \cdot |\lambda_G^{\mathrm{Piv}}|^{m_2} \cdot |\chi_G(H)| \\
&\leq 2^{-\binom{k}{2}} \sum_{r=1}^{\lfloor k/2 \rfloor} \sum_{G\in\mathcal{G}_{k,2r}} 2^{-rm_1} 2^{-2rm_2} \\
&\leq 2^{-\binom{k}{2}} \sum_{r=1}^{\infty} 2^{2rk-2} 2^{-rm} \\
&\leq 2^{-\binom{k}{2}+2k-m},
\end{aligned}$$

where we use that $m > 2k$ so the sum converges. ◀

We will use Lemma 20 to show that, in a graph $G \sim \mathbb{G}(n, 1/2)$ with $U \subseteq V(G)$, by repeatedly locally complementing/pivoting at distinct vertices outside U, the distribution of $G \circ (x_t)_t[U]$ becomes quickly uncorrelated from the initial state $G[U]$. However, to apply Lemma 20, we need that the local complementation/pivot steps are actually independent; this relies on the initial graph being uniformly random. In fact, we need that the steps of the random walk are independent even when we choose the sequence $(x_t)_t$ based on $G - U$. Towards that end, we prove the following technical lemma.

▶ **Lemma 21.** *Let $W \subseteq \hat{V} \subseteq [n]$ and $U = [n] \setminus \hat{V}$, and fix a graph $\hat{G}$ with vertex set $\hat{V}$. Let $v_1, \dots, v_t \in W$ be a (possibly repeating) sequence of vertices depending on $\hat{G}$. Let G be a random graph with vertex set $[n]$ drawn from $\mathbb{G}(n, 1/2)$ conditioned on $G[\hat{V}] = \hat{G}$. Partition $\binom{[n]}{2}$ into $E_1 = \binom{\hat{V}}{2} \cup [W, U]$ and $E_2 = \binom{U}{2} \cup [\hat{V} \setminus W, U]$. Let $G' = G * (v_i)_{i=1}^t$. Then $E(G') \cap E_2$ is uniformly random and independent of $E(G) \cap E_1$.*

We think of our random walk as first revealing the edges of $G[\hat{V}] = \hat{G}$ to choose the sequence $v_1, \dots, v_t$. As we perform the random walk, we reveal edges between the corresponding vertices $v_1, \dots, v_t$ and U. The set W will correspond to these revealed vertices. Lemma 21 shows that the next step in our random walk is independent of all revealed information.

Proof of Lemma 21. Fix a subset A of E_1. It suffices to show that conditioned the event that $E(G) \cap E_1 = A$, the distribution of $E(G') \cap E_2$ is uniformly random. We proceed by induction on t. If $t = 0$ then $G' = G$, so by definition of $\mathbb{G}(n, 1/2)$, $E(G') \cap E_2$ is uniformly random.

Suppose $t \geq 1$ and let $G'' = G * (v_i)_{i=1}^{t-1}$; by the induction hypothesis, $E(G'') \cap E_2$ is uniformly random conditioned on $E(G) \cap E_1$. Observe that $G' = G'' * v_t$ is obtained by the involutive map $H \mapsto H \triangle K_T$, where $T = N_{G''}(v_t)$ is determined exactly by $E(G) \cap E_1$. This induces an involutive map $E(G'') \cap E_2 \mapsto E(G') \cap E_2$, and therefore preserves the uniform measure. ◀

▶ Remark 22. We note that because the above proposition holds for every graph $\hat{G}$, it also holds if we let $\hat{G}$ be uniformly random, and thus it holds when $G \sim \mathbb{G}(n, 1/2)$ and $v_1, \dots, v_t$ is a random sequence depending on $G[\hat{V}]$.

Observe that Lemma 21 implies that conditioning on $G - U$ and some previous mixing steps $x_1, \dots, x_{t-1} \subseteq W$, as long as x_t is disjoint from W and U, we have that both $G[U]$ and the edges from x_t to U are uniformly random. This implies that each step of our random walk is independent of the previous steps. With this, we conclude the final random walk result.

▶ **Lemma 23.** *Let $G \sim \mathbb{G}(n + k, 1/2)$ with partition $V(G) = \hat{V} \sqcup U$, $|U| = k$. Let $\hat{G}$ be a graph on vertex set $\hat{V}$ and let $(x_i)_{i=1}^{\ell}$ be a sequence of disjoint singletons and pairs from $\hat{V}$ such that $\hat{G} \circ (x_i)_{i=1}^{\ell}$ is well-defined and $|\bigcup_i x_i| > 2k$. Then,*

$$\left| \mathbb{P}\left[G \circ (x_i)_{i=1}^{\ell}[U] = G[U] \;\middle|\; G[\hat{V}] = \hat{G} \right] - 2^{-\binom{k}{2}} \right| \leq 2^{2k - \binom{k}{2} - |\bigcup_i x_i|}.$$

Proof. For times $t = 0, 1, \dots, \ell$, define $G_t \coloneqq G \circ (x_i)_{i=1}^{t}$, and define the probability distribution $\mu_t \in [0,1]^{\mathcal{G}_k}$ as the distribution of $H_t := (G_t \triangle G)[U]$, conditioned on $G[\hat{V}] = \hat{G}$. For example, μ_0 is the point mass distribution δ_{I_k}.

At time t, H_{t-1} is a function of $G[\hat{V}] = \hat{G}$ and $N_G(w)$ for $w \in \bigcup_{i=1}^{t-1} x_i$. If $x_t = \{v\}$, then $H_t = H_{t-1} \triangle K_S$ where $S = N_{G_{t-1}}(v) \cap U$. Similarly, if $x_t = \{v, v'\}$, then $H_t = H_{t-1} \triangle K^{\triangle}_{S,T}$, where $S = N_{G_{t-1}}(v) \cap U$ and $T = N_{G_{t-1}}(v') \cap U$. By Lemma 21 (applied with $W = \bigcup_{i<t} x_i$), we have that S (resp. T) is a uniformly random subset of U, independent of $G[\hat{V}]$ and $N_G(u)$ for $u \in \bigcup_{i<t} x_i$ and thus S (resp. T) is independent of H_{t-1}. Then by definition, if $|x_t| = 1$ then we have exactly $\mu_t = \mathrm{Com}(\mu_{t-1})$, and if $|x_t| = 2$ then $\mu_t = \mathrm{Piv}(\mu_{t-1})$. We then apply Lemma 20 (noting that the x_i are disjoint so $m = |\bigcup_i x_i|$) to conclude

$$\left| \mathbb{P}\left[(G_\ell \triangle G)[U] = I_k \;\middle|\; G[\hat{V}] = \hat{G} \right] - 2^{-\binom{k}{2}} \right| = |\mu_\ell(I_k) - \mu_{\mathrm{unif}}(I_k)| \;\leq\; 2^{2k - \binom{k}{2} - |\bigcup_i x_i|},$$

as desired. ◀

3.2 Proof of Theorem 3

We now use the reordering Lemma 12 to show that when J, J' are sufficiently different, the graphs G_J and $G_{J'}$ are sufficiently uncorrelated by applying the random walk described in Section 3.1.

▶ **Lemma 24.** *Let $G \sim \mathbb{G}(n+k, 1/2)$, $U \subseteq V(G)$ with $|U| = k$, and let $J, J' \subseteq [n]$ with $|J \triangle J'| > 2k$. Defining $G_J, G_{J'}$ as in Equation (1), we have*

$$\left|\mathbb{P}[G_J[U] = G_{J'}[U]] - 2^{-\binom{k}{2}}\right| \leq 2^{2k-\binom{k}{2}-|J\triangle J'|}$$

Proof. Let $J = \{i_1 < \ldots < i_\ell\}$ and $J' = \{j_1 < \ldots < j_{\ell'}\}$. Observe that

$$G_{J'} = G_J * v_{i_\ell} * \cdots * v_{i_2} * v_{i_1} * v_{j_1} * v_{j_2} * \cdots * v_{j_{\ell'}}. \tag{2}$$

Fix $\hat{G} \in \mathcal{G}_n$, and condition on the event $G[\hat{V}] = \hat{G}$, which depends only on the edges inside $\hat{V}$. By the reordering Lemma 12, there is a sequence $(x_i)_{i=1}^r$ (depending on $\hat{G}$) with the three properties from that lemma such that $G_{J'}[U] = G_J \circ (x_i)_{i=1}^r[U]$. By property (III), we note that $|\bigcup_i x_i| \geq |J \triangle J'|$, since a vertex v_i appears exactly once in Equation (2) if $i \in J \triangle J'$. Let $\hat{G}_J = \hat{G} * (v_{i_t})_{t=1}^\ell$, so $G[\hat{V}] = \hat{G}$ if and only if $G_J[\hat{V}] = \hat{G}_J$. Then by Lemma 23,

$$\begin{aligned}\left|\mathbb{P}\left[G_{J'}[U] = G_J[U] \;\middle|\; G[\hat{V}] = \hat{G}\right] - 2^{-\binom{k}{2}}\right| &= \left|\mathbb{P}\left[G_J \circ (x_i)_{i=1}^r[U] = G_J[U] \;\middle|\; G_J[\hat{V}] = \hat{G}_J\right] - 2^{-\binom{k}{2}}\right| \\ &\leq 2^{2k-\binom{k}{2}-|\bigcup_{i\leq r} x_i|} \\ &\leq 2^{2k-\binom{k}{2}-|J\triangle J'|},\end{aligned}$$

as desired. We apply the law of total probability over all $\hat{G} \in \mathcal{G}_n$ to obtain the unconditioned bound. ◀

Before we complete the second moment method calculation, we need one more fact about the independence implicit in our construction.

▶ **Proposition 25.** *Let $G \sim \mathbb{G}(n+k, 1/2)$, $U \subseteq V(G)$ with $|U| = k$, and let $J, J' \subseteq [n]$. Defining $G_J, G_{J'}$ as in Equation (1), the graphs $G_J[U]$ and $(G_J \triangle G_{J'})[U]$ are independent.*

Proof. We use a different but equivalent sampling procedure to obtain G_J and $G_{J'}$. First, sample $G_J \sim \mathbb{G}(n, 1/2)$ uniformly at random, which is the correct distribution by Proposition 13. In particular, the sets $E(G_J[U])$ and $E(G_J) \setminus E(G_J[U])$ are independent. Next, compute $G_{J'}$ directly using Equation (2). Observe that the set $E(G_J \triangle G_{J'})$ is a function only of $E(G_J) \setminus E(G_J[U])$ since this procedure for obtaining $G_{J'}$ depends on the edges incident to the v_i's. Thus the graphs $G_J[U]$ and $(G_J \triangle G_{J'})[U]$ are independent, as desired. ◀

We now perform the second moment calculation.

▶ **Lemma 26.** *Let $G \sim \mathbb{G}(n+k, 1/2)$. Fix a vertex set $U \subseteq V(G)$ with $|U| = k$ and a graph H on U. Then H is a vertex-minor of G with probability at least $1 - 2^{2k}(3/4)^n - 2^{-n+\binom{k}{2}+2k\log_2 n}$.*

Proof. For all $J \subseteq [n]$, construct G_J as in (1). Let X_J be the indicator that $G_J[U] = H$, and let $X = \sum_{J\subseteq[n]} X_J$. Recall that $\mathbb{E}[X] = 2^{n-\binom{k}{2}}$ by linearity of expectation and Proposition 13. We compute

$$\begin{aligned}\mathrm{Var}[X] &= \sum_{J,J'\subseteq[n]} \mathbb{E}[X_J X_{J'}] - \mathbb{E}[X_J]\mathbb{E}[X_{J'}] \\ &= \sum_{J,J'\subseteq[n]} \mathbb{P}[G_J[U] = H \wedge G_J[U] = G_{J'}[U]] - \mathbb{P}[G_J[U] = H]\mathbb{P}[G_{J'}[U] = H] \\ &= \sum_{J,J'\subseteq[n]} \mathbb{P}[G_J[U] = H]\mathbb{P}[G_J[U] = G_{J'}[U]] - \mathbb{P}[G_J[U] = H]\mathbb{P}[G_{J'}[U] = H],\end{aligned}$$

where we use the independence from Proposition 25. Recall that $G_J[U], G_{J'}[U]$ are both uniformly random, so by Lemma 24 we have

$$\begin{aligned}\mathrm{Var}[X] &= \sum_{J\subseteq[n]} 2^{-\binom{k}{2}} \sum_{J'\subseteq[n]} \left(\mathbb{P}[G_J[U] = G_{J'}[U]] - 2^{-\binom{k}{2}}\right) \\ &= \sum_{J\subseteq[n]} 2^{-\binom{k}{2}} \sum_{J'\triangle J\subseteq[n]} \left(\mathbb{P}[G_J[U] = G_{J'}[U]] - 2^{-\binom{k}{2}}\right) \\ &\leq \sum_{J\subseteq[n]} 2^{-\binom{k}{2}} \left(\sum_{\substack{J'\triangle J\subseteq[n] \\ |J'\triangle J|>2k}} 2^{2k-\binom{k}{2}-|J'\triangle J|} + \sum_{\substack{J'\triangle J\subseteq[n] \\ |J'\triangle J|\leq 2k}} 1 \right) \\ &= \sum_{J\subseteq[n]} 2^{-\binom{k}{2}} \left(\sum_{i=2k+1}^{n} \binom{n}{i} 2^{2k-\binom{k}{2}-i} + \sum_{i=0}^{2k} \binom{n}{i} \right) \\ &\leq \sum_{J\subseteq[n]} 2^{-\binom{k}{2}} \left(2^{2k-\binom{k}{2}} \sum_{i=0}^{n} \binom{n}{i} 2^{-i} + n^{2k} \right) \\ &\leq \sum_{J\subseteq[n]} 2^{-\binom{k}{2}} \left(2^{2k-\binom{k}{2}} (3/2)^n + n^{2k} \right) \\ &= 2^{n-\binom{k}{2}} \left(2^{2k-\binom{k}{2}} (3/2)^n + n^{2k} \right).\end{aligned}$$

(To obtain the bound $\sum_{i=0}^{2k} \binom{n}{i} \leq n^{2k}$, consider for example the surjection $f : [n]^{2k} \to \binom{n}{\leq 2k}$ given by $f(x_1, \ldots, x_{2k}) = \{x_1, \ldots, x_{2k}\}$, except $f(2k, 2k-1, \ldots, 1) = \emptyset$.) In conclusion, by Chebyshev's inequality (Lemma 14) we have

$$\mathbb{P}[X = 0] \leq \frac{\mathrm{Var}[X]}{\mathbb{E}[X]^2} \leq \frac{2^{n-\binom{k}{2}} \left(2^{2k-\binom{k}{2}} (3/2)^n + n^{2k} \right)}{2^{2n-2\binom{k}{2}}} = 2^{2k}(3/4)^n + 2^{-n+\binom{k}{2}} n^{2k}$$

as desired. ◀

We are now ready to prove our main result via the union bound over all choices of $U \subseteq V(G)$ and graphs H with vertex set U. We first restate the theorem for convenience.

▶ **Theorem 3.** *For all $c > 0$, if $G \sim \mathbb{G}(n, 1/2)$ with $n \geq (1+c)\frac{1}{2\log_2(4/3)}k^2$, then G is k-vertex-minor universal with probability at least $1 - 2^{-(1+o(1))ck^2/2}$.*

Proof. Let $G \sim \mathbb{G}(n, 1/2)$, where $n = (1+c)\frac{1}{2\log_2(4/3)}k^2$. Here we allow $c = c(k)$ to be increasing with k, but it is lower bounded by some positive constant. By Lemma 26, the probability that a given graph H on k given vertices of $V(G)$ is not a vertex-minor of G is at most $2^{2k}(3/4)^{n-k} + 2^{-n+k+\binom{k}{2}}(n-k)^{2k} = 2^{2k}(3/4)^{(1+o(1))n}$.

By the union bound, we have

$$\begin{aligned}\mathbb{P}[G \text{ is not } k\text{-vertex-minor universal}] &\leq \binom{n}{k} 2^{\binom{k}{2}} \cdot \left(2^{2k}(3/4)^{(1+o(1))n}\right) \qquad (3)\\ &\leq \exp_2\left(k\log_2 n + \frac{k^2}{2} + 2k - (1+o(1))\log_2(4/3)n\right)\\ &= \exp_2\left(O(k\log(ck)) + \frac{k^2}{2} - (1+o(1))\frac{1+c}{2}k^2\right)\\ &= \exp_2\left(O(k\log(ck)) - (1+o(1))\,ck^2/2\right).\end{aligned}$$

Thus, whenever $n = (1+c)\frac{1}{2\log_2(4/3)}k^2$, we have $\mathbb{P}[G \text{ is } k\text{-vm-universal}] \geq 1 - 2^{-(1+o(1))ck^2/2}$, as desired. ◀

3.3 Proof of reordering Lemma 12

First, we restate the vertex-minor reordering lemma:

▶ **Lemma 12.** *Fix a set $\hat{V}$. Let $v_1, \ldots, v_\ell \in \hat{V}$ be a (possibly repeating) sequence and let $\hat{G}$ be a graph with $V(\hat{G}) = \hat{V}$. Then there is a sequence $x_1, \ldots, x_r$ of singletons and pairs from $\hat{V}$ such that for any graph G with $\hat{V} \subseteq V(G)$ and $G[\hat{V}] = \hat{G}$, we have*

- **(I)** *$G * v_1 * v_2 \cdots * v_\ell - \hat{V} = G \circ x_1 \cdots \circ x_r - \hat{V}$.*
- **(II)** *The sets $x_1, \ldots, x_r$ are pairwise disjoint.*
- **(III)** *If $v \in \hat{V}$ appears exactly once in $(v_i)_{i=1}^{\ell}$, then $v \in x_j$ for some $j \in [r]$.*

Moreover, any choice of $(x_i)_i$ satisfying (I) and (II) for all G also satisfies (III).

We note that if $\hat{V}$ is an independent set in G, the complementations $*v_i$ are commutative and self-inverse, so we can choose $(x_i)_i$ to be any ordering of those vertices v_i which appear in the sequence an odd number of times. If not, then the complementations interact in some fixed way determined only by $G[\hat{V}]$. The proof idea is to pull out one *special* vertex $v \in \hat{V}$ at a time, and use Theorem 11 to force that v appears at most once in the resulting sequence $(x_i)_i$. We do this via the following inductive lemma in which the ordering may depend on the host graph G. We will then show that the ordering does in fact work for all graphs G with $G[\hat{V}] = \hat{G}$.

▶ **Lemma 27.** *For any graph G with $V(G) = \hat{V} \sqcup U$ and $v_1, \ldots, v_\ell \in \hat{V}$, and for any special vertex $v \in \hat{V}$, there exists a sequence $(y_i)_{i=1}^{r}$ satisfying (I) and (II) for G such that one of the following holds:*

1. *we have $v \notin \bigcup_i y_i$,*
2. *we have $v \in y_1$, or*
3. *we have $y_2 = \{v\}$ and $y_1 = \{w\}$ for some $w \in \hat{V}$ with $vw \in E(G)$.*

Proof. Let $H = G * v_1 * \cdots * v_\ell[U]$, so H is a vertex-minor of G. We proceed by induction on $n := |V(G)|$; the base case $n = 1$ is trivial. Let $v \in \hat{V}$ be arbitrary.

By Theorem 11, H is a vertex-minor of $G - v$, $G * v - v$, or $G \times vw - v$ for some w adjacent to v. In the first case, we apply the induction hypothesis to $G - v$, and clearly the resulting sequence $(y_i)_i$ satisfies item 1. In the second case, we apply the induction hypothesis to $G * v - v$ to obtain the sequence $(y_i)_{i\geq 2}$. Then clearly setting $y_1 = \{v\}$ satisfies item 2.

In the final case, we apply the induction hypothesis to $G \times vw - v$ for some w adjacent to v such that w is the special vertex to obtain the sequence $(y_i)_{i\geq 2}$. We then split into cases based on the location of w. If $w \notin \bigcup_{i\geq 2} y_i$, then setting $y_1 = \{v, w\}$ gives the desired sequence

$(y_i)_{i\geq 1}$ satisfying item 2. If $y_2 = \{w\}$, then note $G\times vw*w = G*w*v$, and so replacing y_2 with $\{v\}$ and setting $y_1 = \{w\}$ gives the desired sequence $(y_i)_{i\geq 1}$ satisfying item 3. If $y_2 = \{w, u\}$, then by Lemma 10, $G \times vw \times wu = G \times vu$, and so replacing y_2 with $\{v, u\}$ yields the desired sequence $(y_i)_{i\geq 2}$ satisfying item 2. Finally, if $y_2 = \{u\}, y_3 = \{w\}$ with $uw \in E(G \times vw)$, then we use the fact that $G \times vw * u * w = G \times vw \times uw * u = G \times vu * u = G * u * v$, and so by replacing y_2, y_3 with $\{u\}, \{v\}$ respectively, we get the desired sequence $(y_i)_{i\geq 2}$ satisfying item 3. ◀

Finally, to construct a sequence $(x_i)_i$ which satisfies Lemma 12 for all graphs G with $G[\hat{V}]$, we apply 27 to a special gadget which encodes all possible structures that can appear in G.

Proof of Lemma 12. Let $\hat{V}$ be a set, and fix a sequence $v_1, \ldots, v_\ell \in \hat{V}$ and a graph $\hat{G}$ on vertex set $\hat{V}$. To show that we can pick $(x_i)_i$ to depend only on $\hat{G}$, we apply Lemma 27 to a universal "gadget" graph defined as follows. Let $\mathbf{G}$ have vertex set $\hat{V} \cup [3 \cdot 2^{3|\hat{V}|}]$ by setting $\mathbf{G}[\hat{V}] = \hat{G}$, placing $2^{3|\hat{V}|}$ disjoint copies of the 3 vertex path P_3, and adding edges from $\hat{V}$ to the copies of P_3 such that all of the $2^{3|\hat{V}|}$ possible sets of edges occur between $\hat{V}$ and a copy of P_3. This has the property that for any graph G on vertex set $\hat{V} \cup \{u_1, u_2\}$ with $G[\hat{V}] = \hat{G}$, there exist j_1, j_2 such that $\mathbf{G}[\hat{V} \cup \{j_1, j_2\}]$ is isomorphic to G with the isomorphism $\hat{V} \mapsto \hat{V}$ and $u_i \mapsto j_i$. Such an isomorphism can be found by taking the copy of P_3 with the correct adjacency to $\hat{V}$ and letting j_1, j_2 be either adjacent or nonadjacent vertices in the P_3.

▷ Claim 12.1. For all $k \geq 2$, if the sequence $(x_i)_{i=1}^r$ satisfies properties (I) and (II) for the gadget $\mathbf{G}$, then it satisfies property (III).

Proof. Suppose $v \in \hat{V}$ appears exactly once in $\{v_i\}_i$ in position i^*, and suppose $(x_i)_i$ does not contain v. Expanding out $\circ(x_i)_i = *(w_i)_{i=1}^m$ as a sequence of local complementations for $w_i \in \hat{V} \setminus \{v\}$, for $\mathbf{G}' = \mathbf{G} * v_1 * \cdots * v_{i^*-1}$, we have

$$\mathbf{G}' * v = \mathbf{G}' * v_{i^*-1} * \cdots * v_1 * w_1 * \cdots * w_m * v_\ell * \cdots * v_{i^*+1}. \tag{4}$$

We show this is impossible. Let RHS denote the right-hand side of (4). Choose vertices $j_1, j_2 > n$ such that $j_1 j_2 \notin E(\mathbf{G})$ and $N_{\mathbf{G}}(j_1) \cap \hat{V} = N_{\mathbf{G}}(j_2) \cap \hat{V} = \{v\}$; these vertices exist by definition of $\mathbf{G}$. Then we note $j_1 j_2 \notin E(\mathbf{G}')$ and $N_{\mathbf{G}'}(j_1) = N_{\mathbf{G}}(j_1)$, $N_{\mathbf{G}'}(j_2) = N_{\mathbf{G}}(j_2)$. Then $j_1 j_2 \in E(\mathbf{G}' * v)$ but $j_1 j_2 \notin E(\text{RHS})$, because no local complementation step can add an edge incident to j_1, j_2. This contradicts (4), so $(x_i)_i$ contains v. ◁

We now show that if a sequence satisfies Lemma 27 for $\mathbf{G}$, then it satisfies Lemma 12. Let $(x_i)_{i=1}^r$ be the sequence given by Lemma 27 for the gadget $\mathbf{G}$. Let G be an arbitrary graph with $\hat{V} \subseteq V(G)$ and $G[\hat{V}] = \hat{G}$. We need to show that the sequence satisfies condition (I) for G. For this it suffices to show that for all $u_1, u_2 \in V(G) \setminus \hat{V}$, we have $u_1 u_2 \in E(G * (v_i)_{i=1}^\ell)$ if and only if $u_1 u_2 \in E(G \circ (x_i)_{i=1}^j)$. Indeed, letting $G' = G[\hat{V} \cup \{u_1, u_2\}]$, there exist $j_1, j_2 \in V(\mathbf{G})$ such that $\mathbf{G}[\hat{V} \cup \{j_1, j_2\}]$ is isomorphic to G with isomorphism $\hat{V} \mapsto \hat{V}$ and $u_i \mapsto j_i$. In particular, this means $G' * (v_i)_i - \hat{V} = G' \circ (x_i)_i - \hat{V}$, so we conclude that $u_1 u_2 \in E(G' * (v_i)_i)$ if and only if $u_1 u_2 \in E(G' * (v_i)_i)$, as desired. Thus we conclude $G * (v_i)_i - \hat{V} = G \circ (x_i)_i - \hat{V}$, so all three properties hold. ◀

4 Vertex-minor Ramsey and concluding remarks

We now prove our bounds on the vertex-minor Ramsey problem stated in the introduction.

▶ **Theorem 8.** *For all $k \geq 0$,*

$$(1+o(1))\frac{1}{2\log_2 3}k^2 \leq R_{\mathrm{vm}}(k) \leq 2^k - 1.$$

Proof. We first prove the upper bound. When $k = 0, 1$ this is satisfied with equality. If $k \geq 2$, let $N = R_{\mathrm{vm}}(k) - 1$, so there is a graph G on N vertices with $U \subseteq V(G)$ an independent set in G such that $|U| \leq k-1$ and G does not contain a larger independent set as a vertex-minor. For all $S \subseteq U$, let $V_S = \{v \in V(G) \setminus U : N(v) \cap U = S\}$. Then we have the disjoint union $V(G) = U \cup \bigcup_{S \subseteq U} V_S$. We now claim that $|V_S| \leq \min\{2, |S|\}$ for all $S \subseteq U$. Assuming this, we conclude

$$R_{\mathrm{vm}}(k) - 1 = N \leq (k-1) + 1 \cdot \binom{k-1}{1} + 2 \cdot (2^{k-1} - k) = 2^k - 2.$$

Note that if $x \in V_\emptyset$, then $U \cup \{x\}$ is an independent set, contradicting the maximality of U. Suppose towards a contradiction that $x, y \in V_{\{u\}}$ for some $u \in U$. By locally complementing at u, we may assume that $xy \notin E(G)$. Then $U \cup \{x, y\} \setminus \{u\}$ is an independent set, contradicting the maximality of U.

Suppose towards a contradiction that $|S| \geq 2$ and $x, y, z \in V_S$. Let $u \in S$. By locally complementing at u, we may assume that $G[\{x, y, z\}]$ contains at most 1 edge. If $\{x, y, z\}$ is an independent set in G, then $U \cup \{y, z\} \setminus \{u\}$ is an independent set in $G \times ux$. Otherwise without loss of generality $yz \in E(G)$. Then $U \cup \{y, z\} \setminus \{u\}$ is an independent set in $G * x * u$. In every case we obtain an independent set of size larger than U as a vertex-minor, a contradiction.

For the lower bound, let $G \sim \mathbb{G}(n, 1/2)$. Note that G contains I_k as a vertex-minor if and only if G is locally equivalent (l.e.) to some graph H with $\alpha(H) \geq k$. A result of Bahramgiri and Beigi [2] states that for any graph H on n vertices, there are at most 3^n graphs locally equivalent to H. Then, by a union bound,

$$\begin{aligned}\mathbb{P}[G \text{ l.e. } H,\ \alpha(H) \geq k] &\leq 3^n \mathbb{P}[\alpha(G) \geq k] \\ &\leq 3^n \binom{n}{k} 2^{-\binom{k}{2}} \leq \exp_2\left(n\log_2 3 + k\log_2 n - k^2/2 + k/2\right) < 1,\end{aligned}$$

as long as $n \leq (1+o(1))\frac{1}{2\log_2 3}k^2$. ◀

We note that our upper bound is the correct answer for $k \leq 3$. (For $k = 3$, it is not hard to verify that the wheel on 6 vertices does not contain an independent of size 3 as a vertex-minor.) However, since the lower bound in Theorem 8 comes from the random graph, it is natural to believe that the polynomial lower bound is closer to the truth for sufficiently large k than our modest upper bound. This belief leads us to Conjecture 9, restated below.

▶ **Conjecture 9.** $R_{\mathrm{vm}}(k) \leq \mathsf{poly}(k)$.

By Theorem 3, the random graph $\mathbb{G}(n, 1/2)$ cannot be a counterexample, and indeed it is possible that $R_{\mathrm{vm}}(k) = O(k^2)$. We note that proper vertex-minor closed classes have the Erdős-Hajnal property [10]. This implies that if we restrict our graphs to any proper

vertex-minor closed class, they contain an independent set of size $\Omega(n^c)$ as a vertex-minor for some $c > 0$ possibly depending on the class. We also make the connection between pivot-minor universality and its corresponding Ramsey-type question.

▶ **Definition 28.** *Let $R_{\text{piv}}(k)$ be the minimum n such that any n-vertex graph contains an independent set or clique of size k as a pivot-minor.*

Note that unlike the definition of $R_{\text{vm}}(k)$, we need to allow either a clique or an independent set in this definition since K_n does not contain any non-trivial independent set as a pivot-minor.

We note that trivially $R_{\text{vm}}(k-1) \leq R_{\text{piv}}(k) \leq R(k)$, the diagonal Ramsey number. Theorem 5 supports the following conjecture, which would imply Conjecture 9.

▶ **Conjecture 29.** $R_{\text{piv}}(k) \leq \mathsf{poly}(k)$.

We note that proper pivot-minor closed classes also have the Erdős-Hajnal property [19], so this conjecture holds if we restrict to any proper pivot-minor closed class. We also improve the trivial upper bound of $R(k)$ for $R_{\text{piv}}(k)$.

▶ **Theorem 30.** *For all $k \geq 0$, $R_{\text{piv}}(k) \leq (k-1)(2^k - 1) + 1$.*

Proof. Let G be a graph with no independent set or clique of size k as a pivot-minor on $R_{\text{piv}}(k) - 1$ vertices. By possibly replacing G with a pivot-equivalent graph, we let U be an independent set in G such that G does not contain a larger independent set as a pivot-minor. For all $S \subseteq U$, let $V_S = \{v \in V(G) \setminus U : N(v) \cap U = S\}$. Clearly $V_\emptyset$ is empty by the maximality of U. For S containing a vertex u, we claim that V_S can not contain an independent set of size 3. Indeed otherwise if $\{x, y, z\} \in V_S$ is independent, then $U \cup \{y, x\} \setminus \{u\}$ is an independent set in $G \times ux$. We also note that V_S can not contain an induced path on 3 vertices. Indeed if x, y, z are the vertices of an induced path in V_S in that order, then $U \cup \{y, x\} \setminus \{u\}$ is an independent set in $G \times ux$. Clearly V_S can not contain a clique of size k by definition of G. It follows that $G[V_S]$ is a disjoint union of cliques and thus $|V_S| \leq 2(k-1)$. Thus

$$R_{\text{piv}}(k) - 1 \leq (k-1) + (2^{k-1} - 1)(2k-2) = (k-1)(2^k - 1). \qquad \blacktriangleleft$$

We make some final conjectures about vertex-minor universality. Theorem 3 and our proof of the lower bound in Theorem 8 together show that for any $\varepsilon > 0$, the random graph $G \sim \mathbb{G}(n, 1/2)$ is with high probability $(\alpha - \varepsilon)\sqrt{n}$-vertex-minor universal but not $(\beta + \varepsilon)\sqrt{n}$-vertex-minor universal, where $\alpha = \sqrt{2\log_2(4/3)} \approx 0.911$ and $\beta = \sqrt{2\log_2(3)n} \approx 1.78$. It is natural to conjecture that there is a sharp threshold for universality, as follows.

▶ **Conjecture 31.** *There exists $C \in [\sqrt{2\log_2(4/3)}, \sqrt{2\log_2(3)}]$ such that for any $\varepsilon > 0$, with high probability $G \sim \mathbb{G}(n, 1/2)$ is $(C - \varepsilon)\sqrt{n}$-vertex-minor universal and not $(C + \varepsilon)\sqrt{n}$-vertex-minor universal.*

It is also natural to ask for what values of p the random graph $\mathbb{G}(n, p)$ is k-vertex-minor universal for n polynomial in k. The main difficulty in extending our approach to $p \neq 1/2$ is that the random walk defined in Section 3.1 now has steps which are correlated to each other: after flipping an edge which was not yet revealed, its probability of existing is now $1 - p$

instead of p. If one could get around this issue, the resulting random walk would then have the second largest eigenvalue bounded in absolute value by the max of $1-2p^2, 1-2(1-p)^2$, and $1-2p(1-p)$. Assuming without loss of generality that $p \leq 1/2$, this means it would suffice to run the random walk for $O(k^2/p^2)$ steps. Thus we conjecture the following.

▶ **Conjecture 32.** *If $p = \omega(1/\sqrt{n})$ is at most $1/2$ and $G \sim \mathbb{G}(n,p)$ or $G \sim \mathbb{G}(n,1-p)$, then G is k-vertex-minor universal with high probability for some $k = \Omega(p\sqrt{n})$.*

If true, this would qualitatively generalize Theorem 3, although unlike Theorem 3 it is not necessarily tight up to a constant for all p. Conjecture 32 would also imply that $\mathbb{G}(n,p)$ is not a counterexample to Conjecture 9 for any p. This follows for instance by noting that if p is outside the range $[n^{-1/4}, 1-n^{-1/4}]$, then $\mathbb{G}(n,p)$ already contains a clique or independent set of size $\Omega(n^{1/4}\log n)$.

After the appearance of an earlier draft of this paper, Chao and Xu [9] verified Conjecture 32 up to a logarithmic factor.

Abstract

We devise an error-reduction procedure that transforms a PRG for length-n, width-w read-once branching programs with error $1/\mathrm{poly}(n)$ and seed length s_0, over any alphabet, into a weighted PRG with seed length

$$s_0 + O\left(\log\frac{1}{\varepsilon} + \log\log\left(\frac{\log w}{\log n}\right)\cdot\log w\right).$$

Using this reduction, we improve upon the state-of-the-art weighted PRG constructions of Hoza (RANDOM 2021) and Cheng and Wu (SODA 2026), achieving optimal dependence on the program's arity while matching the best known bounds in all other parameters.

Our motivation for obtaining optimal dependence on the arity stems from a result of Cheng and Hoza (CCC 2020, ToC 2022), who showed that a PRG with optimal arity and error dependence yields a PRG with seed length $O(\log^{3/2} n)$ (for, say, constant width), thereby breaking the long-standing log-squared barrier.

1 Introduction

The question of whether $\mathbf{BPL} = \mathbf{L}$ is one of the central open problems in computational complexity theory [1, 3, 26]. It asks whether randomness provides additional computational power to space-bounded algorithms, or equivalently, whether every probabilistic logspace algorithm can be fully derandomized with only a constant-factor increase in space. Despite decades of intensive study, the problem remains open. Nonetheless, the prevailing belief is that $\mathbf{BPL} = \mathbf{L}$, a conjecture supported by plausible circuit lower bounds [28, 20, 19]. Importantly, unlike in the time-bounded setting, there are currently no known barriers that rule out unconditional derandomization of **BPL**.

Progress toward this goal has been strikingly limited. Beyond a small number of landmark results, there has been essentially no improvement for several decades. Already in the work of Savitch [40] and Borodin, Cook, and Pippenger [3], it was shown that $\mathbf{BPL} \subseteq \mathbf{L}^2$. The only substantial strengthening of this bound was obtained by Saks and Zhou [39], who proved that $\mathbf{BPL} \subseteq \mathbf{L}^{3/2}$. This result, established nearly 30 years ago, has remained essentially unimproved to this day, with only a quite recent sub-polynomial improvement due to Hoza [22].

The primary approach to resolving **BPL** vs. **L** is via the construction of pseudorandom generators (PRGs) for read-once branching programs (BPs), which constitute the standard nonuniform model associated with space-bounded Turing machines. We refer the reader to Definition 5 for a formal definition. For present purposes, it suffices to note that the length of a BP, denoted by n, corresponds to the number of random bits read by the algorithm (and is therefore bounded by its running time), while the width w captures the space usage and is, in fact, exponential in the space bound. For naive derandomization of **BPL** via PRGs, one should consider $w = \mathrm{poly}(n)$.

In a seminal paper, Nisan [33] constructed an explicit ε-error PRG for BPs of length n and width w with seed length $O\big(\log n \cdot \log\big(\frac{nw}{\varepsilon}\big)\big)$. This construction – together with its expander-based variant due to Impagliazzo, Nisan, and Wigderson [25] – remains the state of the art in the general setting. An improvement in the regime $w \gg n$ was obtained by Armoni [2] and was recently simplified in [8], shaving a factor of $\log\Big(\frac{\log w}{\log(n/\varepsilon)}\Big)$ from the seed length.[1]

By contrast, an optimal PRG has seed length $O\big(\log\big(\frac{nw}{\varepsilon}\big)\big)$; if such a generator were also space-efficient, it would immediately imply $\mathbf{BPL} = \mathbf{L}$. Remarkably, despite more than three decades of subsequent work, Nisan's construction has not been improved. In fact, except for the case of $w = 3$ [31], or when additional structural restrictions are imposed on the BPs (see, e.g., [29, 16, 5, 17, 36, 18, 9]), no PRG is known to break the so-called log-squared barrier; that is, to achieve seed length $o(\log^2 n)$ for constant error ε, when $w = \mathrm{poly}(n)$, or even when the width is as small as $w = 4$.

Weighted pseudorandom generators

To bypass this long-standing stalemate, Braverman, Cohen, and Garg [4] introduced a new type of pseudorandom object called a *weighted pseudorandom generator (WPRG)*. A WPRG relaxes the classical definition of a PRG while still enabling the derandomization of two-sided

[1] Armoni's generator uses the classical Nisan–Zuckerman generator [34], that gives optimal seed length in the extreme regime of $n = \mathrm{polylog}(w)$.

error probabilistic algorithms. Specifically, in a WPRG each seed is assigned a weight – which may be positive, negative, and potentially unbounded – and the desired ε-approximation is achieved via a weighted sum rather than a simple average.

In [4], the authors constructed a WPRG with an almost optimal dependence on the error parameter ε, achieving seed length $\widetilde{O}(\log n \cdot \log(nw) + \log(1/\varepsilon))$. While the error parameter is taken to be constant in the most naive PRG-based approach to derandomizing **BPL**, it plays a crucial role in more refined derandomization procedures, most notably the Saks–Zhou algorithm. The latter involves multiple composition steps, necessitating small error and making the dependence on ε crucial. Indeed, Braverman et al. [4] and Chattopadhyay and Liao [6] showed that one can prove $\mathbf{BPL} \subseteq \mathbf{L}^{4/3}$ even without breaking the log-squared barrier. Concretely, they showed that such a derandomization result would follow from the existence of a space-efficient WPRG with seed length $O(\log^2 n + \log(w/\varepsilon))$.

As observed in [4], WPRGs readily yield hitting sets. Consequently, their result led to the first improved construction of hitting sets for BPs since the work of Nisan [33], with a much simplified follow-up construction due to Hoza and Zuckerman [24].

Since then, WPRGs have attracted significant attention. They have inspired simpler and improved constructions [30, 6, 14, 36, 22], culminating in the WPRG of Hoza [22], which removes all double-logarithmic factors, obtaining seed length $O(\log n \cdot \log(nw) + \log(1/\varepsilon))$ and in the very recent state-of-the-art construction of Cheng and Wu [12], which achieves further improvements in the regime $w \gg n$.

These works incorporate ideas from fast Laplacian solvers and were also the basis for significantly improved generators for restricted models [23, 36, 9]. The limitations of these techniques have been investigated in [13]. Developments in WPRGs have led to progress on several long-standing problems. Notably, they were leveraged by Hoza to improve the Saks–Zhou derandomization mentioned above [22], and have also enabled substantial advances on the closely related problem of iterated matrix multiplication [15, 35]. Moreover, the error reduction techniques have recently been used to show that **BPL** is contained in logspace-uniform $\mathbf{AC}^1$ [11].

Braverman, Cohen, and Garg [4] emphasized the role of the error parameter ε, showing that simultaneously improving the seed-length dependence on both ε and w would yield a significant improvement to the Saks–Zhou algorithm, even without breaking the log-squared barrier. Moreover, such an improvement need only be achieved for WPRGs, rather than for standard PRGs. While [4] and follow-up works significantly improved the dependence on ε, progress on the width parameter w has remained much more elusive. To date, the only work in this direction that we are aware of is due to Raz and Reingold [37], which presents an intriguing, albeit seemingly stalled, approach.

Cheng and Hoza [10] proposed an intriguing approach toward breaking the log-squared barrier, showing that seed length $O(\log^{3/2} n)$ can be obtained even without *directly* improving the dependence on either n or w. Instead, such an improvement follows from *simultaneously* improving the dependence of PRGs on two secondary parameters: the error ε and the program's arity $|\Sigma|$. We discuss this result below. This underscores the somewhat surprising importance of arity dependence.

1.1 Our Result

The main result of this paper is a construction of WPRGs that achieves optimal dependence on both ε and Σ, while matching the state-of-the-art bounds in n and w. As in prior work, our WPRG is obtained via an error-reduction procedure.

▶ **Theorem 1** (see also Theorem 21). *There exists an explicit reduction that transforms a PRG for length-n, width-w branching programs with seed length s_0 and error $\varepsilon_0 = 1/\mathrm{poly}(n)$, over any alphabet, into a WPRG with error ε and seed length*

$$s_0 + O\left(\log\frac{1}{\varepsilon} + \log\log\left(\frac{\log w}{\log n}\right)\cdot\log w\right).$$

Instantiating Theorem 1 with Armoni's PRG [2], we obtain the following corollary.

▶ **Corollary 2.** *There exists an explicit WPRG for length-n, width-w branching programs over alphabet Σ, achieving error ε with seed length*

$$\log_2|\Sigma| + O\left(\log\frac{1}{\varepsilon} + \frac{\log^2 n + \log n\cdot\log w}{\max(1,\log\log w - \log\log n)} + \log\log\left(\frac{\log w}{\log n}\right)\cdot\log w\right).$$

Corollary 2 improves upon all known WPRGs for general branching programs, including in the regime $w = n^{O(1)}$, where the seed length simplifies to

$$\log_2|\Sigma| + O\big(\log(1/\varepsilon) + \log^2 n\big).$$

In particular, it matches the recent construction of Cheng and Wu [12] in the parameters n, w, and ε, while improving the dependence on Σ. Although this dependence is not made explicit in [12] (nor in most prior work), it is straightforward to verify that their construction – as well as several other recent WPRGs (particularly [22], which is also state-of-the-art in the regime $w = n^{O(1)}$) – exhibits suboptimal dependence on Σ, typically incurring an additional multiplicative factor of $\frac{\log(1/\varepsilon)}{\log n}$.[2]

By contrast, some earlier WPRG constructions (e.g., [4, 14]), while slightly inferior in overall seed length, achieve optimal dependence on Σ. Thus, the contribution of Corollary 2 is to attain optimal dependence on Σ while matching the best known bounds in all other parameters. Moreover, our construction and its analysis appear to be simpler than those of [12], which rely on "weighted pseudorandom reductions" – a sequence of alphabet-reduction and length-reduction steps combined with different PRGs and WPRGs. Furthermore, in the regime $w = n^{O(1)}$, our construction is significantly simpler, and is comparable in simplicity to [22].

As discussed above, our motivation for achieving optimal dependence on the alphabet size stems from its implications for breaking the log-squared barrier [10]. We provide an alternative proof of this implication that requires truly optimal dependence on the alphabet, namely $\log_2|\Sigma|$, as achieved in Corollary 2 for WPRGs. We prove

▶ **Theorem 3.** *Assume there exists an explicit PRG with seed length*

$$\log_2|\Sigma| + O(\log n\cdot\log(nw) + \log(1/\varepsilon)).$$

Then there exists an explicit PRG with seed length[3]

$$\log_2|\Sigma| + O\left(\log^{3/2} n + \log n\cdot\log w + \sqrt{\log n}\cdot\log(1/\varepsilon)\right).$$

---

[2] Specifically, the recent work of Cheng and Wu incurs an additional multiplicative factor of $\frac{\log(n/\varepsilon)}{\log(nw)}$. See [12, Theorem 3.2] in the latest arXiv revision. We also note that in the $n = \mathrm{polylog}(w)$ regime, there exists an $2^{-\log^{0.99} w} \ll \varepsilon \ll 1/\mathrm{poly}(w)$ for which the [12] construction achieves a quadruple-log savings over our construction.

[3] Using error reduction, one can obtain linear dependence on $\log(1/\varepsilon)$ at the cost of producing a WPRG rather than a PRG (see the full version for details [7]).

For the complete details, see [7, Section 5]. The Cheng–Hoza reduction (Lemma 4.9 in [10]) is a recursive construction that uses randomness samplers at each step. Our construction is also recursive, but uses only the hypothesized PRG. We also note that compared to Theorem 3, the applies even when the hypothesized PRG has only $O(\log|\Sigma|)$ dependence on the alphabet size.

2 Proof Overview

In this section, we provide an informal overview of Theorem 1, and outline our alternative proof of the Cheng–Hoza result as given in Theorem 3. The reader may skip this part and proceed directly to the formal sections of the paper. Recall that this theorem takes a PRG for length-n, width-w BPs with error $\varepsilon_0 = 1/n$ and seed length s_0, and produces a WPRG with error ε and seed length

$$s_0 + O\left(\log\frac{1}{\varepsilon} + \log\log\left(\frac{\log w}{\log n}\right)\cdot\log w\right)$$

in the regime $\frac{1}{\varepsilon} > w > n$. When $w < n$ (and more generally, for $w = n^{O(1)}$), the more involved step of our construction can be skipped, yielding a seed length $s_0 + O(\log\frac{1}{\varepsilon})$, and resulting in a significantly simpler construction.

The first component we need for proving Theorem 1 is a variant of the Richardson iteration, which we now turn to discuss.

2.1 Incremental and asymmetric Richardson iteration

The transformation underlying Theorem 1 uses the Richardson iteration, which is by now the standard tool for reducing the error of a PRG. However, our use of the Richardson iteration is more refined, and we begin by briefly describing it here (see Section 4.1 for the formal and complete treatment). For our purposes, the Richardson iteration – or rather, the variant of it used here – is an algorithm Rich that takes as input two WPRGs W_L and W_R for the same length n and width w, with corresponding errors ε_L and ε_R, and produces a new WPRG, denoted

$$\mathrm{Rich}(W_L, W_R),$$

with error guarantee $\varepsilon_L\varepsilon_R$ and seed length

$$s_L + O\left(\log\frac{1}{\varepsilon_L\varepsilon_R}\right).$$

In fact, both the error guarantee and the seed length are slightly more intricate (see Lemma 15), but for the purpose of this overview, it is best to suppress the exact dependence.

How our use of Richardson iteration differs. There are several differences between our implementation of the Richardson iteration and those in the literature. While these distinctions provide useful context, the following discussion is primarily intended for experts; the reader may proceed with the proof overview without focusing on these differences.

In a nutshell, prior works apply the Richardson iteration to a single PRG using several correlated samples, taken with both positive and negative weights, to achieve error cancellation and thus obtain a lower error. The correlated seeds in these works are generated using an auxiliary PRG for BPs. In contrast, our approach reduces the error of two PRGs (and

even WPRGs) which may be imbalanced in their error guarantees and seed lengths. The correlated seeds are obtained via extractors rather than PRGs, allowing for finer control over the seed length of the reduction, which is crucial in the presence of asymmetric WPRGs.

A second difference is our incremental application of the Richardson iteration: rather than applying it in a "one-shot" manner to achieve the desired error, we observe that it is preferable to invoke Richardson on just two instances and then compose the resulting procedure sufficiently many times. This approach is more economical, as the correlated seeds need not meet the final error guarantee from the start. Instead, the early iterations can operate with more coarsely correlated seeds.

Getting back to the proof overview of Theorem 1, the transformation proceeds in two phases:

- Phase 1: Reduce the error from $1/n$ to $1/w$.[4]
- Phase 2. Reduce the error from $1/w$ to the desired error ε.

2.2 Phase 1 – amplifying from inverse-length to inverse-width error

For the first phase – which is the more involved part, and can be skipped in the regime $w = n^{O(1)}$, yielding a simpler construction. The key technical transformation is summarized in the following proposition (see Proposition 19 for the formal statement).

▶ **Proposition 4** (informal). *For any integer $t \geq 1$, a WPRG with error guarantee $\varepsilon_0 < 1/n$ and seed length s_0 can be transformed into a WPRG with error $\varepsilon = \varepsilon_0^t$ and seed length*

$$s_0 + O\left(t^2 \cdot \log \frac{1}{\varepsilon_0} + \log w\right).$$

To be more precise, we assume a bound on the weights of the given WPRG as a function of the other parameters, in particular the error guarantee. This invariant, which we call *error-dominated* (see Definition 16), is preserved throughout our transformations, including the one given in Proposition 4. This ensures that the weights remain under control without the need to track them explicitly. In this informal overview, we will ignore them altogether.

The comb reduction. The proof of Proposition 4 proceeds by applying the Richardson iteration recursively in a "comb-like" manner, as depicted in Figure 1 (which may explain the name).[5] More formally, given a WPRG W_0 with error ε_0 and seed length s_0, we define a sequence of WPRGs $W_1, \ldots, W_{t-1}$ by setting, for each $j \geq 1$,

$$W_j = \mathrm{Rich}\left(W_{j-1}, W_0\right).$$

[4] Strictly speaking, we start with a slightly smaller error, e.g., $1/n^c$ for some constant $c > 1$. We ignore this technicality here.

[5] Using a comb-like construction rather than a balanced binary tree allows us to exploit the asymmetry of the Richardson iteration described above. The "left loss" is the extractor's seed length, whereas the "right loss" combines the extractor's entropy loss with the entropy lost by revealing the program's intermediate state. When $w \gg n$, these losses differ substantially, and the comb lets the growing seed on the left absorb the larger loss on the right. A similar balancing appears already in [8].

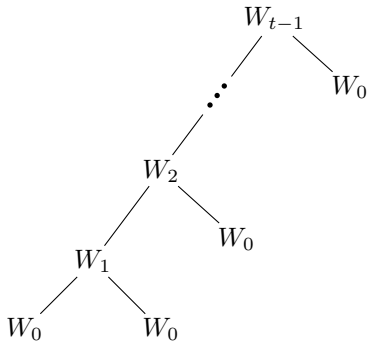

Figure 1 Recursive "comb" structure.

It is easy to see that for each $j \geq 1$, the WPRG W_j has error guarantee $\varepsilon_j = \varepsilon_0^{j+1}$. Consequently, the seed length s_j satisfies the recurrence

$$s_j = s_{j-1} + O\left(\log \frac{1}{\varepsilon_0^{j+1}}\right),$$

which readily yields the seed length bound stated in Proposition 4. The additive $\log w$ term arises from a technical consideration that we suppress in this informal discussion.

Comb of combs. Applying Proposition 4 with $t = \frac{\log w}{\log(1/\varepsilon_0)}$ yields a WPRG with the desired error ε, albeit with a seed length that has a *quadratic* dependence on $\log w$. To understand how this can be avoided, we first ask what error we can "buy" with an additive $O(\log w)$ term in the seed – a cost we are willing to incur. Since the seed length in Proposition 4 is $s_0 + O(t^2 \cdot \log(1/\varepsilon_0))$, we can set

$$t = t_1 = \sqrt{\frac{\log w}{\log(1/\varepsilon_0)}},$$

thereby increasing the seed length by an additive $O(\log w)$ term over s_0. The resulting error guaranteed by Proposition 4 is then $\varepsilon_1 = \varepsilon_0^{t_1}$. Let us (re)denote the resulting WPRG by W_1, which has seed length $s_1 = s_0 + O(\log w)$.

Generally, the error ε_1 is not sufficiently small, and so we repeat the process and construct a new WPRG $W_2 = \mathsf{Comb}_{t_2}(W_1)$ (hence the name "comb-of-combs"; see Figure 2 for an illustration.). Again, we wish to incur only an additive $O(\log w)$ increase in the seed length. Thus, we choose t_2 so that $t_2^2 \cdot \log(1/\varepsilon_1) = \log w$, which yields

$$t_2 = \left(\frac{\log w}{\log(1/\varepsilon_0)}\right)^{1/4} = \sqrt{t}.$$

The resulting error is then $\varepsilon_2 = \varepsilon_0^{t^{1+\frac{1}{2}}}$. Continuing in a recursive manner, we define $W_j = \mathsf{Comb}_{t_j}(W_{j-1})$, with $t_j = \sqrt{t_{j-1}}$. This results in error

$$\varepsilon_j = \varepsilon_0^{t^{1+\frac{1}{2}+\frac{1}{4}+\cdots+\frac{1}{2^{j-1}}}}$$

using seed length $s_0 + O(j \cdot \log w)$. Assuming now that $\varepsilon_0 = 1/n$, a calculation shows that for $\ell = \log\log\left(\frac{\log w}{\log n}\right)$, the WPRG W_ℓ achieves error $1/w$ and seed length $s_0 + O(\ell \cdot \log w)$, which is nearly linear in $\log w$, since ℓ is an extremely slowly growing function.

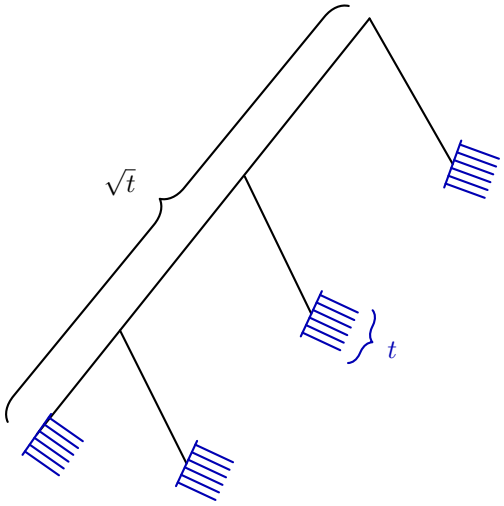

Figure 2 One level illustration of the comb of combs reduction.

2.3 Phase 2 – amplifying from inverse-width error

Once the error is below $1/w$, or if we are already in the regime $w = n^{O(1)}$, there is no further benefit to using asymmetric Richardson iteration, although the incremental approach remains advantageous. To obtain the final WPRG, we therefore compose the Richardson iterations in a binary-tree-like fashion, with the initial WPRG placed at the leaves. More precisely, let W_0 denote the WPRG obtained in the previous sections, with error guarantee $1/w$ and seed length s_0. We then define, for $j = 1, \ldots, h = \log\left(\frac{\log(1/\varepsilon)}{\log w}\right)$,

$$W_j = \mathrm{Rich}(W_{j-1}, W_{j-1}).$$

It is easy to verify that W_h achieves the desired error guarantee ε and has seed length

$$s_0 + 2^h \log w = s_0 + O(\log(1/\varepsilon)).$$

To wrap up, starting with a PRG with error $1/n$ and seed length s_0, the overall seed length, accounting for both phases, is

$$s_0 + O\left(\log \frac{1}{\varepsilon} + \log\log\left(\frac{\log w}{\log n}\right) \cdot \log w\right),$$

as claimed in Theorem 1. Moreover, note that in the regime $w = n^{O(1)}$, only the second phase is invoked, yielding a seed length of $s_0 + O(\log \frac{1}{\varepsilon})$.

2.4 Improving Nisan's PRG via optimal alphabet and error dependence

In this section, we give an overview of our alternative proof of the Cheng–Hoza reduction, as given in Theorem 3, showing that optimal dependence on the alphabet and error suffices to break the log-squared barrier. More precisely, recall that the goal here is to break the log-squared dependence on the length n in Nisan's PRG, assuming the existence of a PRG with optimal alphabet and error dependence. Concretely, suppose we are given a PRG with seed length

$$\log|\Sigma| + O\left(\log^2 n + \log n \cdot \log w + \log \frac{1}{\varepsilon}\right).$$

Our goal in proving Theorem 3 is to show that there exists an efficient transformation which then yields a PRG with seed length

$$\log|\Sigma| + O\left(\log^{3/2} n + \log n \cdot \log w + \sqrt{\log n} \cdot \log \frac{1}{\varepsilon}\right).$$

As we bear no news regarding the dependence on the width w, indeed, our construction exhibits the same $\log n \cdot \log w$ dependence as all previous constructions, we ignore the width parameter for simplicity.[6] Under this simplification, we assume the existence of a PRG with seed length $\log|\Sigma| + O(\log^2 n + \log \frac{1}{\varepsilon})$, and aim to construct a PRG with seed length $\log|\Sigma| + O(\log^{3/2} n + \sqrt{\log n} \cdot \log \frac{1}{\varepsilon})$. The idea is to exploit the optimal dependence on Σ, as follows.

The PRG is constructed recursively with respect to the length n. Fix a parameter r (for the impatient reader, we note that we will take $r = \sqrt{\log n}$), and let $R = 2^r$ and $t = \frac{\log n}{r}$. We construct a sequence of PRGs $G_0, G_1, \ldots, G_t$, all for the same width w and alphabet Σ, where

$$G_j \colon \{0,1\}^{d(j)} \to \Sigma^{R^j}.$$

Note that the final PRG G_t is for length-n BPs, and is the PRG produced by the transformation.

The first PRG, G_0, is simply the identity function, so $d(0) = \log_2|\Sigma|$. For $j \geq 1$ we define G_j by composing R concatenated copies of G_{j-1}. The naive approach would be to define

$$G_j(z) = G_{j-1}(z_1) \circ G_{j-1}(z_2) \circ \cdots \circ G_{j-1}(z_R),$$

where the seed z is partitioned into R disjoint blocks. But this results in an unacceptable blow-up in the seed length, $d(j) = R \cdot d(j-1)$, which ultimately yields a trivial PRG.

Instead, we use the hypothesized PRG to recycle the seeds of the R calls to G_{j-1}. In particular, let H_j denote the hypothesized PRG used to construct G_j. It has the form

$$H_j \colon \{0,1\}^{d(j)} \to \Sigma_j^R,$$

where $\Sigma_j = \{0,1\}^{d(j-1)}$. With H_j in place, we define G_j via "sparsified folding":[7]

$$G_j(z) = G_{j-1}\left(H_j(z)_1\right) \circ G_{j-1}\left(H_j(z)_2\right) \circ \cdots \circ G_{j-1}\left(H_j(z)_R\right).$$

Note that H_j is a PRG with very large alphabet size, exponential in the seed length of G_{j-1}, yet its output length is only R, which we will take to be much smaller. It is at this point that we capitalize on the excellent dependence on the alphabet size. Indeed, by our hypothesis, the seed length of H_j satisfies

$$d(j) = \underbrace{\log|\Sigma_j|}_{d(j-1)} + O\left(r^2 + \log\frac{1}{\varepsilon_H}\right),$$

where ε_H is the error parameter of H_j (taken uniformly across the j-s). Solving the recurrence yields

$$d(t) = O\left(t \cdot \left(r^2 + \log\frac{1}{\varepsilon_H}\right)\right) + \log|\Sigma|.$$

[6] Alternatively, the reader may think of the width w as a constant; recall that breaking the log-squared barrier remains open even for width $w = 4$.

[7] A similar length reduction step is also used in [12].

In the full version [7], we prove that correlating the R seeds using a BP does indeed work, yielding a final error ε bounded by $n\varepsilon_H$. This, together with our choice $t = \frac{\log n}{r}$ yields that the seed length is

$$d(t) = O\left(\frac{\log n}{r} \cdot \left(r^2 + \log n + \log \frac{1}{\varepsilon}\right)\right) + \log|\Sigma|.$$

Optimizing by setting $r = \sqrt{\log n}$, we get the desired seed length.

3 Preliminaries

All logarithms in this paper are taken to base 2, unless otherwise stated. Whenever we write $x \sim A$ for A being a set, we mean that x is sampled uniformly at random from the flat distribution over A. We denote by U_n the random variable distributed uniformly over $\{0,1\}^n$.

We say $f\colon \Lambda_1 \to \Lambda_2^\star$ is explicit if it's computable in time $\mathrm{poly}(\log|\Lambda_1|)$. We mostly do not keep precise track of the space complexity of our error-reduction procedure. A suitable bound follows from standard results on the space complexity of compositions, together with the space complexity of the underlying PRG whose error is being reduced.

3.1 Matrices, Branching Programs, and Space Complexity

A matrix is Boolean if all its entries are in $\{0,1\}$, and stochastic if all its entries are nonnegative and the sum of each column is 1. Denote by $\mathrm{BSto}(w)$ the set of $w \times w$ boolean stochastic matrices. We will denote by $\|\cdot\|$ the induced ℓ_1 norm, i.e., $\|A\| = \max_j \sum_i |A_{i,j}|$.

We start by defining standard-order, read-once, branching programs.

▶ **Definition 5** (branching program). *Let Σ be some alphabet and let $n, w \in \mathbb{N}$. An (n, w, Σ) branching program (BP) is a sequence $B = (B_1, \ldots, B_n)$, where each $B_i\colon \Sigma \to \mathrm{BSto}(w)$.*

For $i \le j$ we let $B_{i\to j}$ be the $(j-i+1, \Sigma, w)$ BP $(B_i, \ldots, B_j)$.

▶ **Definition 6.** *The* value *of an (n, w, Σ) BP $B = (B_1, \ldots, B_n)$ on $x = (x_1, \ldots, x_n) \in \Sigma^n$, denoted $B(x)$, is the realized $w \times w$ matrix of B when fed by x, i.e.,*

$$B(x) = B_n(x_n) \cdot B_{n-1}(x_{n-1}) \cdots B_1(x_1).$$

If B is the empty sequence, we set $\emptyset(x) = I_w$.

▶ **Definition 7** (weighted PRG). *We say (G, μ) is an $(n, w, \Sigma, \Gamma, \varepsilon)$-WPRG against BPs with seed length s if:*

- *$G\colon \{0,1\}^s \to \Sigma^n$ and $\mu\colon \{0,1\}^s \to \mathbb{R}$,*
- *For every (n, w, Σ) BP $B = (B_1, \ldots, B_n)$, it holds that*

$$\left\|\mathbb{E}_{x\sim\{0,1\}^s}[\mu(x) \cdot B(G(x))] - \mathbb{E}_{x\sim\Sigma^n}[B(x)]\right\| \le \varepsilon,$$

- *For every $x \in \{0,1\}^s$, $|\mu(x)| \le \Gamma$.*

When $\mu \equiv 1$, the notion coincides with that of a PRG, in which case we omit the Γ from the tuple.

For $1 \le i \le j \le n$ we let $G_{i\to j}\colon \{0,1\}^s \to \Sigma^{j-i+1}$ be the corresponding truncation of G's output. Note that if (G, μ) is an $(n, w, \Sigma, \Gamma, \varepsilon)$ WPRG, then $(G_{i\to j}, \mu)$ is an $(j-i+1, w, \Sigma, \Gamma, \varepsilon)$ WPRG. We will often omit the subscript $i \to j$ when the length of the corresponding BP is clear from context.

3.2 Known PRG Constructions

▶ **Theorem 8** ([25]). *For any positive integers n, w, any error parameter $\varepsilon > 0$ and any alphabet Σ, there exists an explicit $(n, \Sigma, w, \varepsilon)$ PRG with seed length*

$$s = \log|\Sigma| + O\Big(\log n \cdot \log\Big(\frac{nw}{\varepsilon}\Big)\Big).$$

When $w \gg n$, Armoni's PRG [2] improves upon the INW generator. When instantiated with modern extractors, it works for all ranges of parameters [27], and has the optimal dependence on Σ [8].

▶ **Theorem 9** ([2, 27, 8]). *For any positive integers n, w, any error parameter $\varepsilon > 0$ and any alphabet Σ, there exists an explicit $(n, \Sigma, w, \varepsilon)$ PRG with seed length*

$$s = \log|\Sigma| + O\left(\frac{\log(nw/\varepsilon)\log n}{\max(1, \log\log w - \log\log(n/\varepsilon))}\right).$$

3.3 Seeded Extractors

The *support* of a random variable X distributed over some domain Ω is the set $x \in \Omega$ for which $\Pr[X = x] \neq 0$, which we denote by $\mathrm{Supp}(X)$. The *total variation distance* (or, statistical distance) between two random variables X and Y over the same domain Ω is defined as $|X - Y| = \max_{A \subseteq \Omega}(\Pr[X \in A] - \Pr[Y \in A])$. Whenever $|X - Y| \leq \varepsilon$ we say that X is ε-close to Y and denote it by $X \approx_\varepsilon Y$.

For a function $f\colon \Omega_1 \to \Omega_2$ and a random variable X distributed over Ω_1, $f(X)$ is the random variable distributed over Ω_2 obtained by choosing x according to X and computing $f(x)$. For a set $A \subseteq \Omega_1$, $f(A) = \{f(x) : x \in A\}$. For every $f\colon \Omega_1 \to \Omega_2$ and two random variables X and Y distributed over Ω_1 it holds that $|f(X) - f(Y)| \leq |X - Y|$, and this is often referred to as the data-processing inequality.

▶ **Definition 10** (min-entropy). *Let X be a discrete random variable over a set $\mathcal{X}$. The* min-entropy *of X, denoted by $H_\infty(X)$, is defined as*

$$H_\infty(X) = \min_{x \in \mathcal{X}}(-\log\Pr[X = x]) = -\log\left(\max_{x \in \mathcal{X}}\Pr[X = x]\right). \tag{1}$$

▶ **Definition 11** ((n,k) source). *An (n,k)* source *is a random variable X distributed over $\{0,1\}^n$ such that its min-entropy is at least k, i.e., $H_\infty(X) \geq k$. Equivalently, it is a distribution where for all $x \in \{0,1\}^n$,*

$$\Pr[X = x] \leq 2^{-k}. \tag{2}$$

▶ **Definition 12** (extractor). *A function $\mathsf{Ext}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ is a (k,ε) (seeded) extractor if the following holds. For every (n,k) source X it holds that $\mathsf{Ext}(X, Y) \approx_\varepsilon U_m$, where Y is uniformly distributed over $\{0,1\}^d$ and is independent of X.*

We will use two extractors, one in the balanced regime, and one in the unbalanced regime.

▶ **Theorem 13** ([21]). *There exists a constant $c_{\mathsf{seed}} \geq 1$ such that the following holds. For every positive integer n, and any $\Delta < n$ and $\varepsilon > 0$, there exists an explicit $(k = n - \Delta, \varepsilon)$ extractor $\mathsf{Ext}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^n$, where $d = c_{\mathsf{seed}} \cdot (\Delta + \log(n/\varepsilon))$.*

▶ **Theorem 14** ([38, 6]). *There exist constants $c_{\mathsf{seed}}, c_{\mathsf{loss}} \geq 1$ such that the following holds. For every positive integer n, and any $\Delta < n$ and $\varepsilon > 0$, there exists an explicit $(k = n - \Delta, \varepsilon)$ extractor $\mathsf{Ext}\colon \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$, where $d = c_{\mathsf{seed}} \cdot \log(\Delta/\varepsilon)$ and $m = n - c_{\mathsf{loss}} \cdot (\Delta + \log\frac{1}{\varepsilon})$.*

4 Our Error Reduction Procedure

In this section we prove Theorem 1 and deduce Corollary 2. We begin with an informal overview of the Richardson iteration technique. This procedure depends on a parameter k that governs the quality of error reduction: roughly, an error-ε PRG is transformed into an error-ε^k WPRG. As discussed in the proof overview, in this work we observe that it is more economical to work with $k = 2$ and then compose the resulting WPRGs.

Our use of the Richardson iteration is asymmetric. In particular, in our error reduction we apply the iteration to WPRGs with varying error parameters. To set the stage, we first review, at an informal level, the Richardson iteration with parameter $k = 2$ in the symmetric setting. With this intuition in place, we then proceed in Section 4.1 to formally construct the Richardson iteration with parameter $k = 2$ for the asymmetric case.

Suppose we are given

- $w \times w$ sub-stochastic matrices $M_1, \ldots, M_n$, and,
- Crude approximations $\widetilde{M}_{i,j}$ to $M_i M_{i-1} \cdots M_j$ for all $1 \le j < i \le n$ (for $j = i$ we naturally take $\widetilde{M}_{i,i} = M_i$).

In the context of space bounded derandomization, [32] describe a method to use $M_1, \ldots, M_n$ to refine the crude approximations to much better approximations. First, they "plant" the matrix product problem within a matrix inversion problem. Specifically, they form the $(n+1) \times (n+1)$ block matrix

$$M = \begin{pmatrix} 0 & 0 & 0 & \cdots & 0 & 0 \\ M_1 & 0 & 0 & \cdots & 0 & 0 \\ 0 & M_2 & 0 & \ddots & \vdots & \vdots \\ \vdots & \vdots & \ddots & \ddots & 0 & 0 \\ 0 & 0 & \cdots & M_{n-1} & 0 & 0 \\ 0 & 0 & \cdots & 0 & M_n & 0 \end{pmatrix} \tag{3}$$

and define $L = I - M$. Then they observe that the inverse of L is:

$$(L^{-1})_{i,j} = \begin{cases} M_{i-1} \cdots M_j & \text{if } i > j, \\ I & \text{if } i = j, \\ 0 & \text{otherwise.} \end{cases}$$

Thus, the product we wish to approximate is a block within L^{-1}. We can use the crude approximations $\widetilde{M}_{i-1,j}$ to form the matrix

$$\widetilde{L^{-1}}_{i,j} = \begin{cases} \widetilde{M}_{i-1,j}, & \text{if } i > j, \\ I, & \text{if } i = j, \\ 0, & \text{if } i < j. \end{cases}$$

and $\widetilde{L^{-1}}$ is a crude approximation to L^{-1}. Prior works apply Richardson iteration to get a better approximation to L^{-1}. Specifically they take

$$\widehat{\widetilde{L^{-1}}} = 2\widetilde{L^{-1}} - \widetilde{L^{-1}} L \widetilde{L^{-1}}, \tag{4}$$

and it is immediate to check that

$$\left\| I - L\widehat{\widetilde{L^{-1}}} \right\| = \left\| I - L\widetilde{L^{-1}} \right\|^2.$$

Thus, $\widehat{\widetilde{L^{-1}}}$ yields a quadratically improved approximation of L^{-1} and therefore also of $M_1 \cdot \ldots \cdot M_n$. An explicit formula for the approximation of $M_1 \cdot \ldots \cdot M_n$ can be derived: For every $n \geq 3$,

$$\widehat{\widetilde{M}}_{n+1,1} = \sum_{r=1}^{n-2} \widetilde{M}_{n,r+2} M_{r+1} \widetilde{M}_{r,1} - \sum_{r=1}^{n-3} \widetilde{M}_{n,r+2} \widetilde{M}_{r+1,1}. \tag{5}$$

For example, for $n = 4$, the approximation of $M_4 M_3 M_2 M_1$ is

$$\widehat{\widetilde{M}}_{5,1} = \widetilde{M}_{4,3} M_2 M_1 + M_4 M_3 \widetilde{M}_{2,1} - \widetilde{M}_{4,3} \widetilde{M}_{2,1}.$$

Observe that Equation (5) is expressed as the difference of two sums. In the first (positive) sum, each summand is a product of three terms – two given approximations with an input matrix M_r sandwiched in the middle. In the second (negative) sum, the product omits this middle input matrix.

[36] and [14] independently notice that if the approximations $\widetilde{M}$ are obtained with a PRG, then the approximation $\widehat{\widetilde{M}}$ can be realized with a WPRG [8]. A naive (and expensive) implementation of this would construct the WPRG for $\widehat{\widetilde{M}}$ using two independent calls to the WPRGs for $\widetilde{M}$. A better idea is to recycle the seeds needed for the two calls to the WPRG of $\widetilde{M}$. In this work we explore what happens when we employ two different WPRGs, each with a different accuracy level, and we show that this leads to better WPRGs.

4.1 Asymmetric Richardson Iteration

In this section we make the above idea precise.

Construction. We are given two WPRGs, which we think of as a "left" WPRG and a "right" one, possibly with different parameters, and an extractor.

- An $(n, w, \Sigma, \Gamma_L, \varepsilon_L)$ WPRG (G^L, μ_L) with seed length s_L.
- An $(n, w, \Sigma, \Gamma_R, \varepsilon_R)$ WPRG (G^R, μ_R) with seed length s_R.
- A $(k, \varepsilon_{\mathsf{Ext}})$ extractor $\mathsf{Ext}\colon \{0,1\}^{s_L} \times \{0,1\}^{d_{\mathsf{Ext}}} \to \{0,1\}^{s_R}$, where $k = s_L - \log \frac{w}{\varepsilon_{\mathsf{Ext}}}$.

The construction of our new WPRG

$$\mathrm{Rich}_{\mathsf{Ext}}((G^L, \mu_L), (G^R, \mu_R)) = (G, \mu)$$

goes as follows. We interpret the set of seeds S as $[2n-5] \times \{0,1\}^{s_L} \times \{0,1\}^{d_{\mathsf{Ext}}} \times \{0,1\}^{d_{\mathsf{Ext}}}$. Given $(t, x_L, y_1, y_2) \in S$, we set $t' = t - n + 2$, and define

$$G(t, x_L, y_1, y_2) = \begin{cases} G^L_{1\to t}(x_L) \circ \mathsf{Ext}(x_L, y_2)_{[1,\log|\Sigma|]} \circ G^R_{t+2\to n}(\mathsf{Ext}(x_L, y_1)) & \text{if } t \leq n-2, \\ G^L_{1\to t'+1}(x_L) \circ G^R_{t'+2\to n}(\mathsf{Ext}(x_L, y_1)) & \text{otherwise.} \end{cases}$$

$$\mu(t, x_L, y_1, y_2) = (2n-5) \cdot \begin{cases} \mu_L(x_L) \cdot \mu_R(\mathsf{Ext}(x_L, y_1)) & \text{if } t \leq n-2, \\ -\mu_L(x_L) \cdot \mu_R(\mathsf{Ext}(x_L, y_1)) & \text{otherwise.} \end{cases}$$

Note that the construction exactly corresponds to Equation (5), where we use two different WPRGs for approximating the matrices. Notice that the first $n-2$ terms come with a positive sign, and the last $n-3$ terms with a negative sign.

[8] The use of weights here is essential, as some of terms in Equation (5) come with a negative weight.

▶ **Lemma 15.** *Given* (G^L, μ_L), (G^R, μ_R), *and* Ext *as above, it holds that* (G, μ) *is an* $(n, w, \Sigma, \Gamma, \varepsilon)$ *WPRG, where:*

- *The seed length* $s = \log|S|$ *satisfies* $s = \log(2n-5) + s_L + 2d_{\mathsf{Ext}}$,
- *The weight of* G *is at most* $\Gamma = c \cdot n\Gamma_L\Gamma_R$ *for some constant* $c \geq 1$, *and,*
- *The error* ε *is bounded by* $\varepsilon \leq 4(n+1)^2\varepsilon_L\varepsilon_R + \Gamma \cdot \varepsilon_{\mathsf{Ext}}$.

Proof. The weighted generator (G, μ) treats each seed as a quadruple (t, x_L, y_1, y_2). Here $t \in [2n-5]$ specifies which of the $(n-2)$ "positive" or $(n-3)$ "negative" summands in the Richardson expansion is selected; $x_L \in \{0,1\}^{s_L}$ is drawn according to μ_L; and $y_1, y_2 \in \{0,1\}^{d_{\mathsf{Ext}}}$ are independent extractor seeds. Encoding t requires $\log(2n-5)$ bits, x_L requires s_L bits, and the two extractor seeds contribute $2\,d_{\mathsf{Ext}}$ bits in total, giving a seed length of

$$s = \log(2n-5) + s_L + 2\,d_{\mathsf{Ext}}.$$

Each output of (G, μ) has weight

$$\mu(t, x_L, y_1, y_2) = \pm(2n-5)\,\mu_L(x_L)\,\mu_R\big(\mathsf{Ext}(x_L, y_1)\big),$$

and therefore satisfies

$$|\mu(t, x_L, y_1, y_2)| \leq (2n-5)\,\Gamma_L\,\Gamma_R.$$

We move to analyzing the error of the weighted PRG.

Constructing approximate inverses. Let B be an (n, w, Σ) BP with transition matrices $M_1, \ldots, M_n$. Let L be the corresponding $(n+1)w \times (n+1)w$ block matrix defined in Equation (3) whose inverse L^{-1} encodes all partial products $M_i \cdots M_{j+1}$. We form two approximate inverses $L^{-1(L)}$ and $L^{-1(R)}$ by replacing each block $M_{i,j}$ with

$$\widetilde{M}^{(L)}_{i,j} = \mathop{\mathbb{E}}_{x \sim \{0,1\}^{s_L}}\Big[\mu_L(x) \cdot B_{i\to j}\big(G^L(x)\big)\Big] \quad \text{or} \quad \widetilde{M}^{(R)}_{i,j} = \mathop{\mathbb{E}}_{x \sim \{0,1\}^{s_R}}\Big[\mu_R(x) \cdot B_{i\to j}\big(G^R(x)\big)\Big],$$

respectively. Recalling that (G^L, μ_L) and (G^R, μ_R) have errors ε_L and ε_R, we have

$$\big\|M_{i,j} - \widetilde{M}^{(L)}_{i,j}\big\| \;\leq\; \varepsilon_L, \quad \big\|M_{i,j} - \widetilde{M}^{(R)}_{i,j}\big\| \;\leq\; \varepsilon_R.$$

Summing these errors over the $n{+}1$ block rows gives

$$\big\|L^{-1} - L^{-1(L)}\big\| \;\leq\; (n{+}1)\,\varepsilon_L, \quad \big\|L^{-1} - L^{-1(R)}\big\| \;\leq\; (n{+}1)\,\varepsilon_R.$$

As $\|L\| \leq 2$,

$$\big\|I - L^{-1(L)}L\big\| \;\leq\; 2(n{+}1)\,\varepsilon_L, \qquad \big\|I - L^{-1(R)}L\big\| \;\leq\; 2(n{+}1)\,\varepsilon_R.$$

Asymmetric Richardson. "Vanilla" Richardson refines a *single* crude inverse $A \approx L^{-1}$ via

$$A \longmapsto 2A - ALA,$$

which satisfies $\|I - (2A - ALA)L\| = \|I - AL\|^2$. In principle, introducing two approximations looks unnecessary–one could just reuse the more accurate one. In our setting, however, the two appearances of $\widetilde{L^{-1}}$ are generated from *different seeds*: the left term is driven by

x_L, while the right term is obtained from x_L through an extractor and therefore may have different accuracy. This asymmetry naturally leads us to use a Richardson-type update that mixes two approximations,

$$R = L^{-1(L)} + L^{-1(R)} - L^{-1(L)} L L^{-1(R)}.$$

A short calculation shows that

$$I - RL = (I - L^{-1(L)}L)(I - L^{-1(R)}L).$$

Consequently,

$$\|I - RL\| \le \|I - L^{-1(L)}L\| \, \|I - L^{-1(R)}L\| \le 4(n+1)^2 \varepsilon_L \varepsilon_R,$$

and in particular the bottom-left block satisfies

$$\||R[n+1,1] - M_n \cdots M_1\| \le 4(n+1)^2 \varepsilon_L \varepsilon_R.$$

Uncorrelated seeds. Assume that the seed x_R for G_R and the symbol $\sigma \in \Sigma$ are sampled independently from x_L and uniformly. Given $t \in [2n-5]$, we consider the above two cases. When $t \in [n-2]$, letting $r = t$, the generator outputs $G^L_{1\to r}(x_L) \circ \sigma \circ G^R_{r+2\to n}(x_R)$. Then,

$$\mathbb{E}_{x_L,x_R,\sigma}\Big[\mu_L(x_L)\,\mu_R(x_R)\,B\big(G^L_{1\to r}(x_L) \circ \sigma \circ G^R_{r+2\to n}(x_R)\big)\Big] = \widetilde{M}^{(R)}_{n,r+2}\, M_{r+1}\, \widetilde{M}^{(L)}_{r,1}.$$

When $t > n-2$, we denote r to be such that $t = n-2+r$, and now

$$\mathbb{E}_{x_L,x_R}\Big[\mu_L(x_L)\,\mu_R(x_R)\,B\big(G^L_{1\to r+1}(x_L) \circ G^R_{r+2\to n}(x_R)\big)\Big] = -\,\widetilde{M}^{(R)}_{n,r+2}\, \widetilde{M}^{(L)}_{r+1,1}.$$

Averaging over $t \in [2n-5]$ and multiplying by $2n-5$ yields exactly

$$\sum_{r=1}^{n-2} \widetilde{M}^{(L)}_{n,r+2}\, M_{r+1}\, \widetilde{M}^{(R)}_{r,1} - \sum_{r=1}^{n-3} \widetilde{M}^{(L)}_{n,r+2}\, \widetilde{M}^{(R)}_{r+1,1},$$

which is the $(n+1,1)$-block of the Richardson matrix R. Thus, when x_R and σ are drawn independently, the weighted generator's output matches $R[n+1,1]$.

Correlating x_R and σ with x_L via two extractor calls. We now replace the independent choices (x_R, σ) by

$$x_R = \mathsf{Ext}(x_L, y_1) \in \{0,1\}^{s_R}, \quad \sigma = \mathsf{Ext}(x_L, y_2)_{[1,\log|\Sigma|]} \in \Sigma,$$

where y_1, y_2 are independent uniform seeds (and independent of x_L). We bound the difference in the ℓ_1 norm of the $(n+1,1)$-block contribution.

We use the standard seed-recycling argument for width-w ROBPs. Conditioning on reaching the state $q \in [w]$ after reading x_L reveals at most, roughly, $\log w$ bits of information; Formally, except with probability at most $\varepsilon_{\mathsf{Ext}}$, this conditioning reduces the *min-entropy* of the left seed by at most $\log(w/\varepsilon_{\mathsf{Ext}})$. Setting $\Delta := \log(w/\varepsilon_{\mathsf{Ext}})$, and using our extractor $\mathsf{Ext} : \{0,1\}^{s_L} \times \{0,1\}^{d_{\mathsf{Ext}}} \to \{0,1\}^{s_R}$ with entropy loss Δ and error $\varepsilon_{\mathsf{Ext}}$, the condition

$$s_L - \Delta \ge s_L - \log \frac{w}{\varepsilon_{\mathsf{Ext}}} = k$$

guarantees that $\mathsf{Ext}(x_L, U)$ is $\varepsilon_{\mathsf{Ext}}$-close to uniform even after conditioning on q. Consequently, for any functions f_L, f_R,

$$\left\|\mathbb{E}_{x_L,y}\big[B\big(f_L(x_L)\circ f_R(\mathsf{Ext}(x_L,y))\big)\big] - \mathbb{E}_{x_L,x_R}\big[B\big(f_L(x_L)\circ f_R(x_R)\big)\big]\right\| \le 2\varepsilon_{\mathsf{Ext}}.$$

Taking the weights into account, recalling that $|\mu_L| \le \Gamma_L$ and $|\mu_R| \le \Gamma_R$, we have

$$\begin{aligned}\Big\|\mathbb{E}_{x_L,y}\big[(2n-5)\mu_L(x_L)\mu_R(\mathsf{Ext}(x_L,y))\cdot B(f_L(x_L)\circ f_R(\mathsf{Ext}(x_L,y)))\big] \\ - \mathbb{E}_{x_L,x_R}\big[(2n-5)\mu_L(x_L)\mu_R(x_R)\cdot B(f_L(x_L)\circ f_R(x_R))\big]\Big\| \le c\cdot(2n-5)\Gamma_L\Gamma_R\varepsilon_{\mathsf{Ext}}\end{aligned}$$

for some constant $c \ge 1$. The ultimate error bound is obtained by the triangle inequality. ◀

To conclude this section, we define a useful invariant which will be helpful towards establishing our WPRG.

▶ **Definition 16.** *We say that an $(n, w, \Sigma, \Gamma, \varepsilon)$ WPRG is* error-dominated *if*

$$\Gamma \le \frac{1}{c(n+1)^3\varepsilon},$$

where c is the same constant from Lemma 15.

Note that error-dominated WPRGs necessarily have low error. We record the following observation.

▷ Claim 17. Keeping the notation above, particularly the constant c from Lemma 15, assume that both (G^L, μ_L) and (G^R, μ_R) are error-dominated, and that

$$\varepsilon_{\mathsf{Ext}} \le \frac{n^2\varepsilon_L\varepsilon_R}{c\Gamma}.$$

Then, (G, μ) is error-dominated.

Proof. By Lemma 15, the composed generator satisfies

$$\Gamma = cn\,\Gamma_L\Gamma_R \qquad \text{and} \qquad \varepsilon \le 4(n+1)^2\varepsilon_L\varepsilon_R + \Gamma\varepsilon_{\mathsf{Ext}}.$$

Using $\varepsilon_{\mathsf{Ext}} \le \frac{n\varepsilon_L\varepsilon_R}{c\Gamma}$, we get

$$\varepsilon \le \big(4(n+1)^2 + n^2\big)\varepsilon_L\varepsilon_R \le 5(n+1)^2\varepsilon_L\varepsilon_R.$$

Since (G^L, μ_L) and (G^R, μ_R) are error-dominated,

$$\Gamma_L \le \frac{1}{c(n+1)^3\varepsilon_L} \qquad \text{and} \qquad \Gamma_R \le \frac{1}{c(n+1)^3\varepsilon_R}.$$

Therefore,

$$\Gamma \le cn\Gamma_L\Gamma_R \le \frac{cn}{c^2(n+1)^6}\cdot\frac{1}{\varepsilon_L\varepsilon_R} \le \frac{cn}{c^2(n+1)^6}\cdot\frac{5(n+1)^2}{\varepsilon} = \frac{n}{c(n+1)^4}\cdot\frac{1}{\varepsilon} \le \frac{1}{c(n+1)^3\varepsilon}.\text{◁}$$

4.2 A Comb Reduction

In this section we define a comb-like construction, that composes our asymmetric Richardson construction given in Section 4.1 as follows. For some base (error-dominated) WPRG W_0, and a sequence of extractors $\mathsf{Ext}_1, \ldots, \mathsf{Ext}_t$, we define W_i recursively as

$$W_i = \mathrm{Rich}_{\mathsf{Ext}_i}(W_{i-1}, W_0).$$

We denote by $W_0 = (G_0, \mu_0)$ our $(n, w, \Sigma, \Gamma_0, \varepsilon_0)$ error-dominated WPRG, and by s_0 its seed length. We proceed to set the parameters of our extractors, each of the t extractors

$$\mathsf{Ext}_i \colon \{0,1\}^{s(i)} \times \{0,1\}^{d(i)} \to \{0,1\}^{s_0}$$

is given in Theorem 14 and set to have error $\varepsilon_{\mathsf{Ext}}(i)$, where the $\varepsilon_{\mathsf{Ext}}(i)$'s are as follows. Define, for each $i \in [t]$, $\varepsilon(i) = (5(n+1)^2\varepsilon_0)^i\varepsilon_0$. Note that the sequence of $\varepsilon(i)$-s satisfy $\varepsilon(i) = 5(n+1)^2\varepsilon(i-1)\cdot\varepsilon_0$. For each $i \in [t]$ set

$$\varepsilon_{\mathsf{Ext}}(i) = \frac{n^2\varepsilon_0}{c\Gamma(i)} \cdot \varepsilon(i-1),$$

where $\Gamma(i) = (cn\Gamma_0)^i\Gamma_0$. Note that the $\Gamma(i)$-s satisfy the recurrence relation $\Gamma(i) = cn\Gamma(i-1)\Gamma_0$.

By Lemma 15, the input lengths satisfy $s(1) = s_0 + c_{\mathsf{seed}} \log(w/\varepsilon_{\mathsf{Ext}}(1))$, and for each $2 \le i \le t$,

$$s(i+1) = s(i) + 2c_{\mathsf{seed}} \log(\log w/\varepsilon_{\mathsf{Ext}}(i+1)) + \log(2n-5).$$

We record that:

▷ Claim 18. For every $i \in [t]$ it holds that

$$\log \frac{1}{\varepsilon_{\mathsf{Ext}}(i)} = O\left(i \log \frac{n\Gamma_0}{\varepsilon_0}\right),$$
$$s(i) = s_0 + O\left(\log w + i^2 \log \frac{n\Gamma_0}{\varepsilon_0}\right),$$

and

$$d(i) = O\left(\log\log w + i \log \frac{n\Gamma_0}{\varepsilon_0}\right).$$

Proof. By definition of $\varepsilon_{\mathsf{Ext}}(i)$ and error domination from Claim 17:

$$\varepsilon_{\mathsf{Ext}}(i) = \frac{\varepsilon(i-1)\varepsilon_0 n^2}{c\Gamma(i)} \ge \frac{1}{c} \cdot \varepsilon(i-1)\varepsilon_0 n^2 \cdot c(n+1)^3\varepsilon(i) \ = \frac{(n+1)n^2\varepsilon(i)^2}{5},$$

so

$$\log \frac{1}{\varepsilon_{\mathsf{Ext}}(i)} = O\left(i \cdot \log \frac{n\Gamma_0}{\varepsilon_0}\right).$$

For the WPRG's seed length, we have

$$\begin{aligned} s(i) &= s_0 + s(1) + (i-1)\cdot\log(2n-5) + 2c_{\mathsf{seed}} \sum_{k=2}^{i} \log \frac{\log w}{\varepsilon_{\mathsf{Ext}}(k+1)} \\ &= s_0 + O\left(\log w + i \log\log w + i^2 \log \frac{n\Gamma_0}{\varepsilon_0}\right). \end{aligned}$$

By the construction given in Section 4.1, the entropy loss of each extractor is $\Delta(i) = \log(w/\varepsilon_{\mathsf{Ext}}(i))$. Thus, we can indeed output s_0 bits as

$$s(i) \geq s_0 + c_{\mathsf{loss}}\left(\Delta(i) + \log\frac{1}{\varepsilon_{\mathsf{Ext}}(i)}\right).$$

We thus get that

$$d(i) = O\left(\log\log w + \log\frac{1}{\varepsilon_{\mathsf{Ext}}(i)}\right) = O\left(\log\log w + i\log\frac{n\Gamma_0}{\varepsilon_0}\right). \qquad \lhd$$

We denote this section's transformation, which on input W_0 construct W_t, as $\mathsf{Comb}_t(W_0)$. The parameters of the construction are summarized in the following theorem, whose proof readily follows from Lemma 15, Claim 17, and Claim 18.

▶ **Proposition 19.** *Keeping the above notation, assuming $\varepsilon_0 \leq 1/n^5$ and that $s_0 \geq \log|\Sigma| + \Omega(\log(w/\varepsilon_0))$, $\mathsf{Comb}_t(W_0)$ is an error-dominated $(n, w, \Sigma, \Gamma_t, \varepsilon_t)$ WPRG with seed length*

$$s_0 + O\left(t^2\log\frac{1}{\varepsilon_0} + \log w\right),$$

and error $\varepsilon_t = \varepsilon_0^{t/2}$.

We emphasize that error domination of the WPRG is preserved, and moreover, that if W_0 is explicit, W_t is explicit as well.

4.3 Amplifying from Inverse-Length to Inverse-Width Error

To reduce the error from $n^{-\Omega(1)}$ to $w^{-\Omega(1)}$, we define a "comb-of-combs" construction as follows. Letting W_0 be an error dominated $(n, w, \Sigma, \Gamma_0, \varepsilon_0)$ WPRG that satisfies the assumptions of Proposition 19, for some $t_1, \ldots, t_\ell$, we define the sequence of WPRGs defined by

$$W_i = \mathsf{Comb}_{t_i}(W_{i-1}),$$

and set $\mathsf{CoC}_{t_1,\ldots,t_\ell}(W_0) = W_\ell$.

Concretely, we start with $\varepsilon_0 = 1/n^5$, choose

$$\ell = \log\log\left(\frac{\log w}{\log n}\right),$$

and for each $i \in [\ell]$, we take

$$t_i = 2\left(\frac{\log w}{\log n}\right)^{2^{-i}}.$$

Under this choice of parameters, $\mathsf{CoC}_{t_1,\ldots,t_\ell}(W_0)$ satisfies the following.

▶ **Proposition 20.** *Keeping the above notation,*

$$\mathsf{CoC}_{t_1,\ldots,t_\ell}(W_0)$$

is an explicit error-dominated $(n, w, \Sigma, \Gamma, \varepsilon)$ WPRG with $\varepsilon = 1/w$, seed length $s_0 + O(\ell\log w)$.

Proof. First, note that the fact that W_ℓ is error dominated already follows from Proposition 19, and we proceed to analyzing the error. Letting ε_i be the error of W_i, by Proposition 19 we know that $\varepsilon_i = \varepsilon_{i-1}^{t_i/2}$. By our choice of t_i-s, denoting $r = \frac{\log w}{\log n}$, we get that

$$\varepsilon_\ell = \varepsilon_0^{2^{-\ell}\prod_{i\in[\ell]} t_i} = \varepsilon_0^{\prod_{i\in[\ell]} r^{2^{-i}}} = \varepsilon_0^{r^{1-2^{-\ell}}}.$$

Now, $2^\ell = \log r$, so $r^{1-2^{-\ell}} = r/2$. Recalling that $\varepsilon_0 = n^{-5}$, we get $\varepsilon_0^{r/2} = n^{-5r/2} \le 1/w$.

For the seed length, denote by s_i the seed length of W_i. By Proposition 19, we know that each $s_i = s_{i-1} + O(t_i^2 \log(1/\varepsilon_{i-1}))$. Fixing some $i \in [\ell]$, note from the above that

$$t_i^2 \cdot \log\frac{1}{\varepsilon_{i-1}} = t_i^2 \cdot r^{1-2^{-(i-1)}} \log\frac{1}{\varepsilon_0} = 4r^{2^{-i+1}} \cdot r^{1-2^{-i+1}} \log\frac{1}{\varepsilon_0} = 20\log n \cdot r = 20\log w.$$

Thus, $s_i = s_{i-1} + O(\log w)$ and we're done with the seed length caclculation. Finally, note that in order to invoke Proposition 19, we need to make sure that $s_i \ge \log|\Sigma| + \Omega(\log(w/\varepsilon_i))$, which follows from the fact that $t_i^2 \log(1/\varepsilon_{i-1}) = \Omega(\log(1/\varepsilon_i))$ and that $s_0 \ge \log|\Sigma| + \Omega(\log w)$. ◀

4.4 Amplifying to an Arbitrary Error

Once we achieved an error of $1/w$, we reduce the error to an arbitrary desired error ε by recursively applying the Richardson iteration on the same WPRG, i.e., at the base of the recursion we use CoC above on the given base-WPRG W. More formally, we start with $V_0 = \mathsf{CoC}_{t_1,\ldots,t_\ell}(W)$ as above, set

$$h = \log\left(\frac{\log(1/\varepsilon)}{\log(w/6n^2)}\right),$$

and for each $i \in [h]$, define

$$V_i = \mathrm{Rich}_{\mathsf{Ext}_i}(V_{i-1}, V_{i-1}),$$

where the extractors $\mathsf{Ext}_1, \ldots, \mathsf{Ext}_h$ are defined as follows. We denote the seed length of each $(n, w, \Sigma, \Gamma_i, \varepsilon_i)$ WPRG V_i by s_i, and the seed length of W by $s(W)$. Each

$$\mathsf{Ext}_i \colon \{0,1\}^{s_{i-1}} \times \{0,1\}^{d_i} \to \{0,1\}^{s_{i-1}}$$

is taken to be the $(k_i, \varepsilon_{\mathsf{Ext}_i})$ extractor of Theorem 13 as in Section 4.2, where $k_i = s_{i-1} - \log(w/\varepsilon_{\mathsf{Ext}_i})$, and $\varepsilon_{\mathsf{Ext}_i} = \frac{n^2\varepsilon_{i-1}^2}{c\Gamma_i}$. By Lemma 15, we have the recurrence relation relating the seed lengths of the WPRGs

$$s_i = s_{i-1} + 2d_i + O(\log n) = s_{i-1} + O(\log(1/\varepsilon_{\mathsf{Ext}_i})),$$

and the recursive relation of the errors is $\varepsilon_i \le 6n^2\varepsilon_{i-1}^2$. Solving for the recursion, recalling $\varepsilon_0 = 1/w$, we get

$$\varepsilon_i \le \left(\frac{6n^2}{w}\right)^{2^i}.$$

Our choice of h guarantees a final error of $\varepsilon_h \le \varepsilon$.

By Theorem 13, the seed length

$$d_i = O\left(\log(w/\varepsilon_{\mathsf{Ext}_i})\right) = O(\log(1/\varepsilon_i)) = O\left(2^i \log w\right),$$

and so the recurrence simplifies to $s_i = s_{i-1} + O(2^i \log w)$, yielding

$$s_h = s_0 + O(2^h \log w) = s_0 + O(\log(1/\varepsilon)).$$

By Proposition 20,

$$s_0 = s(W) + O\left(\log\log\left(\frac{\log w}{\log n}\right)\cdot\log w\right),$$

and so the final seed length is

$$s_h = s(W) + O\left(\log\frac{1}{\varepsilon} + \log\log\left(\frac{\log w}{\log n}\right)\cdot\log w\right).$$

We summarize this in the following theorem, which is the formal version of Theorem 1 whose proof follows by the above calculations, also noting that the constructed WPRGs remain error-dominated and explicit.

▶ **Theorem 21.** *Keeping the above notation, let W be an explicit error-dominated $(n, w, \Sigma, \Gamma_0, \varepsilon_0 = 1/n^5)$ WPRG with seed length $s(W)$. Then, V_h is an error-dominated $(n, w, \Sigma, \Gamma, \varepsilon)$ WPRG with seed length*

$$s(W) + O\left(\log\frac{1}{\varepsilon} + \log\log\left(\frac{\log w}{\log n}\right)\cdot\log w\right).$$

Finally, for our base-WPRG we'll choose Armoni's explicit PRG from Theorem 9.

▶ **Corollary 22.** *For any positive integers n, w such that $w > n$, any $\varepsilon > 0$, and any alphabet Σ, there exists an explicit $(n, w, \Sigma, \Gamma, \varepsilon)$ WPRG with seed length*

$$\log|\Sigma| + O\left(\frac{\log^2 n + \log n\cdot\log w}{\log\log w - \log\log n} + \log\log\left(\frac{\log w}{\log n}\right)\cdot\log w + \log\frac{1}{\varepsilon}\right).$$

and $\Gamma \le \max\left\{1, \frac{1}{\mathrm{poly}(n)\cdot\varepsilon}\right\}$. In particular, when $w = 2^{n^\alpha}$ for some constant $\alpha \in (0,1)$, the seed length above becomes

$$\log|\Sigma| + O\left((\log\log\log w)\cdot\log w + \log\frac{1}{\varepsilon}\right).$$

When w is only polynomial in n, we can perform the error reduction step of Section 4.4 directly, and for the base-PRG, we can use the simpler INW generator (see Theorem 8) and get the following corollary.

▶ **Corollary 23.** *For any positive integers n, w such that $w = n^{O(1)}$, any $\varepsilon > 0$, and any alphabet Σ, there exists an explicit $(n, w, \Sigma, \Gamma, \varepsilon)$ WPRG with seed length*

$$\log|\Sigma| + O\left(\log^2 n + \log\frac{1}{\varepsilon}\right)$$

and $\Gamma \le \max\left\{1, \frac{1}{\mathrm{poly}(n)\cdot\varepsilon}\right\}$.

Abstract

We give two algorithms for *output-sparse matrix multiplication* (OSMM), the problem of multiplying two $n \times n$ matrices A, B when their product AB is promised to have at most $O(n^\delta)$ many non-zero entries for a given value $\delta \in [0, 2]$. We then show how to speed up these algorithms in the *fully sparse matrix multiplication* (FSMM) setting, where the input matrices A, B are themselves sparse. All of our algorithms work over arbitrary rings.

Our first, deterministic algorithm for OSMM works via a two-pass reduction to compressed sensing. It runs in roughly $n^{\omega(\delta/2,1,1)}$ time, where $\omega(\cdot,\cdot,\cdot)$ is the rectangular matrix multiplication exponent. This substantially improves on prior deterministic algorithms for output-sparse matrix multiplication.

Our second, randomized algorithm for OSMM works via a reduction to compressed sensing and a variant of matrix multiplication verification, and runs in roughly $n^{\omega(\delta-1,1,1)}$ time. This algorithm and its extension to the fully sparse setting have running times that match those of the (randomized) algorithms for OSMM and FSMM, respectively, in recent work of Abboud, Bringmann, Fischer, and Künnemann (SODA, 2024). Our algorithm is quite simple when taking a suitable compressed sensing scheme as a black box.

1 Introduction

The Matrix Multiplication Problem (MM) is to compute the product AB of two $n \times n$ matrices A, B given as input. It is one of the most fundamental problems in computer science. The running time $O(n^\omega)$ of the fastest algorithm for MM is governed by the *matrix multiplication exponent* $\omega \leq 2.372$ (see [2] for the current best bound), and it is a major open question whether $\omega = 2$.

While one line of work has sought to improve ω, another has tried to find faster algorithms for important special cases of MM. In this work, we give new algorithms for the *Output-Sparse Matrix Multiplication Problem* (OSMM), where the product AB of the input matrices A and B is promised to be *sparse*. Specifically, we consider MM when AB is promised to have $O(n^\delta)$ many non-zero entries for a parameter $\delta \in [0, 2]$. We denote this problem for matrices over a ring R by δ-OSMM$_R$. We also discuss how to extend our algorithms to the *fully sparse* setting, in which the input matrices A and B are themselves sparse. This setting was recently studied in depth in seminal work of Abboud, Bringmann, Fischer, and Künnemann [1].

1.1 Our Work

Our main results are a deterministic algorithm and a randomized algorithm for OSMM over arbitrary rings R including, in particular, finite fields, the integers, and the real numbers. The algorithms perform a similar number of ring operations regardless of R.

Define the *rectangular matrix multiplication exponent* $\omega(\alpha, \beta, \gamma)$ to be the infimum over values $\omega' \geq 0$ such that there is an algorithm for multiplying an $n^\alpha \times n^\beta$ matrix and an $n^\beta \times n^\gamma$ matrix in $O(n^{\omega'})$ time. Define the *dual matrix multiplication exponent* $\omega^\perp$ to be the supremum over values $\omega' \geq 0$ such that $\omega(1, 1, \omega') = 2$.[1]

The theorems corresponding to our main two OSMM algorithms are as follows. Our first algorithm dramatically improves on the state of the art for deterministic algorithms; see the comparison with prior work in Figure 1 and Section 1.2.

▶ **Theorem 1** (Deterministic OSMM). *Let $\delta \in [0, 2]$, let R be a ring, and let $\varepsilon > 0$ be a constant. There is a deterministic algorithm for solving δ-OSMM$_R$ on $n \times n$ matrices that performs $O(n^{\omega(\delta/2,1,1)+\varepsilon})$ operations over R.*

Our second, randomized algorithm, presented in Theorem 2, has running time that matches an algorithm from [1] using a reduction to a variant of the Matrix Multiplication Verification Problem (MMV). See Section 1.2 for a comparison of our Theorem 2 and the algorithm in [1]. We show that the running times of these algorithms are optimal in Section 4.3.

▶ **Theorem 2** (Randomized OSMM). *Let $\delta \in [0, 2]$, let R be a ring, and let $\varepsilon > 0$ be a constant. There is a randomized algorithm for solving δ-OSMM$_R$ on $n \times n$ matrices that performs $O(n^{\beta+\varepsilon})$ operations over R, where*

$$\beta := \begin{cases} 2 & \text{if } \delta \leq 1 + \omega^\perp \ , \\ \omega(\delta - 1, 1, 1) & \text{otherwise} \ . \end{cases}$$

[1] The dual matrix multiplication exponent is often denoted by α in the literature.

Since $\omega^{\perp} \geq 0.321$ [35], the algorithms in Theorems 1 and 2 run in essentially optimal n^2 time for all $\delta \leq 0.642$ and $\delta \leq 1.321$, respectively. Furthermore, both algorithms run in $O(n^{\omega-\varepsilon})$ time for some $\varepsilon = \varepsilon(\delta) > 0$ for every $\delta < 2$.[2] That is, both algorithms are faster than the fastest known algorithms for matrix multiplication as long as AB is promised to be even, say, $n^{1.99}$-sparse. We also extend our algorithms to the *fully sparse* setting where the input matrices A, B are themselves sparse (in addition to having the promise that their product AB is sparse), and get faster algorithms in this case; see Section 4 and Theorems 18 and 19. Although we choose to highlight our somewhat simpler OSMM algorithms, they actually follow as corollaries from our algorithms for the fully sparse case.

We note that our extension of Theorem 2 to the fully sparse setting (given in Theorem 19) is equivalent to [1, Lemma 3.1], the main technical lemma in [1] for fully sparse matrix multiplication on general rings. However, our corresponding algorithm uses different techniques and is arguably simpler. In Proposition 20 we also show that our randomized algorithms in Theorems 2 and 19 (and therefore also [1, Lemma 3.1]) are *optimal* via a reduction from rectangular matrix multiplication.

We also provide an exposition of a nearly optimal, deterministic compressed sensing that works over any ring in an appendix of the full version of this paper [6]. The scheme instantiates the compressed sensing scheme from [7] with the expander construction from [17]. Although likely known as folklore, this scheme does not seem to have been analyzed in detail before.

1.2 Applications and Comparison with Prior Work

Input- and output-sparse matrix multiplication have a number of applications including answering certain database queries [4, 34, 10], computing transitive closures in sparse graphs [34, 8], multi-source breadth-first search [37, 16, 13], Markov clustering [33], and error correction of matrix products [14, 23, 32].[3]

A long line of work has studied both input- and output-sparse matrix multiplication [18, 36, 20, 28, 4, 30, 24, 21, 34, 23, 32, 10, 1]. Our deterministic algorithm in Theorem 1 substantially improves on prior deterministic δ-OSMM algorithms for most values of δ, and is never slower than them. See Figure 1. As noted above, our algorithm runs in essentially optimal quadratic time for $\delta \leq 0.642$, and for every constant $\delta < 2$ it runs in $O(n^{\omega-\varepsilon})$ time for some $\varepsilon = \varepsilon(\delta) > 0$.

The main prior works on deterministic OSMM are Kutzkov [24], which gives a $O(n^2 + n^{2\delta+1})$-time algorithm for OSMM over the reals, and Künnemann [23], which gives a $O(n^{2+\delta/2} + n^{2\delta})$-time algorithm for OSMM over the integers. Their algorithms only run in $O(n^{\omega-\varepsilon})$ time for $\delta < (\omega-1)/2 \approx 0.686$ and $\delta < 2(\omega-2) \approx 0.744$, respectively. (One can also show analytically that Theorem 1 is at least as fast as [24, 23] for all δ.[4]) Moreover, if one is interested in only using "combinatorial algorithms" for matrix multiplication (i.e., assuming that $m \times n \times p$ rectangular MM takes $O(mnp)$ time), our deterministic algorithm runs in $\widetilde{O}(n^{2+\delta/2})$ time. So, our algorithm is strictly faster than the algorithms in [24, 23] for $\delta > 4/3$.

[2] Note that $\delta - 1 \leq \delta/2$ for $\delta \in [0, 2]$ so the randomized algorithm in Theorem 2 is always at least as fast as the deterministic algorithm in Theorem 1.

[3] We note that error correction of matrix products is equivalent to OSMM.

[4] By Theorem 7 we have that $\omega(1, 1, \delta/2) \leq 1.825 + 0.548\delta/2$ from which it follows that $\omega(1, 1, \delta/2) \leq 2\delta + 1$ for all $\delta \geq 0.5$. So, our algorithm is always at least as fast as the algorithm in [24]. Furthermore, by Proposition 6, Item 1, $\omega(\delta/2, 1, 1) \leq 2 + \delta/2$ and so our algorithm is always at least as fast as the algorithm in [23].

Our randomized OSMM algorithm in Theorem 2 and the breakthrough randomized algorithm in [1] both run in roughly $n^{\omega(\delta-1,1,1)}$ time. They work in a similar way at a very high level, however there are notable differences. Perhaps more starkly, unlike [1], our randomized algorithm works by reducing OSMM to a variant of the Matrix Multiplication Verification (MMV) problem. Moreover, solving this variant of MMV is the algorithm's *only* use of randomness.

The algorithms in Theorem 2 and [1] both work by (implicitly) partitioning the output matrix AB into blocks of rows or columns with similar sparsity, "densifying" corresponding blocks in the input matrices, multiplying these dense blocks, and then recovering the (sparse) output matrix. To do this, [1] uses hash functions for the densification and a method for computing a small overapproximation of the support of the output matrix. On the other hand, our randomized OSMM algorithm, given in Algorithm 2, works directly with the primitives of a compressed sensing scheme, and it is simple to describe and analyze when these are taken as a black box. In particular, our algorithm performs densification by multiplying by a measurement matrix, and recovers (parts of) the output matrix via sparse recovery. (One can also interpret the hashing-based densification method in [1] as multiplying by a certain (random) measurement matrix. Our algorithm and analysis abstract this out.) See Section 1.3 for a detailed technical overview of our algorithms.

We also note a connection between our algorithm for OSMM and an algorithm from [5] for the All Zeroes Problem, the problem of checking whether $AB = 0$ for two $n \times n$ input matrices A, B. (We note that [23] showed that the All Zeroes Problem and the better-known MMV problem are essentially equivalent under a nearly sparsity-preserving reduction.) Specifically, Theorem 1 achieves the same running time of roughly $n^{\omega(\delta/2,1,1)}$ for δ-OSMM that a deterministic algorithm in [5] achieved for the All Zeroes Problem with the same promise that the input matrices A, B satisfy $\|AB\|_0 \leq O(n^\delta)$. The All Zeroes Problem with the guarantee $\|AB\|_0 \leq O(n^\delta)$ reduces to δ-OSMM (this is a trivial decision-to-search reduction), and so one can view Theorem 1 as an upgrade of the deterministic algorithm in [5]. We also emphasize again that Theorems 1 and 2 work over *any* ring R whereas the algorithms from each of [24, 23, 5] only work on specific domains.

The sole deterministic OSMM algorithm that is faster than ours is an algorithm that (only) works for multiplication over nonnegative integers in [1, Lemma 3.11].[5] Their algorithm's running time is stated for the fully sparse setting, but it runs in roughly $O(n^{\omega(\delta-1,1,1)})$ time in the output sparse setting. This matches the running time of randomized algorithms in their work and ours for OSMM over general rings.

1.3 Technical Overview

We next give an overview of our algorithms, which use simple primitives: fast rectangular matrix multiplication, a compressed sensing scheme with good parameters, and an algorithm for a variant of matrix multiplication verification. Define $\|\boldsymbol{v}\|_0$ (respectively, $\|M\|_0$) to be the number of non-zero entries in (i.e., Hamming weight of) a vector $\boldsymbol{v}$ (respectively, matrix M). We call a vector $\boldsymbol{v}$ (respectively, matrix M) *t-sparse* if $\|\boldsymbol{v}\|_0 \leq t$ (respectively, if $\|M\|_0 \leq t$).

[5] We note that algorithms for matrix multiplication over nonnegative integers imply algorithms for Boolean matrix multiplication as a special case. Recall that the (i, j)th entry of the Boolean product of matrices $A, B \in \{0, 1\}^{n\times n}$ is defined as $\vee_{k=1}^{n}(A_{i,k} \wedge B_{k,j})$. To compute this product it suffices to compute the standard matrix product AB over the integers and replace all positive entries of the output with ones.

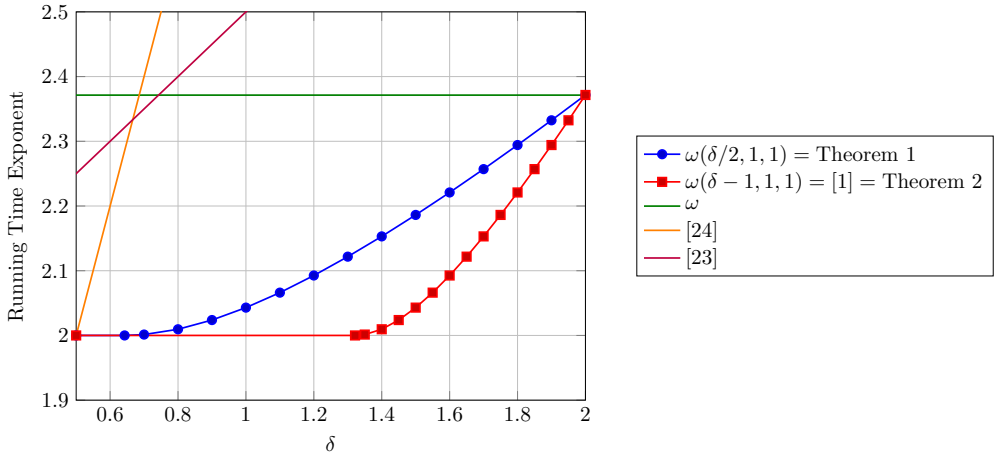

Figure 1 A plot of the running time exponents of several algorithms for δ-OSMM, with arbitrarily small polynomial factors suppressed. The blue curve gives the running time of our deterministic algorithm from Theorem 1, which runs in $n^{\omega(\delta/2,1,1)}$ time. The red curve gives the running time of the randomized algorithm from [1] and our randomized algorithm from Theorem 2. These algorithms both run in roughly $n^{\omega(\delta-1,1,1)}$ time. The points on the curves come from upper bounds on rectangular MM exponents in [35], and the line segments connecting them are justified by the convexity of $\omega(\cdot, 1, 1)$. We also plot the running time exponents of the $O(n^{\max\{2,2\delta+1\}})$-time algorithm of Kutzkov [24] and the $O(n^{\max\{2+\delta/2,2\delta\}})$-time algorithm of Künnemann [23] – which are the main prior works giving *deterministic* algorithms for OSMM – as well as the MM exponent ω.

1.3.1 Output-column-sparse MM using compressed sensing

In the *compressed sensing* problem with parameters $n, m, t \in \mathbb{Z}^+$ with $1 \le t \le n$, the goal is to compute an $m \times n$ matrix $H = H(m, n, t)$ called a *measurement matrix*, and to design an efficient *sparse recovery* algorithm $\mathcal{R}$ (depending on H) such that for every t-sparse vector $\boldsymbol{x}$ of length n, $\mathcal{R}(H\boldsymbol{x}) = \boldsymbol{x}$. That is, the goal is for $\mathcal{R}$ to be able to recover any t-sparse vector $\boldsymbol{x}$ from $H\boldsymbol{x}$.

Several previous works including [20] use compressed sensing to solve MM in the case where every column $\boldsymbol{c}_i$ of the output matrix $C = (\boldsymbol{c}_1, \ldots, \boldsymbol{c}_n) := AB$ is promised to be t-sparse. The technique works by computing HAB parenthesized as $(HA)B$ using fast rectangular matrix multiplication, and then recovering the columns $\boldsymbol{c}_i$ of $C = AB$ from HC using $\mathcal{R}$ as $\boldsymbol{c}_i = \mathcal{R}(H\boldsymbol{c}_i)$ for $i = 1, \ldots, n$. If computing H takes $T_{\mathcal{M}}(n)$ time, $\mathcal{R}$ takes $T_{\mathcal{R}}(n)$ time, and $m = O(n^\beta)$ for some $\beta \in [0, 1]$, then for any constant $\varepsilon > 0$ the overall running time of this algorithm is

$$O(T_{\mathcal{M}}(n) + n^{\omega(\beta,1,1)+\varepsilon} + n \cdot T_{\mathcal{R}}(n)) \ . \tag{1}$$

We note that [20] uses the compressed sensing scheme of [19]. The compressed sensing scheme there has good parameters and has a fast sparse recovery algorithm $\mathcal{R}$. However, while [19] uses a polynomial-time construction of expanders, it is unclear that its construction runs in better-than-n^ω time. (We achieve $T_{\mathcal{M}}(n) = \widetilde{O}(n)$ time in Theorem 13.)

1.3.2 Reducing OSMM to compressed sensing

As our first contribution, we show how to replace the assumption in the above compressed-sensing-based algorithm for MM that every column of $C = AB$ is t-sparse with the "global" assumption that C is t^2-sparse. If $t^2 = O(n^\delta)$, this is exactly the assumption in δ-OSMM.

To do this, we use a two-pass reduction, which roughly speaking first computes a matrix C' that agrees with C on sparse columns and then computes all rows of $C - C'$. This reduction appears formally as Algorithm 1.

Assume without loss of generality that $\mathcal{R}$ always outputs *some* vector of length n even when its input is not t-sparse. More specifically, assume that $\boldsymbol{c}'_i := \mathcal{R}(H\boldsymbol{c}_i)$ is always a vector of length n with the guarantee that $\boldsymbol{c}'_i = \boldsymbol{c}_i$ if $\boldsymbol{c}_i$ is t-sparse. Let $C' := (\boldsymbol{c}'_1, \ldots, \boldsymbol{c}'_n)$. The key observation is that if $C = AB$ is t^2-sparse, then *every* row of $C - C'$ must be t-sparse.[6] (Similar observations were previously used, e.g., in the proof of [14, Theorem 4.3] and in [5].) To see this, note that if C is t^2-sparse, then it has fewer than t columns that are *not* t-sparse, and that these are the only (potentially) non-zero columns in $C - C'$. We can then recover the entries of $(C - C')^T$ (and therefore also C, since we know C') by computing $H(C - C')^T$ as $(HB^T)A^T - H(C')^T$ and then running $\mathcal{R}$ on each column of the result.

1.3.3 Reducing OSMM to compressed sensing and a variant of MMV

Our second reduction is from OSMM to compressed sensing and a variant of the matrix multiplication verification problem (MMV) that we call Column-Wise-MMV. The goal of Column-Wise-MMV is, given three matrices A, B, and C' as input, to identify all of the indices $i \in [n]$ such that $\boldsymbol{c}_i \neq \boldsymbol{c}'_i$, where $C = (\boldsymbol{c}_1, \ldots, \boldsymbol{c}_n) := AB$ and $C' = (\boldsymbol{c}'_1, \ldots, \boldsymbol{c}'_n)$. This reduction appears formally as Algorithm 2.

The main idea of our second reduction is to sequentially "guess and check" all columns of C of sparsity at most 2^i for $i = 0, \ldots, \lceil \log n \rceil$. Namely, in iteration i we use a compressed sensing scheme as above to compute a matrix C' that agrees with all columns of C of sparsity at most $t = 2^i$. (As before, we assume that $\mathcal{R}$ always outputs some vector of length n regardless of its input.) We then use our Column-Wise-MMV oracle to identify which of the columns of C were computed correctly in C'. We use this information to update the corresponding columns of our output matrix and to remove the corresponding columns from B. We emphasize that this reduction itself is deterministic, and the only use of randomness in the algorithm summarized in Theorem 2 comes from solving Column-Wise-MMV.

Correctness follows simply by analyzing the last iteration (in which $i = \lceil \log n \rceil$) since each column of C has sparsity at most $n \leq 2^{\lceil \log n \rceil}$. In fact, the reduction does not require an upper bound on the sparsity of C as input and works regardless of this sparsity – it is a reduction from MM, not just OSMM. However, the sparser C is the faster the reduction is. Let $J_{i+1} \subseteq [n]$ be the set of indices of columns of C with more than 2^i non-zero entries.[7]

Assume that it is possible to multiply the $m \times n$ measurement matrix H by an arbitrary $n \times n$ matrix A in $O(n^{2+\varepsilon})$ time for any constant $\varepsilon > 0$. When we instantiate the reduction with the concrete compressed sensing scheme described in Theorem 13 this will be the case since our measurement matrices H will be sparse. Then the bottleneck in each iteration i is computing the product of HA (an $m \times n$ matrix) and B (an $n \times |J_i|$ matrix). Let $\alpha := i/\log n$. We know that $|J_{i+1}| \leq O(n^\delta/2^i) = O(n^{\delta-\alpha})$, and if $m \approx t = 2^i = n^\alpha$ then it is possible to compute the product of HA and B in roughly $n^{\omega(\alpha,1,\delta-\alpha)}$ time. By Corollary 8,

[6] Note that it is *not* the case that every non-zero entry of C must be contained in a t-sparse row or column. For example, if $C = (\boldsymbol{e}_1 \cdot \mathbf{1}^T) + (\mathbf{1} \cdot \boldsymbol{e}_1) \in \mathbb{Z}^{n \times n}$ then $C_{1,1} = 2$ and both the first column and first row of C have n non-zero entries. (Here $\boldsymbol{e}_1$ and $\mathbf{1}$ denote the first standard normal basis vector and the all-ones vector, respectively.) Yet, C is $O(n)$-sparse.

[7] In Algorithm 2, J_{i+1} can technically be a subset of these columns if the sparse recovery algorithm happens to succeed (i.e., when $\mathcal{R}(H\boldsymbol{x}) = \boldsymbol{x}$) at an earlier iteration $j < i$ even when $\boldsymbol{x}$ is not 2^j-sparse. But, $|J_{i+1}|$ being smaller only makes the algorithm run faster.

$\omega(\alpha, 1, \delta - \alpha) \leq \omega(\delta - 1, 1, 1)$ for any α, and so the claimed running time of $O(n^{\omega(\delta-1,1,1)+\varepsilon})$ follows since we only need to compute $O(\log n)$ such matrix products and the multiplicative $\log n$ factor gets absorbed by the ε in the exponent.

1.3.4 From Output-Sensitive MM to Fully Sparse MM

In Section 4, we extend our algorithms to the *fully sparse* case where we consider the sparsity of the $n \times n$ input matrices A, B in addition to the sparsity of AB. I.e., we are promised not only that $\|AB\|_0 \leq O(n^{\delta_{\text{out}}})$ for some $\delta_{\text{out}} \in [0, 2]$, but also that $\|A\|_0, \|B\|_0 \leq O(n^{\delta_{\text{in}}})$ for $\delta_{\text{in}} \in [0, 2]$.[8] For $\alpha, \beta, \gamma \in [0, 1]$, define $\omega_{\delta_{\text{in}}}(\alpha, \beta, \gamma)$ to be the infimum over $\omega' \geq 0$ such that it is possible to compute the product of an $n^\alpha \times n^\beta$ matrix A and an $n^\beta \times n^\gamma$ matrix B in $O(n^{\omega'})$ time when $\|A\|_0, \|B\|_0 \leq O(n^{\delta_{\text{in}}})$. We note that there are algorithms showing that $\omega_{\delta_{\text{in}}}(\alpha, \beta, \gamma)$ is smaller than $\omega(\alpha, \beta, \gamma)$ for sufficiently small values of δ_{in} [36, 22].

Theorem 18 (respectively, Theorem 19) extends our deterministic (respectively, randomized) algorithm in Theorem 1 (respectively, Theorem 2) to the fully sparse setting. Theorem 18 achieves a running time of roughly $O(n^{\omega_{\delta_{\text{in}}}(\delta_{\text{out}}/2,1,1)} + n^{\delta_{\text{out}}/2+1})$, which is equal to the $O(n^{\omega(\delta_{\text{out}}/2,1,1)})$ running time of Theorem 1 when $\delta_{\text{in}} = 2$, i.e., when there is no promise on the sparsity of A, B as in δ_{out}-OSMM.

Theorem 19 achieves a running time of roughly $O(n^{\delta_{\text{in}}} + n^\beta)$, for

$$\beta := \max_{\eta \in [0, \min\{\delta_{\text{out}}, 1\}]} \omega_{\delta_{\text{in}}}(\eta, 1, \delta_{\text{out}} - \eta) \ .$$

Although this expression looks intricate, it appears in [1, Lemma 3.1] (to which it is equivalent) and arises naturally in our FSMM proof of optimality; see Proposition 20. (For $\delta_{\text{out}} \geq 1$ and $\delta_{\text{in}} = 2$, we also get that $\omega_{\delta_{\text{in}}}(\eta, 1, \delta_{\text{out}} - \eta) \leq \omega(\delta_{\text{out}} - 1, 1, 1)$ by Corollary 8, and moreover $\omega(\delta_{\text{out}} - 1, 1, 1) \geq 2 \geq \delta_{\text{in}}$. So, we achieve the running time of Theorem 2.)

Extending our algorithms to the fully sparse setting essentially only uses basic facts about input-sparse matrix multiplication and properties of our compressed sensing scheme. Specifically, it uses the fact that our measurement matrix H has very sparse columns, and that on input $H\boldsymbol{x}$ for a t-sparse vector $\boldsymbol{x}$ of length n, $\mathcal{R}$ runs in time roughly t rather than time roughly n. In particular, we use that such a matrix H admits fast multiplication by any matrix A, and if A is sparse then HA is still nearly as sparse. (To achieve all of this, we use sparse representations of matrices and vectors.)

1.3.5 Instantiating our reductions

To instantiate our reductions and turn them into the algorithms summarized by Theorems 1 and 2, we need to give an explicit compressed sensing scheme and an algorithm for Column-Wise-MMV.

We use a compressed sensing scheme due to Berinde, Gilbert, Indyk, Karloff and Strauss [7], which requires certain expander graphs. To make the scheme of [7] deterministic and obtain good parameters, we instantiate it with the expander graphs later studied in Guruswami, Umans, and Vadhan [17]. In particular, our measurement matrices H correspond to the adjacency matrices of the bipartite expanders constructed in [17] from Parvaresh-Vardy codes. They are sparse and binary. The main theorem summarizing this scheme is Theorem 13.

[8] Without loss of generality we can take $\delta_{\text{out}} \leq 2\delta_{\text{in}}$.

For completeness, we present and analyze the expander construction in [17] and the sparse recovery algorithm in [7] in an appendix of the full version of this paper [6]. We show that they are both very efficient. Additionally, we observe that the sparse recovery algorithm in [7] works not just over the real numbers (as it was originally presented), but over arbitrary rings.

We emphasize the subtlety of identifying an appropriate compressed sensing scheme for our purposes. We need algorithms that compute the measurement matrix and perform sparse recovery not just in (arbitrary) polynomial time, but in nearly quadratic and nearly linear time, respectively. Moreover, we need these algorithms to be deterministic – many works on compressed sensing sample a random measurement matrix H (see, e.g., [9, 15]). Finally, for Theorem 2 we need multiplication by H to be very efficient.

The algorithm for Column-Wise-MMV that we use (stated formally in Lemma 16) is a modified version of Freivalds's algorithm for "plain" MMV [12]. This algorithm is the only use of randomness in our our randomized OSMM algorithm, and so if it could be derandomized efficiently then we would get a *deterministic* algorithm for δ-OSMM running in roughly $n^{\omega(\delta-1,1,1)}$ time. (Similarly, this algorithm is the only use of randomness in our randomized FSMM algorithm.)

1.3.6 An alternative randomized algorithm

We note that it is possible to implement a variant of our randomized algorithm that achieves a similar running time to Theorem 2 if it is possible to approximate the number of non-zero entries in each column of $C = (\boldsymbol{c}_1, \ldots, \boldsymbol{c}_n) = AB$ to within a constant factor efficiently.

In fact, we can compute estimates $\tilde{c}_i$ of the sparsity of each column $\boldsymbol{c}_i$ satisfying $1/2 \cdot \|\boldsymbol{c}_i\|_0 < \tilde{c}_i < 2 \cdot \|\boldsymbol{c}_i\|_0$ with high probability using a randomized algorithm from [31]. We can then use these estimates to multiply A and B efficiently. We first partition the columns of B (and therefore AB) into blocks B_j, where B_j consists of all columns $\boldsymbol{b}_i$ such that $2^{j-1} \leq \tilde{c}_i < 2^j$ for $j = 1, \ldots, r$, where $r \approx \log_2 n$. We then compute AB_j for each j using the algorithm for output-column-sparse matrix multiplication sketched earlier using the assumption (which holds with high probability) that each column of AB_j is 2^{j+1}-sparse.

We note that the column-sparsity-estimation-based algorithm sketched here uses randomness in a different way from Theorem 2; it uses randomness to estimate column sparsities and does not need to solve Column-Wise-MMV. However, we believe that the reduction from OSMM to Column-Wise-MMV that we use to prove Theorem 2 – which can be viewed as a search-to-decision reduction of sorts – is elegant and more amenable to derandomization. In particular, a strong resolution to the famous question of derandomizing Freivalds's algorithm would derandomize Theorem 2 as well.

2 Preliminaries

By $\mathbb{Z}^+$ we denote the set of positive integers. For $n \in \mathbb{Z}^+$, $[n]$ denotes the set $\{1, \ldots, n\}$. Let R be a ring, $\boldsymbol{v} \in R^n$ be a vector, and $M \in R^{m \times n}$ be a matrix. Then by $\|\boldsymbol{v}\|_0$ and $\|M\|_0$ we denote the number of non-zero entries in $\boldsymbol{v}$ and M, respectively. We say $\boldsymbol{v}$ (respectively, matrix M) is *t-sparse* if $\|\boldsymbol{v}\|_0 \leq t$ (respectively, if $\|M\|_0 \leq t$). We say that M is *t-column-sparse* if each of its columns is t-sparse. For an $n \in \mathbb{Z}^+$, $\mathbf{0}_n$ and $\mathbf{1}_n$ denote n-dimensional vectors with all zeros and all ones, respectively.

We use $\log(\cdot)$ to denote the logarithm base 2, i.e., $\log(2^n) = n$. We use the notation $\widetilde{O}(\cdot)$ to suppress polylogarithmic factors in the argument.

We state the running time bounds of our algorithms in terms of operations over a ring R, but these bounds immediately imply algorithms with similar running times (in the usual sense) over many standard domains. Over the integers with entries in $[-M, M]$ each operation requires at most $\mathrm{poly}(\log M, \log n)$ time, and over finite fields $\mathbb{F}_q$ each operations requires at most $\mathrm{poly}(\log q, \log n)$ time. Assigning unit cost to operations on real numbers is standard in the Real RAM model.

2.1 Matrix Multiplication

We first define the main two variants of matrix multiplication that we study.

▶ **Definition 3** (Output and Fully Sparse Matrix Multiplication). *Let R be a ring, and let $\delta_{in}, \delta_{out} \in [0, 2]$. We define the $(\delta_{in}, \delta_{out})$-*Fully Sparse Matrix Multiplication Problem *over R ($(\delta_{in}, \delta_{out})$-FSMM$_R$) as follows. The input consists of $A, B \in R^{n\times n}$ for some $n \in \mathbb{Z}^+$ with $\|A\|_0, \|B\|_0 \le O(n^{\delta_{in}})$ satisfying the promise that $\|AB\|_0 \le O(n^{\delta_{out}})$. The goal is to compute AB.*

*We additionally define the δ_{out}-*Output-Sparse Matrix Multiplication Problem *over R (δ_{out}-OSMM$_R$) as $(2, \delta_{out})$-FSMM$_R$.*

When both $\delta_{\mathrm{in}} = 2$ and $\delta_{\mathrm{out}} = 2$ this corresponds to the problem of matrix multiplication in its general form. Furthermore, note that since the product of two t-sparse matrices is t^2-sparse, we may without loss of generality assume that $\delta_{\mathrm{out}} \le 2\delta_{\mathrm{in}}$.

We next define rectangular matrix multiplication exponents, input-sparse rectangular matrix multiplication exponents, and the dual matrix multiplication exponent.

▶ **Definition 4** (Rectangular and Input-Sparse Rectangular Multiplication Exponents). *For constants $\alpha, \beta, \gamma \ge 0$, the* rectangular matrix multiplication exponent $\omega(\alpha, \beta, \gamma)$ *is the infimum over all $\omega' \ge 0$ such that the product of $A \in \mathbb{Z}^{n^\alpha \times n^\beta}$ and $B \in \mathbb{Z}^{n^\beta \times n^\gamma}$ can be computed using $O(n^{\omega'})$ arithmetic operations.*

We extend this notation and use $\omega_{\delta_{in}}(\alpha, \beta, \gamma)$ to denote the case when both A and B are promised to be $O(n^{\delta_{in}})$-sparse for $0 \le \delta_{in} \le \max\{\alpha + \beta, \beta + \gamma\}$.

We note that the *square matrix multiplication exponent* ω is simply $\omega := \omega(1, 1, 1)$, and that $\omega_{\delta_{\mathrm{in}}}(\alpha, \beta, \gamma) \le \omega_{\max\{\alpha+\beta, \beta+\gamma\}}(\alpha, \beta, \gamma) = \omega(\alpha, \beta, \gamma)$ for all $\alpha, \beta, \gamma \ge 0$.

▶ **Definition 5** (Dual Matrix Multiplication Exponent). *The* dual matrix multiplication exponent $\omega^\perp$ *is defined as*

$$\omega^\perp := \sup\{\omega' \ge 0 : \omega(1, 1, \omega') = 2\} .$$

A beautiful line of work [27, 3, 11, 26, 35, 2] has established strong bounds on multiplication exponents, in particular showing that

$$\omega < 2.371339 \quad [2] ,$$
$$\omega^\perp \ge 0.321334 \quad [35] .$$

2.2 Properties of Matrix Multiplication Exponents

Next we list several properties of rectangular matrix multiplication exponents $\omega(\cdot, \cdot, \cdot)$.

▶ **Proposition 6** ([29]). *Let $\alpha_1, \alpha_2, \alpha_3, \beta_1, \beta_2, \beta_3, \lambda \ge 0$. The following hold:*

1. $\max(\alpha_1 + \alpha_2, \alpha_1 + \alpha_3, \alpha_2 + \alpha_3) \le \omega(\alpha_1, \alpha_2, \alpha_3) \le \alpha_1 + \alpha_2 + \alpha_3$.
2. $\omega(\lambda\alpha_1, \lambda\alpha_2, \lambda\alpha_3) = \lambda \cdot \omega(\alpha_1, \alpha_2, \alpha_3)$.

3. $\omega(\alpha_1+\beta_1,\alpha_2+\beta_2,\alpha_3+\beta_3) \le \omega(\alpha_1,\alpha_2,\alpha_3)+\omega(\beta_1,\beta_2,\beta_3)$.
4. *For any permutation* $\pi:[3]\to[3]$, $\omega(\alpha_1,\alpha_2,\alpha_3)=\omega(\alpha_{\pi(1)},\alpha_{\pi(2)},\alpha_{\pi(3)})$.
5. $\omega(\alpha,\beta,\gamma)$ *is continuous and non-decreasing in its arguments for* $\alpha,\beta,\gamma \ge 0$.

We will make use of the following upper bound on $\omega(\alpha,1,1)$.

▶ **Theorem 7** ([29, 25]). *Let* $\alpha\in[0,1]$. *Then*

$$\omega(\alpha,1,1) \le \begin{cases} 2 & \text{if } 0\le\alpha\le\omega^\perp\ , \\ 2+\dfrac{\omega-2}{1-\omega^\perp}\cdot(\alpha-\omega^\perp) \le 1.825+0.548\alpha & \text{if } \omega^\perp<\alpha\le 1\ . \end{cases}$$

We next give an upper bound on rectangular matrix multiplication exponents $\omega(1,\alpha,\beta)$ with three potentially distinct arguments.

▶ **Corollary 8.** *Let* $\alpha,\beta,\gamma\in[0,1]$ *be such that* $\beta+\gamma\ge 1$. *Then* $\omega(\alpha,\beta,\gamma)\le\omega(\alpha,1,\beta+\gamma-1)$.

Proof. If $\beta=\gamma=1$, the statement holds trivially. Otherwise we can assume that $\beta+\gamma<2$. Let $\lambda=(1-\gamma)/(2-\beta-\gamma)\ge 0$. Then we have that

$$\begin{aligned}\omega(\alpha,\beta,\gamma) &= \omega(\lambda\alpha+(1-\lambda)\alpha,\lambda+(1-\lambda)(\beta+\gamma-1),\lambda(\beta+\gamma-1)+(1-\lambda)) \\ &\le \omega(\lambda\alpha,\lambda,\lambda(\beta+\gamma-1))+\omega((1-\lambda)\alpha,(1-\lambda)(\beta+\gamma-1),(1-\lambda)) \\ &= \lambda\cdot\omega(\alpha,1,\beta+\gamma-1)+(1-\lambda)\cdot\omega(\alpha,\beta+\gamma-1,1) \\ &= \omega(\alpha,1,\beta+\gamma-1)\ ,\end{aligned}$$

where the inequality uses Proposition 6, Item 3, the following equality uses Proposition 6, Item 2, and the last one uses Proposition 6, Item 4. ◀

2.3 Input-Sparse Matrix Multiplication

In this paper, we assume *sparse representations* of vectors and matrices. Specifically, we represent a vector $\boldsymbol{x}\in R^n$ by a list of index-value pairs of its non-zero entries. We represent a matrix $A=(\boldsymbol{a}_1,\ldots,\boldsymbol{a}_n)\in R^{m\times n}$ using lists of the non-zero entries of each column $\boldsymbol{a}_i$, sorted by i.

We next give a basic algorithm for matrix multiplication when one of the matrices is column-sparse. This algorithm is folklore, and appears in work at least as early as Gustavson [18].

▶ **Proposition 9** (Naïve Input-Sparse Matrix Multiplication). *Let* $A\in R^{m\times n}, B\in R^{n\times p}$ *for a ring* R *and* $m,n,p\in\mathbb{Z}^+$. *Let* A *be* t*-column-sparse for* $t\in\mathbb{Z}^+$. *Then* $\|AB\|_0\le t\cdot\|B\|_0$, *and there is a deterministic algorithm that computes* AB *using* $t\cdot\|B\|_0\cdot\mathrm{poly}(\log n)$ *arithmetic operations over* R.

Proof. For $i\in[n]$, let b_i be the number of non-zero elements in the ith row of B. If we consider the multiplication of A and B as a sum of outer products, then for every $k\in[n]$, the outer product of the kth column of A and the kth row of B can be computed using at most $t\cdot b_k$ multiplications, and has sparsity at most $t\cdot b_k$. Therefore, $\|AB\|_0\le\sum_{i\in[n]}t\cdot b_k=t\cdot\|B\|_0$. The running time of this algorithm is bounded by $t\cdot\|B\|_0\cdot\mathrm{poly}(\log n)$, where the $\mathrm{poly}(\log n)$ factor accounts for the sparse representation. ◀

Next, we present known bounds on the complexity of matrix multiplication when the input matrices are sparse. The following bound was proven for square matrices in [36], and was generalized to rectangular matrices in [22] (see also [1, Lemma 4.2]).

▶ **Theorem 10** ([36, 22]). *Let $\alpha, \beta, \gamma > 0$ and $0 \le \delta_{in} \le \max\{\alpha+\beta, \beta+\gamma\}$. Then*

$$\omega_{\delta_{in}}(\alpha,\beta,\gamma) \le \min_{\eta\in[0,\beta]} \max\{\omega(\alpha,\eta,\gamma),\, 2\delta_{in}-\eta\}\ .$$

Next, we list two additional bounds on sparse rectangular matrix multiplication exponents $\omega_{\delta_{\text{in}}}(\cdot,\cdot,\cdot)$.

▶ **Proposition 11.** *Let $\alpha, \beta, \gamma > 0$. The following hold:*

1. *If $0 \le \delta_{in} \le \max\{\alpha+\beta, \beta+\gamma\}$, then $\omega_{\delta_{in}}(\alpha,\beta,\gamma) \le \delta_{in} + \min\{\alpha,\gamma\}$.*
2. *If $\delta_{in} \ge \max\{\alpha,\gamma\}$, then $\omega_{\delta_{in}}(\alpha,\beta,\gamma) \ge \alpha+\gamma$.*

Proof. The first bound follows from Proposition 9 by noting that every $n^\alpha \times n^\beta$ matrix is n^α-column-sparse (and that the transpose of an $n^\beta \times n^\gamma$ matrix is n^γ-column-sparse).

For the second bound, consider $A = (\mathbf{1}, \mathbf{0}, \ldots, \mathbf{0}) \in R^{n^\alpha \times n^\beta}$ and $B = (\mathbf{1}, \mathbf{0}, \ldots, \mathbf{0})^T \in R^{n^\beta \times n^\gamma}$. Note that $\|A\|_0, \|B\|_0 \le O(n^{\delta_{\text{in}}})$, and $\|AB\|_0 = n^{\alpha+\gamma}$. Therefore, any algorithm computing AB must have running time at least $\Omega(n^{\alpha+\gamma})$. ◀

3 Output-Sparse Matrix Multiplication

We now present our main technical results on OSMM. In Section 3.1, we formally define compressed sensing schemes and state our main theorem about a concrete such scheme. In Section 3.2, we give a reduction from δ-OSMM to compressed sensing and instantiate the reduction to give our roughly $n^{\omega(\delta/2,1,1)}$-time deterministic algorithm for δ-OSMM, proving Theorem 1. In Section 3.3, we introduce a variant of matrix multiplication verification (MMV) and give a reduction from OSMM to compressed sensing and this MMV variant. We then instantiate the reduction to give our roughly $n^{\omega(\delta-1,1,1)}$-time randomized algorithm for δ-OSMM, proving Theorem 2.

3.1 Compressed Sensing

We will use the following formalization of a compressed sensing scheme.

▶ **Definition 12.** *Let R be a ring and let $m = m(n,t)$ be a non-decreasing, integer-valued function. An m-*compressed sensing scheme *over R is a pair of algorithms $(\mathcal{M}, \mathcal{R})$ that work as follows. On inputs n and t in unary with $1 \le t \le n$, $\mathcal{M}$ outputs a matrix $H \in R^{m\times n}$. On input $H\boldsymbol{x}$ for a vector $\boldsymbol{x} \in R^n$ satisfying $\|\boldsymbol{x}\|_0 \le t$, $\mathcal{R}$ outputs $\boldsymbol{x}$.*[9]

Here the matrix H output by $\mathcal{M}$ is called a *measurement matrix*, and $\mathcal{R}$ is called a *sparse recovery algorithm*. We will crucially use the following theorem about an explicit compressed sensing scheme from [7] (which we instantiate with a construction of expanders from [17]) in both of our main algorithms. The claim in Theorem 13 follows implicitly by combining [7, 17], but we include a full proof for completeness. However, the proof is somewhat involved and so we defer it to an appendix of the full version of this paper [6].

[9] In fact, the sparse recovery algorithm $\mathcal{R}$ needs to know the value of n, and often it also needs t and H as well. This is usually handled by having the algorithm $\mathcal{M}$ also compute a string σ as preprocessing that is passed as auxiliary input to $\mathcal{R}$. Without loss of generality, we assume that σ encodes H, n, and t, but it could also encode more. So, formally we should write $\mathcal{R}(H\boldsymbol{x}, \sigma)$ for running $\mathcal{R}$ on $H\boldsymbol{x}$, but for conciseness we often abuse notation and simply write $\mathcal{R}(H\boldsymbol{x})$.

▶ **Theorem 13** ([7]). *Let R be a ring and let $\alpha > 0$ be a constant. There is a deterministic m-compressed sensing scheme $(\mathcal{M}, \mathcal{R})$ over R with $m = m(n,t) = t^{1+\alpha} \cdot \mathrm{poly}(\log n)$. The algorithm $\mathcal{M}$ runs in time $\widetilde{O}(n)$, and the algorithm $\mathcal{R}$ performs $t^{1+\alpha} \cdot \mathrm{poly}(\log n)$ arithmetic operations over R.*

Furthermore, the measurement matrix $H := \mathcal{M}(1^n, 1^t)$ is binary and d-column-sparse for $d = \mathrm{poly}(\log n)$, and therefore can be multiplied by an arbitrary vector $\boldsymbol{x} \in R^n$ using $\|\boldsymbol{x}\|_0 \cdot \mathrm{poly}(\log n)$ addition operations over R.[10]

3.2 Deterministic OSMM via a Reduction to Compressed Sensing

In this section, we start by giving our two-pass reduction from OSMM to compressed sensing in Algorithm 1. One may also view this reduction as a meta-algorithm. Making it into an explicit algorithm requires using an explicit compressed sensing scheme (we note this in the "Subroutine" heading in the specification of Algorithm 1).

Algorithm 1 Deterministic output-sparse matrix multiplication over a ring R.

Input: Matrices $A, B \in R^{n \times n}$ over a ring R, and $t \in \mathbb{Z}^+$ such that $\|AB\|_0 \le t^2$.
Subroutine: An m-compressed sensing scheme $(\mathcal{M}, \mathcal{R})$ over R.
Output: The product $C = AB$.

1 Compute a measurement matrix $H \in R^{m \times n} := \mathcal{M}(1^n, 1^t)$.
2 Compute $D = (\boldsymbol{d}_1, \ldots, \boldsymbol{d}_n) := HAB$ using fast rectangular MM.
3 Compute $D' := (\mathcal{R}(\boldsymbol{d}_1), \ldots, \mathcal{R}(\boldsymbol{d}_n))$. // t-sparse columns of $C = AB$ agree with D'.
4 Compute $F = (\boldsymbol{f}_1, \ldots, \boldsymbol{f}_n) := (H(AB - D')^T)$ using fast rectangular MM.
5 Compute $F' := (\mathcal{R}(\boldsymbol{f}_1), \ldots, \mathcal{R}(\boldsymbol{f}_n))$. // $F' = (AB - D')^T$.
6 **return** $D' + (F')^T$.

We next analyze Algorithm 1.

▶ **Theorem 14.** *Let R be a ring, and let $A, B \in R^{n \times n}$ be matrices satisfying $\|AB\|_0 \le t^2$ for $t \in \mathbb{Z}^+$ with $t^2 \le O(n^\delta)$ for some $\delta \in [0,2]$. Let $(\mathcal{M}, \mathcal{R})$ be an m-compressed sensing scheme over R with $m = m(n,t) \le O(t \cdot n^\alpha)$ for some $\alpha > 0$. Then on input A, B, Algorithm 1 outputs the matrix product $C := AB$. Furthermore, if $\mathcal{M}$ runs in time $T_{\mathcal{M}}(n,t)$ and $\mathcal{R}$ runs in time $T_{\mathcal{R}}(n,t)$ then for any constant $\varepsilon > 0$, Algorithm 1 performs*

$$O(T_{\mathcal{M}}(n,t) + n \cdot T_{\mathcal{R}}(n,t) + n^{\omega(\delta/2+\alpha,1,1)+\varepsilon})$$

arithmetic operations over R.

Proof. We start by proving correctness. Let $C = (\boldsymbol{c}_1, \ldots, \boldsymbol{c}_n)$, $D' = (\boldsymbol{d}'_1, \ldots, \boldsymbol{d}'_n)$, and $F' = (\boldsymbol{f}'_1, \ldots, \boldsymbol{f}'_n)$. We assume without loss of generality that $\mathcal{R}$ outputs *some* vector in R^n on every input $\boldsymbol{y} \in R^m$ (including when $\boldsymbol{y} \neq H\boldsymbol{x}$ for any t-sparse $\boldsymbol{x} \in R^n$).

We note that C has at most t columns $\boldsymbol{c}_i$ that are not t-sparse, since otherwise we would have $\|C\|_0 > t^2$. Furthermore, by the specification of $\mathcal{R}$, $\boldsymbol{d}'_i = \mathcal{R}(H\boldsymbol{c}_i) = \boldsymbol{c}_i$ for each $i \in [n]$ such that $\boldsymbol{c}_i$ is t-sparse. It follows that every row of $C - D'$ is t-sparse, and therefore that every column of $(AB - D')^T$ is t-sparse. From this and again using the specification of $\mathcal{R}$, we get that $F' = (AB - D')^T$. Correctness then follows by noting that $C = AB = D' + (F')^T$.

[10] Assuming that H and $\boldsymbol{x}$ are given in sparse representation by lists of non-zero entries (as in the output of the algorithm $\mathcal{M}$).

We next analyze the time complexity of Algorithm 1. It makes one call to $\mathcal{M}$ on input $(1^n, 1^t)$, which takes time at most $T_{\mathcal{M}}(n,t)$, and $2n$ calls to $\mathcal{R}$, which takes time at most $2n \cdot T_{\mathcal{R}}(n,t)$. Furthermore, because $H \in R^{m\times n}$ for $t = O(n^{\delta/2})$ and $m \le O(t \cdot n^{\alpha}) = O(n^{\delta/2+\alpha})$, HAB and $H(AB - D')^T$ can be computed in time $O(n^{\omega(\delta/2+\alpha,1,1)+\varepsilon})$ for any constant $\varepsilon > 0$ using fast rectangular matrix multiplication. All other operations run in $O(n^2) \le O(n^{\omega(\delta/2+\alpha,1,1)})$ time. The result follows by summing the running time bounds for each of these components. ◀

Our main theorem about solving OSMM deterministically follows as a corollary.

▶ **Theorem 1** (Deterministic OSMM). *Let $\delta \in [0,2]$, let R be a ring, and let $\varepsilon > 0$ be a constant. There is a deterministic algorithm for solving δ-OSMM$_R$ on $n \times n$ matrices that performs $O(n^{\omega(\delta/2,1,1)+\varepsilon})$ operations over R.*

Proof. We instantiate the compressed sensing scheme subroutine needed in Algorithm 1 with the scheme described in Theorem 13. Let $\alpha > 0$ be a constant, which we will set later, and let α' be a constant satisfying $0 < \alpha' < \alpha$. From Theorem 13, we have that there exists a deterministic m-compressed sensing scheme where $m = m(n,t) = t^{1+\alpha'} \cdot \mathrm{poly}(\log n) \le O(tn^{\alpha})$, with $T_{\mathcal{M}}(n,t) \le T_{\mathcal{M}}(n,n) \le \widetilde{O}(n) \le O(n^{1+\alpha})$ and $T_{\mathcal{R}}(n,t) \le T_{\mathcal{R}}(n,n) \le O(n^{1+\alpha})$. Furthermore, we have that $\omega(\delta/2+\alpha,1,1) \le \omega(\delta/2,1,1) + \omega(\alpha,0,0) = \omega(\delta/2,1,1) + \alpha$ by Proposition 6, Items 1 and 3. Using the fact that $\omega(\delta/2,1,1) \ge 2$ for all $\delta \in [0,2]$, we then have that for any constant $\varepsilon' > 0$ the algorithm performs at most

$$\begin{aligned} O(T_{\mathcal{M}}(n,t) + n \cdot T_{\mathcal{R}}(n,t) + n^{\omega(\delta/2+\alpha,1,1)+\varepsilon'}) &\le O(n^{1+\alpha} + n^{2+\alpha} + n^{\omega(\delta/2,1,1)+\alpha+\varepsilon'}) \\ &\le O(n^{\omega(\delta/2,1,1)+\alpha+\varepsilon'}) \end{aligned}$$

operations over R. To prove the claim, we need to show that the algorithm performs at most $O(n^{\omega(\delta/2,1,1)+\varepsilon})$ operations. This follows by choosing $\varepsilon', \alpha > 0$ such that $\varepsilon' + \alpha \le \varepsilon$. ◀

3.3 Randomized OSMM via a Reduction to a Variant of MMV and Compressed Sensing

In this section, we get a roughly $n^{\omega(\delta-1,1,1)}$-time algorithm for δ-OSMM by reducing to a variant of MMV and to compressed sensing.

3.3.1 Column-Wise Matrix Multiplication Verification

In this section, we introduce and give an algorithm for the variant of MMV in which the goal is to check whether each column of AB is equal to its corresponding column in C'.

▶ **Definition 15.** *For a ring R, the Column-Wise MMV problem over R (Column-Wise-MMV$_R$) is defined as follows. The input consists of matrices $A \in R^{m\times n}$, $B \in R^{n\times p}$, and $C' = (\boldsymbol{c}'_1, \ldots, \boldsymbol{c}'_p) \in R^{m\times p}$. Let $C = (\boldsymbol{c}_1, \ldots, \boldsymbol{c}_p) := AB$. The goal is to output the set $J \subseteq [p]$ of indices of columns on which C and C' differ, i.e.,*

$$J := \{j \in [p] : \boldsymbol{c}_j \neq \boldsymbol{c}'_j\} \ .$$

We note that "normal" MMV corresponds to deciding whether $J = \emptyset$ in Definition 15, and so MMV easily reduces to Column-Wise-MMV. We next argue that a slight variant of Freivalds's algorithm [12] also solves Column-Wise-MMV in nearly quadratic time.

▶ **Lemma 16** (Freivalds's algorithm for Column-Wise-MMV)**.** *Let R be a ring and let $c \in \mathbb{Z}^+$ be a constant. For any $m, n, p \in \mathbb{Z}^+$, there is a randomized algorithm that solves* Column-Wise-MMV$_R$ *on matrices $A \in R^{m\times n}, B \in R^{n\times p}, C' \in R^{m\times p}$ performing $O(\max\{mn, np\} \cdot \log(mnp))$ arithmetic operations over R and has a success probability of at least $1 - 1/(mnp)^c$. In particular, when $m, p = O(n)$, the algorithm performs $O(n^2 \log n)$ arithmetic operations over R and has a success probability of at least $1 - 1/n^c$.*

Proof. The algorithm works as follows. First, it samples a uniformly random matrix $X \sim \{0,1\}^{N\times m}$ for $N := \lceil (c+1)\log(mnp)\rceil$. It then computes $D = (\boldsymbol{d}_1, \ldots, \boldsymbol{d}_p) := X(AB - C')$, and outputs $J' := \{i \in [p] : \boldsymbol{d}_i \neq \boldsymbol{0}\}$.

We start by showing correctness of the algorithm, i.e., that $J' = J$ for J as defined in Definition 15. For a fixed non-zero vector $\boldsymbol{y} \in R^m$ and a uniformly random $\boldsymbol{x} \sim \{0,1\}^m$, $\Pr[\langle \boldsymbol{x}, \boldsymbol{y}\rangle \neq 0] \geq 1/2$. Indeed, this follows by noting that each term $x_i y_i$ in $\langle \boldsymbol{x}, \boldsymbol{y}\rangle = \sum_{i=1}^m x_i y_i$ for non-zero y_i is equal to 0 with probability $1/2$ and an induction argument. So, for any non-zero column $\boldsymbol{y}_i$ of $AB - C'$, we get that $\Pr[X\boldsymbol{y}_i = \boldsymbol{0}] \leq 1/2^N$. (If $\boldsymbol{y}_i = 0$, then $X\boldsymbol{y}_i = \boldsymbol{0}$ with probability 1.) Taking a union bound over the at most p non-zero columns of $AB - C'$, we then get that the probability that there exists a non-zero column $\boldsymbol{y}_i$ of $AB - C'$ such that $\boldsymbol{d}_i = \boldsymbol{0}$ is at most $p/2^N \leq p/(mnp)^{c+1} \leq 1/(mnp)^c$, as needed.

Furthermore, the algorithm runs in $O(N \cdot \max\{mn, np\}) = O(\max\{mn, np\} \cdot \log(mnp))$ time, which finishes the analysis. ◀

3.3.2 The Reduction and its Analysis

We next give our reduction from OSMM (and in fact, simply MM) to Column-Wise-MMV and compressed sensing in Algorithm 2. We sometimes use sets to index the rows and columns of a matrix. I.e., for finite sets I and J we use notation like $A \in R^{I\times J}$ to denote a matrix over a ring R with $|I|$ rows indexed by I and $|J|$ columns indexed by J. Similarly, we use notation like $A_{I',J'}$ to denote the submatrix of $A \in R^{I\times J}$ with rows indexed by $I' \subseteq I$ and columns indexed by $J' \subseteq J$.

In Theorem 17, we analyze Algorithm 2. We again emphasize that its correctness does not depend on the sparsity of AB; only its running time does. Furthermore, the same algorithm works regardless of the sparsity of AB.

▶ **Theorem 17.** *Let $A, B \in R^{n\times n}$ over a ring R, let $(\mathcal{M}, \mathcal{R})$ be an m-compressed sensing scheme with $m = m(n,t) \leq O(tn^\alpha)$ for some $\alpha \in (0, \omega^\perp)$, and let* ColMMV *be an algorithm for* Column-Wise-MMV *over R. Then on input $A, B \in R^{n\times n}$, Algorithm 2 outputs the matrix product $C = AB$.*

Furthermore, let $T_{\mathcal{M}}(n,t)$ and $T_{\mathcal{R}}(n,t)$ denote the running times of $\mathcal{M}$ and $\mathcal{R}$, respectively, let $T_H(n,t)$ denote the time needed to multiply $H := \mathcal{M}(1^n, 1^t)$ by an $n \times n$ matrix, and let $T_V(m,n,p)$ denote the running time of ColMMV *on input matrices $A \in R^{m\times n}, B \in R^{n\times p}, C \in R^{m\times p}$. If $\|AB\|_0 \leq O(n^\delta)$ for $0 \leq \delta \leq 2$ then the algorithm performs*

$$\widetilde{O}(n^{\beta+\varepsilon} + T_{\mathcal{M}}(n,n) + n \cdot T_{\mathcal{R}}(n,n) + T_H(n,n) + T_V(n,n,n))$$

arithmetic operations over R for any constant $\varepsilon > 0$, where

$$\beta := \begin{cases} 2 & \text{if } \delta + \alpha \leq 1 + \omega^\perp \text{ ,} \\ \omega(\delta + \alpha - 1, 1, 1) & \text{otherwise .} \end{cases}$$

Proof. Assume without loss of generality that $\delta \geq 1$. If not, set $\delta = 1$, and using that $\alpha \leq \omega^\perp$ conclude that $\beta = 2$. Let $C = (\boldsymbol{c}_1, \ldots, \boldsymbol{c}_n)$.

Algorithm 2 Matrix multiplication using column-wise matrix multiplication verification.

Input: Matrices $A, B \in R^{n\times n}$ over a ring R.
Subroutine: An m-compressed sensing scheme $(\mathcal{M}, \mathcal{R})$ over R.
Subroutine: An algorithm ColMMV for Column-Wise-MMV.
Output: The product AB.

Set $J_0 := [n]$.
Initialize a matrix $C' = (\boldsymbol{c}'_1, \ldots, \boldsymbol{c}'_n) \in R^{n\times n}$ arbitrarily.
for $i = 0, 1, \ldots, \lceil \log n \rceil$ **do**
  Set $t := 2^i$.
  Compute $H := \mathcal{M}(1^n, 1^t) \in R^{m\times n}$. // $m = m(n,t)$.
  Compute $B' := B_{[n],J_i} \in R^{[n]\times J_i}$. // Restrict B to columns indexed by J_i.
  Compute $D = (\boldsymbol{d}_j)_{j\in J_i} := HAB' \in R^{[m]\times J_i}$.
  Compute $F = (\boldsymbol{f}_j)_{j\in J_i} := (\mathcal{R}(\boldsymbol{d}_j))_{j\in J_i} \in R^{[n]\times J_i}$.
  Compute $J_{i+1} := \text{ColMMV}(A, B', F)$. // Indices of columns that differ in AB', F.
  for $j \in J_i \setminus J_{i+1}$ **do**
    Set $\boldsymbol{c}'_j := \boldsymbol{f}_j$.
return C'

We argue that after the ith iteration of the for loop, $\boldsymbol{c}'_j = \boldsymbol{c}_j$ for all $j \in [n]$ such that $\|\boldsymbol{c}_j\|_0 \le 2^i$. Indeed, this follows from the fact that for such an index j, $\boldsymbol{f}_j = \mathcal{R}(H\boldsymbol{c}_j) = \boldsymbol{c}_j$ by the definition of a compressed sensing scheme with $t = 2^i$, and therefore we have that $j \notin J_{i+1}$. (As in the proof of Theorem 14 we assume that $\mathcal{R}$ always outputs *some* vector in R^n, regardless of its input.) In particular, because $\|\boldsymbol{c}_j\|_0 \le n \le 2^{\lceil \log n \rceil}$ for all columns $\boldsymbol{c}_j$, $\boldsymbol{c}'_j = \boldsymbol{c}_j$ for all $j \in [n]$ after the last iteration of the for loop, which implies that $C' = C$, as needed.

We next turn to analyzing the algorithm's running time. We upper bound the worst-case running time of a single iteration (iteration i) of the for loop, and note that the loop performs $O(\log n)$ iterations. The $\mathcal{M}(1^n, 1^t)$ call takes time $T_{\mathcal{M}}(n,t) \le T_{\mathcal{M}}(n,n)$, the $|J_i| \le n$ calls to $\mathcal{R}$ take time at most $|J_i| \cdot T_{\mathcal{R}}(n,t) \le n \cdot T_{\mathcal{R}}(n,n)$, and the call to ColMMV takes time at most $T_V(n, n, |J_i|) \le T_V(n,n,n)$.

It remains to upper bound the complexity of computing HAB' in the ith iteration, which we compute parenthesized as $(HA)B'$. Computing $A' := HA$ takes $T_H(n,t) \le T_H(n,n)$ time by assumption,[11] and it remains to compute $A'B'$, which we do using rectangular matrix multiplication. For $i = 0$, we have $t = 1$ and $m = m(n,t) = O(n^\alpha)$. Therefore, computing $A'B'$ takes $O(n^{\omega(\alpha,1,1)+\varepsilon}) = O(n^{\omega(\delta+\alpha-1,1,1)+\varepsilon})$ time. For $i \ge 1$, we have $t = 2^i$ and $(t/2) \cdot |J_i| \le \|AB\|_0$, which holds because J_i consists of indices of columns of AB with more than $t/2$ non-zero entries.

Let $\eta, \gamma \ge 0$ be such that $t = O(n^\eta)$ and $|J_i| = O(n^\gamma)$. Then because $A' \in R^{m\times n}$ for $m = m(n,t) = O(tn^\alpha) = O(n^{\eta+\alpha})$ and $B' \in R^{n\times|J_i|}$, $A'B'$ can be computed in $O(n^{\omega(\eta+\alpha,1,\gamma)+\varepsilon})$ time for any constant $\varepsilon > 0$. Furthermore, since $(t/2) \cdot |J_i| \le \|AB\|_0 \le O(n^\delta)$, we have that $\eta + \gamma \le \delta$. If $\eta + \alpha + \gamma \le 1$, then by Proposition 6, Item 1, $\omega(\eta+\alpha, 1, \gamma) \le \eta + \alpha + 1 + \gamma \le 2$. Otherwise, if $\eta + \alpha + \gamma > 1$, then by Proposition 6, Item 4 and Corollary 8, $\omega(\eta+\alpha, 1, \gamma) \le \omega(\eta+\alpha+\gamma-1, 1, 1) \le \omega(\delta+\alpha-1, 1, 1)$, as needed. ◀

[11] When instantiating this reduction each matrix H will be sparse. Such matrices admit fast multiplication.

Our main theorem about solving OSMM via a randomized algorithm follows as a corollary.

▶ **Theorem 2** (Randomized OSMM). *Let $\delta \in [0,2]$, let R be a ring, and let $\varepsilon > 0$ be a constant. There is a randomized algorithm for solving δ-OSMM$_R$ on $n \times n$ matrices that performs $O(n^{\beta+\varepsilon})$ operations over R, where*

$$\beta := \begin{cases} 2 & \text{if } \delta \leq 1 + \omega^{\perp} \ , \\ \omega(\delta - 1, 1, 1) & \text{otherwise} \ . \end{cases}$$

Proof. Assume without loss of generality that $\delta \geq 1$. If not, set $\delta = 1$. We instantiate the compressed sensing scheme subroutine needed in Algorithm 2 with the scheme described in Theorem 13. The running time analysis follows from a similar argument as in the proof of Theorem 1, combined with the guarantee that $T_H(n,n) \leq \widetilde{O}(n^2)$ from Theorem 13 and the guarantee that $T_V(n,n,n) \leq \widetilde{O}(n^2)$ from Lemma 16. In particular, the fact that H can be multiplied by an arbitrary vector $\boldsymbol{x}$ in $\widetilde{O}(\|\boldsymbol{x}\|_0)$ time implies that H can be multiplied by an arbitrary matrix $A \in R^{n \times n}$ in $\widetilde{O}(n^2)$ time. This implies that $T_H(n,n) \leq \widetilde{O}(n^2)$.

Furthermore, the algorithm in Lemma 16 is randomized and succeeds with probability $1 - 1/n^c$ for any constant $c > 0$. Fix any such $c > 0$. Algorithm 2 makes $O(\log n)$ calls to ColMMV, and so by taking a union bound we get that all of these calls succeed with probability at least $1 - O(\log n / n^c) = 1 - o(1)$. It follows that Algorithm 2 succeeds with probability $1 - o(1)$, as needed. ◀

4 Fully Sparse Matrix Multiplication

In this section, we describe how to extend our main algorithms for OSMM to the fully sparse setting when the input matrices A, B are promised not only to satisfy $\|AB\|_0 \leq O(n^{\delta_{\text{out}}})$ but also $\|A\|_0, \|B\|_0 \leq O(n^{\delta_{\text{in}}})$ for some $\delta_{\text{in}} \in [0,2]$.

4.1 Deterministic FSMM

We first give our deterministic algorithm for FSMM, which follows by instantiating Algorithm 1 with the compressed sensing scheme in Theorem 13 as in the proof of Theorem 1.

▶ **Theorem 18** (Deterministic FSMM). *Let $\delta_{in}, \delta_{out} \in [0,2]$, let R be a ring, and let $\varepsilon > 0$ be a constant. There is a deterministic algorithm for solving $(\delta_{in}, \delta_{out})$-FSMM$_R$ on $n \times n$ matrices that performs $O(n^{\beta+\varepsilon})$ operations over R, where*

$$\beta := \max\{\delta_{out}/2 + 1, \omega_{\delta_{in}}(\delta_{out}/2, 1, 1)\} \ .$$

Proof sketch. We refer to Algorithm 1, instantiated with the compressed sensing scheme in Theorem 13, and show how to implement its operations under the assumption that $\|A\|_0, \|B\|_0 \leq O(n^{\delta_{\text{in}}})$. Let $\alpha > 0$ be a small constant to be set in the analysis. We first note that $T_{\mathcal{M}}(n,t) \leq \widetilde{O}(n)$ as before.

We now analyze the time needed to compute $D = HAB$. By Theorem 13, H is poly$(\log n)$-column-sparse, and so it is possible to compute $A' := HA$ in $\widetilde{O}(n^{\delta_{\text{in}}})$ time by Proposition 9. Since $\|A'\|_0 = \widetilde{O}(n^{\delta_{\text{in}}})$ and $H, A' \in R^{m \times n}$ for $m = O(n^{\delta_{\text{out}}/2+\alpha})$, it is possible to compute the product $A'B$ in $O(n^{\omega_{\delta_{\text{in}}}(\delta_{\text{out}}/2,1,1)+\varepsilon})$ time for any constant $\varepsilon > 0$ (assuming that $\alpha > 0$ is chosen to be sufficiently small; see the proof of Theorem 1). We note that $\omega_{\delta_{\text{in}}}(\delta_{\text{out}}/2, 1, 1) \geq \delta_{\text{in}}$ (since simply reading in an $n \times n$ matrix B with $\Theta(n^{\delta_{\text{in}}})$ non-zero entries takes $\Omega(n^{\delta_{\text{in}}})$ time), and so computing HAB takes $O(n^{\omega_{\delta_{\text{in}}}(\delta_{\text{out}}/2,1,1)+\varepsilon})$ time overall.

Furthermore, by Theorem 13, $T_{\mathcal{R}}(t,n) \leq t^{1+\alpha} \cdot \text{poly}(\log n) \leq \widetilde{O}(n^{\delta_{\text{out}}/2+\alpha})$ since $t = O(n^{\delta_{\text{out}}/2})$, and so computing D' and F' takes $\widetilde{O}(n^{\delta_{\text{out}}/2+\alpha+1})$ time. Finally, we analyze the time needed to compute F. Computing $H(AB)^T$ can be done in $O(n^{\omega_{\delta_{\text{in}}}(\delta_{\text{out}}/2,1,1)+\varepsilon})$ time for any constant $\varepsilon > 0$ as with computing D. Furthermore, D' has at most $O(n^{\delta_{\text{out}}/2})$ non-zero columns, and so, again using the fact that H is $\text{poly}(\log n)$-column-sparse, it takes $\widetilde{O}(n^{\delta_{\text{out}}/2+1})$ time to compute $H(D')^T$. The claim follows. ◀

We recover Theorem 1 from Theorem 18 by noting that $\omega_2(\delta_{\text{out}}/2,1,1) = \omega(\delta_{\text{out}}/2,1,1)$ and that $\omega(\delta_{\text{out}}/2,1,1) \geq \delta_{\text{out}}/2+1$ (by Proposition 6, Item 1).

Using the bounds on $\omega_{\delta_{\text{in}}}(\delta_{\text{out}}/2,1,1)$ from Proposition 11, Item 1 and Theorem 10, we conclude that for every $\varepsilon > 0$, $(\delta_{\text{in}}, \delta_{\text{out}})$-FSMM$_R$ can be solved using $O(n^{\delta_{\text{out}}/2+1+\varepsilon} + n^{\delta_{\text{out}}/2+\delta_{\text{in}}+\varepsilon})$ or $O(n^{\delta_{\text{out}}/2+1+\varepsilon} + n^{\sigma+\varepsilon})$ operations over R, where

$$\sigma \leq \min_{\eta \in [0,1]} \max\{\omega(\delta_{\text{out}}/2, \eta, 1),\ 2\delta_{\text{in}} - \eta\}\ . \tag{2}$$

4.2 Randomized FSMM

We now give our randomized algorithm for FSMM as Theorem 19. It follows by instantiating Algorithm 2 with the compressed scheme in Theorem 13 as in the proof of Theorem 2. We recall that Theorem 19 is equivalent to [1, Lemma 3.1], although the algorithm that it is based on uses different techniques.

▶ **Theorem 19** (Randomized FSMM). *Let $\delta_{in} \in [1,2], \delta_{out} \in [0, 2\delta_{in}]$, let R be a ring, and let $\varepsilon > 0$ be a constant. There is a randomized algorithm for solving $(\delta_{in}, \delta_{out})$-FSMM$_R$ on $n \times n$ matrices that performs $O(n^{\delta_{in}+\varepsilon} + n^{\beta+\varepsilon})$ operations over R, where*

$$\beta := \max_{\substack{\eta_1,\eta_2 \in [0,1]\,, \\ \eta_1+\eta_2=\delta_{out}}} \omega_{\delta_{in}}(\eta_1, 1, \eta_2)\ .$$

Proof sketch. We refer to Algorithm 2, instantiated with the compressed sensing scheme in Theorem 13, and show how to implement its operations under the assumption that $\|A\|_0, \|B\|_0 \leq O(n^{\delta_{\text{in}}})$.

As in the proof of Theorem 2, we upper bound the worst-case running time of a single iteration (iteration i) of the for loop for $i \geq 1$ (as the running time for $i = 0$ does not affect the final bound). Furthermore, as noted there, we have that $t \cdot |J_i| = O(n^{\delta_{\text{out}}})$ at each iteration of the loop. I.e., choosing $\eta_1 > 0$ so that $t = 2^i = O(n^{\eta_1})$, we have that $|J_i| \leq O(n^{\eta_2})$ where $\eta_2 \leq \min\{1, \delta_{\text{out}} - \eta_1\}$. We then have that $m = O(tn^{\alpha}) = O(n^{\eta_1+\alpha})$ for an arbitrarily small constant $\alpha > 0$ to be set in the analysis. We note that $T_{\mathcal{M}}(n,t) \leq \widetilde{O}(n)$. Moreover, we have that computing F takes $|J_i| \cdot T_{\mathcal{R}}(n,t) \leq n^{\delta_{\text{out}}-\eta_1} \cdot t^{1+\alpha} \cdot \text{poly}(\log n) = \widetilde{O}(n^{\delta_{\text{out}}+\alpha})$ time.

We next sketch how to modify the algorithm in the proof of Lemma 16 to run in $\widetilde{O}(n^{\delta_{\text{in}}})$ time. We note that the matrix X sampled there has $O(\log n)$ rows, and that we need to compute XAB' and XF. Computing XA and $(XA)B'$ takes $\widetilde{O}(n^{\delta_{\text{in}}})$ time by Proposition 9. On the other hand, we have that $\mathcal{R}$ runs in $t^{1+\alpha} \cdot \text{poly}(\log n) = \widetilde{O}(n^{\eta_1+\alpha})$ time, and therefore each of the $|J_i| = O(n^{\delta_{\text{out}}-\eta_1})$ columns of F must be $\widetilde{O}(n^{\eta_1+\alpha})$ sparse. Therefore, we can compute XF in time $\widetilde{O}(n^{\delta_{\text{out}}+\alpha})$ time.

It remains to analyze the time complexity of computing $D = HAB'$, since all other operations are efficient. We have that $A' := HA$ can be computed in $\widetilde{O}(n^{\delta_{\text{in}}})$ time by Theorem 13. Furthermore, since H is $\text{poly}(\log n)$ column sparse, A' is itself $\widetilde{O}(n^{\delta_{\text{in}}})$ sparse. It follows that $HAB' = A'B'$ can also be computed in $O(n^{\omega_{\delta_{\text{in}}}(\eta_1,1,\eta_2)+\varepsilon})$ time for any constant $\varepsilon > 0$.

To finish the proof, we note that the for loop uses at most $O(\log n)$ iterations, and then bound the running time of each iteration. The running time of the ith iteration is bounded from above by $\widetilde{O}(n^{\delta_{\text{out}}+\alpha} + n^{\delta_{\text{in}}} + n^{\omega_{\delta_{\text{in}}}(\eta_1,1,\eta_2)+\varepsilon})$ for arbitrarily small constants α and ε. In particular, to prove the claim, it suffices to show that both δ_{out} and $\omega_{\delta_{\text{in}}}(\eta_1, 1, \eta_2)$ are bounded from above by β. First, by the definition of β, we have that $\omega_{\delta_{\text{in}}}(\eta_1, 1, \eta_2) \leq \beta$.

Second, by Proposition 11, Item 2, we have that

$$\beta \geq \omega_{\delta_{\text{in}}}(\eta^*, 1, \delta_{\text{out}} - \eta^*) \geq \delta_{\text{out}} \ ,$$

where $\eta^* := \min\{1, \delta_{\text{out}}\}$. Indeed, Proposition 11, Item 2 applies because of the following bounds. First, $\eta^* = \min\{1, \delta_{\text{out}}\} \leq 1 \leq \delta_{\text{in}}$. Second, if $\delta_{\text{out}} < 1$, then $\delta_{\text{out}} - \eta^* = \delta_{\text{out}} - \delta_{\text{out}} = 0 \leq \delta_{\text{in}}$. Third, if $\delta_{\text{out}} \geq 1$, then $\delta_{\text{out}} - \eta^* = \delta_{\text{out}} - 1 \leq 2 - 1 = 1 \leq \delta_{\text{in}}$. Here we have repeatedly used the assumption that $\delta_{\text{in}} \geq 1$. ◀

We recover Theorem 2 from Theorem 19 by setting $\delta_{\text{in}} = 2$ and noting that for $\delta_{\text{out}} \geq 1$,

$$\max_{\substack{\eta_1,\eta_2\in[0,1]\,,\\ \eta_1+\eta_2=\delta_{\text{out}}}} \omega_{\delta_{\text{in}}}(\eta_1, 1, \eta_2) = \max_{\substack{\eta_1,\eta_2\in[0,1]\,,\\ \eta_1+\eta_2=\delta_{\text{out}}}} \omega(\eta_1, 1, \eta_2) \leq \omega(\delta_{\text{out}} - 1, 1, 1)$$

by Corollary 8.

While we state Theorem 19 for $\delta_{\text{in}} \geq 1$ for simplicity, we remark that the proof can be extended to the case of $\delta_{\text{in}} \in [0, 2]$. The main challenge in this case is that we cannot afford to run the algorithm $\mathcal{M}$ it time $\widetilde{O}(n)$ anymore (as this bound might be larger than the claimed upper bound on the running time of the algorithm). To overcome this, we note that the construction of the matrix H in our compressed sensing scheme (presented in full in an appendix of the full version of this paper [6]) is in fact strongly explicit. That is, one can compute all non-zero entries of a given column of H, and therefore multiply by H efficiently without even running the algorithm $\mathcal{M}$ first.

4.3 Optimal FSMM (and OSMM)

We now prove that our randomized algorithm for FSMM in Theorem 19 (which is equivalent to [1, Lemma 3.1]) is optimal in the sense that any improvement on it would imply a corresponding improvement on input-sparse rectangular matrix multiplication exponents. In fact, we show an *equivalence* between these exponents and the running time exponent for $(\delta_{\text{in}}, \delta_{\text{out}})$-FSMM$_R$. We also show an analogous result for the optimality of the algorithm in Theorem 2 for OSMM.

▶ **Proposition 20.** *Let $\delta_{in} \in [1, 2]$, $\delta_{out} \in [0, 2\delta_{in}]$, let R be a ring, and let $\beta \geq 0$. Then there is a randomized algorithm for $(\delta_{in}, \delta_{out})$-FSMM$_R$ that runs in time $O(n^{\beta+\varepsilon})$ for every constant $\varepsilon > 0$ if and only if $\beta \geq \max\{\delta_{in}, \omega_{\delta_{in}}(\eta_1, 1, \eta_2)\}$ for all $\eta_1, \eta_2 \in [0, 1]$ with $\eta_1 + \eta_2 = \delta_{out}$.*

Furthermore, if $\delta_{out} \in [1, 2]$ then there is a randomized algorithm for δ_{out}-OSMM that runs in time $O(n^{\beta+\varepsilon})$ for every constant $\varepsilon > 0$ if and only if $\beta \geq \omega(\delta_{out} - 1, 1, 1)$.

Proof. Let $\eta_1, \eta_2 \in [0, 1]$ with $\eta_1 + \eta_2 = \delta_{\text{out}}$. We reduce the problem of computing the product of $A \in R^{m\times n}$ and $B \in R^{n\times p}$ for $m = O(n^{\eta_1})$ and $p = O(n^{\eta_2})$ when A and B are both $O(n^{\delta_{\text{in}}})$-sparse to $(\delta_{\text{in}}, \delta_{\text{out}})$-FSMM$_R$. The reduction simply outputs $A' := (A^T, \mathbf{0}, \ldots, \mathbf{0})^T \in R^{n\times n}$ and $B' := (B, \mathbf{0}, \ldots, \mathbf{0}) \in R^{n\times n}$. I.e., A' and B' are simply A and B padded with enough rows and columns of 0s, respectively, to make them square. It is easy to recover the product AB from the product $A'B'$. Furthermore, $\|A'\|_0 = \|A\|_0 = O(n^{\delta_{\text{in}}})$, $\|B'\|_0 = \|B\|_0 = O(n^{\delta_{\text{in}}})$, and, because $AB \in R^{m\times p}$, $\|A'B'\|_0 \leq mp \leq O(n^{\eta_1+\eta_2}) = O(n^{\delta_{\text{out}}})$, as needed. Because the

reduction worked for arbitrary $\eta_1, \eta_2 \in [0,1]$ with $\eta_1 + \eta_2 = \delta_{\text{out}}$, we get that if there is an algorithm using $O(n^{\beta+\varepsilon})$ operations over R for $(\delta_{\text{in}}, \delta_{\text{out}})$-FSMM$_R$ for some $\beta > 0$ and any $\varepsilon > 0$, then $\omega_{\delta_{\text{in}}}(\eta_1, 1, \eta_2) \le \beta$. Furthermore, we trivially have that such β must satisfy $\beta \ge \delta_{\text{in}}$ since it takes $\Omega(n^{\delta_{\text{in}}})$ time to read an $(\delta_{\text{in}}, \delta_{\text{out}})$-FSMM$_R$ instance.

On the other hand, Theorem 19 implies that if $\beta \ge \delta_{\text{in}}$ and $\beta \ge \omega_{\delta_{\text{in}}}(\eta, 1, \delta_{\text{out}} - \eta)$ for all $\eta \in [0, \delta_{\text{out}}]$ then $(\delta_{\text{in}}, \delta_{\text{out}})$-FSMM$_R$ is solvable using $O(n^{\beta+\varepsilon})$ many operations over R.

The result for OSMM follows by combining the padding argument above, instantiated with $\delta_{\text{in}} = 2$ and $\eta = 1$, and Theorem 2. ◀

Abstract

We study the problem of estimating the number of edges in an undirected, unweighted graph using sublinear query access. We consider a query model that preserves the structure of Independent Set (IS) queries, but augments their output with a random certificate: given a vertex subset, the oracle returns a uniformly random edge from the induced subgraph if one exists, and returns null otherwise.

Using this access, we give a randomized algorithm that outputs a $(1 \pm \varepsilon)$-approximation to the number of edges with constant success probability using $\widetilde{O}(\log^2 m)$ queries. This implies an exponential separation from both standard IS queries and global random edge-sampling models: estimating the number of edges using standard IS queries require $\widetilde{\Theta}\left(\min\left\{\sqrt{m}, \frac{n}{\sqrt{m}}\right\}\right)$ queries, while direct random edge-sample access requires $\widetilde{\Theta}(\sqrt{m})$ samples. Beyond separation in query complexity, our algorithm is output-sensitive: its query complexity is polylogarithmic in the number of edges in the graph. This aligns with the classical objective in group testing, where one seeks algorithms that are both worst-case optimal and instance-adaptive.

Conceptually, our model connects group testing, the decision–versus–counting dichotomy, graph property testing, and the "power of a random certificate", and can be viewed as a structured form of conditional sampling of edges in graphs.

1 Introduction

We consider the problem of estimating the number of edges in an undirected, unweighted, simple graph using a sublinear number of queries. Let $G = (V, E)$ be a graph with $V = [n] := \{1, 2, \ldots, n\}$ vertices and $|E| = m$ edges. Given query access to G and an approximation parameter $\varepsilon \in (0, 1)$, the objective is to output an estimate $\widehat{m}$ such that

$$(1-\varepsilon)m \;\le\; \widehat{m} \;\le\; (1+\varepsilon)m$$

with success probability at least $2/3$.

Query model and our result

We work in a query model built on *Independent Set* (`IS`) queries, introduced by [6]. The `IS` query takes a subset of vertices $U \subseteq V$ and returns whether U is an independent set.

We consider the *Independent Set with Certificate* query, denoted by `ISC`, which takes as input a subset of vertices $U \subseteq V$ and returns

$$\texttt{ISC}(U) = \begin{cases} e \sim \mathrm{Unif}(E(U)), & \text{if } E(U) \neq \emptyset, \\ 0, & \text{otherwise,} \end{cases}$$

where $E(U)$ denotes the set of edges in the subgraph of G induced by U, and $\mathrm{Unif}(S)$ denotes the uniform distribution over a (nonempty) set S.

Importantly, the `ISC` query preserves the structural constraint of a standard `IS` query: the algorithm specifies exactly the same vertex subsets as in the IS model, and the only difference lies in the response, which returns a uniformly random edge as a certificate whenever the induced subgraph is nonempty.

[6] showed that the number of edges in a graph can be estimated using

$$\widetilde{O}\left(\min\left\{\frac{n^2}{m}, \sqrt{m}\right\}\right) \;=\; \widetilde{O}(n^{2/3})$$

`IS` queries, establishing a polynomial separation from local query based algorithms that require $\Theta(n)$ queries in the worst case [27]. In a subsequent work, [21] nearly resolved the query complexity of edge estimation using IS queries by showing that

$$\widetilde{\Theta}\left(\min\left\{\frac{n}{\sqrt{m}}, \sqrt{m}\right\}\right)$$

queries are both necessary and sufficient. In particular, this implies a worst-case complexity of $\widetilde{\Theta}(\sqrt{n})$ `IS` queries.

Our main result shows that the natural enrichment of `IS` queries with random certificates yields an exponential separation from standard `IS` queries for edge estimation, achieving polylogarithmic query complexity in m.

▶ **Theorem 1** (Main result). *There exists a randomized algorithm that, given access to a graph G through `ISC` queries and an approximation parameter $\varepsilon \in (0, 1/3)$, outputs an estimate $\widehat{m}$ of the number of edges m in G such that, with probability at least $2/3$,*

$$(1-\varepsilon)m \;\le\; \widehat{m} \;\le\; (1+\varepsilon)m.$$

The algorithm uses $O(\varepsilon^{-2} \log^2 m \cdot \log\log m)$ `ISC` queries in expectation.

The query complexity of the algorithm is *strictly output-sensitive* in the sense that it depends only on the number of edges, with no dependence on n, even in lower-order terms.

Theorem 1 not only demonstrates the power gained by augmenting IS access with random certificates over standard IS access, but also underscores the strength of sampling within induced subgraphs. When edges can only be sampled uniformly at random from the entire graph, estimating the number of edges requires $\widetilde{\Theta}(\sqrt{m})$ samples [30]. In contrast, allowing the algorithm to sample a uniformly random edge from a queried induced subgraph yields an exponential separation from global random edge-sampling, achieving query complexity $\widetilde{O}(\log^2 m)$.

In what follows, we highlight conceptual connections between our results and query model with several well-studied themes, including group testing, graph property testing, the power of random certificates, decision versus counting problems, and conditional sampling.

Group testing perspective

The introduction of IS queries in graph algorithms was originally motivated by ideas from *group testing*. In classical group testing, introduced by [25] and studied extensively since then, the goal is to infer the size of an unknown set of defective items by querying subsets of a known universe [3]. A standard group test returns only a binary result indicating whether the queried subset contains at least one defective item.

This viewpoint applies naturally to graph edge estimation. Here, edges play the role of defective items, and the allowed vertex pairs for queries impose structural constraints on the possible subsets of edges that can be queried. [6] introduced both IS and Bipartite Independent Set (BIS) queries through this lens. A BIS query takes two disjoint vertex sets as input and returns whether there exists an edge with one endpoint in each set.

In the same vein, [13] and [5] introduced the Edge Emptiness query EE to study triangle estimation and connectivity in graphs, respectively. An EE query specifies a set of candidate edges and reports whether at least one of them exists in the graph.

Decision versus counting

In a series of seminal works, [32, 33] studied the relationship between approximate counting and decision access for Boolean formulas. In particular, they showed that given decision access to satisfiability, one can approximately count the number of satisfying assignments of any Boolean formula on n variables using only $O(\log n)$ such queries.

Our work establishes an analogous phenomenon in the setting of graph edge estimation: augmenting decision-style IS queries with a random certificate enables efficient approximate counting of edges in a graph.

Conditional sampling

Our model also bears a close conceptual relationship to work on property testing and estimation with conditional sampling access. In distribution testing, a conditional sampling oracle [18, 16] allows the algorithm to specify a subset of the domain and receive a sample drawn from the distribution restricted to that subset. Such structured sampling can lead to exponential savings over standard sampling in tasks such as uniformity testing, support size estimation, and testing of joint distributions [15, 9, 14, 10].

In our setting, the ISC oracle plays an analogous role: the algorithm specifies a vertex subset, and if the induced subgraph is nonempty, it receives a uniformly random edge from that subgraph. Thus, ISC can be viewed as a structured conditional sampling primitive over

the edge set of the graph, where the conditioning is constrained to induced subgraphs. Our results demonstrate that, as in distribution testing, such conditional access can fundamentally change the complexity of estimation problems in graphs.

Power of a random certificate

Studying the power of random certificates for approximate counting is an important question across a variety of query models [31, 17]. These works show that augmenting group queries with access to random certificates can lead to significant reductions in query complexity.

In the graph setting, several queries have been introduced from the viewpoint of group queries while retaining the structural properties of the graph. Two notable examples are `IS` and `BIS`, introduced by [6] for estimating the number of edges. Our `ISC` query fits naturally within this framework: it preserves the structure of `IS` while adding a random certificate. In particular, our algorithm achieves substantially lower query complexity compared to algorithms using only `IS` access, and also improves over the best known $\widetilde{O}(\log^5 n)$-query algorithm based on `BIS` access due to [2].

The main difference between the power of random certificates studied in [31, 17] and our setting is that our query oracles are group graph queries that retain the structural properties of the underlying graph.

Graph property testing

Estimating the number of edges in a graph with sublinear queries has been studied in several access models. Early works focused on local queries such as degree, neighbour, and pair queries [28, 29, 27, 34], which provide fine-grained access but face inherent limits for edge estimation.

This led to models that incorporate global information. In particular, augmenting local access with random edge sampling [4, 26, 7] enables more efficient estimation. More recently, a finer-grained analysis of edge estimation under local queries enriched with random edge sampling have provided an understanding of the tradeoffs between local and global access [11, 12, 19, 7].

Another line of work studies structured global queries, notably `IS` and `BIS` [6, 21, 2]. These queries provide decision-only access over vertex subsets while preserving graph structure, and have been extended to hypergraphs [23, 8, 24]. We discussed their known upper and lower bounds earlier in the Introduction.

Finally, [1] showed that augmenting `IS` queries with additional local queries yields a quadratic separation from using `IS` queries alone, further illustrating the power of combining different query primitives. Other than the `BIS` query, all query models discussed above requires polynomial number of queries in the worst case.

Notations

Throughout, the notation $\widetilde{O}(f)$, suppress factors polynomial in $1/\varepsilon$ and $\log f$. For an integer k, we define $[k] = \{1, \ldots, k\}$. We write $a = (1 \pm \varepsilon)b$ to indicate that a is a $(1 \pm \varepsilon)$-approximation of b.

Throughout, we use $G = (V, E)$ to denote the input graph with $m = |E|$ number of edges and $V = |V|$ vertices. For a subset $U \subseteq V$, let $m(U)$ be the number of edges in the graph induced by the subset U.

2 Technical overview

We give a high-level description of our algorithm for estimating the number of edges in an undirected graph using Independent Set with Certificate (`ISC`) queries. Conceptually, our approach converts approximate counting into a sequence of controlled decisions and sampling steps that gradually reduce the graph while preserving a constant fraction of its edges.

A central conceptual contribution is the use of *approximation preserving subsets* and *approximation preserving sequences*, which formalise how much of the graph's edge mass is retained at each stage and guide both the algorithm and its analysis. We leverage graph sparsification techniques to enable iterative construction of approximation-preserving sequences on graphs using `ISC` queries.

Outline of the Algorithm

At a high level, our algorithm maintains a nested sequence of vertex subsets

$$V = U_0 \supseteq U_1 \supseteq \cdots \supseteq U_\kappa,$$

where each U_j contains a constant fraction of the edges of U_{j-1}. The algorithm alternates between two modes:

- If the current induced subgraph is "small" (that is, has fewer than τ edges), we estimate its edge count directly.
- Otherwise, we construct a smaller approximation preserving subset of the graph by randomly partitioning the vertex set and selecting a part that provably retains a constant fraction of the edges.

This iterative reduction of the graph continues until we reach a subset U_κ whose edge count is small enough to estimate accurately; we set the threshold for U_κ to be a sufficiently large constant. The final estimate of m is then reconstructed by multiplying the relative edge losses across all steps.

Where the $\widetilde{O}(\log^2 m)$ query complexity comes from

A key novelty of our approach is that all complexity bounds are driven by $\log m$ rather than $\log n$. This is achieved through three ideas that are not present in prior `IS` or `BIS` based algorithms:

- *Random certificates enable output-sensitive sparsification:* Unlike decision-only `IS` or `BIS` queries, ISC queries allow us to estimate how many edges of a subset lie in a randomly chosen part, which lets us iteratively construct smaller induced subgraphs to work on while tracking edge mass locally.
- *Approximation Preserving Sequence:* Instead of estimating m directly, we construct a chain of subsets $U_0 \supseteq U_1 \supseteq \cdots \supseteq U_\kappa$ such that each U_j retains a constant fraction of edges of U_{j-1}. Crucially, we establish κ to be $O(\log m)$ in expectation, independent of n. We also bound the number of queries required to construct this sequence as $O(\kappa^2)$ and bound its expectation.
- *Local multiplicative reconstruction:* We only need to estimate the ratios $p_j = \frac{m(U_j)}{m(U_{j-1})}$, each of which is $\Omega(1)$ due to the $U_0, \ldots, U_\kappa$ being an approximation preserving subsequence. This keeps the per-level query complexity small and makes the overall cost in expectation $\widetilde{O}(\kappa^2) = \widetilde{O}(\log^2 m)$.

Estimating Small Edge Counts

Fix a threshold τ. One can design an algorithm that makes $O(\sqrt{\tau})$ `ISC` queries and guarantees the following with desired probability about a given subset $U \subseteq V$. If $m(U) \leq \tau$, then the algorithm reports an approximation of $m(U)$. Moreover, if $m(U) \geq 8\tau$, the algorithm reports that $m(U)$ is large. The proof is based on the birthday paradox. The details can be found in Section 3.

Graph Sparsification

The idea here is to leverage graph sparsification to construct a smaller subset of vertices to work on at each step. We partition U uniformly at random into two subsets U^1 and U^2. A graph sparsification lemma, along the result of [6], shows that with desired probability,

$$\left| \frac{m(U)}{2} - \sum_{i=1}^{2} m(U^i) \right| \leq c\sqrt{m(U)} \log m(U).$$

We provide the proof in Section 4. Intuitively, this means that the total number of edges inside U^1 and U^2 is close to half of $m(U)$, up to a lower-order error term. As long as $m(U)$ is sufficiently large, this implies that at least one of U^1 or U^2 must contain a constant fraction of the edges of U. More precisely, there exists an absolute constant ζ_{sp} such that if $m(U) \geq \zeta_{\text{sp}}$, then with probability at least $1 - 1/m(U)$, at least one of $m(U^1)/m(U)$ and $m(U^2)/m(U)$ is at least $1/8$, and both $m(U^1)/m(U)$ and $m(U^2)/m(U)$ are at most $3/4$.

Choosing the Good Part

After partitioning U into U^1 and U^2, we must identify which part retains an appropriate fraction of the edges. Note that this step is fundamentally enabled by the `ISC` queries. The idea is to take a random sample of the edges in U, and check whether it is preserved in the induced subgraph of either U^1 or U^2.

To do this, we draw random edges from U via `ISC` queries. Let $\widehat{p}(U^i)$ be the fraction of sampled edges that fall inside U^i, for $i \in [2]$. If $\widehat{p}(U^i) \geq 1/16$, we select U^i as the next subset; otherwise, we pick an arbitrary part. A Chernoff bound guarantees that, with desired probability, we correctly identify a subset satisfying

$$\frac{1}{32} \leq \frac{m(U^i)}{m(U)} \leq \frac{3}{4}.$$

Such subsets are called *approximation preserving subsets*. The upper bound of $3/4$ is useful to bound the final query complexity and the lower bound of $1/32$ is useful for guaranteeing the quality of the estimator.

Constructing an Approximation Preserving Sequence

Starting with $U_0 = V$, we iterate:

1. Run threshold checking on U_j.
2. If $m(U_j) < \tau$, stop and set $U_\kappa = U_j$.
3. Otherwise, sparsify U_j and select an approximation preserving subset U_{j+1}.

This yields a sequence $V = U_0 \supseteq U_1 \supseteq \cdots \supseteq U_\kappa$, where, with probability at least $4/5$, each U_j satisfies

$$\frac{1}{32} \leq \frac{m(U_j)}{m(U_{j-1})} \leq \frac{3}{4}.$$

Final Estimation

For each $j \in [\kappa]$, define

$$p_j = \frac{m(U_j)}{m(U_{j-1})}.$$

Then we have the identity

$$m = \frac{m(U_\kappa)}{\prod_{j=1}^{\kappa} p_j}.$$

Instead of estimating each $m(U_j)$ from scratch, we estimate only the ratios p_j. Because each $p_j = \Omega(1)$ by construction of the approximation preserving sequence, we can estimate each p_j using small number of queries, independent of n or $m(U_j)$. This yields an estimate $\widehat{p}_j$ satisfying the following with desired probability.

$$\widehat{p}_j = (1 \pm \varepsilon/O(\sqrt{\kappa}))\, p_j$$

Note that the entire approximation preserving subsequence is constructed a priori. Hence, we know κ during the final estimation phase that we use to fix the approximation parameters appropriately for the multiplicative estimation for each $p_j, j \in [\kappa]$. Let $\widehat{m}(U_\kappa)$ be the estimate obtained via the birthday-based estimator. Our final output is

$$\widehat{m} = \frac{\widehat{m}(U_\kappa)}{\prod_{j=1}^{\kappa} \widehat{p}_j}.$$

A careful multiplicative error analysis shows that this is a $(1 \pm \varepsilon)$-approximation to m.

Proof Roadmap

The correctness proof proceeds in the following stages:

- *Threshold correctness:* We show that the collision-based test reliably distinguishes between $m(U) < \tau$ and $m(U) \geq 8\tau$, and that the birthday-paradox estimator is accurate when $m(U) < \tau$.
- *Constructing approximation preserving subsequence:* While we decrease the failure probability of choosing a good subset at each iteration, the probability of failure of the sparsification step depends on the number of edges remaining. This necessitates a careful analysis of the failure probability of the sparsification step and of our threshold-checking mechanisms to establish the correctness of our algorithm and query complexity bounds.
- *Multiplicative reconstruction:* Given our approximation preserving subsequence, we estimate each p_j with appropriately scaled approximation error. Then, we bound the cumulative error from estimating all p_j and show that the product estimator preserves a global $(1 \pm \varepsilon)$ approximation.
- *Complexity analysis:* We show that $\mathbb{E}[\kappa] = O(\log m)$ and that the total query complexity is dominated by estimating the p_j's, yielding an overall expected complexity of $\widetilde{O}(\log^2 m/\varepsilon^2)$.

Outline

We begin in Section 3, where we present the threshold-checking algorithm and show how to estimate the edge count when the number of edges is below a given threshold. In Section 4, we describe the algorithm for constructing an approximation-preserving subsequence. In Section 4.1, we establish how graph sparsification yields an approximation-preserving subset,

and use this result in Section 4.2 to construct an approximation-preserving subsequence. Finally, in Section 5, we present the complete algorithm for edge estimation. Appendix A discusses some useful concentration inequalities.

3 Threshold checking

Let a fixed threshold ($\tau \geq 1$) be given. We consider the following threshold-checking problem: given a subset of vertices $U \subseteq V$, determine whether $m(U) < \tau$. If this condition holds, the goal is to estimate the $(1 \pm \varepsilon)$ approximation of $m(U)$.

To address this task, we present two algorithms `IsCollision` and `BirthdayEstimate` based on the birthday paradox techniques [30, Chapter 5]. `IsCollision` distinguishes between the cases $m(U) < \tau$ or $m(U) \geq 8\tau$ (Lemma 2). `BirthdayEstimate` outputs an $(1 \pm \varepsilon)$ approximation of $m(U)$, if $m(U) < \tau$ (Lemma 3). The corresponding guarantees are stated below. For details, see the full version of the paper [20].

▶ **Lemma 2** (Correctness of `IsCollision`). *For a subset $U \subseteq V$ and a threshold $\tau \geq 1$, the following statements hold for `IsCollision` with probability at least $1 - \delta$:*

(i) *If $m(U) \leq \tau$, then `IsCollision` outputs 1.*

(ii) *If $m(U) \geq 8\tau$, then `IsCollision` outputs 0.*

The number of `ISC` queries made is $O(\sqrt{\tau}\log(\delta^{-1}))$

Suppose that a collision is detected, i.e., `IsCollision` outputs 1. We can obtain a $(1 \pm \varepsilon)$-approximation of $m(U)$ using additional `ISC` queries. This estimation procedure is implemented in `BirthdayEstimate`.

▶ **Lemma 3** (Correctness of `BirthdayEstimate`). *For a subset $U \subseteq V$, threshold $\tau \geq 1$ and approximation error $\varepsilon > 0$. If $m(U) \leq \tau$, then `BirthdayEstimate` outputs an $(1 \pm \varepsilon)$ estimate of $m(U)$ with probability at least $15/16$. The number of `ISC` query made is $\Theta\left(\varepsilon^{-1}\sqrt{\tau}\right)$.*

4 Sparsification

In this section, we will describe a procedure to generate an approximation preserving sequence (formally defined below) $U_0, \ldots, U_\kappa$ with probability at least $7/8$. Moreover, the expected query complexity of the procedure is $O(\log^2 m)$.

▶ **Definition 4** (Approximation preserving subset). *For $U, U' \subset V$ such that $U' \subseteq U$, we say that U' is an* approximation preserving subset *of U if*

$$\frac{1}{32} \leq \frac{m(U')}{m(U)} \leq \frac{3}{4}.$$

▶ **Definition 5** (Approximation preserving sequence). *For a sequence $U_0, U_1, \ldots, U_\kappa \subseteq V$ with $U_0 \supseteq U_1 \supseteq \ldots \supseteq U_\kappa$, We say that $U_0, U_1, \ldots, U_\kappa$ is an* approximation preserving sequence *if U_{i-1} is an approximation preserving subset of U_i for all $i \in [\kappa]$.*

Formally, we will prove the following lemma in this section.

▶ **Lemma 6** (Approximate sequence lemma). *There exists an algorithm that outputs an approximation preserving sequence $U_0, U_1, \ldots, U_\kappa$ with probability at least $4/5$. The expected value of κ is $O(\log m)$, and the expected number of `ISC` queries made is $O(\log^2 m)$.*

To prove the above lemma, we start with $U_0 = V$, and find U_i iteratively. Informally speaking, we stop with U_κ when $m(U_\kappa)$ is *small enough*. In Section 4.1, we discuss a procedure (`ApproxSubset` corresponding to Lemma 7) that generates a U' which is an approximation preserving subset of U, with specified probability, for any given U as long as $m(U)$ is *large*. In Section 4.2, we describe the procedure (`ApproxSequence` corresponding to Lemma 12) that uses `IsCollision` and `ApproxSubset` iteratively to generate an approximation preserving subsequence $U_0, \ldots, U_\kappa$. Essentially, `IsCollision` is used to determine whether the number of edges in the current subset U_i is small or large and `ApproxSubset` is used to generate a good subset as long as $m(U_i)$ is large.

4.1 Procedure to find approximate preserving subset

In this section, we describe the procedure `ApproxSubset` (see Algorithm 1) for finding the approximation preserving subset $U' \subseteq U$, for any given U and prove its guarantee.

Algorithm 1 `ApproxSubset`(U, δ).

Require: `ISC` query access to G and a confidence parameter $\delta \in (0, 1)$.
Ensure: A subset $U' \subseteq U$.

```
Uniformly and independently partition U into U^1 and U^2.
Uniformly and independently sample O(log(δ^{-1})) random edges from U and let S be
    the multi-set of sampled edges.
Compute p̂(U^i) = (1/|S|) Σ_{e∈S} 1_{e∈U^i} for i ∈ {1,2}.
if There exists i ∈ {1,2} such that p̂(U^i) ≥ 1/16 then
    return U^i as U'
else
    return U^1 or U^2 arbitrarily as U'.
end if
```

Formally, we will prove the following.

▶ **Lemma 7** (Approximate subset lemma). *Let ζ_{sp} be a suitably large constant. Consider `ApproxSubset` that takes $U \subseteq V$ as input and produces $U' \subseteq U$ as the output.*

- **(i)** $\mathbb{E}[m(U')] \leq m(U)/2$;
- **(ii)** *If $m(U) \geq \zeta_{\text{sp}}$, with probability $1 - \delta - 1/m(U)$, U' is an approximation preserving subset of U.*

The construction of an approximation-preserving subset U' proceeds in two steps. First, we sparsify the graph by randomly partitioning the set U into U^1 and U^2 (see Lemma 8). When $m(U)$ is large enough, this partition guarantees the existence of U^i such that $m(U^i)$ is a constant fraction of $m(U)$ (Corollary 10). In the second step, we identify such an approximation-preserving subset from U^1 and U^2 (Lemma 11). Combining these results yields the proof of Lemma 7.

We prove the following variant of the graph sparsification result of Beame et al. [6].

▶ **Lemma 8** (Graph Sparsification). *For a given $\delta \in (0, 1)$, there exists an absolute constant c such that the following holds. Let $G = (V, E)$ be a graph with n vertices and m edges. Let U^1 and U^2 be a uniformly random partition of V. Then,*

- **(i)** $\mathbb{E}[m(U^1) + m(U^2)] = m(U)/2$;
- **(ii)** $\Pr\left[\left|m/2 - \sum_{i=1}^{2} m(U^i)\right| \geq c\sqrt{m}\log(m/\delta)\right] \leq \delta$.

We will need the following lemma to prove the above graph sparsification lemma.

▶ **Lemma 9.** *Let A be a set of ℓ elements. For every element $t \in A$, one assigns a color independently and uniformly from $\{1,2\}$. Let $C^{(i)}$ be the number of vertices in A with color i, for any $i \in \{1,2\}$. Then for $\delta \in (0,1)$, we have*

$$\Pr\left[\left|C^{(1)} - C^{(2)}\right| \geq \sqrt{6\ell \log(4\delta^{-1})}\right] \leq \delta \text{ and } \mathbb{E}\left[\left|C^{(1)} - C^{(2)}\right|\right] \leq \sqrt{\ell}$$

Proof. For $t \in A$, let X_t be the indicator random variable that is 1 if t is assigned color 1 and 0 otherwise. Then, $C^{(1)} = \sum_{t \in A} X_t$ and $\mathbb{E}\left[C^{(1)}\right] = \ell/2$. Using Chernoff's inequality (Lemma 19) with $\varepsilon = \sqrt{(6/\ell)\log(4/\delta)}$, we have

$$\Pr\left[\left|C^{(1)} - \frac{\ell}{2}\right| > \frac{\varepsilon\ell}{2}\right] \leq 2\exp\left(\frac{6\log(4\delta^{-1})}{\ell} \cdot \frac{\ell}{6}\right) \leq \frac{\delta}{2} \tag{1}$$

Similarly, we can have the same bound for color 2.

$$\Pr\left[\left|C^{(2)} - \frac{\ell}{2}\right| > \frac{\varepsilon\ell}{2}\right] \leq \frac{\delta}{2} \tag{2}$$

Observe that $\left|C^{(1)} - C^{(2)}\right| \leq \left|C^{(1)} - (\varepsilon\ell/2)\right| + \left|C^{(2)} - (\varepsilon\ell/2)\right|$. Therefore

$$\Pr\left[\left|C^{(1)} - C^{(2)}\right| > \varepsilon\ell\right] \leq \delta$$

For $t \in A$, let Y_t be a random variable that is 1 if t is assigned the color 1 and -1 otherwise. Then $C^{(1)} - C^{(2)} = \sum_{t \in A} Y_t = Y$. We have that $\Pr[Y_t = 1] = \Pr[Y_t = 1] = 1/2$, then

$$\mathbb{E}[Y_t] = 0 \text{ and } \mathbb{E}[Y_t^2] = 1$$

By the independence of Y_t, we get

$$\mathbb{E}[Y^2] = \sum_{t \in A} \mathbb{E}[Y_t^2] + \sum_{u \neq v} \mathbb{E}[Y_u Y_v] = \ell$$

Finally, we have $\mathbb{E}[|Y|] \leq \sqrt{\mathbb{E}[|Y|^2]} = \sqrt{\mathbb{E}[Y^2]} \leq \sqrt{\ell}$. ◀

We now prove Lemma 8.

Proof of Lemma 8. Let each vertex $t \in V$ be associated with a random variable $Y_t \in \{1,2\}$ such that $\Pr[Y_t = 1] = 1/2$. For $i \in \{1,2\}$, define $U^i = \{t \in V \mid Y_t = i\}$ and

$$f(Y_1, \ldots, Y_n) = m(U^1) + m(U^2).$$

A fixed edge is counted by f if and only if both its endpoints are assigned the same label, which occurs with probability $1/2$. Therefore, $\mathbb{E}[f] = m/2$.

Consider the Doob martingale $X_0, X_1, \ldots, X_n$, where $X_t = \mathbb{E}[f(Y_1, \ldots, Y_n) | Y_1, \ldots, Y_t]$. For a fix values of $Y_1, \ldots, Y_{t-1}$, we have,

$$X_{t-1} = \frac{g(1) + g(2)}{2}, \text{ where } g(i) = \mathbb{E}[f(Y_1, \ldots, Y_n) | (Y_1, \ldots, Y_{t-1}) \cap (Y_t = i)]$$

Since, X_t is either $g(1)$ or $g(2)$, we have $|X_t - X_{t-1}| \leq |g(1) - g(2)|$. Let $N(t)$ be the set of neighbours of the vertex t and $\deg(t) = |N(t)|$. Let $N_{<t} = N(t) \cap [t-1]$ and

$N_{>t} = N(t) \cap \{(t+1), \ldots, n\}$. Let $C^{(i)}_{<t}$ and $C^{(i)}_{>t}$ be the number of vertices in $N_{<t}$ and $N_{>t}$ respectively. So,

$$\Delta_t = |g(1) - g(2)| = \left| C^{(1)}_{<t} + \mathbb{E}\left[C^{(1)}_{>t} \mid Y_t = 1\right] - C^{(2)}_{<t} - \mathbb{E}\left[C^{(2)}_{>t} \mid Y_t = 2\right] \right|$$

The above equation is true because any edge with vertices in $[t-1]$ will have the same contribution to $g(1)$ and $g(2)$. Similarly, any edge which have one vertex in $[t-1]$ and another in $\{(t+1), \ldots, n\}$ or both of its vertices in $\{(t+1), \ldots, n\}$ will have the same contribution. Using Lemma 9, we have with probability at least $1 - \delta'$,

$$\Delta_t \leq \sqrt{6\deg(t) \log \frac{4}{\delta'}} + \sqrt{\deg(t)} \leq 2c\sqrt{\deg(t) \log \frac{1}{\delta'}} = c_t$$

Let $\mathcal{B}$ be the event that there exits a t such that $\Delta_t > c_t$. Let n_a be the set of active vertices (vertices with degree at least 1). Therefore, using union bound $\Pr[\mathcal{B}] \leq 4n_a\delta' \leq 4m\delta'$.

Let $S = \sum_{t=1}^{n} c_t^2 = \sum_{t=1}^{n} 4c^2 \deg(t) \log(4/\delta') = O(m \log(1/\delta'))$ and $s = c\sqrt{m}\log(1/\delta')$. Using Lemma 21, we have

$$\Pr\left[\left|f - \frac{m}{2}\right| > s\right] \leq 2\exp\left(-\frac{s^2}{2S}\right) + \Pr[\mathcal{B}] \leq \delta' + 4m\delta'$$

Replacing δ' with δ/cm for a sufficiently large constant, we obtain

$$\Pr\left[\left|\frac{m}{2} - \sum_{i=1}^{2} m(U^i)\right| \geq c\sqrt{m}\log\left(\frac{m}{\delta}\right)\right] \leq \delta$$

which completes the proof. ◀

▶ **Corollary 10.** *For a subset $U \subseteq V$, suppose there exists a sufficiently large absolute constant ζ_{sp} such that $m(U) \geq \zeta_{\text{sp}}$. Let U^1 and U^2 be a uniformly random partition of U. Then, with probability at least $1 - \frac{1}{m(U)}$, the following hold.*

- **(i)** $\frac{m(U^1)}{m(U)} \geq 1/8$ *or* $\frac{m(U^2)}{m(U)} \geq 1/8$;
- **(ii)** $\frac{m(U^1)}{m(U)} \leq 3/4$ *and* $\frac{m(U^2)}{m(U)} \leq 3/4$.

Proof. Taking ζ_{sp} to be sufficiently large, we have $c\sqrt{m(U)}\log m(U) \leq \frac{m(U)}{4}$. So, by taking $\delta = 1/m(U)$ in Lemma 8, we

$$\Pr\left[\frac{m(U)}{4} \leq \sum_{i=1}^{2} m(U^i) \leq \frac{3\,m(U)}{4}\right] \geq 1 - \frac{1}{m(U)}\,.$$

This implies that, with probability at least $1 - 1/m(U)$, at least one of $m(U^1)/m(U)$ and $m(U^2)/m(U)$ is at least $1/8$, and both $m(U^1)/m(U)$ and $m(U^2)/m(U)$ are at most $3/4$. ◀

To prove the guarantees of `ApproxSubset` described in Algorithm 1, we need Lemma 11.

▶ **Lemma 11.** *With probability at least $1-\delta$, the following statements hold for `ApproxSubset`*

- **(i)** *If $\frac{m(U^i)}{m(U)} \geq \frac{1}{8}$, then $\widehat{p}(U^i) \geq \frac{1}{16}$.*
- **(ii)** *If $\frac{m(U^i)}{m(U)} < \frac{1}{32}$, then $\widehat{p}(U^i) < \frac{1}{16}$.*

The number of `ISC` queries made is $O\left(\log(\delta^{-1})\right)$.

Proof. Consider a subset $U^i \subseteq U$ for any $i \in \{1,2\}$. For each sampled edge, define the indicator random variable

$$X_j = \begin{cases} 1 & \text{if the } j^{\text{th}} \text{ sampled edge lies in } U^i, \\ 0 & \text{otherwise.} \end{cases}$$

Observe that $\mathbb{E}[X_j] = \frac{m(U^i)}{m(U)}$.

Define the fraction of sampled edges that belong to U^i by $X = \frac{1}{|S|}\sum_{j\in[|S|]} X_j$. where S is the multiset of sampled edges (Line 2) obtained via `ISC` queries on U. Note that $X = \widehat{p}(U^i)$ and hence

$$\mathbb{E}[\widehat{p}(U^i)] = \frac{1}{|S|}\sum_{j\in[|S|]} \mathbb{E}[X_j] = \frac{m(U^i)}{m(U)} = \frac{m(U^i)}{m(U)}.$$

Applying Hoeffding's bound (Lemma 20), we get

$$\Pr\left(\left|\widehat{p}(U^i) - \frac{m(U^i)}{m(U)}\right| \geq \tfrac{1}{32}\right) \leq \exp\left(-\frac{|S|}{2}\cdot(1/32)^2\right) \leq \delta/2.$$

The last inequation holds since $|S| = O(\log 1/\delta)$. Using the union bound over $i \in \{1,2\}$, we get the desired result. ◀

We now give the proof of Lemma 7, using Lemma 8, Corollary 10 and Lemma 11

Proof of Lemma 7. In `ApproxSubset`, the set U is partitioned uniformly at random into U^1 and U^2. From Lemma 8(i),

$$\mathbb{E}[m(U^1) + m(U^2)] = m(U)/2.$$

Since U' is either U^1 or U^2, it follows that $\mathbb{E}[m(U')] \leq m(U)/2$, proving part (i).

We now prove part (ii). Let $\mathcal{E}_{\text{apx}}$ denote the event that U' is an approximation-preserving subset of U, that is, $1/32 \leq m(U')/m(U) \leq 3/4$. Let $\mathcal{E}$ be the event that at least one of $m(U^1)/m(U)$ and $m(U^2)/m(U)$ is at least $1/8$, and both $m(U^1)/m(U)$ and $m(U^2)/m(U)$ are at most $3/4$. By Corollary 10,

$$\Pr[\mathcal{E}] \geq 1 - \frac{1}{m(U)}.$$

Let us condition on the event $\mathcal{E}$. It suffices to bound $\Pr[\mathcal{E}_{\text{apx}} \mid \mathcal{E}]$. Then both $m(U^1)/m(U)$ and $m(U^2)/m(U)$ are at most $3/4$, and at least one of $m(U^1)/m(U)$ and $m(U^2)/m(U)$ is at least $1/8$; w.l.o.g. assume $m(U^1)/m(U) \geq 1/8$. If $m(U^2)/m(U) \geq 1/32$, then since $U' \in \{U^1, U^2\}$ we immediately have $1/32 \leq m(U')/m(U) \leq 3/4$, that is, $\Pr[\mathcal{E}_{\text{apx}} \mid \mathcal{E}] = 1$. Otherwise $m(U^2)/m(U) < 1/32$. By Lemma 11, with probability at least $1-\delta$, we obtain $\widehat{p}(U^1) \geq 1/16$ and $\widehat{p}(U^2) < 1/16$, implying $U' = U^1$. Consequently $1/32 \leq m(U')/m(U) \leq 3/4$ holds with probability at least $1-\delta$ conditioned on $\mathcal{E}$. Thus in all cases

$$\Pr[\mathcal{E}_{\text{apx}} \mid \mathcal{E}] \geq 1 - \delta.$$

Therefore,

$$\Pr[\mathcal{E}_{\text{apx}}] \geq \Pr[\mathcal{E}] \cdot \Pr[\mathcal{E}_{\text{apx}} \mid \mathcal{E}] \geq 1 - \frac{1}{m(U)} - \delta.$$ ◀

Algorithm 2 `ApproxSequence`(V).

Require: `ISC` access to graph G.
Ensure: A nested sequence $U_1, U_2, \cdots, U_\kappa$.
1: Initialize $U_0 \leftarrow V$; *coll* $\leftarrow 1$; $\kappa \leftarrow 0$
2: **while** *true* **do**
3: *coll* $\leftarrow$ `IsCollision`$(U_\kappa, \zeta_{\text{sp}}, \frac{1}{2^{\kappa+5}})$
4: **if** *coll* equals 1 **then**
5: **break**
6: **else**
7: $U_{\kappa+1} \leftarrow$ `ApproxSubset`$(U_\kappa, \frac{1}{2^{\kappa+5}})$
8: $\kappa \leftarrow \kappa + 1$
9: **end if**
10: **end while**
11: **return** $U_1, U_2, \cdots, U_\kappa$

4.2 Procedure to find approximate preserving sequence

We now describe the algorithm `ApproxSequence` (see Algorithm 2), which constructs the sparsification sequence used by the main estimator.

▶ **Lemma 12** (Correctness of `ApproxSequence`). *Consider* ***`ApproxSequence`*** *as described in Algorithm 2. With probability at least* $4/5$*, it outputs an approximation preserving sequence* $U_1, U_2, \ldots, U_\kappa$ *such that* $m(U_\kappa) \leq 8\zeta_{\text{sp}}$*. Here* ζ_{sp} *is given large constant. The number of* ***`ISC`*** *queries made is* $O(\kappa^2)$*.*

Proof.

Correctness. Let us consider the event $\mathcal{E}_{\text{col}}$ that denotes

- There does not exist a j such that the algorithm goes to the next iteration if $m(U_j) \leq \zeta_{\text{sp}}$.
- For any j such that the algorithm goes to the next iteration if $m(U_j) \geq 8\zeta_{\text{sp}}$.

The probability of $\mathcal{E}_{\text{col}}$ is lower bounded by `IsCollision` succeeds in all iterations during the run of the algorithm. Using the union bound, we have

$$\Pr[\mathcal{E}_{\text{col}}] \geq 1 - \sum_{i=1}^{\infty} \frac{1}{2^{i+5}} \geq 1 - \frac{1}{2^5} \sum_{i=1}^{\infty} \frac{1}{2^i} \geq 1 - \frac{1}{16} = \frac{15}{16}.$$

Let us continue the argument under the conditional space that $\mathcal{E}_{\text{col}}$ has occurred.

We assume $m(U_0) = m$ is sufficiently large; hence, the algorithm does not terminate in the first iteration, given that $\mathcal{E}_{\text{col}}$ has occurred. Let $U_0, \ldots, U_\kappa$ be the output of the algorithm, where κ is a positive integer. Conditioned on the event $\mathcal{E}_{\text{col}}$, we have $m(U_j) \geq \zeta_{\text{sp}}$ for every $j \leq \kappa - 1$.

We prove the claim by induction on κ. For each $j \geq 0$, let $\mathcal{E}_j$ denote the event which is that the algorithm executes iteration j and either terminates with, $m(U_j) \leq 8\zeta_{\text{sp}}$, or it produces an approximation preserving subset U_{j+1} such that $m(U_{j+1}) \leq \frac{3m(U_j)}{4}$.

Let $\mathcal{E}_{\leq j}$ denote the event that $\mathcal{E}_i$ occurs for all $i \in [j]$, that is,

$$\mathcal{E}_{\leq j} = \bigcap_{i=1}^{j} \mathcal{E}_i.$$

Equivalently, $\mathcal{E}_{\leq j}$ is the event that the algorithm runs for j iterations, such that $U_0, \ldots, U_j$ is an approximation preserving sequence, and at iteration j either it produces U_{j+1}, an approximation preserving subset of U_j such that $m(U_{j+1}) \leq \frac{3m(U_j)}{4}$, or the algorithm terminates with $m(U_j) \leq 8\zeta_{\text{sp}}$.

The induction hypothesis is that

$$\Pr[\mathcal{E}_{\leq j}] \;\geq\; 1 - \delta_{\leq j},$$

where

$$\delta_i \;=\; \frac{1}{m(U_i)} + \frac{1}{2^{i+5}}, \qquad \text{and} \qquad \delta_{\leq j} \;=\; \sum_{i=0}^{j} \delta_i.$$

We first prove the base case. That is, $\Pr[\mathcal{E}_0] \geq 1 - \delta_0$. Recall that we assume that $m(U_0) = m$ is sufficiently large. Moreover, we assume that event $\mathcal{E}_{\text{col}}$ has occurred and algorithm produced a sequence $U_0, \ldots, U_\kappa$ with $\kappa \geq 1$. So, $\mathcal{E}_0$ occurs if `ApproxSubset` reports an approximate preserving subset U_{j+1}. By Lemma 7, this occurs with probability at least $1 - \delta_0$.

For the inductive step, we mainly show that $\Pr[\mathcal{E}_j \mid \mathcal{E}_{\leq j-1}] \geq 1 - \delta_j$ for $j \geq 1$. Let us argue that it is sufficient. Note that $\delta_{\leq j} = \delta_{\leq j-1} + \delta_j$ for $j \geq 1$ and

$$\Pr[\mathcal{E}_{\leq j}] = \Pr[\mathcal{E}_{\leq j-1} \cap \mathcal{E}_j] = \Pr[\mathcal{E}_{\leq j-1}] \cdot \Pr[\mathcal{E}_j \mid \mathcal{E}_{\leq j-1}].$$

By the induction hypothesis, $\Pr[\mathcal{E}_{\leq j-1}] \geq 1 - \delta_{\leq j-1}$. We will show that

$$\Pr[\mathcal{E}_j \mid \mathcal{E}_{\leq j-1}] \geq 1 - \delta_j.$$

Therefore,

$$\begin{aligned}
\Pr\left[\mathcal{E}_{\leq j}\right] &= \Pr\left[\mathcal{E}_{\leq j-1}\right] \cdot \Pr\left[\mathcal{E}_j \mid \mathcal{E}_{\leq j-1}\right] \\
&\geq (1 - \delta_{\leq j-1})(1 - \delta_j) \\
&\geq 1 - \delta_{\leq j-1} - \delta_j \\
&= 1 - \delta_{\leq j}.
\end{aligned}$$

Consider any j with $1 \leq j \leq \kappa - 1$. Under the conditional space $\mathcal{E}_{\text{col}}$ and along with the fact that we assume $m(U_0) = m$ is sufficiently large, $m(U_j) \geq \zeta_{\text{sp}}$ for each $j \leq \kappa - 1$.

We consider two cases: $m(U_j) \geq 8\zeta_{\text{sp}}$, and $\zeta_{\text{sp}} \leq m(U_j) \leq 8\zeta_{\text{sp}}$, and analyse them individually.

Case 1: $(m(U_j) > 8\zeta_{\text{sp}})$. Recall that we are assuming that the event $\mathcal{E}_{\text{col}}$ has occurred. So, `ApproxSequence` does not terminate after executing `IsCollision` and execute `ApproxSubset`. Moreover it produces an approximate preserving subset U_{j+1} with $m(U_{j+1}) \leq \frac{3m(U_j)}{4}$, that is event $\mathcal{E}_j$ occurs, when `ApproxSubset` reports an approximate preserving subset U_{j+1} with $m(U_{j+1}) \leq \frac{3m(U_j)}{4}$. By Lemma 7 and Line 7 of `ApproxSequence`, this occurs with probability at least $1 - \delta_j$ where,

$$\delta_j = \frac{1}{m(U_j)} + \frac{1}{2^{j+5}}$$

Hence,

$$\Pr[\mathcal{E}_j \mid \mathcal{E}_{\leq j-1}] \geq 1 - \delta_j^{(1)},$$

Case 2: $(\zeta_{\text{sp}} \leq m(U_j) \leq 8\zeta_{\text{sp}})$. In this case, we show that

$$\Pr[\mathcal{E}_j \mid \mathcal{E}_{\leq j-1}] \geq 1 - \delta_j$$

regardless of whether `ApproxSequence` terminates after executing `IsCollision` or proceeds to execute `ApproxSubset`.

In the former case, the claim follows directly from the definition of $\mathcal{E}_j$ together with the fact that $m(U_j) \leq 8\zeta_{\text{sp}}$. In the latter case, `ApproxSequence` produces an approximate preserving subset U_{j+1} of U_j provided that `ApproxSubset` returns an approximate preserving subset U_{j+1}. By Lemma 7, this occurs with probability at least $1 - \delta_j$, where

$$\delta_j \leq \frac{1}{m(U_j)} + \frac{1}{2^{j+5}}.$$

Hence,

$$\Pr[\mathcal{E}_j \mid \mathcal{E}_{\leq j-1}] \geq 1 - \delta_j.$$

We are done with the proof of the inductive step. We summarize the above discussion as follows. $\Pr[\mathcal{E}_{\text{col}}] \geq 15/16$. When the event $\mathcal{E}_{\text{col}}$ occurs, $\Pr[\mathcal{E}_j \mid \mathcal{E}_{j-1}] \geq 1 - \delta_j$ for all $j \geq 0$. Moreover, $\Pr[\mathcal{E}_{\leq j}] \geq 1 - \delta_{\leq j}$ for all $j \geq 0$. Recall that the algorithm outputs a sequence $U_0, \ldots, U_{\kappa-1}$. The events $\mathcal{E}_{\text{col}}$ and $\mathcal{E}_{\leq \kappa-1}$ occur with probability at least

$$\Pr[\mathcal{E}_{\text{col}}] - \delta_{\leq \kappa-1}.$$

Hence, the following facts hold with the same probability:

1. $U_0, \ldots, U_\kappa$ is an approximate preserving sequence, that is,

$$\frac{1}{32} \leq \frac{m(U_i)}{m(U_{i-1})} \leq \frac{3}{4}, \text{ where } i \in [\kappa].$$

2. $m(U_j) \geq \zeta_{\text{sp}}$ for each $j \leq \kappa - 1$, and $m(U_\kappa) \leq 8\zeta_{\text{sp}}$.

Note that `ApproxSequence` produces an approximation-preserving sequence $U_1, U_2, \cdots, U_\kappa$ such that $m(U_\kappa) \leq 8\zeta_{\text{sp}}$ whenever both of the above conditions hold. This occurs with probability at least $1/5$, provided $\delta_{\kappa-1} \leq 1/10$, since $\Pr[\mathcal{E}_{\text{col}}] \geq 15/16$.

We complete the proof of correctness of `ApproxSequence` by showing that $\delta_{\kappa-1} \leq 1/10$.

$$\delta_{\leq \kappa-1} = \sum_{i=0}^{\kappa-1} \frac{1}{m(U_j)} + \frac{1}{2^{j+5}} \leq \sum_{i=0}^{\infty} \frac{1}{2^{j+4}} + \sum_{i=0}^{\kappa-1} \frac{1}{m(U_j)} \leq \frac{1}{16} + \sum_{i=0}^{\kappa-1} \frac{3^{\kappa-1-i}}{4^{\kappa-1-i}\zeta_{\text{sp}}}.$$

The last inequation holds since $m(U_{\kappa-1}) \geq \zeta_{\text{sp}}$ and $m(U_i) \leq \frac{3m(U_{i-1})}{4}$ for all $i \in [\kappa - 1]$. We obtain the bound of $\delta_{\leq \kappa-1}$ as below:

$$\delta_{\leq \kappa-1} = \frac{1}{16} + \frac{1}{\zeta_{\text{sp}}} \sum_{i=0}^{\kappa-1} \frac{3^{\kappa-1-i}}{4^{\kappa-1-i}} = \frac{1}{16} + \frac{1}{\zeta_{\text{sp}}} \sum_{i=0}^{\kappa-1} \frac{3^i}{4^i} \leq \frac{1}{16} + \frac{2}{\zeta_{\text{sp}}} \leq \frac{1}{10}.$$

Here we have used the fact that ζ_{sp} is a large constant.

Query Complexity. From Lemma 2 and 11, the number of `ISC` queries made by `IsCollision` (for a constant threshold $\tau = \zeta_{\text{sp}}$) and `ApproxSubset` over κ iterations is,

$$O\left(\sum_{j=1}^{\kappa} \log(2^{\kappa+5})\right) = O\left(\kappa^2\right)$$ ◀

Note that the number of iterations and the query complexity of `ApproxSequence` (as mentioned in the above lemma) are random variables. We will argue their expectation in the following lemma. Moreover, when we discuss the full algorithm in Section 5 (that uses `ApproxSequence` as a subroutine), we show that the query complexity of the full algorithm is $O(\kappa^2 \cdot \log \kappa)$, where κ is the number of iterations of `ApproxSequence`. The following lemma will be useful in establishing the final query complexity in Section 5.

▶ **Lemma 13.** $\mathbb{E}[\kappa] = O(\log m)$, $\mathbb{E}[\kappa^2] = O(\log^2 m)$, *and* $\mathbb{E}[\kappa^2 \log \kappa] = O(\log^2 m \cdot \log \log m)$.

From Lemma 12 and Lemma 13, Lemma 6 follows. In the rest of the section, we prove Lemma 13 and Lemma 6.

Proof of Lemma 13. Here, we prove that

$$\mathbb{E}\left[\kappa^2 \log \kappa\right] = O(\log^2 m \log \log m)$$

The remaining bounds follow similarly.

We want to analyse $\mathbb{E}[\kappa^2 \log \kappa]$ where the expectation is over the distribution of κ for a run of the algorithm. To analyse this, we consider two different cases. For the first case, let t^* denote the time when the algorithm generates a subgraph with less than or equal to ζ_{sp} edges. Formally, we define t^* as the time t such that $m(U_t) \leq \zeta_{\text{sp}}$, and $m(U_{t-1}) > \zeta_{\text{sp}}$. If this is not the case, i.e. when $m(U_t) > \zeta_{\text{sp}}$ holds throughout the algorithm, we show that $\kappa = O(\log m)$.

First, we bound the expectation of $m(U_t)$ for some $t \in [\kappa]$. By Lemma 7, we have

$$\mathbb{E}\left[m(U_t) \mid m(U_{t-1})\right] \leq \frac{m(U_{t-1})}{2}.$$

By a inductive argument, and the fact that $m(U_0) = m$, we have

$$\mathbb{E}[m(U_t)] = \mathbb{E}[\mathbb{E}[m(U_t) \mid m(U_{t-1})]] \leq \frac{\mathbb{E}[m(U_{t-1})]}{2} \leq \ldots \leq \frac{m}{2^t} \tag{3}$$

Now, when $m(U_j) > \zeta_{\text{sp}}$ holds throughout the algorithm, we have

$$\zeta_{\text{sp}} < \mathbb{E}\left[m(U_\kappa)\right] \leq \frac{m}{2^\kappa} \implies \kappa = O(\log m)$$

Hence, we now focus on the case when there exists a $t^* \leq \kappa$. Note that t^* is unique for a run of the algorithm. Once, the algorithm reaches t^*, the probability of the algorithm terminating depends on the calls to `IsCollision` succeeding. We start with analysing the conditional expectation of $\kappa^2 \log \kappa$ given t^*.

$$\begin{aligned}
\mathbb{E}\left[\kappa^2 \log \kappa \mid t^*\right] &= \sum_{j=1}^{\infty} j^2 \log j \Pr\left[\kappa = j \mid t^*\right] \\
&= \sum_{j=1}^{t^*-1} j^2 \log j \Pr\left[\kappa = j \mid t^*\right] + \sum_{j=t^*}^{\infty} j^2 \log j \Pr\left[\kappa = j \mid t^*\right] \\
&= \sum_{j=t^*}^{\infty} j^2 \log j \Pr\left[\kappa = j \mid t^*\right] && \text{(As } t^* \leq \kappa\text{)}
\end{aligned}$$

$$\leq \sum_{j=t^*}^{\infty} j^2 \log j \Pr[\kappa \geq j \mid t^*]$$
$$\leq \sum_{j=t^*}^{\infty} \frac{j^2 \log j}{2^{j+5}}$$
$$= O\left(t^{*2} \log t^*\right) \tag{4}$$

Now, we analyse the distribution of t^*. We use (3) to obtain a bound on the probabilities of different values of t^*.

$$\begin{aligned}\Pr[t^* = t] \leq \Pr[t^* \geq t] &\leq \Pr[m(U_t) > \zeta_{\text{sp}}] \\ &\leq \frac{\mathbb{E}[m(U_t)]}{\zeta_{\text{sp}}} && \text{Markov's Inequality (Lemma 17)} \\ &\leq \frac{m}{2^t \zeta_{\text{sp}}} && \text{Equation (3)} \end{aligned} \tag{5}$$

Now, we bound the expectation of $\kappa^2 \log \kappa$.

$$\begin{aligned}\mathbb{E}[\kappa^2 \log \kappa] &= \mathbb{E}\left[\mathbb{E}\left[\kappa^2 \log \kappa \mid t^*\right]\right] \\ &= \mathbb{E}[t^{*2} \log t^*] && \text{(Equation (4))} \\ &= \sum_{j=1}^{\infty} j^2 \log j \Pr[t^* = j] \\ &= \sum_{j=1}^{2\log m} j^2 \log j \Pr[t^* = j] + \sum_{j=2\log m+1}^{\infty} j^2 \log j \Pr[t^* = j] \\ &\leq 8 \log^2 m \log\log m \sum_{j=1}^{2\log m} \Pr[t^* = j] + \sum_{2\log m}^{\infty} \frac{m j^2 \log j}{2^j \zeta_{\text{sp}}} \\ &= O\left(\log^2 m \log\log m\right)\end{aligned}$$

which proves the desired result. ◀

Lemma 6 follows from the algorithm `ApproxSequence` (Algorithm 2) along with Lemma 12 and Lemma 13.

5 Full algorithm

In this section, we present the full algorithm for estimating the number of edges using `ISC` queries and prove our main result stated below.

▶ **Theorem 1** (Main result). *There exists a randomized algorithm that, given access to a graph G through `ISC` queries and an approximation parameter $\varepsilon \in (0, 1/3)$, outputs an estimate $\widehat{m}$ of the number of edges m in G such that, with probability at least $2/3$,*

$$(1-\varepsilon)m \;\leq\; \widehat{m} \;\leq\; (1+\varepsilon)m.$$

The algorithm uses $O(\varepsilon^{-2} \log^2 m \cdot \log\log m)$ `ISC` queries in expectation.

`EdgeEstimation` (Algorithm 4) begins by calling `ApproxSequence` which outputs an approximation preserving sequence $U_1, \ldots, U_\kappa$, where each $p_i = m(U_i)/m(U_{i-1})$ is bounded below by a constant. This ensures that each ratio can be estimated efficiently. To estimate

each p_i, we use the subroutine `MulEstimation` which returns an $(1 \pm \varepsilon)$-approximation of p_i. The procedure `MulEstimation` is described in Algorithm 3 and its guarantee is established in Lemma 14.

Algorithm 3 `MulEstimation`$(U', U, \varepsilon, \delta)$.

Require: $U' \subseteq U$ and `ISC` access to the subset $U \subseteq V$.
Ensure: $\widehat{p}(U')$
1: Uniformly and Independently sample $O\left(\log(\delta^{-1})/\varepsilon^2\right)$ random edges from U and let S be the multi-set of sampled edges.
2: **return** $\widehat{p}(U') = \frac{1}{|S|}\sum_{e\in S} \mathbf{1}_{e\in U'}$.

Algorithm 4 `EdgeEstimation`(V, ε).

Require: `ISC` access to any subset $U \subseteq V$.
Ensure: An estimate of $\widehat{m}$
1: $U_1, U_2, \cdots, U_\kappa \leftarrow$ `ApproxSequence`(V)
2: $\widehat{m}_b \leftarrow$ `BirthdayEstimate`$(U_\kappa, 8\zeta_{\text{sp}}, \frac{\varepsilon}{3})$
3: Initialize $\widehat{p}_i \leftarrow 1$, for all $i \in [\kappa]$
4: **for** $i = 1$ to κ **do**
5: $\quad \widehat{p}_i \leftarrow$ `MulEstimation`$(U_i, U_{i-1}, \frac{\varepsilon}{200\sqrt{\kappa}}, \frac{1}{16\kappa})$
6: **end for**
7: $\widehat{m} \leftarrow \widehat{m}_b / \prod_{i=1}^{\kappa} \widehat{p}_i$
8: **return** $\widehat{m}$

▶ **Lemma 14** (Correctness of `MulEstimation`). *For subsets $U' \subseteq U \subseteq V$ and $\varepsilon > 0$, If $p(U') = \frac{m(U')}{m(U)} \geq \frac{1}{32}$, then `MulEstimation` outputs $\widehat{p}(U') = (1+x)p(U')$, where $\mathbb{E}[x] = 0$ and $x \in (-\varepsilon, \varepsilon)$ with probability at least $1-\delta$. The number of `ISC` queries made is $O\left(\log(\delta^{-1})/\varepsilon^2\right)$.*

Proof. Let X_j be the indicator random variable such that,

$$X_j = \begin{cases} 1 & \text{If the } j^{th} \text{ sampled edge is in } U' \\ 0 & \text{Otherwise} \end{cases}$$

Define number of edges sampled that belong to U' is $X = \sum_{j\in[|S|]} X_j$, where S is the multi-set of sampled edges (Line 2) and the expected size of X is

$$\mathbb{E}[X] = \sum_{j\in[|S|]} \mathbb{E}[X_j] = |S| \cdot \frac{m(U')}{m(U)} = |S| \cdot p(U') \geq \frac{|S|}{32}$$

Therefore,

$$\mathbb{E}[x] = \mathbb{E}\left[\frac{\widehat{p}(U')}{p(U')}\right] - 1 = \frac{\mathbb{E}[X]}{|S|\,p(U')} - 1 = 0$$

By the Chernoff Bound (see Lemma 19), we have

$$\Pr[x \in (-\varepsilon,\varepsilon)] = \Pr\left[\widehat{p}(U') \in (1\pm\varepsilon)p(U')\right] = \Pr\left[X \in (1\pm\varepsilon)\,\mathbb{E}[X]\right] \geq 1 - 2\exp\left(-\frac{\varepsilon^2\,|S|}{96}\right) \geq 1-\delta,$$

where the last step uses $|S| = O\left(\log(\delta^{-1})/\varepsilon^2\right)$. ◀

Now, we prove the guarantees of `EdgeEstimation` In particular, we prove the correctness of `EdgeEstimation` and its query complexity in Lemma 16 and Lemma 15, respectively.

▶ **Lemma 15.** *The expected query complexity of `EdgeEstimation` is* $O(\log^2 m \cdot \log\log m)$.

Proof. From Lemma 14, the number of `ISC` queries made by `MulEstimation` in j-th iteration is

$$O\left(\frac{\log(16\kappa)}{\varepsilon'^2}\right) \text{ where } \varepsilon' = \frac{\varepsilon}{200\sqrt{\kappa}}$$

Summing over κ iterations, we get

$$O\left(\sum_{j=1}^{\kappa} \frac{\log(\kappa)}{\varepsilon'^2}\right) = O\left(\kappa^2 \frac{\log\kappa}{\varepsilon^2}\right)$$

From Lemma 12, the number of `ISC` queries made by `ApproxSequence` is $O(\kappa^2)$. Finally, from Lemma 3, the number of `ISC` queries made by `BirthdayEstimate` is $O\left(\sqrt{8\zeta_{\text{sp}}}/\varepsilon\right) = O(1/\varepsilon)$. Combining all contributions, the total number of `ISC` queries made by `EdgeEstimation` is dominated by `MulEstimation`, and hence is, $O(\kappa^2 \log\kappa/\varepsilon^2)$. From Lemma 13,

$$\mathbb{E}[\kappa^2 \log\kappa] = O(\log^2 m \log\log m)$$

which bounds the expected query complexity. ◀

▶ **Lemma 16.** *In `EdgeEstimation`, the estimate* $\widehat{m}$ *is an* $(1 \pm \varepsilon)$*-approximation to* m *with probability at least* $3/4$.

Proof. Let $\mathcal{E}_1 = \mathcal{E}_{\text{sub}} \cap \mathcal{E}_{\text{bir}}$, where $\mathcal{E}_{\text{sub}}$ be the event that `ApproxSequence` outputs an approximation-preserving sequence $U_1, U_2, \ldots, U_\kappa$ with $m(U_\kappa) \le 8\zeta_{\text{sp}}$. From Lemma 12 we have $\Pr[\mathcal{E}_{\text{sub}}] \ge 4/5$.

$\mathcal{E}_{\text{bir}}$ be the event that `BirthdayEstimate` outputs an $(1 \pm \varepsilon/3)$ approximation of $m(U_\kappa)$ from Lemma 3. Also, from Lemma 3, we have $\Pr[\mathcal{E}_{\text{bir}} \mid \mathcal{E}_{\text{sub}}] \ge 15/16$. Therefore,

$$\Pr[\mathcal{E}_1] = \Pr[\mathcal{E}_{\text{sub}}] \Pr[\mathcal{E}_{\text{bir}} \mid \mathcal{E}_{\text{sub}}] \ge 1 - \left(\frac{1}{5} + \frac{1}{16}\right) \ge \frac{59}{80}$$

Let $\mathcal{E}_2$ be the event that `MulEstimation`$(U_i, U_{i-1}, \varepsilon', 1/16\kappa)$ outputs $\widehat{p_i} = (1 \pm x_i/4)p_i$ such that $\mathbb{E}[x_i] = 0$ and $x_i \in (-4\varepsilon', 4\varepsilon')$ for all $i \in [\kappa]$, where $\varepsilon' = \frac{\varepsilon}{200\sqrt{\kappa}}$. Therefore, using Lemma 14 and applying the union bound over all $i \in [\kappa]$,

$$\Pr[\mathcal{E}_2 \mid \mathcal{E}_1] = 1 - \sum_{j=1}^{\kappa} \frac{1}{16\kappa} \ge \frac{15}{16}.$$

Let $\mathcal{E}_3$ be the event that $|\sum_{i=1}^{\kappa} x_i| \le \varepsilon/9$. By Hoeffding's bound (Lemma 20),

$$\begin{aligned}\Pr[\mathcal{E}_3 \mid \mathcal{E}_1 \cap \mathcal{E}_2] &= 1 - \Pr\left[\left|\sum_{i=1}^{\kappa} x_i\right| > \frac{\varepsilon}{9} \,\middle|\, \mathcal{E}_1 \cap \mathcal{E}_2\right] \\ &\ge 1 - 2\exp\left(-\frac{2\varepsilon^2}{81\sum_{i=1}^{\kappa}\left(\frac{2\varepsilon}{50\sqrt{\kappa}}\right)^2}\right) \ge 1 - \frac{1}{e^{12}}. \end{aligned} \tag{6}$$

Hence,

$$\Pr[\mathcal{E}_1 \cap \mathcal{E}_2 \cap \mathcal{E}_3] = \Pr[\mathcal{E}_1] \cdot \Pr[\mathcal{E}_2|\mathcal{E}_1] \cdot \Pr[\mathcal{E}_3 \mid \mathcal{E}_1 \cap \mathcal{E}_2] \geq 1 - \left(\frac{21}{80} + \frac{1}{16} + \frac{1}{e^{12}}\right) \geq \frac{2}{3}$$

In what follows, we assume that all of the events $\mathcal{E}_1$, $\mathcal{E}_2$ and $\mathcal{E}_3$ occur. Since, $\Pr[\mathcal{E}_1 \cap \mathcal{E}_2 \cap \mathcal{E}_3] \geq 2/3$, it is enough to argue that `EdgeEstimation` returns an $(1 \pm \varepsilon)$-approximation to m when all $\mathcal{E}_1$, $\mathcal{E}_2$ and $\mathcal{E}_3$ holds.

Combining the output of `MulEstimation` over the κ iterations, we get,

$$\prod_{i=1}^{\kappa} \widehat{p}_i = \prod_{i=1}^{\kappa} p_i \cdot \prod_{i=1}^{\kappa} \left(1 + \frac{x_i}{4}\right)$$

Using the fact that for each $x_i \in (0, 1)$, it can be shown that

$$1 - \frac{\sum_{i=1}^{\kappa} x_i}{4} \leq \prod_{i=1}^{\kappa} \left(1 + \frac{x_i}{4}\right) \leq 1 + \sum_{i=1}^{\kappa} x_i$$

Since event $\mathcal{E}_3$ occurs,

$$\prod_{i=1}^{\kappa} p_i \cdot \left(1 - \frac{\varepsilon}{36}\right) \leq \prod_{i=1}^{\kappa} \widehat{p}_i \leq \prod_{i=1}^{\kappa} p_i \cdot \left(1 + \frac{\varepsilon}{9}\right)$$

Using the fact that for any $\varepsilon \in (0, 1/3)$, we have $1 - 3\varepsilon \leq (1 + \varepsilon)^{-1}$ and $(1 - \varepsilon)^{-1} \leq 1 + 3\varepsilon$. We get,

$$\left(1 - \frac{\varepsilon}{3}\right) \cdot \frac{1}{\prod_{i=1}^{\kappa} p_i} \leq \frac{1}{\prod_{i=1}^{\kappa} \widehat{p}_i} \leq \frac{1}{\prod_{i=1}^{\kappa} p_i} \cdot \left(1 + \frac{\varepsilon}{12}\right) \tag{7}$$

Since $\mathcal{E}_1$ occurs, i.e., $\mathcal{E}_{\text{bir}}$ occurs, $\widehat{m}_b$ satisfies the following:

$$\left(1 - \frac{\varepsilon}{3}\right) \cdot m(U_\kappa) \leq \widehat{m}_b \leq \left(1 + \frac{\varepsilon}{3}\right) \cdot m(U_\kappa) \tag{8}$$

Combining (7) and (8), we get,

$$\left(1 - \frac{\varepsilon}{3}\right)^2 \cdot \frac{m(U_\kappa)}{\prod_{i=1}^{\kappa} p_i} \leq \widehat{m} = \frac{\widehat{m}_b}{\prod_{i=1}^{\kappa} \widehat{p}_i} \leq \left(1 + \frac{\varepsilon}{12}\right)\left(1 + \frac{\varepsilon}{3}\right) \cdot \frac{m(U_\kappa)}{\prod_{i=1}^{\kappa} p_i}$$

Since, $p_i = \frac{m(U_i)}{m(U_{i-1})}$ for each $i \in [\kappa]$ and $U_0 = V$, $\frac{m(U_\kappa)}{\prod_{i=1}^{\kappa} p_i} = m(U_0) = m$. So, simplifying the above expression, we have

$$(1 - \varepsilon)\, m \leq \widehat{m} \leq (1 + \varepsilon)\, m. \qquad \blacktriangleleft$$

A Concentration Inequalities

We use the following concentration bounds.

▶ **Lemma 17** (Markkov's inequlaity, see [30]). *Let X be a random variable that assumes only nonnegative values. Then, for all $a > 0$*

$$\Pr[X \geq a] \leq \frac{\mathbb{E}[X]}{a}.$$

▶ **Lemma 18** (Chebyshev's inequality, see [30]). *Let X be a random variable and $a > 0$, Then*

$$\Pr[|X - \mathbb{E}[X]| > a] \leq \frac{\mathrm{Var}(X)}{a^2}.$$

▶ **Lemma 19** (Multiplicative Chernoff bound, see [30]). *Let $X_1, X_2, ..., X_t$ be i.i.d. random variables where $\Pr[X_i = 1] = p$ and $\Pr[X_i = 0] = 1 - p$ for all $i \in [t]$, and $X = \sum_{i\in[t]} X_i$. Then, we have*

$$\Pr[X \leq (1-\varepsilon)\,\mathbb{E}[X]] \leq \exp\left(-\frac{\varepsilon^2\,\mathbb{E}[X]}{3}\right) \qquad 0 \leq \varepsilon < 1$$

$$\Pr[X \geq (1+\varepsilon)\,\mathbb{E}[X]] \leq \exp\left(-\frac{\varepsilon^2\,\mathbb{E}[X]}{2}\right) \qquad \varepsilon \geq 0$$

▶ **Lemma 20** (Hoeffding's bound, see [30]). *Let $X_1, X_2, \ldots, X_t$ be independent random variables such that for all $i \in [t]$, $\mathbb{E}[X] = \mu$ and $\Pr[a \leq X_i \leq b] = 1$. Then*

$$\Pr\left[\left|\frac{1}{t}\sum_{i=1}^{t} X_i - \mu\right| \geq \varepsilon\right] \leq 2\exp\left(-\frac{2t\varepsilon^2}{(b-a)^2}\right).$$

▶ **Lemma 21** (See [22]). *Let f be any function of t independent random variables $Y_1, \ldots, Y_t$ and let $X_i = \mathbb{E}[f(Y_1, \ldots, Y_t)|Y_1, \ldots, Y_i]$ for $i \in [t]$ and $X_0 = \mathbb{E}[f(Y_1, \ldots, Y_t)]$. Let $\mathcal{B}$ be the event that there exists $i \in [t]$ such that $|X_i - X_{i-1}| > c_i$ where $c_1, \ldots, c_t$ are some non negative numbers. Let $S = \sum_{i=1}^{t} c_i^2$, then*

$$\Pr[|X_t - X_0| > s] \leq 2\exp\left(-\frac{s^2}{2S}\right) + \Pr[\mathcal{B}].$$

Glauber Dynamics for Random Field Ising Models on Bounded Degree Graphs

Yi Han
Institute for Advanced Study, Princeton, NJ, USA

Abstract

We study the ferromagnetic random field Ising model (RFIM) on a graph $G = (V, E)$ having maximal degree Δ, where the external field at each vertex is an i.i.d. random variable. When the random field distribution is sufficiently anti-concentrated, we prove that with high probability over the quenched randomness of the external field, the Glauber dynamics of this RFIM mixes in polynomial time as a consequence of a Poincaré inequality. This model is relevant to the Griffiths phase where the correlations decay exponentially fast in expectation over the quenched random field, but contraction does not hold point-wise due to the existence of weak fields that lead to low-temperature behavior. Previously, fast mixing of Glauber dynamics under large disorder was only proven on the integer lattice, and for RFIM on general graphs, only a sampling algorithm based on self-avoiding walks was known.

1 Introduction

Consider a finite graph $G = (V, E)$, the random field Ising model (RFIM) on G at inverse temperature $\beta > 0$ is defined as the following random probability measure on $\{-1, +1\}^V$:

$$\mu_G(\sigma) \propto \exp\{H(\sigma)\}, \quad \sigma \in \{-1, +1\}^V, \tag{1.1}$$

where H is the following Hamiltonian

$$H(\sigma) = \beta \sum_{(u,v)\in E} \sigma_u \sigma_v + \sum_{u\in V} h_u \sigma_u. \tag{1.2}$$

Here $h = (h_u)_{u\in V}$ are i.i.d. random variables. The vector h is called the external field, serving as a quenched source of disorder in this model.

There has been much recent attention on RFIM on (subgraphs of) the integer lattice $\mathbb{Z}^d$ in the statistical physics literature. In $d = 2$, the existence of an arbitrarily small random field is predicted by Imry and Ma [20] to suppress the low temperature phase of the zero field ($h = 0$) Ising model, so that uniqueness and decay of correlations hold for any $\beta > 0$. The prediction was confirmed by Aizenman and Wehr [1], who proved that the expected influence on the spin at the origin by different boundary conditions at distance r away should decay with r. For the Gaussian case $h_u \sim \mathcal{N}(0, \sigma^2)$, the breakthrough work [12] confirmed

that the influence decays exponentially in r at all $\beta > 0$ and $\sigma > 0$. This no longer holds for RFIM with dimension $d \geq 3$ and small disorder, where there is a phase transition as β varies. For small disorder, there is no decay of influence when $\beta = \infty$ [19] and when β sufficiently large [3], and this is recently proven throughout the entire low temperature regime [11].

Beyond the integer lattice, the RFIM on a general graph G has also attracted interest from a computational complexity perspective. For a large $\beta > 0$ and general external field h, estimating the partition function of μ_G up to a multiplicative error is a #BIS-hard problem in the worst case [4], and polynomial-time approximation algorithms are not expected to exist. However, the random field may turn this hard computational problem into a feasible one: for bounded degree graphs G and large enough σ where $h_u \sim \mathcal{N}(0, \sigma^2)$, [18] constructed a polynomial time approximation algorithm for the partition function of μ_G over a $1 - o(1)$ probability realization of the external fields h.

For a general graph G, it becomes much less tractable to study the influence decay of a RFIM with small or moderate disorder h_u (that is, smaller σ if $h_u \sim \mathcal{N}(0, \sigma^2)$). This is because current RFIM papers on $\mathbb{Z}^d$ that capture the influence decay at $d = 2$ or the phase change at $d = 3$ use the geometry of $\mathbb{Z}^d$ in a fundamental way and such a delicate description is hard to expect on a general graph G. As a natural next step, in this paper we study effective sampling algorithms for the RFIM μ_G on a general graph G. For sufficiently large disorder (say, larger σ), it is straightforward to verify the decay of correlations for this RFIM via a percolation argument.

In contrast, even for relatively large disorder, the RFIM still possesses major difficulties from a sampling perspective. We consider the Glauber dynamics for RFIM, where we recall that Glauber dynamics (introduced in [16]; see also [22] for more background) is a discrete time random process $(X_n(v))_{v \in V, n \in \mathbb{N}_+}$ reversible w.r.t. μ_G, that at each step n selects a vertex $v \in V$ uniformly with probability $\frac{1}{|V|}$ and then resamples $X_n(v)$ according to the conditional distribution

$$X_n(v) \sim \mu_G(\sigma_v \in \cdot \mid (\sigma_w)_{w \neq v} = (X_{n-1}(w))_{w \neq v}), \tag{1.3}$$

and where we set $X_n(w) = X_{n-1}(w)$ for all $w \neq v$. If we assume that all the $|h_u|$ are uniformly larger than some fixed constant, then it is straightforward to show that the Glauber dynamics for RFIM mixes in time $O(n \log n)$, as in [18], Theorem 7. However, in the typical RFIM setting, although most external fields h_u are large, there are large regions where the absolute values of external fields $|h_u|$ are small, and the Glauber dynamics does not contract at these vertices (see [18], Remark 7). To avoid this problem, [18] constructed a polynomial sampling algorithm for RFIM μ_G on general bounded degree graphs G utilizing the Weitz self-avoiding walk tree [24], which is a global algorithm that differs in spirit from the Glauber update rule. As a future direction, [18] asked whether one can use Markov chain based algorithms (such as Glauber dynamics) to effectively sample from RFIM.

For Glauber dynamics of RFIM on $\mathbb{Z}^d, d \geq 2$, [14] conducted a detailed study for the mixing time of μ_G and designed a sampling algorithm at weak disorder. Under a notion of weak spatial mixing that measures averaged influence decay within a ball, they constructed a polynomial time sampling algorithm for RFIM based on a weak Poincaré inequality for Glauber dynamics. Under a stronger notion of influence decay and in particular when random fields have large disorder (h_u have good anti-concentration), they prove that Glauber dynamics for μ_G mixes in polynomial time as a corollary of a full Poincaré inequality. However, the proof in [14] is highly dependent on the lattice structure of $\mathbb{Z}^d$ due to a coarse graining argument in Section 5, and in Section 4 also somewhat relies on a volume growth exponent on G that rules out graphs of exponential volume growth. Therefore, the Glauber dynamics of μ_G on general graphs G had remained open.

The main result of this paper is a Poincaré inequality for μ_G which implies polynomial time mixing for μ_G.

Let $\mathcal{E}_G$ denote the Dirichlet form of the (discrete time) Glauber dynamics, so that for any test function $\varphi : \{-1,+1\}^V \to \mathbb{R}$,

$$\mathcal{E}_G(\varphi,\varphi) := \frac{1}{2|V|}\sum_{\sigma\sim\sigma'}\frac{\mu_G(\sigma)\mu_G(\sigma')}{\mu_G(\sigma)+\mu_G(\sigma')}(\varphi(\sigma)-\varphi(\sigma'))^2, \tag{1.4}$$

so that the summation is taken over pairs $\sigma,\sigma' \in \{-1,1\}^V$ differing only at one coordinate. Then we define the spectral gap of the chain via

$$\mathbf{gap}_G := \inf_{\varphi}\frac{\mathcal{E}_G(\varphi,\varphi)}{\mathrm{Var}_G(\varphi)} \tag{1.5}$$

with the infimum taken over all test functions $\varphi : \{-1,1\}^V \to \mathbb{R}$ with non-zero variance.

1.1 Polynomial time mixing for Glauber dynamics of RFIM with large disorder

Before stating the main technical result, we outline the anti-concentration assumptions on the external field h in the following:

▶ **Assumption 1.1.** *Let $\Delta \geq 3$ and $p_0 \in (0,1)$ be a constant such that $p_0(\Delta-1) < 1$, let $K = K(p_0) > 0$ be a constant such that*

$$\rho = \rho(\beta,\Delta,K) := \frac{e^{\Delta\beta-K}}{e^{\Delta\beta-K}+e^{-\Delta\beta+K}}, \tag{1.6}$$

is less than $\frac{p_0}{4}$. Suppose that the RFIM μ_G with external field h is such that $(h_u)_{u\in V}$ are i.i.d. and such that

$$\mathbb{P}_h(|h_u| \leq K) < \frac{p_0}{2}.$$

We then denote by

$$\alpha_* = \frac{1}{2}\log\frac{(\Delta-2)^{\Delta-2}}{p_0(\Delta-1)^{\Delta-1}(1-p_0)^{\Delta-2}}.$$

Note that for fixed $\Delta > 0$, $\alpha_* \uparrow \infty$ as $p_0 \downarrow 0$.

For a graph $G = (V,E)$, we use $|V|$ for the number of vertices in G.

Our first main result on Glauber dynamics for RFIM for any bounded degree graph G is as follows:

▶ **Theorem 1.2.** *Let $G = (V,E)$ be a graph of degree at most Δ. Assume that Assumption 1.1 is satisfied for some $p_0 \in (0,1)$, then with $\mathbb{P}_h$- probability at least $1 - O_{\beta,\Delta,p_0}(\frac{1}{|V|})$ over the external field (here O_{β,Δ,p_0} denotes constants that may depend on β, Δ and p_0), the spectral gap of RFIM measure μ_G satisfies*

$$\mathbf{gap}_G \geq |V|^{-1}\exp\left(-\frac{16\beta\Delta\ln|V|}{\alpha_*}\right),$$

and the ϵ- mixing time of Glauber dynamics for μ_G is

$$t_{mix}(P,\epsilon) = O\left(|V|^{1+\frac{16\beta\Delta}{\alpha_*}}\left(\beta\Delta|V| + \|h\|_1 + \log(1/\epsilon)\right)\right).$$

Here $\|h\|_1 := \sum_{x\in V}|h_x|$.

▶ Remark 1.3. One may also consider the following more general model with different edge weights β_{uv}. Suppose that for each edge $(u,v) \in E$ we assign a constant $\beta_{uv} \in \mathbb{R}$ such that $|\beta_{uv}| \leq \beta$. Consider the following Hamiltonian $\widetilde{H}$ and Ising model $\mu_{\widetilde{G}}$:

$$\widetilde{H}(\sigma) = \sum_{(u,v)\in E} \beta_{uv}\sigma_u\sigma_v + \sum_{u\in V} h_u\sigma_u, \quad \mu_{\widetilde{G}}(\sigma) \approx \exp\{\widetilde{H}(\sigma)\}, \quad \sigma \in \{-1,1\}^V. \tag{1.7}$$

In the ferromagnetic case $\beta_{uv} \geq 0$ with nonconstant edge weights, the same strategy should be adaptable by using edge-dependent tilting rates. We do not pursue this extension here. However, when some $\beta_{uv} < 0$, the edge-tilt localization scheme that we will use breaks down, so Theorem 1.2 does not readily extend to non-monotone systems.

▶ Remark 1.4. We note that on the integer lattice $\mathbb{Z}^d$, [14], Section 5 obtained a mixing time $O(|V|^{1+o(1)})$ for a high probability realization of h via a coarse graining argument (they considered a continuous time Glauber dynamics where vertices are updated at rate 1, and we rewrite their runtime in the discrete setting). We consider much more general graphs (such as expander graphs), and by setting $p_0 > 0$ sufficiently small (so that $\frac{16\Delta\beta}{\alpha_*} \leq \epsilon$) we can achieve $O(|V|^{2+\epsilon})$ mixing time for any $\epsilon > 0$. Note that the spectral gap scales like $|V|^{-1-\epsilon}$ when $p_0 > 0$ is small, which is almost optimal up to the $\epsilon > 0$.

We also note that the anti-concentration condition is designed for a worst case percolation argument to work through, and thus may not be the weakest possible condition. Previous papers concerning a large external field also work under these types of conditions, see [18] and [14], Section 5.

1.2 Overview of the proof

The RFIM measure μ_G is difficult to study by itself since it does not satisfy the Dobrushin condition or standard notions of spectral independence when β is large. Motivated by the recent application of localization schemes of Chen and Eldan [9], we will seek a continuous (and stochastic) deformation of μ_G to a target measure that is already known to satisfy a functional inequality such as Poincaré inequality, and that the deformation approximately preserves certain statistics, such as variance, of μ_G.

How can we choose a proper localization scheme for RFIM? The first candidate choice is the stochastic localization scheme in [9] where we use a Brownian motion on the localizing path. The exact path of localization still requires a delicate choice: one standard deformation is to use the localization path to weaken the quadratic interaction, so that μ_G is deformed to

$$\nu_t^1(\sigma) \propto \exp\{\beta(1-t)\sum_{(u,v)\in E} \sigma_u\sigma_v + \sum_{u\in V}(h_u + y_u^1(t))\sigma_u\}, \quad \forall\sigma \in \{-1,+1\}^V,$$

where $(y_u^1(t))_{u\in V}$ is a random external field defined by stochastic integrals of the adjacency matrix of G with respect to a Brownian motion, see [9], Fact 14 for the formula. This deformation, while useful for many important models (cf. [15], [9]), does not work well for RFIM μ_G because the external field h_u is changed to a random external field $h_u + y_u^1(t)$ that differs at each time t, and the quadratic interaction is also changed along the path. We find it hard to uniformly control ν_t^1 over all realizations of the stochastic localization path $y_u^1(t)$ with respect to **a single quenched realization** of the external field $(h_u)_{u\in V}$. In contrast, in the RFIM setting the authors of [14] chose another stochastic localization path that fixes the quadratic interaction and changes only the external field. Then μ_G deforms to

$$\nu_t^2(\sigma) \propto \exp\{\beta\sum_{(u,v)\in E} \sigma_u\sigma_v + \sum_{u\in V}(h_u + y_u^2(t))\sigma_u\}, \quad \forall\sigma \in \{-1,+1\}^V.$$

The distribution of this random external field $y_u^2(t)$ follows $t\sigma^* + B_t$ where B_t is a standard Brownian motion at time t and σ^* is independently sampled from $\sigma^* \sim \nu_0^2$. In this second localization, although the external field gains more randomness, the quadratic form is unchanged and the property WSM(C) can be passed along the localization path in a high probability sense (but not for every realization of the localization path). Thanks to this high probability preservation of WSM(C), the authors of [14] can transfer functional inequalities for ν_T^2 for a large T back to weak functional inequalities for μ_G. This idea is called virtually increasing the external field since the measure ν_T^2 is a RFIM with the same quadratic term but having a much stronger disorder in the random field. Via this strong disorder, they used a coarse graining idea on $\mathbb{Z}^d$ to verify that, for a sufficiently large T, the measure ν_T^2 satisfies a Poincaré inequality. This transfers back into weak Poincaré inequalities for μ_G on $\mathbb{Z}^d$, which shows rapid mixing of Glauber dynamics from a warm start. Then they constructed a polynomial time sampling algorithm from μ_G via Glauber dynamics on increasingly large subsets of the graph. However, the final step of coarse graining of ν_T^2 significantly restricts the geometry of G where the algorithm converges.

We take a different view towards designing localizing schemes of RFIM measures on general graphs. We need a localization path that (1) maintains a good control of the relevant covariance/correlation matrix of ν_t along the localization path, and the estimate holds for any possible pinning with respect to a single quenched external field h; and (2) the terminal measure is easy to analyze. The very recent paper [8] introduced an edge field localization scheme which is a piecewise deterministic jump Markov process that does not use SDEs. Notably, this localization path does not change the external field of RFIM and allows a quenched probability control over h. The construction is as follows. We first re-parametrize RFIM as a probability measure on $\{0,1\}^V$ rather than $\{-1,+1\}^V$. Then for any target measure μ on $\{0,1\}^V$, proceed as follows. Pick a family of events on the configuration $\sigma \in \{0,1\}^V$: $A_{(u,v)} := \{\sigma_u = \sigma_v = 1\}$ for each edge $(u,v) \in E$. Let $\mathcal{A}$ denote the collection of these events $A_{(u,v)}$. For the configuration σ denote by

$$Z_{A_{(u,v)}}(\sigma) = \mathbf{1}_{\sigma \in A_{(u,v)}}, \quad Z(\sigma) = \{A_{(u,v)} \in \mathcal{A} : \sigma \in A_{(u,v)}\}.$$

We first sample $X \sim \mu$, then for each $A_{(u,v)} \in \mathcal{A}$ we independently sample a uniform random variable $U_{(u,v)} \sim \mathrm{Unif}[0,1]$. Then we define the set of events revealed at time t:

$$T_t := \{A_{(u,v)} \in \mathcal{A} : X \in A, U_{A_{(u,v)}} \le t\}.$$

Then the localization path is the following posterior distribution, for each $S \subset \mathcal{A}$:

$$\mu_t^S(\sigma) = \mathbb{P}(X = \sigma \mid T_t = S) \propto \mu(\sigma) \cdot (1-t)^{|Z(\sigma)|} \cdot \mathbf{1}[S \subset Z(\sigma)].$$

Then observe that μ_t^S is still an Ising model on G with vertices along edges that are associated to an event in S pinned at 1, and the quadratic interactions reduce from 4β to $4\beta + \ln(1-t)$. It remains to upper bound the operator norm of a certain correlation matrix of μ_t^S uniformly over all pinnings on S and uniformly over all quadratic interaction coefficients $4\beta + \ln(1-t)$ whenever it is within $[0, 4\beta]$. As the random external fields h are unchanged along the path, we can apply a percolation argument and take a grand coupling of all these tilted RFIM models to deduce, with very high probability over h, a uniform upper bound for operator norm of the correlation matrix. Finally, we take the terminal time $\theta_* = 1 - \exp(-4\beta)$, where the conditional measure is a product measure for any pinning S and approximate tensorization of variance directly follows. This approach only relies on a percolation argument and completely bypasses fine local geometries of $\mathbb{Z}^d$. Unlike other terminal-time choices

based on high-temperature tensorization, the current edge-field denoising flow is stopped when the posterior becomes a product measure; therefore, no separate high-temperature case results are needed.

1.3 Facts, notations and conventions

1.3.1 Graph distance and boundary

Let $G = (V, E)$ be a graph. For any two vertices $u, v \in V$ we use $d(u, v)$ to denote the graph distance between u and v in G.

For a subset $A \subset V$, denote by $\partial A := \{v \in G : v \notin A, \exists w \in A, (v, w) \in E\}$ the boundary of A. For any fixed configuration $\tau \in \{-1, 1\}^{\partial A}$ on ∂A, we denote by μ_A^τ the restriction of the Ising model μ_G to A with the boundary condition τ.

Let $(u, v) \in E$ be an edge of G, for any $l \in \mathbb{N}_+$ we denote by $B((u, v), l)$ the l-neighborhood of the edge (u, v):

$$B((u, v), l) := \{w \in G : d(w, u) \le l \text{ or } d(w, v) \le l\} = B(u, l) \cup B(v, l). \tag{1.8}$$

1.3.2 Markov chain mixing times

Let P be a Markov operator on Ω with invariant measure ν, P being reversible with respect to ν. Let μ be an initial distribution that is absolutely continuous with respect to ν.

The total-variation mixing time is defined by

$$t_{mix}(P, \epsilon; \mu) = \min\{t > 0; |P^t[\mu](A) - \nu(A)| \le \epsilon, \forall A \subset \Omega\},$$

and we set

$$t_{mix}(P, \epsilon) = \max_{x \in \Omega} t_{mix}(P, \epsilon, \delta_x).$$

Then we have the following standard fact, see, for example, [21, Chapters 12–13]:

▶ **Fact 1.5.** *Assume that for all $x \in \Omega$, $\nu(\{x\}) \ge \eta$. Then*

$$t_{mix}(P, \epsilon) \le C\mathbf{gap}(P)^{-1}(\log(1/\eta) + \log(1/\epsilon)),$$

and

$$t_{mix}(P, \epsilon) \le C\rho_{LS}(P)^{-1}(\log\log(1/\eta) + \log(1/\epsilon)).$$

1.3.3 FKG and coupling

If we assume that all the RFIM interactions are positive, then μ_G satisfies useful correlation inequalities including the FKG inequality. That is, for a subset $A \subset V$ and a non-decreasing function $\varphi : \{-1, 1\}^A \to \mathbb{R}$, the mean of φ is monotone in the boundary condition: $\mu_A^\tau(\varphi) \le \mu_A^{\tau'}(\varphi)$ whenever boundary conditions satisfy $\tau \le \tau'$ pointwise.

Again assuming monotonicity, for the two boundary conditions $\tau \le \tau'$, it is standard to use the monotone coupling to couple μ_A^τ and $\mu_A^{\tau'}$. Specifically, we fix an ordering $v_1, \cdots, v_k$ of vertices in A and we then draw uniform random variables $U_1, \cdots, U_k$ independently. Then the coupling $(\sigma^\tau, \sigma^{\tau'})$ can be constructed sequentially where for each $i \ge 1$ we shall sample $\sigma_{v_i}^\tau$, $\sigma_{v_i}^{\tau'}$ from the conditional distributions given $(\sigma_{v_j}^\tau)_{j<i}$, τ and $(\sigma_{v_j}^{\tau'})_{j<i}, \tau'$ where we use the common randomness in U_i. The coupling is clearly monotone in the boundary conditions: $\sigma^\tau \le \sigma^{\tau'}$ whenever $\tau \le \tau'$.

Without assuming monotonicity, let $A \subset V$ and consider a class of Ising measures $\mu_1, \mu_2, \cdots, \mu_t$ on A with boundary conditions $\tau_1, \cdots, \tau_t$ on ∂A, where each Ising measure may have different interactions and external fields, and each μ_i may be further pinned at some $A_i \subset A$ by some value $\tau_i' \in \{-1,1\}^{A_i}$. Then we can use the same uniform random variable to couple $\mu_1, \cdots, \mu_t$ as above. Specifically, we again fix an ordering $v_1, \cdots, v_k$ of A and draw uniform random variables $U_1, \cdots, U_k$ independently. Then we construct a coupling of $(\sigma^1, \cdots, \sigma^t)$ where $\sigma^1 \sim \mu_1, \cdots, \sigma^t \sim \mu_t$ sequentially so that for each $i \geq 1$ we sample $\sigma^1_{v_i}, \cdots, \sigma^t_{v_i}$ from their respective conditional distributions given $(\sigma^r_{v_j})_{j<i}, 1 \leq r \leq t$ and $\tau_1, \cdots, \tau_t$, using U_i as common randomness. If v_i is already pinned in μ_r then we output the pinned value for $\sigma^r_{v_i}$.

1.4 Change of coordinates for RFIM

The current RFIM measure is defined on $\{-1,+1\}^V$ but we will frequently change its coordinates to a measure on $\{0,1\}^V$. The following fact summarizes the change of coordinates:

▶ **Fact 1.6.** *Let μ_G be the RFIM measure* (1.1) *defined on $\{-1,+1\}^V$. Then it admits an equivalent expression*

$$\mu_G(\sigma') \propto \exp\{4\beta \sum_{(u,v)\in E} \sigma'_u\sigma'_v + \sum_u (2h_u - 2\beta d_u)\sigma'_u\}, \quad \forall \sigma' \in \{0,1\}^V,$$

where $\sigma'_u = \frac{\sigma_u+1}{2}$ for each $u \in V$. Here d_u is the degree of u in G for each $u \in V$. Similarly, the RFIM measure $\mu_{\widetilde{G}}$ defined in (1.7) *admits an equivalent expression*

$$\mu_{\widetilde{G}}(\sigma') \propto \exp\{4 \sum_{(u,v)\in E} \beta_{uv}\sigma'_u\sigma'_v + \sum_u (2h_u - 2 \sum_{v:(u,v)\in E} \beta_{uv})\sigma'_u\}, \quad \forall \sigma' \in \{0,1\}^V.$$

Namely, after the change of coordinates, the external fields are shifted by a deterministic, vertex dependent constant but remain independent.

2 Edge-field localization schemes and spectral independence

In this section we introduce the general framework of edge tilted localization process of [8]. Then we introduce an edge field localization process for the RFIM μ_G and provide criteria for its spectral stability.

2.1 Entropy conservation and localization schemes

Consider a domain $D \subseteq \mathbb{R}$ and a convex function $\phi : D \to \mathbb{R}$. Consider μ a distribution on a finite set Ω and sample $X \sim \mu$. For any real-valued function $f : \Omega \to \mathbb{R}$, define the ϕ-entropy of f with respect to μ by

$$\mathrm{Ent}^\phi_\mu[f] := \mathrm{Ent}^\phi[f(X)] := \mathbb{E}[\phi(f(X))] - \phi(\mathbb{E}[f(X)]).$$

If ν is a probability measure on Ω absolutely continuous with respect to μ, we define the ϕ-divergence between ν and μ via

$$D_\phi(\nu \,||\, \mu) := \mathrm{Ent}^\phi_\mu\left[\frac{\nu}{\mu}\right].$$

In this paper we focus on the following two specific cases

- $\phi(x) = \chi^2(x) := x^2$, so that χ^2-entropy of f is equivalent to the variance of f, and
- $\phi(x) = \mathbf{KL}(x) := x \log x$, which induces the KL-divergence

$$D_{KL}(\nu \,||\, \mu) = \sum_{\sigma\in\Omega} \nu(\sigma) \log \frac{\nu(\sigma)}{\mu(\sigma)}.$$

We now introduce some notations from [8] on the conservation and decay of entropy for a Markov operator. To be consistent with the notations in [8], we use the state space $\{0,1\}^n$ rather than $\{-1,1\}^n$. The formula for the RFIM measure μ_G on the new coordinate $\{0,1\}^n$ is explicitly written in Fact 1.6.

▶ **Definition 2.1** (Approximate tensorization of ϕ-entropy). *We say that a distribution μ on $\{0,1\}^n$ satisfies K-approximate tensorization of ϕ-entropy if for any function $f : \Omega \to \mathbb{R}$ and any $X \sim \mu$,*

$$\mathrm{Ent}^{\phi}[f(X)] \leq K \cdot \sum_{i=1}^{n} \mathbb{E}[\mathrm{Ent}^{\phi}[f(X) \mid X_{-i}]],$$

where we denote by X_{-i} the configuration X restricted to $[n] \setminus \{i\}$.

▶ **Definition 2.2** (Decay of entropy). *Consider a Markov chain $(X_t)_{t\geq 0}$ on Ω having transition matrix P and stationary distribution μ. Then we say that it satisfies decay of ϕ-entropy with rate κ if for all functions $f : \Omega \to \mathbb{R}$,*

$$\mathrm{Ent}_{\mu}^{\phi}[Pf] \leq (1-\kappa)\,\mathrm{Ent}_{\mu}^{\phi}[f].$$

Then we introduce the general notion of a localization process in [8]. We will later specify the exact localization scheme that we shall use.

▶ **Definition 2.3.** *Consider μ a probability distribution on Ω. Then a localization scheme having μ as target distribution is made up of a pair of continuous time processes:*

- *The noising process $(X_t)_{t\in[0,1]}$. This is a Markov process such that $X_0 \sim \mu$ and X_1 follows a Dirac measure.*
- *A denoising process $(Y_t)_{t\in[0,1]}$. This process is defined as the reversal of $(X_t)_{t\in[0,1]}$: $Y_\theta = X_{1-\theta}$. Thus Y_0 is a Dirac measure and $Y_1 \sim \mu$.*

Since X_t is a time reversal of Y_t, we use the denoising process $(Y_t)_{t\in[0,1]}$ to represent the localization scheme and call it the localization process.

We would like the localization path Y_t to have the following nice property:

▶ **Definition 2.4** (Approximate conservation of ϕ-entropy). *For a given denoising process $(Y_t)_{t\in[0,1]}$ and $\theta \in [0,1]$, the process $(Y_t)_{t\in[0,1]}$ satisfies R-conservation of ϕ-entropy up to time θ if for all functions $f : \Omega \to \mathbb{R}_+$,*

$$\mathrm{Ent}^{\phi}[f(Y_1)] \leq R \cdot \mathbb{E}[\mathrm{Ent}^{\phi}[f(Y_1) \mid Y_\theta]].$$

This general notion of localization schemes gives rise to a boosting of mixing properties from a parameter regime where mixing is known, to a new parameter regime where we expect to prove mixing.

▶ **Lemma 2.5** ([6], Lemma 3.13). *Consider $(Y_t)_{t\in[0,1]}$ a denoising process for a distribution μ. Assume we can find some $\theta \in [0,1]$ such that*

1. *The conditional distribution $\mathrm{Law}(Y_1 \mid Y_\theta)$ satisfies K-approximate tensorization of ϕ-entropy.*
2. *The denoising process $(Y_t)_{t\in[0,1]}$ satisfies R-approximate conservation of ϕ-entropy up to time θ.*

Then μ satisfies (KR)-approximate tensorization of ϕ-entropy.

The following property is very useful in verifying approximation conservation of ϕ-entropy:

▶ **Definition 2.6.** *Consider the denoising process $(Y_t)_{t\in[0,1]}$ for a measure μ on Ω. Then the process $(Y_t)_{t\in[0,1]}$ is said to be ϕ-entropically stable with rate C at $\theta \in [0,1]$ if for any given function $f : \Omega \to \mathbb{R}$, denoting by $F = f(Y_1)$, then for any configuration T with $\mathbb{P}(Y_\theta = T) > 0$, we have*

$$\lim_{h\to 0^+} \frac{1}{h} \operatorname{Ent}^\phi[\mathbb{E}[F \mid Y_{\theta+h}] \mid Y_\theta = T] \le \frac{C}{1-\theta} \operatorname{Ent}^\phi[F \mid Y_\theta = T].$$

The property of ϕ-entropic stability implies approximate conservation of ϕ-entropy, as outlined in the following lemma:

▶ **Lemma 2.7** ([6], Theorem 3.16)**.** *Given $C : [0,1] \to \mathbb{R}_{\ge 0}$. Assume that a denoising process $(Y_t)_{t\in[0,1]}$ is ϕ-entropically stable with rate $C(t)$ throughout $t \in [0,1]$. Then for each given $\theta \in [0,1]$, the process $(Y_t)_{t\in[0,1]}$ will satisfy R-approximate conservation of ϕ-entropy up to time θ where we take*

$$R = \exp\left(\int_0^\theta \frac{C(t)}{1-t} dt\right).$$

Therefore, in order to deduce approximate tensorization of ϕ-entropy of μ, we only need to construct a denoising process Y_t which is ϕ-entropically stable.

From approximate tensorization to functional inequalities for Glauber dynamics

We recall here the fact that approximate tensorization of variance (χ^2 entropy) implies a Poincaré inequality for Glauber dynamics:

▶ **Fact 2.8.** *A distribution μ on $\{0,1\}^n$ satisfies C_1- approximate tensorization of variance if and only if the spectral gap for the Glauber dynamics for μ satisfies $\mathbf{gap}_{GL} \ge \frac{1}{C_1 n}$.*

A similar statement holds for modified log-Sobolev inequalities:

▶ **Fact 2.9** ([10], Fact 3.5)**.** *If a distribution μ on $\{0,1\}^n$ satisfies C_1- approximate tensorization of entropy, then the modified log-Sobolev inequality holds for the Glauber dynamics with constant $\rho_0 \ge \frac{1}{C_1 n}$.*

2.2 A special case: vertex field denoising

An important case of localization schemes is the vertex-tilting field dynamics introduced in [7]. Our edge-tilting localization scheme will also be built on this vertex field version, so we give a quick review here. We consider distributions on $\{0,1\}^n$ and identify a configuration $\sigma \in \{0,1\}^n$ with the subset $\{v \in [n] : \sigma_v = 1\}$.

▶ **Definition 2.10.** *Consider a distribution μ on $\{0,1\}^n$ and a sample $X \sim \mu$. Assign, for each $v \in [n]$, an independent random variable $U_v \sim \mathrm{Uniform}[0,1]$. Then the vertex field denoising process with respect to μ is defined by the following process $(Y_t)_{t\in[0,1]}$:*

$$Y_t := \{v \in [n] : X_v = 1 \wedge U_v \le t\}.$$

For a $\theta \in [0,1]$, the tilted distribution $\theta * \mu$ is defined as

$$(\theta * \mu)(\sigma) \propto \mu(\sigma) \cdot \theta^{|\sigma|}, \quad \forall \sigma \in \{0,1\}^n,$$

where $|\sigma| := |\{v \in [n] : \sigma_v = 1\}|$.

▶ **Lemma 2.11** ([8], Proposition 2.14). *For a distribution μ, let $(Y_t)_{t\in[0,1]}$ be the corresponding vertex field denoising process. Then we have*

$$\mathrm{Law}(Y_1 \mid Y_t) = (1-t) * \mu^{Y_t},$$

such that μ^{Y_t} is the conditional law obtained by setting all variables in Y_t pinned to be 1.

Spectral stability of vertex-field denoising process has the following characterization:

▶ **Lemma 2.12** ([5], Proposition 3.3). *Let $(Y_t)_{t\in[0,1]}$ be a vertex-field denoising process with respect to μ on $\{0,1\}^n$. Then for any fixed $\theta \in [0,1]$, the following two claims are equivalent:*

- *$(Y_t)_{t\in[0,1]}$ is spectrally stable with rate C at time θ;*
- *Given any subset S with $\mathbb{P}[Y_\theta = S] > 0$,*

$$\mathrm{Cov}((1-\theta) * \mu^S) \lesssim C \cdot \mathrm{diag}\{\mathbf{m}((1-\theta) * \mu^S)\},$$

where for a distribution ν, $\mathbf{m}(\nu) := \mathbb{E}_{X\sim\nu}[X]$ is its mean vector.

2.3 Edge-field tilting and its localization schemes

The vertex-field denoising process introduced in the last section changes the strength of the external field of an Ising model but keeps quadratic interaction unchanged. This is not sufficient for the RFIM where we wish to weaken the quadratic interaction but to keep the external field fixed. The recent paper [8] pointed out that our goal can be fulfilled by considering a tilting of the edge-field instead of vertex-field, so we remove edges rather than vertices. Before presenting our concrete constructions of edge-field denoising, we outline the abstract framework of [8].

For a given distribution μ on $\{0,1\}^V$ where V is a ground set, let $\mathcal{A}$ be a collection of events, so that each $A \in \mathcal{A}$ is a subset of $\{0,1\}^V$. We take $X \sim \mu$ and for any event $A \in \mathcal{A}$ define $Z_A = Z_A(X) := \mathbf{1}[X \in A]$. Let $Z = Z(X) := (Z_A)_{A\in\mathcal{A}}$.

We let π denote the joint distribution of (X, Z), so that

$$\pi := \mathrm{Law}(X, Z(X)),$$

so that π is a distribution over $\{0,1\}^{V\cup\mathcal{A}}$. Then by construction, $\mu = \pi_V$ and $\mathrm{Law}(Z) = \pi_{\mathcal{A}}$.

▶ **Definition 2.13** (Event-field dynamics, [8]). *Let $\theta \in [0,1]$. The event-field dynamics for μ with respect to $\mathcal{A}$ and tilt θ is the following defined Markov chain on the state space $\Omega(\mu)$:*

From the current state $X_t \in \Omega(\mu)$, the next state X_{t+1} is generated via

1. *($V \to \mathcal{A}$). Set $Z_t := Z(X_t) = \{A \in \mathcal{A} \mid X_t \in A\}$.*
2. *(Down-$\mathcal{A}$) Then generate a random subset $T \subset Z_t$ where we independently remove each $A \in Z_t$ with probability θ;*
3. *(Up-$\mathcal{A}$) Sample $Z_{t+1} \sim (\theta * \pi_{\mathcal{A}})(\cdot \mid Z_{t+1} \supseteq T)$, where we define*

$$\theta * \pi_{\mathcal{A}}(Z) \propto \pi_A(Z) \cdot \prod_{A\in\mathcal{A}} \theta^{\mathbf{1}(Z_A=1)}, \quad \forall Z \in \{0,1\}^{\mathcal{A}},$$

the distribution obtained from $\pi_{\mathcal{A}}$ by tilting the occurrence of each event A by θ.

4. *Sample $X_{t+1} \sim \pi_V(\cdot \mid Z_{t+1})$.*

The only example that we will use in this paper is the following edge-field dynamics:

▶ **Example 2.14** (Edge-field dynamics)**.** Let $G = (V, E)$ be a graph and μ a distribution on $\{0,1\}^V$. We set

$$\mathcal{A} := \{A_{uv} \mid (u,v) \in E\}, \quad \text{where } A_{uv} := \{\sigma : \sigma_u = \sigma_v = 1\}, \quad \forall (u,v) \in E.$$

Given $T \subseteq \mathcal{A}$ generated in the (Down-$\mathcal{A}$) step, we can compute that

$$\mathbb{P}(X_{t+1} = \sigma \mid T) \propto \mu(\sigma) \cdot \theta^{|\mathcal{A}(\sigma)|} \cdot \mathbf{1}[\mathcal{A}(\sigma) \supseteq T],$$

where $\mathcal{A}(\sigma) := \{A_{uv} \in \mathcal{A} : \sigma \in A_{uv}\}$.

Next we recall the definition of an event-field denoising process from [8]. This is mostly a projection of the vertex-field denoising process on the collection of events $\mathcal{A}$.

▶ **Definition 2.15** (Event-field denoising)**.** *Let μ be a distribution on $\{0,1\}^V$ and consider a collection of events $\mathcal{A}$. Denote by π the joint distribution on $\{0,1\}^{V \cup \mathcal{A}}$ and let $(Y'_t)_{t\in[0,1]}$ be the vertex-field denoising process for the marginal $\pi_{\mathcal{A}}$ with $\pi_{\mathcal{A}} = \mathrm{Law}(Y'_1)$. Then event-field denoising process for μ through $\mathcal{A}$, which we denote by $(Y_t)_{t\in[0,1]}$ is defined via*
1. *Sample $Y_1 \sim \pi_V(\cdot \mid Y'_1)$,*
2. *For $t \in [0,1)$, we set $Y_t = Y'_t$.*

In other words, the process follows the vertex field denoising process applied to the event indicators, and finally at $t = 1$ projects onto the vertices in V via the conditional law $\pi_V(\cdot \mid Y'_1)$.

Since $Y_t = Y'_t$ for all $t \in [0,1)$, the spectral stability of $(Y'_t)_{t\in[0,1]}$ implies the spectral stability of $(Y_t)_{t\in[0,1]}$:

▶ **Lemma 2.16** (ϕ-Entropic stability upgrades, [8], Proposition 4.12)**.** *Let $(Y_t)_{t\in[0,1]}$ and $(Y'_t)_{t\in[0,1]}$ be the two denoising processes in Definition 2.15. Then for any $\theta \in [0,1)$, suppose that $(Y'_t)_{t\in[0,1]}$ is ϕ-entropically stable with rate C at time θ, then $(Y_t)_{t\in[0,1]}$ is also ϕ-entropically stable with rate C at time θ.*

Then we specialize to the edge-field dynamics in Example 2.14 and define its own denoising process:

▶ **Definition 2.17** (Edge-field denoising process)**.** *Let $G = (V, E)$ be a graph and μ a distribution on $\{0,1\}^V$. Recall that we define*

$$\mathcal{A} := \{A_{uv} \mid (u,v) \in E\}, \quad \textit{where } A_{uv} := \{\sigma : \sigma_u = \sigma_v = 1\}, \quad \forall (u,v) \in E.$$

Let $(Y_t)_{t\in[0,1]}$ be the event-field denoising process for μ with respect to this family $\mathcal{A}$. Then the resulting process $(Y_t)_{t\in[0,1]}$ is called the edge-field denoising process for μ on G.

In the following, we give an explicit description of the process Y_t. We shall use a notation $\theta \otimes \mu$ for the distribution obtained by tilting the interactions by a factor $\theta > 0$:

$$\theta \otimes \mu(\sigma) \propto \mu(\sigma) \cdot \theta^{m(\sigma)}, \quad \forall \sigma \in \{0,1\}^V,$$

where we denote by $m(\sigma) := |\{(u,v) \in E : \sigma_u = \sigma_v = 1\}|$ the number of edges whose two endpoints are both equal to 1.

The edge field denoising process $(Y_t)_{t\in[0,1]}$ satisfies that its posterior distribution is the target distribution μ with tilted interaction:

▶ **Proposition 2.18.** *Let $(Y_t)_{t\in[0,1]}$ denote the edge-field denoising process. Then its posterior distribution satisfies*

$$\mathrm{Law}(Y_1 \mid Y_t) = (1-t) \otimes \mu^{Y_t},$$

where we recall that μ^{Y_t} denotes the conditional law of μ conditioning on the event that for every edge $(u,v) \in E$ with $Y_t(u,v) = 1$, then A_{uv} occurs, so that $\sigma_u = \sigma_v = 1$.

Proof. For any $\sigma \in \{0,1\}^V$, denote by $Z(\sigma) \in \{0,1\}^{\mathcal{A}}$ the vector that indicates whether each $A_{uv} \in \mathcal{A}$ occurs in the configuration σ. Take $X \sim \mu$, recall that $\pi := \mathrm{Law}(X, Z(X))$ on $\{0,1\}^{V\cup\mathcal{A}}$.

Let (Y'_t) be the vertex-field denoising process for $\pi_{\mathcal{A}}$. Then for any configuration T,

$$\begin{aligned}
&\mathbb{P}[Y_1 = \sigma \mid Y_t = T] \\
&= \mathbb{P}[Y_1 = \sigma \mid Y'_1 = Z(\sigma)] \cdot \mathbb{P}[Y'_1 = Z(\sigma) \mid Y'_t = T] \\
&\propto \mathbb{P}[Y_1 = \sigma \mid Y'_1 = Z(\sigma)] \cdot (1-t)^{|Z(\sigma)|} \cdot \pi_{\mathcal{A}}(Z(\sigma)) \cdot \mathbf{1}[T \subseteq Z(\sigma)] \\
&\propto (1-t)^{m(\sigma)} \cdot \pi(\sigma, Z(\sigma)) \cdot \mathbf{1}[T \subseteq Z(\sigma)].
\end{aligned}$$

This implies $\mathrm{Law}(Y_1 \mid Y_t) = (1-t) \otimes \mu^{Y_t}$ since σ determines $Z(\sigma)$. ◀

2.4 Spectral stability of edge-field dynamics

Thanks to Lemma 2.16, we only need to prove the spectral stability of the denoising process Y'_t. Motivated by the criterion in Lemma 2.12, we define the following correlation matrix for Y'_t:

▶ **Definition 2.19.** *(Second-order correlation matrix) Let μ be a distribution on $\{0,1\}^V$ and $G = (V,E)$ be a graph. Then for $u, v \in V$, denote by uv the event that*

$$uv := \{\sigma \in \{0,1\}^V \mid \sigma_u = \sigma_v = 1\}.$$

Then we define the second order correlation matrix $\mathrm{Cor}^{(2)}_\mu \in \mathbb{R}^{E\times E}$ via

$$\forall (u,v),(w,z) \in E, \quad \mathrm{Cor}^{(2)}_\mu(uv, wz) := \begin{cases} \mu(wz \mid uv) - \mu(wz), & \text{if } \mu(uv) > 0, \\ 0, & \text{otherwise.} \end{cases}$$

▶ Remark 2.20. We define the correlation matrix $\mathrm{Cor}^{(2)}_\mu$ in this form due to the following fact: let μ be a distribution on $\{0,1\}^V$, then $(\mathrm{diag}(\mathbb{E}(\mu)))^{-1} \cdot \mathrm{Cov}_\mu = \mathrm{Cor}_\mu$.

Although $\mathrm{Cor}^{(2)}_\mu$ is not a symmetric matrix, its eigenvalues are all real.

Then we can translate spectral stability into the following criterion:

▶ **Corollary 2.21.** *(Spectral stability via second-order correlations) Let $(Y_t)_{t\in[0,1]}$ denote the edge-field denoising process for μ on the graph $G = (V,E)$. Then for fixed $\theta \in (0,1)$, assume that for every $\Lambda \subset V$ and any feasible pinning $\tau \in \Omega(\mu_\Lambda)$ we have that*

$$\lambda_{max}(\mathrm{Cor}^{(2)}_{(1-\theta)\otimes\mu^\tau}) \le C,$$

then the process $(Y_t)_{t\in[0,1]}$ is spectrally stable with rate C at time θ.

Proof. This follows from combining Definition 2.15, Lemma 2.16 and Lemma 2.12. Note that a conditioning on the event field events A_{uv} is equivalent to conditioning on the vertex events $\sigma_u = \sigma_v = 1$. ◀

2.5 Approximate tensorization at the end of the flow

We first record how the parameter of RFIM model changes under the edge-field denoising process:

▶ **Fact 2.22.** *Let μ be the RFIM measure μ_G. Then for any $\theta \in (0,1)$ and any pinning τ, the Ising measure $(1-\theta)\otimes\mu^\tau$ has quadratic coefficient $4\beta + \ln(1-\theta)$ (on the coordinate $\{0,1\}^V$ in its Hamiltonian form) on edges of G whose both endpoints are not pinned by τ. In particular, when we take $\theta_* = 1-\exp(-4\beta)$, then $(1-\theta_*)\otimes\mu^\tau$ is a product measure.*

Proof. By Fact 1.6, in the coordinate $\{0,1\}^V$ the quadratic coefficient of $\mu = \mu_G$ in the Hamiltonian is 4β. For each unpinned edge, the denoising process Y_t shrinks the probability by multiplying by $1-\theta$ before normalizing, which means changing 4β to $4\beta + \ln(1-\theta)$ in the Hamiltonian coefficient. ◀

For sake of completeness, we note here that when β is sufficiently small, this model is within the realm of spectral independence where approximate tensorization of variance directly follows. We, however, do not use this estimate as we stop the denoising process at θ_* where the conditional law is the product measure.

▶ **Lemma 2.23.** *Let $G=(V,E)$ be a graph of maximal degree at most Δ, and for each $(u,v)\in E$ we are given constants β_{uv} where $|\beta_{uv}|\le\beta$ for all edges. Fix an arbitrary external field $h=(h_u)_{u\in V}$, an arbitrary subset $A\subset V$ and configuration $\tau\in\{0,1\}^A$. Then whenever $\beta\le\frac{1}{\Delta}$, the measure $\mu_{\beta,h}$ defined on $\{0,1\}^{V\setminus A}$ via*

$$\mu_{\beta,h}(\sigma)\propto\exp\Big(\sum_{(u,v)\in E}\beta_{uv}\sigma_u\sigma_v+\sum_{u\in V\setminus A}h_u\sigma_u\Big),\quad\forall\sigma\in\{0,1\}^V:\sigma|_A=\tau$$

satisfies approximate tensorization of variance and approximate tensorization of entropy with constant 2.

Proof. Let Q denote the quadratic interaction matrix in $\mu_{\beta,h}$ where $Q_{uv}=\beta_{uv}$ if $(u,v)\in E$ and $u\notin A$ and $v\notin A$, and set $Q_{uv}=0$ otherwise. Then $\lambda_{max}(Q)\le\beta\Delta$ and $\lambda_{min}(Q)\ge-\beta\Delta$, where $\lambda_{min}(Q),\lambda_{max}(Q)$ are the smallest and largest eigenvalues of Q. Then via Fact 1.6, we can rewrite $\mu_{\beta,h}$ as an Ising model on $\{-1,1\}^V\setminus A$ where the quadratic interaction matrix is $\frac{1}{4}Q$. Then by [2], Theorem 12, $\mu_{\beta,h}$ satisfies approximate tensorization of variance and entropy with constant $\frac{1}{1-(\lambda_{max}(\frac{1}{4}Q)-\lambda_{min}(\frac{1}{4}Q))}\le 2$. ◀

Now we summarize what we have gotten so far, and what remains to be proven in the remaining sections. We will apply the edge field denoising process Y_t to the RFIM μ_G, where we take

$$\theta_* = 1-\exp(-4\beta) \tag{2.1}$$

as a threshold value. This value of θ_* is fixed throughout the paper. We need to upper bound the integral in R in Lemma 2.7 up to time θ_*, and then tensorization of variance/entropy is free for $\mathrm{Law}(Y_1 \mid Y_{\theta_*})$ since the latter is a product measure. For the integral in R, by Proposition 2.18, it suffices to control the second correlation matrix for $(1-\theta)\otimes\mu^\tau$ for all $0\le\theta\le\theta_*$ and all pinning τ. In the next section, we will focus on the operator norm control of that matrix.

3 The spectral norm of correlation matrix with a random field

In this section, we make the following assumption on the external field of RFIM, which is more general than Assumption 1.1 as we only require $|h_v|$ to be independent, but the signs of h_v are not necessarily independent.

▶ **Assumption 3.1.** *Let $p_0 \in (0,1)$ be given such that $p_0(\Delta-1)<1$, let $K = K(p_0) > 0$ be a constant such that*

$$\rho = \rho(\beta, \Delta, K) := \frac{e^{\Delta\beta - K}}{e^{\Delta\beta - K} + e^{-\Delta\beta + K}}, \tag{3.1}$$

is less than $\frac{p_0}{4}$. Suppose that the RFIM μ_G with external field h is such that $(|h_u|)_{u\in V}$ are i.i.d. and such that

$$\mathbb{P}_h(|h_u| \le K) < \frac{p_0}{2}.$$

▶ **Proposition 3.2.** *Let $(u,v) \in E$ be any edge of the graph $G=(V,E)$ of maximal degree Δ. Assume that Assumption 3.1 holds for the given $p_0 \in (0,1)$, then we have, for any $m \ge 1$,*

$$\begin{aligned} &\mathbb{P}\left(\sup_{\theta\in[0,\theta_*],\Lambda,\tau_0\in\Omega(\Lambda)} \sum_{(wz)\in E} |\operatorname{Cor}^{(2)}_{(1-\theta)\otimes\mu^{\tau_0}}(uv,wz)| \ge \Delta m \right) \\ &\le \frac{2}{(1-e^{-\alpha_*})(1-e^{-2\alpha_*})} e^{2\gamma_*} e^{-\alpha_* m}, \end{aligned} \tag{3.2}$$

where $\gamma_* := \ln \frac{1-p_0}{p_0(\Delta-2)}$ and $\alpha_* = \frac{1}{2}\log \frac{(\Delta-2)^{\Delta-2}}{p_0(\Delta-1)^{\Delta-1}(1-p_0)^{\Delta-2}}$.

Proof. For fixed edge (u,v) and the Ising measure $\nu := (1-\theta)\otimes\mu^{\tau_0}$, we construct a coupling of two spins $\sigma^1 \sim \nu$ and $\sigma^2 \sim \nu(\cdot \mid uv)$, where in σ^2 the vertices u, v are both fixed to be 1 and then we reveal σ^1 at u,v and then reveal both σ^1, σ^2 at vertices in $V\setminus\{u,v\}$. Assign uniform random variables $U_x, x\in V$ at each vertex of V, and generate $(\sigma^1)_u$ by the given probability law of ν, then generate $(\sigma^1)_v$ by the given probability law of ν conditioning on σ^1_u. Then we iteratively reveal the vertices of distance 1 to (u,v) in both configurations σ^1,σ^2 in any given sequence, and update the value of σ^1 and σ^2 with respect to the probability laws ν and $\nu(\cdot\mid uv)$, conditioning on the vertices already revealed. Use the same uniform random variable to update each vertex. Note that when we update both σ^1 and σ^2 at $w\neq u,v$, then when $|h_w|>K$, then the probability that the updated spins in σ^1,σ^2 have the sign of h_w is at least $1-\frac{p_0}{4}$, by Assumption 3.1. (the probability that σ^i_w has the same sign as h_w can be computed in the original coordinate $\{-1,1\}^V$ where the expression $\rho(\beta,\Delta,K)$ in Assumption 3.1 is more apparent) Therefore, the subset of V where σ^1 and σ^2 disagree is controlled by the connected component of (u,v) in the percolation process

$$\{|h_x| \le K\} \cup \{\min(U_x, 1-U_x) \le \frac{p_0}{4}\} \tag{3.3}$$

at each $x\in V$, since outside this connected component, σ^1 and σ^2 are updated via the identity coupling. By definition of total variation distance, we have

$$|\operatorname{Cor}^{(2)}_\nu(uv,wz)| \le \mathbb{P}(\sigma^1_{wz} \neq \sigma^2_{wz}) \le \mathbb{P}(\sigma^1_w \neq \sigma^2_w) + \mathbb{P}(\sigma^1_z \neq \sigma^2_z)$$

for our specific coupling (here $\sigma^1_{wz}\neq\sigma^2_{wz}$ means $\sigma^1_w\neq\sigma^2_w$ or $\sigma^1_z\neq\sigma^2_z$), and thus since each vertex is adjacent to at most Δ edges, we multiply by Δ and write

$$\sum_{(wz)\in E} |\operatorname{Cor}^{(2)}_\nu(uv,wz)| \le \Delta\cdot \mathbb{E}_U|\text{connected component of } (u,v) \text{ in } \mathrm{Ber}(p_0) \text{ percolation}|,$$

where the left hand side is a function of h only and the right hand side takes expectation with respect to the uniform measure $(U_x, x \in V)$ in defining the coupling, and the percolation is defined in (3.3). Let $\mathcal{C}_{h,U}(u,v)$ denote the component of (u,v) in this percolation, and denote by $S_{uv}(h) := \frac{1}{\Delta}\sum_{(wz)\in E} |\operatorname{Cor}^{(2)}_{\nu}(uv,wz)|$ (This notation has implicit dependence on θ, Λ, τ_0.) Then for any $s > 0$,

$$\mathbb{P}_h(S_{uv}(h) \geq m) \leq e^{-sm}\mathbb{E}_h \exp(s\mathbb{E}_U|\mathcal{C}_{h,U}|) \leq e^{-sm}\mathbb{E}_{h,U}\exp(s|\mathcal{C}_{h,U}|),$$

applying Jensen in the last step.

Moreover, for any $\theta \in [0,\theta_*]$, any Λ and any boundary condition τ_0, we use the same coupling for ν and $\nu(\cdot \mid uv)$ via the same uniform distribution, and thus the discrepancy region is simultaneously controlled by the same Bernoulli percolation (3.3). That is,

$$\mathbb{P}_h(\sup_{\theta\in[0,\theta_*],\Lambda,\tau_0} S_{uv}(h) \geq m) \leq e^{-sm}\mathbb{E}_{h,U}\exp(s|\mathcal{C}_{h,U}|).$$

In a subcritical Bernoulli percolation, the size of the connected component has exponential tails, see equation (3.5). Taking $s = \alpha_*$ defined below and using equation (3.5), we deduce that (3.2) holds and thus the Proposition is proven.

The rest of the proof is the derivation of (3.5) for the exponential moments for the size of the connected component. We consider a Bernoulli (p_0)-percolation on G whose law is denoted by $\mathbb{P}$, and we use $\mathcal{C}(u,v)$ denote the connected cluster in this percolation where (u,v) are forced open. Then we explore the open cluster of the edge (u,v). Since the maximal degree is at most Δ and (u,v) are forced open, the connected cluster is stochastically bounded by a Galton-Watson forest with two initial particles and offspring distribution $\mathrm{Bin}(\Delta-1,p_0)$, see for example [17]. By the Otter-Dwass formula [13] (and see [23] for the $r=2$ version), if we let $T^{(2)}$ denote the total progeny of the forest, then

$$\mathbb{P}(T^{(2)} = x) = \frac{2}{x}\mathbb{P}(\mathrm{Bin}((\Delta-1)x, p_0) = x-2), \quad \forall x \in \mathbb{N}_+.$$

By Chernoff, whenever $p_0(\Delta-1) < 1$, we have

$$\mathbb{P}(T^{(2)} = x) \leq \frac{2}{x}\left(\frac{1-p_0}{p_0(\Delta-2)}\right)^2 e^{-\xi_* x},$$

where we take $\xi_* = \log\frac{(\Delta-2)^{\Delta-2}}{p_0(\Delta-1)^{\Delta-1}(1-p_0)^{\Delta-2}}$. Then we sum up over integers $x \geq m$ and get

$$\mathbb{P}(|\mathcal{C}(u,v)| \geq m \mid (u,v) \text{ open }) \leq \frac{2}{1-e^{-\xi_*}}\left(\frac{1-p_0}{p_0(\Delta-2)}\right)^2 e^{-\xi_* m}. \tag{3.4}$$

Then we can compute the exponential moment of $\mathcal{C}(u,v)$: take $\alpha_* = \frac{1}{2}\xi_*$, then

$$\mathbb{E}[\exp(\alpha_*|\mathcal{C}(u,v)|) \mid (u,v) \text{ open }] \leq \frac{2}{(1-e^{-2\alpha_*})(1-e^{-\alpha_*})}\left(\frac{1-p_0}{p_0(\Delta-2)}\right)^2. \tag{3.5}$$

◀

Via exactly the same argument, we have the following estimate:

▶ **Proposition 3.3.** *Let $(w,z) \in E$ be any edge of the graph $G = (V,E)$ of maximal degree Δ. Assume that Assumption 3.1 holds for the given $p_0 \in (0,1)$, then we have, for any $m \geq 1$,*

$$\begin{aligned}&\mathbb{P}\left(\sup_{\theta\in[0,\theta_*],\Lambda,\tau_0\in\Omega(\Lambda)}\sum_{(uv)\in E}|\operatorname{Cor}^{(2)}_{(1-\theta)\otimes\mu^{\tau_0}}(uv,wz)| \geq 2\Delta m\right)\\ &\leq \frac{2}{(1-e^{-\alpha_*})(1-e^{-2\alpha_*})}e^{2\gamma_*}e^{-\alpha_* m}.\end{aligned} \tag{3.6}$$

Proof. Consider the same Bernoulli percolation process as in (3.3), and for each $\theta \in (0, \theta_*)$ and pinning τ_0, use the same uniform coupling to generate $\sigma^1 \sim \nu := (1-\theta) \otimes \mu^{\tau_0}$ and $\sigma^2 \sim \nu(\cdot \mid wz)$. By the same argument in the proof of Proposition 3.2, we have

$$\begin{aligned}
&\sum_{(uv)\in E} |\operatorname{Cor}^{(2)}_{\nu}(uv, wz)| \\
&\le 2\mathbb{E}_U \sum_{(uv)\in E} \mathbf{1}((wz) \text{ is in the connected component of } (uv) \text{ in this percolation}) \\
&= 2\mathbb{E}_U \sum_{(uv)\in E} \mathbf{1}((uv) \text{ is in the connected component of } (wz) \text{ in this percolation}) \\
&\le 2\Delta \cdot \mathbb{E}_U |\text{connected component of } (wz) \text{ in } \mathrm{Ber}(p_0) \text{ percolation}|.
\end{aligned}$$

Denote by $S^{\mathrm{col}}_{wz}(h) := \frac{1}{2\Delta} \sum_{(uv)\in E} |\operatorname{Cor}^{(2)}_{\nu}(uv, wz)|$. Then

$$S^{\mathrm{col}}_{wz}(h) \le \mathbb{E}_U |\mathcal{C}_{h,U}(w, z)|.$$

Then the same Chernoff bound and exponential moment applies, concluding the proof. ◀

For a square matrix $A \in \mathbb{R}^{n\times n}$, its operator norm satisfies the following interpolation inequality

$$\|A\| \le \sqrt{\left(\sup_{i\in[n]} \sum_{j=1}^{n} |a_{ij}|\right)\left(\sup_{j\in[n]} \sum_{i=1}^{n} |a_{ij}|\right)}. \tag{3.7}$$

Taking a union bound in Proposition 3.2, we obtain an operator norm upper bound for all Ising models $(1-\theta) \otimes \mu^{\tau_0}$:

▶ **Proposition 3.4.** *Under the same assumption in Proposition 3.2, with probability at least* $1 - O_{\beta,\Delta,p_0}(\frac{1}{|V|})$ *over the randomness in the external field* h*,*

$$\sup_{\theta\in[0,\theta_*],\Lambda,\tau_0\in\Omega(\Lambda)} \| \operatorname{Cor}^{(2)}_{(1-\theta)\otimes\mu^{\tau_0}} \|_{op} \le \frac{4\Delta \ln |V|}{\alpha_*}.$$

Proof. We take $m = \frac{2\ln|V|}{\alpha_*}$ in the estimate (3.2) for each edge (u, v) and take the same value of m in the estimate (3.6) for each edge (w, z). Then with probability at least $1 - 2|V|\Delta \cdot \frac{2}{(1-e^{-\alpha_*})(1-e^{-2\alpha_*})} e^{2\gamma_*} \frac{1}{|V|^2}$, we have

$$\sup_{(uv)\in E} \sum_{(wz)\in E} |\operatorname{Cor}^{(2)}_{(1-\theta)\otimes\mu^{\tau_0}}(uv, wz)|, \ \sup_{(wz)\in E} \sum_{(uv)\in E} |\operatorname{Cor}^{(2)}_{(1-\theta)\otimes\mu^{\tau_0}}(uv, wz)| \le 2\Delta m.$$

Taking these two estimates into (3.7) for $A = \operatorname{Cor}^{(2)}_{(1-\theta)\otimes\mu^{\tau_0}}$ completes the proof. ◀

▶ **Corollary 3.5.** *Under the same assumption in Proposition 3.2, with* $\mathbb{P}_h$*-probability at least* $1 - O_{\beta,\Delta,p_0}(\frac{1}{|V|})$*, the edge field denoising process* $(Y_t)_{t\in[0,1]}$ *satisfies* R*- approximate conservation of variance up to time* θ_* *with constant*

$$R \le \exp\left(\frac{16\beta\Delta \ln |V|}{\alpha_*}\right).$$

Moreover, the RFIM measure μ_G *satisfies approximate tensorization of variance with constant* R*.*

Proof. Note that $\int_0^{\theta_*} \frac{dt}{1-t} = 4\beta$. The claim on (Y_t) follows directly from Proposition 3.4, Lemma 2.7 and Corollary 2.21. The R-approximate tensorization of variance of μ_G then follows from Lemma 2.5, since the posterior $\mathrm{Law}(Y_1 \mid Y_{\theta_*})$ is a product measure. ◀

Now we can conclude the proof of Theorem 1.2:

Proof of Theorem 1.2. The claim on Poincaré constant follows from Fact 2.8 combined with Corollary 3.5. The claim on mixing times follows from Fact 1.5. ◀

Abstract

Motivated by techniques developed in recent progress on lower bounds for sublinear time algorithms (Behnezhad, Roghani and Rubinstein, STOC 2023, FOCS 2023, and STOC 2024) we introduce and study a new class of *randomized algorithmic* processes that we call "Markov Chains with Rewinding". In this setting an agent/*algorithm* interacts with a (partially observable) Markovian *random* evolution by periodically/strategically rewinding the Markov chain to previous states. Depending on the application this may lead the evolution to desired states faster, or allow the agent to efficiently learn or test properties of the underlying Markov chain that may be infeasible or inefficient with passive observation.

We study the task of identifying the initial state in a given partially observable Markov chain. Analysis of this question in specific Markov chains is the central ingredient in the above cited works and we aim to systematize the analysis in our work. Our first result is that any pair of states distinguishable with any rewinding strategy can also be distinguished with a *non-adaptive* rewinding strategy (i.e., one whose rewinding choices are predetermined before observing any outcomes of the chain). Therefore, while rewinding strategies can be shown to be strictly more powerful than passive strategies (i.e., those that do not rewind back to previous states), adaptivity does *not* give additional power to a rewinding strategy in the absence of efficiency considerations.

The difference becomes apparent however when we introduce a natural efficiency measure, namely the *query complexity* (i.e., the number of observations they need to identify distinguishable states). Our second main contribution is to quantify this efficiency gap. We present a non-adaptive rewinding strategy whose query complexity is within a polynomial of that of the optimal (adaptive) strategy, and show that such a polynomial loss is necessary in general.

1 Introduction

In this work, we formally define and study a new class of processes involving interaction between randomness and algorithms. In these processes, that we call *Markov chains with rewinding*, a partially observable Markov chain interacts with an algorithmic agent that has

© Amir Azarmehr, Soheil Behnezhad, Alma Ghafari, and Madhu Sudan;

the ability, at any point in time, to rewind the Markov chain to a previous point of time. We study the problem of *identifying the initial state* in this model, where the goal is for the algorithm to use the observations and the power of rewinding to identify a given (hidden) initial state.

Partially observable Markov chains form a well-established element of the toolkit in computing and arise in both the design and analysis of algorithms. Rewinding of Markov chains captures a natural ability of algorithms that work with Markov chains, and as a result, they have occurred implicitly in a variety of settings (an overview is given in Section 1.2).

This is highlighted centrally in a class of applications of Markov chains with rewinding to *sublinear time algorithms*. For the maximum matching problem, [8, 7, 9] prove strong lower bounds on the query complexity, and hence running time, of sublinear time algorithms by using Markov chains with rewinding to model sublinear algorithms, and then analyzing these chains. Recent works on non-adaptive sublinear lower bounds follow similar paradigms, while not explicitly defining a Markov chain [5, 25]. Additionally, lower bounds for other graph problems in the sublinear-time model, such as edge orientation [22] and acyclicity [11], can also be viewed as instances of this general model.

Despite the prevalence of this phenomenon, rewinding does not appear to have been studied formally in the literature and in particular tools to analyze the power (and limitations) of Markov chains with rewinding have been ad-hoc. Our work is motivated principally by these and aims to build a more systematic toolkit for such analysis.

Markov chains with rewinding. We start with an example to illustrate the problem. Consider the partially observable Markov chain depicted below, where the only observable variable is the color of the current state (i.e., whether it is in $\{a, a', b, b'\}$ or $\{s\}$). The initial state is promised to be either a or a', and our goal is to identify this initial state.

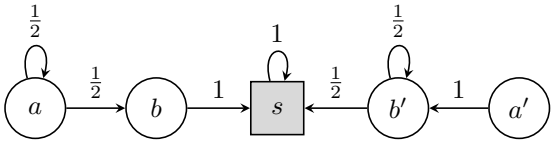

Figure 1.1 Rewinding is stronger than passive observation.

First, note that "passive observations" cannot distinguish a from a': Whether we start from a or a', it takes exactly Geometric$(1/2) + 1$ steps until we reach s and remain there forever. But suppose we are allowed to *rewind* back to any previous state at any time. In this case, we can run the Markov chain for one step to reach state X, and then run D independent steps from X for a sufficiently large D. The idea is that if $X = b'$ (which implies the initial state is a'), then it will most likely have a mix of s and not s next steps, whereas if $X \in \{a, b\}$ (implying that the initial state is a) all next steps will be the same. The following figure illustrates this.

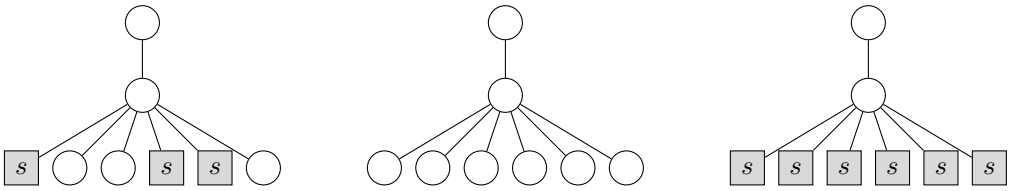

Figure 1.2 Examples of states generated by repeatedly rewinding to the second step.

We now present a more general description of the model, deferring its formalization to Section 3. The input consists of a partially observable Markov chain M, two candidate initial states a and a', and a hidden initial state $X_0 \in \{a, a'\}$. The algorithm interacts with the Markov chain through the hidden initial state X_0. It can either draw states according to the transition probabilities, or rewind the state to an earlier point in time. The drawn states $\{X_t\}_t$ are hidden from the algorithm, but observations $\{Z_t\}_t$ are available, where $Z_t = O(X_t)$. Here O is a fixed observation function mapping each state to its observation, so that $O(X_t)$ is the observation revealed at time t. Eventually, the algorithm must decide whether the initial state X_0 is a or a', based on the observations. We study the runtime and the number of queries (i.e. drawn states) required to do so. Other than the motivation from sublinear-algorithm lower bounds, rewinding formalizes a natural approach to interacting with Markov chains; variations and special cases have been considered repeatedly in previous work (see Section 1.2).

1.1 Our Contributions

Our main focus in this work is on the following fundamental problem:

> *Given a partially observable Markov chain, can a nearly-optimal rewinding strategy be computed efficiently?*

To better understand this question, we first need to formalize the model. We present the formalization in Section 3; We define *rewinding strategies* and *state identification algorithms*. Rewinding strategy refers to the choice of rewinding times throughout the process. A state identification algorithm computes the rewinding strategy through which it interacts with the partially observable Markov chain, and ultimately identifies the initial state based on the observations. We study and compare the power of *adaptive* and *non-adaptive* rewinding strategies for this task, where a non-adaptive strategy determines how to rewind independently of the observations. These lead us to our key complexity measures $\mathsf{QC}_M(a, b)$ (resp. $\mathsf{NAQC}_M(a, b)$) for the adaptive (resp. non-adaptive) *query complexity* of distinguishing state a from b in chain M, i.e. the minimum number of observations required by a rewinding strategy to distinguish the two states. Query complexity provides a benchmark for measuring the efficiency of an algorithm, and a means of proving lower bounds for its runtime.

Crucially, the algorithm is given the full description of the chain $M = (\Omega, P, O)$, here Ω is the (finite) state space of the Markov chain, $\Omega \times \Omega \to [0, 1]$ is its transition probability matrix, and O is the observation function introduced above. What is hidden is only the realized trajectory $\{X_t\}_t$ and the initial state.

We show that there is indeed a polynomial-time algorithm for the question stated at the beginning of this section. Formally, we prove the following theorem.

▶ **Theorem 1.1.** *Given a partially observable Markov chain $M = (\Omega, P, O)$, there exists a non-adaptive algorithm and a constant $c = c(|\Omega|)$ that can distinguish between any two states $a, b \in \Omega$ in time*

$$c \cdot \mathsf{QC}_M(a,b)^{O(|\Omega|)}.$$

Note that we are using the query complexity as our measure of efficiency. That is, we devise a state identification algorithm that chooses the rewinding states in time $\text{poly}(\mathsf{QC}_M(a,b))$ and generates at most $\text{poly}(\mathsf{QC}_M(a,b))$ states. In the statement above, we let M be a Markov chain on state space Ω with a special *sink* state. The only observable signal available to the rewinding algorithm is whether the chain is in the sink state or not (similar to the example in Section 1). We call such Markov chains *canonical* and show that identifying the initial state in canonical Markov chains is essentially as hard as general partially observable Markov chains (see Section 6).

Observe that if non-adaptive algorithms cannot distinguish two states a and b of a Markov chain M, then Theorem 1.1 implies that no adaptive algorithm can do so either. Therefore, non-adaptive algorithms are as powerful as adaptive ones in terms of which pairs of states they can distinguish.

Furthermore, formalized as Theorem 1.2, we show that the power of $\mathsf{QC}_M(a,b)$ in Theorem 1.1 is tight, up to a constant, for the runtime of non-adaptive algorithms. More specifically, we present a partially observable Markov chain M and states a and b, where a polynomial gap exists between the adaptive and non-adaptive query complexity of distinguishing a and b.

▶ **Theorem 1.2.** *There is a choice of M and pair $a, b \in \Omega$ such that for some $c = c(|\Omega|)$,*

$$\mathsf{NAQC}_M(a,b) \geq c \cdot \mathsf{QC}_M(a,b)^{(1-o(1))|\Omega|}.$$

This holds for infinitely many choices of $|\Omega|$ and query complexities.

We remark that the adaptive rewinding strategy presented for this gap can be easily turned into an algorithm with the same run time. Therefore, the polynomial gap is also present between the optimal adaptive and non-adaptive run times of state identification algorithms.

We leave open the question of whether the number of states in the Markov chain can be removed from the run-time exponent. Any solution would require new techniques and necessarily rely on adaptivity, as remarked above. Formally, we ask:

▶ **Open Problem 1.** *Given a partially observable Markov chain $M = (\Omega, P, O)$, candidate initial states $a, b \in \Omega$, and hidden initial state $X_0 \in \{a, b\}$, is there an adaptive state identification algorithm that successfully identifies the initial state in time $\mathsf{QC}_M(a,b)^C$ where constant C is independent of the number of states?*

We believe it is also interesting to compare non-adaptive algorithms against the best non-adaptive benchmark for future work. In particular, we ask:

▶ **Open Problem 2.** *Given a partially observable Markov chain $M = (\Omega, P, O)$, candidate initial states $a, b \in \Omega$, and hidden initial state $X_0 \in \{a, b\}$, is there a non-adaptive state identification algorithm that successfully identifies the initial state in time $\mathsf{NAQC}_M(a,b)^C$ where constant C is independent of the number of states?*

1.2 Related Work

We overview settings where partially observable Markov chains with rewinding have occurred naturally. A highly prevalent instance is the folklore method of converting expected *run times of algorithms* into high probability bounds by restarting the algorithm when it does not halt promptly. This is a special case of rewinding where the underlying state of the algorithm is captured by a Markov chain, and the observation is limited to knowing whether the algorithm has halted or not.

Restarting/rewinding can also help boost the success of algorithms as exemplified in the famed randomized algorithm for 3SAT due to Schöning [24]. In the case of random walks on multi-dimensional lattices, [21] showed that the expected hitting time of the origin is finite when the algorithm is allowed to restart the walk back from the starting point. More general forms of rewinding lead to elegant new approaches to *optimization* and *random sampling* as in the "Go-with-the-winners" algorithm of Aldous and Vazirani [1]. Selecting which state to continue the process from is also studied by [18], where the algorithm decides which Markov chain to advance, in order to minimize the expected time that one of them reaches the target state. In *cryptography*, rewinding arguments play a celebrated role in proving the security of protocols starting with the seminal work of Goldwasser, Micali, and Rackoff [20]. Rewinding is also a central element in defining strong notions of security as in the notion of "resettable zero knowledge" due to Canetti, Goldreich, Goldwasser, and Micali [13].

A related line of work studies other forms of controlled Markov chains. For instance, Azar, Broder, Karlin, Linial, and Phillips [4] introduced biased random walks, in which a controller may, with small probability, override the random transition to steer the walk, and gave tight bounds and polynomial-time algorithms for the optimal control strategy maximizing a long-term benefit.

1.3 Connection to Sublinear-Time Graph Algorithms

To further motivate our model, we overview its connection to sublinear time graph algorithms (or more precisely, lower bounds). Here, we provide a high-level description of this connection in general. Later in Appendix A, we present an explicit connection to the lower bound for testing acyclicity. That is, we show how the lower bound is captured by Markov chains with rewinding.

Let us first briefly overview the model of sublinear-time algorithms for graphs. We are given a graph $G = (V, E)$ to which we have adjacency list query access.[1] Each query can specify a vertex v and an integer $i \geq 1$. The answer to such a query is the i-th neighbor of vertex v stored in an arbitrarily ordered list, or $\perp$ if $\deg(v) < i$. Now, the main question of interest, is the number of such queries needed to estimate a property of the graph. For example, the works of [8, 7, 9] focus on proving lower bounds on the query complexity of estimating the size of maximum matching in the graph (see also [6, 26, 23, 12] for some algorithms). Many other problems can, and have been, studied in this setting, including graph coloring [2], correlation clustering [3], metric properties such as minimum spanning trees [17, 14], Steiner trees [15], TSP [16, 10], and many others.

Remarkably, for many graph properties, we have had *unconditional* query lower bounds that can be matched algorithmically with sublinear time algorithms. However, these lower bound arguments are often ad hoc, and there is a lack of systematic tools to prove them. Our hope is that our model and techniques can serve as a first step towards developing such generic lower bound tools. Let us expand on this connection a bit further.

[1] Another common access model is the adjacency matrix model.

Typically, sublinear time lower bounds are proved by specifying two distributions $\mathcal{D}_{YES}$ and $\mathcal{D}_{NO}$ of graphs, where graphs drawn from $\mathcal{D}_{YES}$ have the desired property and those drawn from $\mathcal{D}_{NO}$ do not. The lower bound then follows by showing that distinguishing these distributions requires many queries to the graph. In most cases, these distributions are constructed by having a few groups $A_1, A_2, \ldots, A_k$ that each vertex may belong to and is kept hidden from the algorithm. The distribution of edges between these groups differs in $\mathcal{D}_{YES}$ and $\mathcal{D}_{NO}$, and thus the task of distinguishing these distributions reduces to identifying these groups. The only useful signal that the algorithm receives, and helps in identifying the groups, is the vertex degrees. This is precisely how the hard instances of [8, 7, 9] for maximum matchings are constructed. Lower bounds for other graph problems in the sublinear-time model, such as edge orientation [22] and acyclicity [11], can also be viewed as instances of this general framework.

Now note that each group A_i can be viewed as a different state of the Markov chain. We let p_{ij} (i.e., the transition probability from A_i to A_j) to be the fraction of edges of group A_i that go to A_j, representing the fact that a random adjacency list neighbor of an A_i node belongs to A_j with probability p_{ij}. We construct these states separately for groups in $\mathcal{D}_{YES}$ and $\mathcal{D}_{NO}$. Then, assuming that the algorithm cannot find cycles (which holds in many lower bounds such as [8, 7, 19, 11]) the task of distinguishing the two distributions reduces to distinguishing if the initial state is among the YES states or the NO states of the Markov chain. Note, in particular, that because the sublinear time algorithm is not constrained to follow a single path in the graph and can adaptively make adjacency list queries to any previously visited vertex, this corresponds to a rewinding strategy on the Markov chain. Therefore, the study of the power and limitations of such rewinding strategies for general Markov chains closely relates to the query complexity of sublinear-time graph algorithms, and can serve as a rich toolkit for proving lower bounds against them.

Paper Arrangement

More examples of Markov chains with rewinding are presented in Section 2. An overview of our techniques appears in Section 2.3. The model is formally defined in Section 3. We examine state partitions, a key tool for our algorithm, in Section 3.1. Proofs of Theorems 1.1 and 1.2 are sketched in Sections 4 and 5 respectively. Finally, in Section 6, we prove the generality of canonical Markov chains. For the full proofs refer to the following version [5].

2 Motivating Examples & Technical Overview

We start this section by presenting examples of rewindable Markov chains along with optimal strategies to distinguish between two candidate initial states. These examples further clarify the model and demonstrate how rewinding strategies can be *non-trivially* effective, and thus hard to prove lower bounds against. After these examples, we outline the techniques used in our algorithms and analyses.

2.1 Example 1: The non-trivial power of (non-adaptive) rewinding

Our first example involves a simple Markov chain on 5 states, inspired by the hard distribution of [8] for graph matchings. The chain is parameterized by an integer d, and its transition probabilities are multiples of $1/d$ as illustrated by the arrows in the figure. There is a special sink state s, and the algorithm can only observe whether a state is sink or non-sink. The goal is to distinguish whether the initial state is a or a'. We show first how the natural strategy to distinguish two candidate initial states a and a' leads to query complexity $\widetilde{O}(d^2)$. A quick look at the chain and the rewinding strategy seems to suggest that such a d^2 complexity is

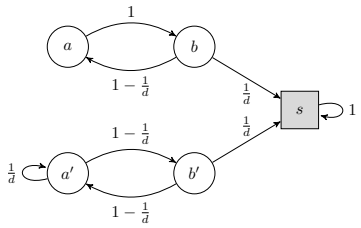

Figure 2.1 A five-state example.

essential; but we show later that a more sophisticated strategy actually distinguishes a from a' in $O(d)$ queries.

A simple algorithm with $\widetilde{O}(d^2)$ query complexity. We say a node in the tree is an A-node if its state is a or a' and a B-node if its state is b or b'. First, we claim that given a node v in the tree, we can determine with probability $1-\varepsilon$ if it is an A or B node with $O(d\log(1/\varepsilon))$ queries – we call this an A/B test. To do this, note that if v is an A-node, any child of v is non-sink (specifically, it is a B-node). Moreover, if v is a B-node, each child has a probability of $1/d$ of being a sink node. Therefore, opening $O(d\log(1/\varepsilon))$ children for a node v is sufficient for A/B testing v.

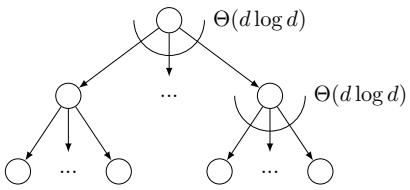

Figure 2.2 An $O(d^2\log^2 d)$-query strategy.

Next, having the A/B test available to us, we aim to assert whether a given A-node v has state a or a'. To do so, we first open $d\log(1/\varepsilon)$ children for v. If v has state a, then all of its children must be B-nodes. On the other hand, if v has state a', each child is an A-node with probability $1/d$, and so at least one must be an A-node with probability $1-(1-1/d)^{d\log(1/\varepsilon)} \geq 1-\varepsilon$. It then suffices to run the A/B test on these children to check if any of them is an A node. This takes total time $O(d^2\log^2(1/\varepsilon))$. Choosing $\varepsilon = 1/d^3$ so that all A/B tests are correct w.h.p., we get an overall query complexity of $O(d^2\log^2 d)$. The final queried tree is non-adaptive and is illustrated on the right.

Improving query complexity to $O(d)$. We now describe how we can improve over the algorithm above, and distinguish the a and a' states with just $O(d)$ queries. Here is the key insight. Suppose that we open a path of length $2d$ from the root and let us condition on not seeing the s node at all (which happens with constant probability). Then, if we start from the a state, we must alternatively visit a and b, finally arriving back at a since the length of the path is even. However, if we start from a', there is a constant probability that we go from a' to a' exactly once throughout the process since $P(a',a') = 1/d$ and the length of the walk is $2d$. If this event happens, we end up in state b'. Therefore, it suffices to run the A/B test on the last vertex of the path – if it happens to be B, we will be sure that we started from a'. Note that the success probability is a small constant, but we can boost it by

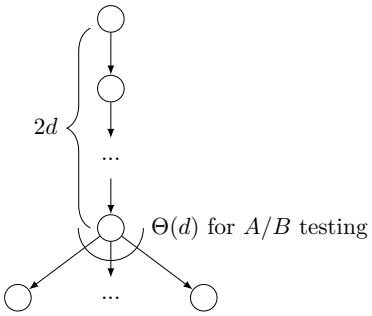

Figure 2.3 An $O(d)$-query strategy.

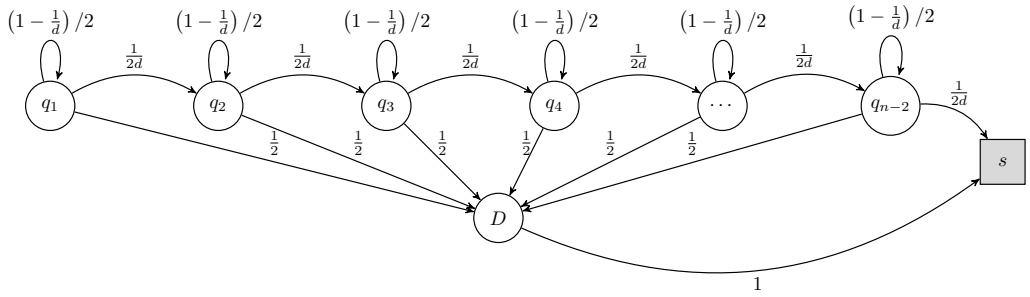

Figure 2.4 A canonical Markov chain for which there is a (large) polynomial gap between adaptive and non-adaptive strategies of distinguishing states q_1 and q_2.

repeating this process multiple times. The figure on the right shows the final query tree (for a single repetition of this process), which again is non-adaptive.

2.2 Example 2: The power of adaptivity

Our second example shows the power of adaptive rewinding strategies compared to non-adaptive ones. This example, illustrated in Figure 2.4, is later used to prove a polynomial gap between the non-adaptive and adaptive query complexities in the worst case (Theorem 1.2). We formalize this in Section 5, but here provide an intuition of how adaptivity helps.

Given a parameter $d \geq 1$, the Markov chain is formed by combining a "simple Markov chain" and a "dummy state". The simple Markov chain consists of a path of states, where each state transitions to the next with probability $\frac{1}{d}$, and stays in the same state otherwise. States can be easily distinguished in the simple Markov chain using $O(n^2 d)$ queries, where $n = |\Omega|$ is the number of states. To do so, it suffices to take random walks from the initial state and examine the time it takes to move to the sink (see Section 5 for the proof).

However, when combined with the dummy state, every state has a $\frac{1}{2}$ chance of jumping to the dummy state (otherwise, it proceeds as before). Then, the dummy state directly moves to the sink with probability 1. As all the states have the same probability of transitioning to the dummy state, moving to the sink through the dummy state reveals no information about the initial state.

Adaptive strategies can easily filter out the dummy state. That is, they can simulate a random walk on the simple Markov chain by checking if the walk has transitioned to the dummy state along the way, and rewinding back to the previous step if it has. As a result,

adaptive strategies retain the $O(n^2 d)$ query complexity even with the dummy state added.

The non-adaptive strategies cannot do the same, i.e. they cannot check whether a random walk has transitioned to the dummy state on the fly (they can only infer it after all the queries are made). Intuitively, to make up for this, they have to take many more random walks from the initial state, so as to guarantee that plenty of them reach the sink without moving through the dummy state. Therefore, the non-adaptive query complexity suffers when the dummy state is added and becomes (approximately) $\Omega(d^n)$. See Section 5 for the proof.

2.3 Technical Overview

Recall that our main goal is to bring a systematic understanding of distinguishing two candidate initial states in a known Markov chain. In this section, we provide a brief overview of our methods. There are two main aspects associated with our task: (1) computing rewinding strategies to distinguish between two initial states, and (2) proving lower bounds for the query complexity of this task. Together the two aspects allow us to establish the efficiency of our algorithm, i.e. that its run time is competitive with the optimal query complexity. Our approach to both aspects heavily utilizes partitions of the state set Ω.

Let $\mathcal{P}$ be a partition of the states, and for a state $a \in \Omega$ let $\mathcal{P}(a)$ denote the "class" of a in $\mathcal{P}$, i.e., the set within the partition $\mathcal{P}$ that contains a. As a subroutine, we study the problem of identifying the class of any given (hidden) state in $\mathcal{P}$, i.e., the task of computing $\mathcal{P}(X_0)$ for a given chain M and partition $\mathcal{P}$ (note that this is a generalization of the A/B test in Section 2.1). By choosing $\mathcal{P}$ carefully, this allows us to distinguish between two states $a, b \in \Omega$. Specifically, it suffices to identify the class of the initial state for some partition $\mathcal{P}$ that separates a and b, i.e., where $\mathcal{P}(a) \neq \mathcal{P}(b)$.

Intuitively, identifying the class within a given partition becomes more difficult as the partition becomes more refined. As an extreme case, the test for the trivial partition $\mathcal{P}_0 = \{\Omega \setminus \{s\}, \{s\}\}$ can be performed without any further queries in a canonical Markov chain since the partial observation at any state determines its class in $\mathcal{P}_0$. Our key tool in the design of algorithms is to assume that for some partition $\mathcal{P}_1$ we know how to identify the states, and then to use this algorithm to build a more refined partition $\mathcal{P}_2$ where we can identify states. Starting this with the trivial partition, we can use this method to work our way up to more and more refined partitions, till we reach a partition that separates a and b at which stage our problem would be solved. The exact details of this refinement step (and how we estimate their query complexity) are described below.

Recall that the goal of Theorem 1.1 is to develop a non-adaptive algorithm that distinguishes between two states a and b in time $O_n(1) \cdot \mathsf{QC}_M(a,b)^{O(n)}$, where n is the number of states and $O_n(1)$ suppresses terms dependent only on n. To do so, we define a weighted directed graph on the partitions: Namely, every partition $\mathcal{P}$ of Ω is a vertex of this graph and there is a weighted edge between every pair of partitions $\mathcal{P}_1 \to \mathcal{P}_2$ where $\mathcal{P}_2$ refines $\mathcal{P}_1$. The weights $w(\mathcal{P}_1, \mathcal{P}_2)$ are formally defined shortly. Intuitively, the main idea is to get a quantity that roughly allows us to determine the class of the initial state in $\mathcal{P}_2$ using approximately $w(\mathcal{P}_1, \mathcal{P}_2)$ calls to the class-identifier for $\mathcal{P}_1$. Note that if there is a path $\mathcal{P}_1 \to \mathcal{P}_2 \to \mathcal{P}_3$ in this graph, then this amounts to saying that classes of $\mathcal{P}_3$ can be identified using roughly $w(\mathcal{P}_1, \mathcal{P}_2) \cdot w(\mathcal{P}_2, \mathcal{P}_3)$ calls to the class identifier for $\mathcal{P}_1$. Thus, given this graph, we can easily devise a non-adaptive strategy for distinguishing between a and b.

For every partition $\mathcal{P}$ we compute the minimum distance from the trivial partition $\mathcal{P}_0$ (using this multiplicative measure of length of a path), and then use the partition $\mathcal{P}$ that separates a from b and has the smallest distance among all such $\mathcal{P}$. In particular, if we

let $\mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_k = \mathcal{P}$ be the shortest path to $\mathcal{P}$, the test for each $\mathcal{P}_i$ can be recursively performed by calling the tests $\mathcal{P}_{i-1}$. This results in a test for $\mathcal{P}_k$ (which recall differentiates between a and b) that uses $c(\mathcal{P}_k) = \prod_{1 \le i \le k} w(\mathcal{P}_{i-1}, \mathcal{P}_i)$ tests. For Theorem 1.1, we also need to prove $c(\mathcal{P}_k) \le \mathsf{QC}_M(a,b)^{O(n)}$ which we discuss shortly, but first we describe how we compute $w(\mathcal{P}_1, \mathcal{P}_2)$.

To understand how a test for $\mathcal{P}_1$ can be used to identify the class in $\mathcal{P}_2$ of a given state, consider, as a warm-up, the original problem of distinguishing between a and b. Equipped with the test for $\mathcal{P}_1$, one can differentiate between a and b as follows: Given a state $x \in \{a, b\}$, we take many samples from the next state (rewinding back to x after each sample) and examine the distribution of their classes in $\mathcal{P}_1$. If the distribution of these classes for a and b are δ-apart in total variation distance, then x can be identified successfully with probability $1 - \varepsilon$ using $O(\log(1/\varepsilon)/\delta^2)$ samples. A similar approach can be taken to distinguish classes of $\mathcal{P}_2$ (instead of two states a and b). This is again captured by the total variation distance of certain distributions which gives us the weight $w(\mathcal{P}_1, \mathcal{P}_2)$ in the graph. Specifically, we can take

$$w(\mathcal{P}_1, \mathcal{P}_2) = \max_{\substack{c,d: \\ \mathcal{P}_1(c)=\mathcal{P}_1(d) \\ \mathcal{P}_2(c)\neq\mathcal{P}_2(d)}} \frac{1}{d_{\mathrm{TV}}^{\mathcal{P}}(c,d)^2},$$

where for $x \in \{c, d\}$, and $d_{\mathrm{TV}}^{\mathcal{P}}(c,d)$ denotes the total variation distance between next states from c and d when projected on $\mathcal{P}$. That is, letting X^c and X^d be the next state of the Markov chain conditioned on the last state being c and d respectively, $d_{\mathrm{TV}}^{\mathcal{P}}(c,d) := d_{\mathrm{TV}}(\mathcal{P}(X^c), \mathcal{P}(X^d))$. Thus, this expression captures the hardest to separate pair of states c and d from different classes of $\mathcal{P}_2$ (and not already separated in $\mathcal{P}_1$) after taking one step on the Markov chain starting at these states, using only a class identifier for $\mathcal{P}_1$.

Turning to our lower bound, recall that we wish to express the shortest path length in terms of the query complexity, i.e. to prove that $\prod_{1 \le i \le k} w(\mathcal{P}_{i-1}, \mathcal{P}_i)$ is at most

$$O_n(1) \cdot (\mathsf{QC}_M(a,b))^{O(|\Omega|)},$$

where $\mathcal{P}_0 \to \mathcal{P}_1 \cdots \to \mathcal{P}_k$ is the shortest path found by our algorithm. The argument has two main components, given a partition $\mathcal{P}$: (1) if two states c and d with $\mathcal{P}(c) = \mathcal{P}(d)$ are far in terms of $d_{\mathrm{TV}}^{\mathcal{P}}$, then $\mathcal{P}$ has a small outgoing edge separating c and d, and (2) if every two states within the same class of $\mathcal{P}$ are close in terms of $d_{\mathrm{TV}}^{\mathcal{P}}$, then it is difficult to distinguish any two states in the same class of $\mathcal{P}$. Note, in particular, that if such a $\mathcal{P}$ does not separate a and b, then it would serve as a "certificate" for the difficulty of distinguishing between them.

We begin by explaining how these components can be applied to obtain upper bounds on the shortest path (equivalently, lower bounds on the query complexity). Consider any partition $\mathcal{P}$, where a and b are not separated. Given that a and b are distinguishable with $\mathsf{QC}_M(a,b)$ queries, we can employ (2) to show there are two states c and d with $\mathcal{P}(c) = \mathcal{P}(d)$ such that $d_{\mathrm{TV}}^{\mathcal{P}}(c,d) = \Omega(1/\mathsf{QC}_M(a,b))$. Then, using (1), we can infer that $\mathcal{P}$ has an outgoing edge of weight at most $O_n(1)/d_{\mathrm{TV}}^{\mathcal{P}}(c,d)^2 = O_n(1) \cdot \mathsf{QC}_M(a,b)^2$. As a result, we can start at $\mathcal{P}_0$ and iteratively take the smallest outgoing edge, which has weight at most $O_n(1) \cdot \mathsf{QC}_M(a,b)^2$, until we reach a partition that separates a and b. The path can take a length of at most $n-1$ since each partition is refined by the next. This gives us a path of length at most $O_n(1) \cdot \mathsf{QC}_M(a,b)^{2n}$ from $\mathcal{P}_0$ to a partition that separates a and b.

Now we discuss each component separately. First, consider a partition $\mathcal{P}$ with two states c and d in the same class of $\mathcal{P}$ that have $d_{\mathrm{TV}}^{\mathcal{P}}(c,d) = D$. Let G be an auxiliary graph where

the vertices are the Markov chain states, and two states are connected if they are closer than D/n in $d_{\mathrm{TV}}^{\mathcal{P}}$. We construct a refinement $\mathcal{P}'$ of $\mathcal{P}$ by letting two states be in the same class of $\mathcal{P}'$ if they are in the same class of $\mathcal{P}$ and the same connected component of G. Observe that $\mathcal{P}'$ separates c and d since $d_{\mathrm{TV}}^{\mathcal{P}}$ forms a metric, and c and d are more are D apart, whereas any two directly connected states are at most D/n apart. Furthermore, the only states that are newly separated by $\mathcal{P}$ are at least D/n apart. Therefore, $\mathcal{P}$ has an outgoing edge of weight at most $(n/D)^2$ to $\mathcal{P}'$.

For the second component, take a partition $\mathcal{P}$ where any two states in the same class of $\mathcal{P}$ are at most θ apart in $d_{\mathrm{TV}}^{\mathcal{P}}$. We show that for any two states a and b with $\mathcal{P}(a) = \mathcal{P}(b)$, it holds $\mathsf{QC}_M(a, b) = \Omega(1/\theta)$. Given two possible initial states a and b to distinguish, we consider two instances of running the rewinding strategy: one with a, and one with b. Let T_a and T_b be the query trees that the rewinding strategy creates in each case. We couple T_a and T_b such that they look the same to the strategy with a large probability. Here, by looking the same, we mean that the states generated in T_a and T_b yield the same observations, i.e. they are both sink or non-sink. In addition, the coupling is such that T_a and T_b are isomorphic w.r.t. $\mathcal{P}$, meaning the corresponding nodes in T_a and T_b have states that are in the same class of $\mathcal{P}$, with a large probability.

We construct our couplings in an inductive manner. In every step, a state $u_a \in T_a$ and the corresponding state $u_b \in T_b$ are chosen by the rewinding strategy to derive the next step. At this point, we need a method to couple the next step drawn from u_a and u_b such that they are both sink or non-sink with a large probability. Such a coupling is not possible for arbitrary states u_a and u_b (e.g. $\mathcal{P}_0(u_a) = \mathcal{P}_0(u_b)$ does not imply the same is true for their next step with a large probability). To do so, we employ the additional property that $\mathcal{P}(a) = \mathcal{P}(b)$, and show that the drawn states can be coupled such that they are in the same class of $\mathcal{P}$ with probability $1 - \theta$. Intuitively, if a rewinding strategy distinguishes between a and b, it should make at least $\Omega(1/\theta)$, so that the above scheme fails and the drawn states are in different classes of $\mathcal{P}$.

We remark that something as strong as the shortest path algorithm is not required for Theorem 1.1. While it is intuitive to use the shortest path as it corresponds to "the cheapest way" for testing $\mathcal{P}$ in our graph, something as simple as Prim's algorithm also works. That is, to prove Theorem 1.1, we essentially show that there exists a partition $\mathcal{P}$ separating a and b which is reachable from $\mathcal{P}_0$ through edges of weight at most $O_n(1) \cdot \mathsf{QC}_M(a, b)^2$. Therefore, Prim's algorithm can find such a $\mathcal{P}$, by starting from $\mathcal{P}_0$ and in each step, adding the minimum outgoing edge to the tree. Also, note that while the shortest path algorithm may use fewer queries in many cases, in the worst case, it uses (asymptotically) the same number of queries as Prim's algorithm (Theorem 1.2).

3 The Formal Model

We use $\mathbb{Z}^{\geq 0}$ to denote the set of non-negative integers. We use $d_{\mathrm{TV}}(\cdot, \cdot)$ to denote the total variation distance between two distributions.

We start by reviewing the standard notions of (partially observable) Markov chains. A sequence of random variable $X_0, X_1, X_2, \ldots$ with $X_t \in \Omega$ for all t is a *Markov chain* if

there exists a transition matrix $P : \Omega \times \Omega \to [0, 1]$ such that for every t and all $x, y \in \Omega$, $\Pr(X_{t+1} = y \mid X_t = x) = P(x, y)$; we write $P(x, \cdot)$ for the distribution from x to the next state. [2] A sequence $Z_0, Z_1, \ldots$ with $Z_t \in \Sigma$ is a *partially observable (p.o.) Markov chain* if

[2] We note that such Markov chains are called *time-invariant* since transition probabilities, conditioned on the current state, are independent of time.

there exists a Markov chain $X_0, X_1, \ldots$ and a function $O : \Omega \to \Sigma$ such that $Z_t = O(X_t)$ for all t. (While a general theory would allow probabilistic functions O, we restrict our attention to deterministic functions in this work.) We refer to Ω as the state space and Σ as the observable space. Note that a partially observable chain M is given by a triple (Ω, P, O).

Next, we turn to the central objects of study in this paper, namely Markov chains with rewinding. Before doing so, we briefly touch upon two views of a rewinding strategy. The formal view is simply as a function that maps a history of observations to a non-negative number (which we view as the number of steps we rewind the current time by). An alternate view is that the rewinding strategy builds a tree where, at each time step, the algorithm picks a node of the current tree, and the next time step produces a new child for this node whose state is independent of that of all other nodes, conditioned on the parent's state. The following definition uses the formal view, but we often switch to the tree view in our analyses.

▶ **Definition 3.1** (Markov Chains with Rewinding). *For a partially observable Markov chain $M = (\Omega, P, O)$ with observable space Σ, a rewinding strategy is a function $A : \Sigma^* \to \mathbb{Z}^{\geq 0}$. A Markov chain $M = (\Omega, P, O)$ in initial state X_0 with rewinding strategy A generates a sequence of random variables $Z_0, Z_1, Z_2, \ldots$, with companion variables $X_1, X_2, \ldots$ as follows: For every $t \geq 0$, we let $Z_t = O(X_t)$ and $X_{t+1} \sim P(X_{t'}, \cdot)$ where $t' = \max\{0, t - A(Z_0, \ldots, Z_t)\}$. We say that a sequence of random variables $Z_0, Z_1, \ldots,$ is a Markov chain with rewinding if there exists a chain M, an initial state X_0, and a rewinding strategy A that generates this sequence.*

Markov chains with rewinding strictly generalize the class of Markov chains, which correspond to *passive observation*, i.e., the rewinding strategy $A(\cdot)$ is the constant function 0, or equivalently, the rewinding tree is a path (and hence "chain"). Another class of rewinding strategies, widely used in algorithm design, picks some threshold $\tau \in \mathbb{Z}^{\geq 0}$ and sets $A(Z_0, \ldots, Z_t) = t$ if $t = 0 \pmod{\tau}$ and $A(Z_0, \ldots, Z_t) = 0$ otherwise. Equivalently, the rewinding tree consists of paths of length τ intersecting at the root. Such strategies may be termed *resetting strategies*. A simple adaptation of resetting is inspired by the "go-with-the-winners" algorithm [1] is the following: $A(Z_0, \ldots, Z_t) = 0$ if $t \neq 0 \pmod{\tau}$ and $\arg\max_\ell \{Z_{t-\ell}\}$ otherwise. That is, the chain-rewinder seeks to maximize the observed variable, and once in every τ steps, it rewinds to a previous state with the highest observable.

An important subclass of strategies which we study in this work are *non-adaptive* rewinding strategies, where $A(Z_0, \ldots, Z_t) = A'(t)$, i.e., the rewinding strategy is a fixed function of the length and does not depend on the actual observations. Note that resettable strategies are special cases of non-adaptive strategies.

The main property of Markov chains we explore is the *identifiability* of the initial state. Specifically, given a p.o. Markov chain M and two candidate initial states $a, b \in \Omega$, we ask how long a rewinding strategy has to run (or how many "queries" it must make to M) to distinguish between these two starting states. The following definition formalizes this notion. It only considers identifiability from an information-theoretical point of view, i.e. the query complexity:

▶ **Definition 3.2** (Query Complexity). *Given a p.o. Markov chain M and rewinding strategy A, let $Z_0^a, Z_1^a, Z_2^a, \ldots$ denote the Markov chain with rewinding obtained from the initial state $X_0 = a$ and let $Z_0^b, Z_1^b, Z_2^b, \ldots$ correspond to the case $X_0 = b$. We say that (M, A, a, b) are (ε, T)-identifiable if $d_{\mathrm{TV}}((Z_0^a, \ldots, Z_T^a), (Z_0^b, \ldots, Z_T^b)) \geq \varepsilon$. The* query complexity *of distinguishing a from b in chain M with rewinding strategy A, denoted $\mathsf{QC}_M^A(a, b)$, is the minimum T such that (M, A, a, b) are $(1/3, T)$-identifiable. Having this, we define:*

- *the (adaptive) query complexity of distinguishing a from b to be:*

$$\mathsf{QC}_M(a,b) = \min_A \mathsf{QC}_M^A(a,b),$$

- *and define the analogous notion for non-adaptive rewinding strategies. Namely,*

$$\mathsf{NAQC}_M(a,b) = \min_{\text{non-adaptive } A} \mathsf{QC}_M^A(a,b).$$

We also consider identifiability from a computational standpoint. That is, we study the time complexity for algorithms that identify the initial state. Such an algorithm produces the rewinding strategy and queries the Markov chain accordingly. Then, it identifies the initial state based on all the observations. We call such algorithms *state identification algorithms*.

▶ **Definition 3.3** (State Identification Algorithms). *The input of a state identification algorithm consists of a p.o. Markov chain $M = (\Omega, P, O)$, two candidate initial states $a, b \in \Omega$, and a hidden initial state $X_0 \in \{a, b\}$. An (adaptive) state identification algorithm in every step $t \geq 0$, computes the rewinding strategy $A(Z_0, \ldots, Z_t)$, after which X_{t+1} is sampled according to $P_{X|Y=X_{t'}}$ with $t' = \max\{0, t - A(Z_0, \ldots, Z_t)\}$, and the observation $Z_{t+1} = O(X_{t+1})$ is revealed to the algorithm. A non-adaptive algorithm computes the rewinding strategy before sampling any states. The algorithm decides the number of steps T, and eventually outputs the identified initial state (a or b). We say the algorithm successfully identifies the initial state if the output is correct with probability $2/3$.*

Finally, we define a special subclass that we refer to as *canonical* p.o. Markov chains. While general p.o. Markov chains are of interest, we state our results in terms of canonical p.o. Markov chains for simplicity. We show later, in Theorem 6.2, that canonical chains capture all chains in our context.

▶ **Definition 3.4** (Canonical p.o. Markov Chains). *We say that p.o. Markov chain $M = (\Omega, P, O)$ is a* canonical *p.o. Markov chain if there exists a state $s \in \Omega$ that is a sink state (i.e., $P(s,s) = 1$ and equivalently $P(s,y) = 0$ for all $y \neq s$), and $O(a) = 1$ if $a = s$ and 0 otherwise.*

Thus, in a canonical p.o. Markov chain, the only observable signal is whether the chain has reached the sink or not; and once one reaches the sink, no further observations reveal information. Such chains are the hardest to learn and hence our focus.

3.1 Partitions

In the rest of this section, we introduce the notion of state partitions, i.e. partitions of Ω, a key tool both for designing rewinding strategies to distinguish between states, and proving lower bounds on the query complexity of this task. Throughout the section we use n as a shorthand for $|\Omega|$, $p(a,b)$ for $P(a,b) = \Pr(X_{t+1} = b \mid X_t = a)$, and $p(a,C)$ for $\sum_{b \in C} p(a,b)$. We use s to denote the sink state.

▶ **Definition 3.5** (Partition). *Given a set Ω, a partition $\mathcal{P}$ is a collection of sets such that each element $a \in \Omega$ appears in exactly one set of the partition. We often refer to these sets as classes, and use $\mathcal{P}(a)$ to denote the class of a in $\mathcal{P}$.*

▶ **Definition 3.6** (Total Variation Distance w.r.t. Partitions). *For two states a and b, and a partition $\mathcal{P}$, the total variation distance of $P(a,\cdot)$ and $P(b,\cdot)$ w.r.t. to $\mathcal{P}$ is*

$$d_{TV}^{\mathcal{P}}(a,b) := \frac{1}{2} \sum_{C \in \mathcal{P}} |p(a,C) - p(b,C)| = \max_{A \subseteq \mathcal{P}} \sum_{C \in A} p(b,C) - p(a,C).$$

Here, A is a collection of the classes in $\mathcal{P}$.

▶ **Lemma 3.7.** *Let $\mathcal{P}$ be a partition of Ω. Given two states a and b, and oracle access to $\mathcal{P}(x)$ for any state $x \in \Omega$, there exists a non-adaptive rewinding strategy that successfully distinguishes between initial states a and b with probability $1 - \varepsilon$ using*

$$O\left(\frac{\log 1/\varepsilon}{\left(d_{\mathrm{TV}}^{\mathcal{P}}(a,b)\right)^2}\right)$$

queries.

Proof. Let $d = d_{\mathrm{TV}}^{\mathcal{P}}(a,b)$, and let $A \subseteq \mathcal{P}$ be the collection of classes where the difference in the distributions is maximized:

$$A := \arg\max_{A \subseteq \mathcal{P}} \sum_{C \in A} p(b,C) - p(a,C).$$

Note that by definition $p(b,A) - p(a,A) = d$. Given a state $x \in \{a,b\}$, we draw $\frac{2\log 1/\varepsilon}{d^2}$ samples of the next step of x (according to distribution $P(x,\cdot)$), and let ρ be the fraction of them that land in A. If the state is a, the expected value of ρ is $p(a,A)$; if the state is b, the expected value is $p(b,A)$; and the difference between the two is equal to d. We declare that the state is a if $\rho < p(a,A) + \frac{d}{2}$ and that it is b otherwise. The probability of error when $x = a$ is equal to:

$$\Pr\left(\rho \geq p(a,A) + \frac{d}{2}\right) \leq \exp\left(-2 \cdot \frac{2\log 1/\varepsilon}{d^2} \cdot \left(\frac{d}{2}\right)^2\right) \leq \varepsilon.$$

Similarly, the probability of error when $x = b$ is equal to:

$$\Pr\left(\rho < p(a,A) + \frac{d}{2}\right) = \Pr\left(\rho < p(b,A) - \frac{d}{2}\right) \leq \varepsilon.$$ ◀

4 A Polynomially Optimal Non-Adaptive Algorithm

4.1 A Non-Adaptive Algorithm with Polynomial Queries

In this section, we present a non-adaptive algorithm that distinguishes any two (distinguishable) states a and b of an n-state canonical Markov chain $M = (\Omega, P)$ (see Definition 3.4) using $O_n(1) \cdot \mathsf{QC}_M(a,b)^{O(n)}$ queries, where recall $\mathsf{QC}_M(a,b)$ is the optimal query complexity of distinguishing a from b with a possibly adaptive rewinding strategy, and $O_n(1)$ is used to suppress terms dependent only on n. In particular, this implies that the gap between adaptive and non-adaptive query strategies is only polynomial so long as the number of states of the Markov chain is constant. We later show in Section 5 that this is the best one can hope for: there are choices of M, a, b where any non-adaptive rewinding strategy requires $\mathsf{QC}_M(a,b)^{\Omega(n)}$ queries.

Formally, we show:

▶ **Theorem 4.1.** *Let $M = (\Omega, P)$ be a canonical p.o. Markov chain with $n = |\Omega|$ states. There is a non-adaptive algorithm (Algorithm 1) that distinguishes any distinguishable states $a, b \in \Omega$ in time*

$$O_n(1) \cdot (\mathsf{QC}_M(a,b) \log \mathsf{QC}_M(a,b))^{2(n-2)} = O_n(1) \cdot \mathsf{QC}_M(a,b)^{O(n)}.$$

This is equivalent to Theorem 1.1.

4.2 An Informal Overview of the Algorithm

The algorithm defines a weighted directed graph $G_M = (V, E)$ where each vertex of the graph corresponds to a partitioning of Ω, the state space of the Markov chain. There is an edge from $\mathcal{P} \in V$ to $\mathcal{P}' \in V$ iff $\mathcal{P}'$ is a refinement of $\mathcal{P}$. Informally speaking, it would be helpful to view each partitioning $\mathcal{P}$ as a *test* that reveals which class of $\mathcal{P}$ a hidden state belongs to. With this view, we define the weight $w(\mathcal{P}, \mathcal{P}')$ of the directed edge $(\mathcal{P}, \mathcal{P}') \in E$ such that it upper bounds the cost of solving test $\mathcal{P}'$ having free access to test $\mathcal{P}$. Once we define this graph G_M, we compute the shortest path tree on G_M (e.g. using Dijkstra's algorithm) starting from the trivial partitioning $\mathcal{P}_0 = \{\Omega \setminus \{s\}, \{s\}\}$ that only separates the sink from the other states. Let $\mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_k$ be the unique path in the tree from $\mathcal{P}_0$ to a partitioning $\mathcal{P}_k$. We will define the cost of $\mathcal{P}_k$ as

$$c(\mathcal{P}_k) = \prod_{i=0}^{k-1} w(\mathcal{P}_i, \mathcal{P}_{i+1}).$$

We prove that each test $\mathcal{P}$ can indeed be solved with (slightly more than) $c(\mathcal{P})$ queries. To distinguish state a from b, the algorithm takes the partitioning $\mathcal{P}$ that separates a from b and has the minimum cost $c(\mathcal{P})$. Our analysis shows that $c(\mathcal{P})$ can be upper bounded by $O_n(1) \cdot \mathsf{QC}_M(a, b)^{O(n)}$.

4.3 The Formal Argument

▶ **Definition 4.2** (Source Partition). *The **source partition** $\mathcal{P}_0$ is the trivial partition where the sink is a singleton class and all the remaining states form another class, i.e.* $\mathcal{P}_0 = \{\Omega \setminus \{s\}, \{s\}\}$.

For the purposes of this section, we only consider the partitions that separate s from every other state, i.e. partitions that refine $\mathcal{P}_0$.

▶ **Definition 4.3** (Partition Graph). *Given a canonical Markov chain $M = (\Omega, P)$, let the partition graph G_M be a weighted directed graph where each node is a partition of the states Ω. For a partition $\mathcal{P}_1$ and a refinement $\mathcal{P}_2$, there is a directed edge from $\mathcal{P}_1$ to $\mathcal{P}_2$ with weight*

$$w(\mathcal{P}_1, \mathcal{P}_2) = \max_{\substack{a,b: \\ \mathcal{P}_1(a)=\mathcal{P}_1(b) \\ \mathcal{P}_2(a)\neq\mathcal{P}_2(b)}} 1/\left(d_{\mathrm{TV}}^{\mathcal{P}_1}(a, b)\right)^2.$$

The lengths of the paths are defined multiplicatively. That is, the length of a path is the product of the weights of its edges. For a partition $\mathcal{P}$, its cost $c(\mathcal{P})$ is equal to the length of the shortest path from $\mathcal{P}_0$ to $\mathcal{P}$.

Below is a formal overview of the algorithm. The details of using the shortest paths to distinguish between states are given in Lemma 4.8. We use the notion of trees for rewinding. That is, if X_t is sampled by rewinding to $X_{t'}$ (i.e. according to distribution $P_{X|Y=X_{t'}}$), then $X_{t'}$ is the parent of X_t in the tree.

To analyze the query complexity of Algorithm 1, we show there exists a path of length $O_n(1) \cdot \mathsf{QC}(a, b)^{2(n-2)}$ to a partition that separates a and b (Lemma 4.7). Then, we show how this path can be used to distinguish between a and b (Lemma 4.8).

First, we prove some auxiliary claims. The following lemma essentially upper-bounds the weight of the smallest outgoing edge of a partition $\mathcal{P}$, based on two states a and b with $\mathcal{P}(a) = \mathcal{P}(b)$.

Algorithm 1 A non-adaptive algorithm with polynomial queries.

Input: A Markov chain $M = (\Omega, P)$, and two states a and b
Let G_M be the partition graph of the Markov chain as in Definition 4.3.
Compute the (multiplicative) shortest path tree on G_M rooted at the trivial partition $\mathcal{P}_0$.
Let $\mathcal{P}$ be a partition separating a and b that minimizes $c(\mathcal{P})$.
Let $\mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_k = \mathcal{P}$ be the shortest path to $\mathcal{P}$.
Let $\varepsilon = \Theta_n\left(\frac{1}{c(\mathcal{P}) \log c(\mathcal{P})}\right)$.
Query a tree of height k, where the vertices at height i have degree $\Theta_n(\log(1/\varepsilon) \cdot w(\mathcal{P}_{i-1}, \mathcal{P}_i))$.
Use the observations in the tree to identify the class of each vertex at height i in $\mathcal{P}_i$ recursively (see Lemma 4.8 for the details).

▶ **Lemma 4.4.** *Take a partition $\mathcal{P}$ and any two states $a, b \in \Omega$ such that $\mathcal{P}(a) = \mathcal{P}(b)$. Then, there exists another partition $\mathcal{P}'$ that refines $\mathcal{P}$ and*

$$w(\mathcal{P}, \mathcal{P}') \leq \left(\frac{n-1}{d_{\mathrm{TV}}^{\mathcal{P}}(a,b)}\right)^2.$$

▶ **Corollary 4.5.** *For a partition $\mathcal{P}$, if $\mathcal{P}$ has no outgoing edge of weight at most h in the partition graph, then for any two states a and b in the same class of $\mathcal{P}$, it holds that*

$$d_{\mathrm{TV}}^{\mathcal{P}}(a,b) < \frac{n-1}{\sqrt{h}}.$$

Proof. Follows directly from Lemma 4.4. ◀

The following claim states that if there exists a partition $\mathcal{P}$ such that every two states in the same class are closer than θ w.r.t. $d_{\mathrm{TV}}^{\mathcal{P}}$, then distinguishing any two states in the same class of $\mathcal{P}$ is difficult (roughly speaking, requires $1/\theta$ queries).

▷ Claim 4.6. For a partition $\mathcal{P}$ that does not separate a and b, let

$$\theta(\mathcal{P}) \coloneqq \max_{\substack{x,y: \\ \mathcal{P}(x)=\mathcal{P}(y)}} d_{\mathrm{TV}}^{\mathcal{P}}(x,y).$$

Then, any (possibly adaptive) rewinding strategy that uses Q queries, can successfully distinguish between a and b with probability at most $\frac{1}{2} + \frac{Q \cdot \theta(\mathcal{P})}{2}$.

Combining Corollary 4.5 and Claim 4.6, for a partition $\mathcal{P}$ with $\mathcal{P}(a) = \mathcal{P}(b)$, we can upper-bound the smallest outgoing edge of $\mathcal{P}$, and prove there exists a short path from $\mathcal{P}_0$ to a partition that separates a and b.

▶ **Lemma 4.7.** *There exists a path of length $O_n(1) \cdot \mathsf{QC}(a,b)^{2(n-2)}$ from $\mathcal{P}_0$ to a partition that separates a and b.*

The following lemma describes how a path of length Q can be used to distinguish the states with (slightly more than) Q queries.

▶ **Lemma 4.8.** *Given a path $\mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_k$ of length Q, one can identify the class of the initial state in $\mathcal{P}_k$ with $O_n(1) \cdot Q \log^k Q$ queries,[3] using a non-adaptive tree of height k where*

[3] recall $k \leq n-2$

on the i-th level the degree of every node is chosen proportionally to $w(\mathcal{P}_{i-1}, \mathcal{P}_i)$ and the class of each node on that level is determined w.r.t. $\mathcal{P}_i$.

Finally, we put Lemmas 4.7 and 4.8 together to derive Theorem 4.1.

Proof of Theorem 4.1. By Lemma 4.7, for any two states a and b, there exists a path of length at most $\mathsf{QC}(a,b)^{2(n-2)}$ ending at a partition that separates a and b. Therefore, the partition $\mathcal{P}$ obtained by computing shortest paths in step 4 of the algorithm has cost at most $\mathsf{QC}(a,b)^{2(n-2)}$. Lemma 4.8 shows how the shortest path to $\mathcal{P}$ can be used in steps 7–8, to identify the class of the initial state in $\mathcal{P}$ using $O_n(1) \cdot (\mathsf{QC}(a,b) \log \mathsf{QC}(a,b))^{2(n-2)}$ queries, hence distinguishing between a and b.

Regarding the runtime, observe that the strategy is implicitly (non-adaptively) computed in $O_n(1)$. The number of state partitions (number of vertices in G_M) is at most $n^n = O_n(1)$. For an edge $\mathcal{P} \to \mathcal{P}'$, the weight can be computed in time $O(n^3)$ by iterating over every relevant pair of states and computing the distance $d_{\mathrm{TV}}^{\mathcal{P}}$ in $O(n)$. Then the shortest path tree can be computed using a polynomial-time algorithm (e.g. Dijkstra's). After the shortest path is computed, the degree on each level of the query tree is determined. For each node of height i, its calls in $\mathcal{P}_i$ can be determined in time $O(2n^2 \cdot \log(1/\varepsilon) \cdot w(\mathcal{P}_{k-1}, \mathcal{P}_k))$, i.e. proportional to the degree. Therefore, the run time of the algorithm is $O_n(1) \cdot (\mathsf{QC}(a,b) \log \mathsf{QC}(a,b))^{2(n-2)} = O_n(1) \cdot (\mathsf{QC}(a,b))^{O(n)}$. ◀

5 The Polynomial Gap of Adaptivity

In this section, we prove the following theorem which directly implies Theorem 1.2.

▶ **Theorem 5.1.** *For any parameters $n, d \geq 1$, there exists a canonical Markov chain $M = (\Omega, P)$ with $n = |\Omega|$ states and two states $a, b \in \Omega$ such that*

$$\mathsf{QC}_M(a,b) = O(n^2 d), \qquad \mathsf{NAQC}_M(a,b) = \Omega(d^{(1-o(1))n}).$$

We remark that the optimal rewinding strategy, which distinguishes between a and b using $O(n^2 d)$ queries, can be trivially turned into an algorithm with the same run time. Therefore, Theorem 5.1 implies the same gap between the optimal adaptive and non-adaptive run times of state identification algorithms. As such, in this section, we abuse the notation and use the terms rewinding strategy and algorithm interchangeably.

We prove the claim given $d > 0$ and, the Markov chain M appeared in Figure 2.4. In this Markov chain, the states form a directed path toward the sink state, with states labeled as $q_1, ..., q_{n-2}$ from left to right. We label the last state as D. For all $i \in [n-3]$, state q_i goes to q_{i+1} with probability $\frac{1}{2d}$. The state q_{n-2} goes to the sink state s with the same probability. Each state in $q_1, ..., q_{n-2}$ goes to itself with probability $\left(1 - \frac{1}{d}\right)/2$. All $q_1, ..., q_{n-2}$ go to the state D with probability $\frac{1}{2}$, while state D goes to the sink with probability 1.

We prove that there exists an adaptive algorithm distinguishing q_1 and q_2 with $O(n^2 d)$ queries, while any non-adaptive algorithm needs at least $\Omega(d^{(1-o(1))n})$ queries. The intuition is as follows. An adaptive algorithm can easily test whether each new state opened is the D state or not by simply doing a test with constant queries, and opening another child instead to continue its path. This is not possible for non-adaptive algorithms that come across the D state with probability $\frac{1}{2}$, and when this happens the algorithm intuitively loses any information on the state it started from. So it needs a lot of paths to account for this loss of information.

▶ **Lemma 5.2.** *There exists an adaptive algorithm that distinguishes q_1 and q_2 in Markov chain M of Figure 2.4 with $O(n^2 d)$ queries.*

▶ **Lemma 5.3.** *Any non-adaptive algorithm distinguishing q_1 and q_2 in Markov chain M of Figure 2.4 needs $\Omega(d^{(1-o(1))n})$ queries.*

Proof of Theorem 5.1. Follows from combining Lemmas 5.2 and 5.3. ◀

6 Generality of Canonical Markov Chains

In this section, we show that identifying the initial state of a canonical Markov chain (Definition 3.4) is (essentially) as hard as the same task in any partially observable Markov chain via a reduction. That takes into account both the query complexity of the rewinding strategy and the runtime of the algorithm. For a state identification algorithm $\mathcal{A}$ we write $\mathrm{T}(\mathcal{A})$ for the time it spends outside the oracle that samples the next state.

In the generalized version, a Markov chain $M = (\Omega, P)$ is complemented by an observation function $O : \Omega \to \Sigma$, i.e. every state $x \in \Omega$ in the Markov chain outputs an observation $O(x) \in \Sigma$. The states remain hidden, but in every step, the algorithm can see the observation and use it to identify the initial states. A canonical Markov chain can be expressed in this generalized version by letting the set of possible observations be $\Sigma = \{0, 1\}$, and letting $O(x) = \mathbf{1}(x = s)$ where s is the sink state. That is, the observation made at any state is whether it is the sink state. First, We show that any adaptive strategy taking Q queries in the generalized model can be emulated in the canonical Markov chain using $O(|\Sigma|Q)$ queries. Secondly, we show that for non-adaptive algorithms, the gap between the query complexity of canonical and generalized Markov chains is at most near-quadratic.

Formally, we define a reduction from a generalized Markov chain M to a canonical Markov chain $\hat{M}$ below. See Figures 6.1 and 6.2 for an example of this reduction.

▶ **Definition 6.1** (Reduction to Canonical Markov chains)**.** *Let $M = (\Omega, P)$ be a Markov chain with state space Ω, transition matrix P, and an observation function $O : \Omega \to \Sigma$ that maps each state to an observable output. Let the emulated Markov chain of M be a canonical Markov chain $\hat{M} = (\hat{\Omega}, \hat{P})$ with state space $\hat{\Omega}$ and transition matrix $\hat{P}$ as follows:*

For each state $x \in \Omega$, there exists a unique corresponding state $\hat{x} = \phi(x)$ in $\hat{\Omega}$, where $\phi : \Omega \to \hat{\Omega}$ is an injective mapping. Let $k = |\Sigma|$ and and $\Sigma = \{\sigma_1, \ldots, \sigma_k\}$. Given a parameter $0 < q < 1$ we have

1. *For every pair of states $x, x' \in \Omega$ with transition probability $p_{x,x'}$ in P, we introduce an extended path in $\hat{M}$ consisting of a series of intermediate states $d_1^{x,x'}, d_2^{x,x'}, \ldots, d_{k-1}^{x,x'}$ with transition probability 1 between consecutive states, such that $\hat{x}$ transitions to $\hat{x}'$ via these intermediate states. $\hat{x}$ transitions to $d_1^{x,x'}$ with probability $qp_{x,x'}$ and $d_{k-1}^{x,x'}$ transitions to $\hat{x}'$ with probability 1.*
2. *To emulate the observation function O, we introduce a set of **special states** $\sigma_1, \sigma_2, \ldots, \sigma_k = s$ in $\hat{M}$, each representing a unique observation in Σ. s is the sink state of the canonical Markov chain $\hat{M}$. Each state $\hat{x} \in \hat{\Omega}$ in $\hat{M}$ transitions to a special state corresponding to its observation in M with probability $1 - q$. Special state σ_i transitions to σ_{i+1} with probability 1 for $i \in [k - 1]$.*

▶ **Theorem 6.2.** *Let $M = (\Omega, P)$ be a Markov chain in the generalized model with an observation function $O : \Omega \to \Sigma$, Then, there exists a canonical Markov chain $\hat{M} = (\hat{\Omega}, \hat{P})$ states and an injective mapping of the states $\phi : \Omega \to \hat{\Omega}$, such that for any two states $a, a' \in \Omega$,*

$$\mathsf{QC}_{\hat{M}}(\phi(a), \phi(a')) = \Theta\big(|\Sigma|\mathsf{QC}_M(a, a')\big).$$

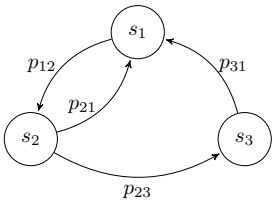

Figure 6.1 Represents a general Markov chain M with observations $\Sigma = \{\sigma_1, \sigma_2, \sigma_3\}$, where $O_{s_1} = \sigma_1, O_{s_2} = \sigma_2$, and $O_{s_3} = \sigma_2$.

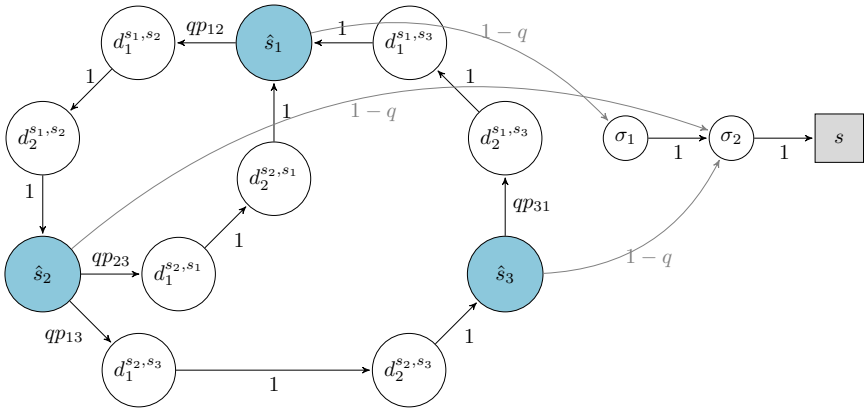

Figure 6.2 Represents a canonical Markov chain $\hat{M}$, with parameter $0 < q < 1$, where there is an injection ϕ that reduces distinguishing states a and a' in M to distinguishing $\phi(a)$ and $\phi(a')$ in $\hat{M}$.

▶ Remark 6.3. This reduction preserves running time up to the same multiplicative overhead: for any adaptive state identification algorithm $\mathcal{A}$ for M that makes Q queries and runs in time $Time(\mathcal{A})$, there is an algorithm $\hat{\mathcal{A}}$ for $\hat{M}$ that runs in time $Time(\mathcal{A}) + O(kQ)$, where $k = |\Sigma|$. Also, any adaptive algorithm $\hat{\mathcal{A}}$ for $\hat{M}$ with Q' queries and time $Time(\hat{\mathcal{A}})$ yields an algorithm for M with $\Omega(Q'/k)$ queries and time $Time(\hat{\mathcal{A}}) + O(Q')$.

▶ **Theorem 6.4.** *Let $M = (\Omega, P)$ be a Markov chain in the generalized model with an observation function $O : \Omega \to \Sigma$, Then, there exists a canonical Markov chain $\hat{M} = (\hat{\Omega}, \hat{P})$ states and an injective mapping of the states $\phi : \Omega \to \hat{\Omega}$, such that for any two states $a, a' \in \Omega$,*

$$\Omega\big(|\Sigma|\mathsf{NAQC}_M(a,a')\big) \leq \mathsf{NAQC}_{\hat{M}}(\phi(a),\phi(a')) \leq \tilde{O}\big(|\Sigma|\mathsf{NAQC}_M(a,a')^2\big).$$

▶ Remark 6.5. If a non-adaptive algorithm $\mathcal{A}$ for Markov chain M uses Q queries and runs in time $Time$, then the induced non-adaptive algorithm $\widehat{\mathcal{A}}$ for $\hat{M}$ can be implemented with $\tilde{O}(kQ^2)$ queries and total running time $Time(\mathcal{A}) + \tilde{O}(kQ^2)$, where $k = |\Sigma|$. Also, any non-adaptive $\hat{\mathcal{A}}$ for $\hat{M}$ with Q' queries and time $Time(\hat{\mathcal{A}})$ yields a non-adaptive algorithm for M with $\Omega(Q'/k)$ queries and running time $Time(\hat{\mathcal{A}}) + O(Q')$.

A Further Connections to Sublinear-Time Graph Algorithms

In this section, we further elaborate on the connections to sublinear-time graph algorithms by giving a concrete example where the lower bound is captured by Markov chains with rewinding.

We examine the lower bound of [11] for testing acyclicity in directed graphs. Given adjacency list access, the algorithm must determine whether the input graph is acyclic or ε-far from acyclic (i.e., at least an ε-fraction of the edges must be removed so that no directed cycles remain in the graph) with a probability of $\frac{2}{3}$. They prove that, for $\varepsilon \leq \frac{1}{16}$, any such algorithm requires at least $\Omega(n^{1/3})$ queries to the adjacency list. We show that this lower bound is captured by our model. First, we examine the case where the algorithm has access

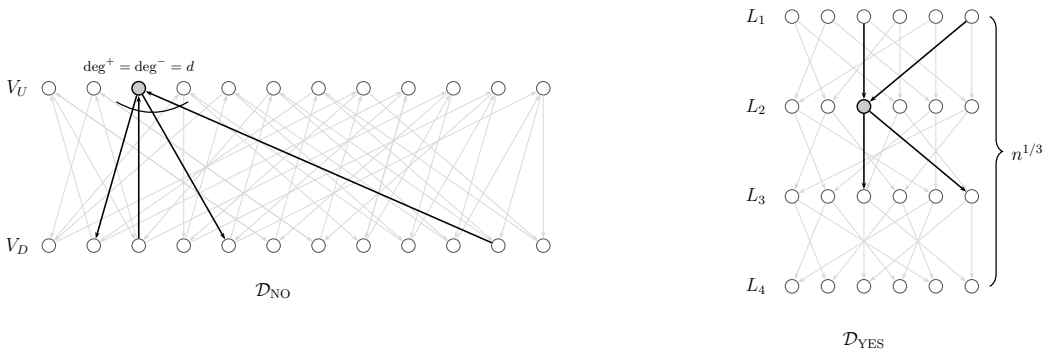

Figure A.1 Sample graphs from the $\mathcal{D}_{\text{YES}}$ (acyclic) and $\mathcal{D}_{\text{NO}}$ (far from acyclic) distributions. The typical vertex has an in-degree and out-degree of d.

only to the outgoing edges (and the out-degree) of a vertex, and later extend it to a setting where the algorithm has access to both the outgoing and incoming adjacency lists at the same time (as well as the in-degree and out-degree).

We start by reviewing the construction of [11]. By Yao's minimax lemma, to prove the lower bound, it suffices to construct two input distributions $\mathcal{D}_{\text{YES}}$ and $\mathcal{D}_{\text{NO}}$, respectively consisting of acyclic and far-from-acyclic graphs, such that any deterministic algorithm with $O(n^{1/3})$ queries fails to distinguish between them with a sufficiently large probability. The construction uses a constant degree-parameter $d \geq 128$ shared between $\mathcal{D}_{\text{YES}}$ and $\mathcal{D}_{\text{NO}}$.

The $\mathcal{D}_{\text{NO}}$ distribution constructs a graph by randomly partitioning the vertices into two groups, V_U and V_D, each of size $n/2$. For the edges, a bipartite d-regular graph between V_U and V_D is chosen uniformly at random and directed towards V_D, and another one is chosen similarly and directed towards V_U. As a result, each vertex in the graph has both in-degree and out-degree equal to d, and the graph is ε-far from acyclic with a high probability of $1 - 2^{-n}$, when $\varepsilon < \frac{1}{16}$ and $d \geq 128$ [11, Lemma 5].

The $\mathcal{D}_{\text{YES}}$ distribution constructs a graph by randomly partitioning the vertices into $n^{1/3}$ groups, $L_1, L_2, \ldots, L_{n^{1/3}}$, each of size $n^{2/3}$. For the edges, for each $1 \leq i < n^{1/3}$, a d-regular graph between L_i and L_{i+1} is chosen uniformly at random and directed towards L_{i+1}. As a result, the graph has no directed cycles and every vertex, except those of L_1 and $L_{n^{1/3}}$, has an in-degree and out-degree equal to d. The distributions are depicted in Figure A.1.

Now, we present the Markov chain that captures this lower-bound construction. The Markov chain consists of two parts: one for $\mathcal{D}_{\text{NO}}$ and one for $\mathcal{D}_{\text{YES}}$. In the NO part, each of the vertex groups V_U and V_D is represented by a state, v_U and v_D respectively. Considering that in the graph, the outgoing edges of V_U go to V_D and the outgoing edges of V_D go to V_U, in the Markov chain, we let v_D transition to v_U, and let v_U transition to v_D with probability 1. To model starting at a random vertex, we use an initial state x_{NO} that transitions to v_D or v_U with probability $\frac{1}{2}$ each. Similarly, in the YES part, each vertex group L_i is represented by a state ℓ_i. Each state ℓ_i for $1 \leq i < n^{1/3}$, transitions to the ℓ_{i+1} with probability 1. To model starting at a random vertex, we use an initial state x_{YES} that transitions to each of $\ell_1, \ell_2 \ldots, \ell_{n^{1/3}}$ with probability $\frac{1}{n^{1/3}}$. As the algorithm interacts with the Markov chain, the only observation it makes is whether the drawn state is $\ell_{n^{1/3}}$ or not. The Markov chain is illustrated in Figure A.2.

Next, we elaborate on how this Markov chain captures the lower bound. The key idea is that an algorithm that makes $O(n^{1/3})$ queries, does not discover any vertex more than once, with a sufficiently high constant probability. That is, the set of edges discovered by the sublinear algorithm does not contain any cycles, even when the directions are ignored. Let $(u_1, i_1), \ldots, (u_q, i_q)$ be the set of queries made to the adjacency lists. We assume without

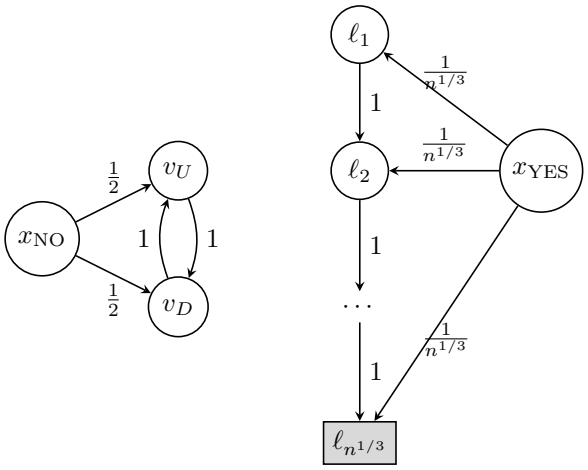

Figure A.2 A Markov chain that models exploring the input graph drawn from the $\mathcal{D}_{\text{YES}}$ and $\mathcal{D}_{\text{NO}}$ distributions. Distinguishing the initial states x_{YES} and x_{NO} is equivalent to distinguishing between the two input distributions.

loss of generality that the queries are unique (i.e., the same query is not made twice), and that the degree of each vertex is revealed to the algorithm as it is discovered.

▶ **Lemma A.1** ([11, Lemma 7]). *Consider any algorithm that makes $q \leq \frac{1}{4} \cdot n^{1/3}$ adjacency-list queries, and let $v_1, \ldots v_q$ be the answers, where $v_k \in V \cup \{\perp\}$. Then, with probability $1 - \frac{1}{16}$, no vertex appears in the answers more than once.*

As a result, we can assume without loss of generality that no vertex appears twice in the answers, since $\frac{1}{16}$ is a negligible probability and when a vertex appears twice, we can simply presume that the algorithm successfully distinguishes between the input distributions. Making this assumption, we argue that distinguishing between the input distributions $\mathcal{D}_{\text{YES}}$ and $\mathcal{D}_{\text{NO}}$ is equivalent to distinguishing between initial states x_{YES} and x_{NO} in the Markov chain. Since there are no repeated vertices, the subgraph explored by the algorithm is a set of rooted trees. When the algorithm explores the neighbors of a vertex u in a group of vertices A, the discovered neighbor v is a random vertex from a neighboring group B. The distribution of B is solely determined by A and does not depend on u.[4] Furthermore, the algorithm observes only the out-degree of each discovered vertex (which is different only for vertices in $L_{n^{1/3}}$), and not its group. This is paralleled by the transition probabilities in the Markov chain, and the partial observation of the state, which only differentiates $\ell_{n^{1/3}}$.

As a result, to prove the lower bound for acyclicity testing, it suffices to prove the following in the context of Markov chains:

▶ **Lemma A.2.** *Any algorithm that distinguishes between the initial states x_{YES} and x_{NO} with a probability of $5/8$, must make $\frac{1}{4} \cdot n^{1/3}$ queries to the Markov chain.*

The proof in [11] essentially argues the same thing, without ever explicitly defining a Markov chain. We give a high-level overview of their proof here. Since the only observation the algorithm can make is whether it has reached $\ell_{n^{1/3}}$ or not, it suffices to bound the probability of reaching $\ell_{n^{1/3}}$ when the initial state is x_{YES}. The next state drawn from x_{YES}

[4] in this construction, B is in fact a deterministic function of A.

is always a state ℓ_i, where $i \in \{1, 2, \ldots, n^{1/3}\}$ is uniformly random. As a result, exploring a tree of depth D from such a state, reaches $\ell_{n^{1/3}}$ with probability of at most $\frac{D+1}{n^{1/3}}$. Therefore, since the sum of the depths of the explored trees is $O(n^{1/3})$, the probability of reaching $\ell_{n^{1/3}}$ throughout the algorithm can be bounded by a constant.

Finally, we show that the lower bound is captured by our model in the more general case, where the algorithm is allowed to query both the incoming and outgoing adjacency lists. To do so, we use a simple gadget. On the YES side of the Markov chain, for each state ℓ_i, we create two paths of length two: A path $\ell_i \to d_i \to \ell_{i+1}$, corresponding to traversing the outgoing edges of L_i, and a path $\ell_i \to u_i \to \ell_{i-1}$, corresponding to traversing the incoming edges of L_i (the NO side is handled similarly). Additionally, we extend the observations made by the algorithm. Other than observing whether the current state is $\ell_{n^{1/3}}$, the algorithm can also observe whether the current state is (1) ℓ_1, the first layer corresponding to vertices with zero in-degree, (2) an auxiliary state d_i, indicating the traversal of an outgoing edge, and (3) an auxiliary state u_i, indicating the traversal of an incoming edge. This allows the algorithm to choose which of the directions it takes, while increasing the number of queries to the Markov chain only by a constant factor. See Section 6 for a discussion of Markov chains with a constant-sized observation alphabet.

One-Way Functions and Polynomial-Time Dimension

Abstract

The theory of randomness in computation has developed around several viewpoints on randomness and information, including statistical tests, compression schemes, betting strategies, and efficiently samplable sources. At the level of computability, several of these viewpoints turn out to be equivalent. A fundamental question is how robust these viewpoints remain when the underlying algorithms are subject to computational resource bounds. This paper studies this question for two polynomial-time notions of information density for infinite binary sequences. Polynomial-time dimension, denoted $\dim_{\mathrm{P}}$, quantifies information density using polynomial-time betting strategies called s-gales. Polynomial-time Kolmogorov complexity rate, denoted $\mathcal{K}_{\mathrm{poly}}$, gives a compression-based notion of polynomial-time information density using polynomial-time descriptions. Hitchcock and Vinodchandran (CCC 2004) showed that $\dim_{\mathrm{P}}(X) \geq \mathcal{K}_{\mathrm{poly}}(X)$ for every sequence X, and asked whether equality always holds. This question was later also posed by Stull.

Our main result proves a duality between the non-robustness of these polynomial-time information-density notions and the existence of one-way functions. Assuming one-way functions exist, we construct a polynomial-time samplable distribution over infinite sequences such that, with probability 1, the sampled sequence X satisfies $\dim_{\mathrm{P}}(X) > \mathcal{K}_{\mathrm{poly}}(X)$ by a uniform gap. Conversely, we show that if some polynomial-time samplable distribution yields such an almost-sure uniform separation, then infinitely-often one-way functions exist. Thus, separations between these two polynomial-time information-density notions over efficiently samplable sources lie at the same frontier as one-way functions, with the reverse direction yielding infinitely-often one-way functions. This duality gives a negative answer, assuming one-way functions, to the open question posed by Hitchcock, Vinodchandran, and Stull. Furthermore, we show that there are individual sequences witnessing separations between $\dim_{\mathrm{P}}$ and $\mathcal{K}_{\mathrm{poly}}$, and that the gap can be made arbitrarily close to 1. We also establish analogous bounds for strong polynomial-time dimension and asymptotic upper polynomial-time Kolmogorov complexity rates. The main technical challenge is to connect finite-length pseudorandomness assumptions with asymptotic information-density measures on infinite sequences. Our proof addresses this by developing several new constructions and arguments involving probabilistic tools such as the Borel–Cantelli lemma, Kolmogorov's inequality for martingales, and techniques for approximating probabilities of efficiently samplable distributions. The work shows that the question of non-robustness for polynomial-time information-density notions, which is prima facie different from standard questions about randomness, pseudorandomness, and cryptography, is in fact intimately related to the existence of one-way functions.

1 Introduction

An infinite binary sequence can contain regularity that is exposed in different ways. A statistical test may detect a deviation from randomness, a short description may compress many of its prefixes, or a betting strategy may turn predictable patterns into unbounded capital. These perspectives lead both to qualitative notions of randomness and quantitative measures of how much randomness remains visible to a given computational model.

This paper studies one such measure: polynomial-time dimension. We address the longstanding open question of whether its betting and compression formulations continue to agree. We give a negative answer under the assumption that one-way functions exist. The connection is not limited to deriving separations from cryptographic assumptions: we also prove a converse showing that such separations over efficiently samplable sources imply infinitely-often one-way functions.

Constructive dimension is an algorithmic analogue of classical Hausdorff dimension for individual infinite sequences. It was introduced by Lutz [27] via *unfair constructive betting strategies* on infinite sequences, called s-gales. Intuitively, an s-gale reads a sequence bit by bit and repeatedly bets its current capital on the next bit. The parameter s controls the payoff rule of the game. When s is smaller, the game is less favorable to the gambler, so success requires the gambler to exploit stronger regularities in the sequence. The gale succeeds on a sequence if its capital becomes arbitrarily large along that sequence. The constructive dimension of a sequence is the infimum over all values of s for which some constructive s-gale succeeds. Thus, constructive dimension is a threshold measure of how difficult it is for constructive betting strategies to extract profit from the sequence.

Lutz [28] and Mayordomo [29] gave an equivalent characterization of constructive dimension of a sequence in terms of the Kolmogorov complexity of its prefixes. Here $K(x)$ denotes the length of the shortest program that outputs the finite string x. In this formulation, the information density of a sequence is measured by comparing the shortest description lengths of its prefixes with their corresponding lengths. More precisely, this compression view is governed by the lower asymptotic rate of prefix complexity, namely the liminf of $K(X \upharpoonright n)/n$, where $X \upharpoonright n$ denotes the first n bits of X. Prefixes that admit much shorter descriptions indicate lower information density, while prefixes that resist compression indicate higher information density. Thus, for constructive dimension, the betting formulation and the compression formulation define the same notion of information density. These equivalent characterizations establish the robustness of constructive dimension as a mathematical concept. They also provide multiple viewpoints that are useful in different contexts for studying randomness and information density. This leaves a natural robustness problem in the polynomial-time setting: whether the compression characterization continues to match the betting characterization once both are restricted to efficient computation.

Polynomial-time dimension is the analogue of constructive dimension at the level of feasible or polynomial-time computation. As above, there are multiple approaches towards quantifying polynomial-time density of information. The *compressibility* approach uses the time-bounded Kolmogorov complexity of finite prefixes of infinite sequences. The resulting quantity, denoted $\mathcal{K}_{\text{poly}}$, is obtained from the lower asymptotic rate of prefix complexity when the programs producing the prefixes are required to run in polynomial time. In other words, $\mathcal{K}_{\text{poly}}$ measures the information density that remains after compression is restricted to efficient descriptions. The *gambling* approach defines polynomial-time dimension, denoted $\dim_{\text{P}}$, using polynomial-time betting algorithms known as s-gales [27]. Here again, an s-gale succeeds if its capital becomes arbitrarily large along the sequence, but now the gale itself must be computable in polynomial time. The value $\dim_{\text{P}}(X)$ is the infimum over all values of s for which some polynomial-time s-gale succeeds on X. Thus, $\dim_{\text{P}}$ measures the information density that cannot be exploited away by any polynomial-time betting strategy.

At the levels of polynomial-space computation [16] and finite-state computation [5, 4], these notions are known to be equivalent. At the polynomial-time level, Hitchcock and Vinodchandran proved that $\dim_{\text{P}}$ is at least as large as $\mathcal{K}_{\text{poly}}$. The converse direction has remained open for two decades. This question of *robustness of polynomial-time dimension* was posed by Hitchcock and Vinodchandran [14, 16], and later mentioned in a survey by Stull (see Open Question 3.71 in [36]).

The positive equivalences at the computability and polynomial-space levels rely on computational power that can effectively search over descriptions or simulate betting strategies. Such conversions are not available at polynomial time. Thus, in the polynomial-time setting, the robustness problem becomes sensitive to the computational limits imposed on the compression and betting algorithms. A related positive characterization is known for polynomial-time dimension when the compression side is formulated using reversible polynomial-time compressors that do not start from scratch [26]. In contrast, the question addressed in this paper concerns the original time-bounded Kolmogorov-complexity formulation of Hitchcock and Vinodchandran.

In this work, we give a surprising negative resolution to this question under the standard cryptographic assumption that one-way functions exist. First, assuming one-way functions, we construct a polynomial-time samplable distribution ν over Σ^∞ for which a set of sequences of ν-measure 1 exhibits a strict dimension gap between $\dim_{\text{P}}$ and $\mathcal{K}_{\text{poly}}$. We then strengthen this from sets to individual sequences, showing that there are sequences for which $\dim_{\text{P}} \neq \mathcal{K}_{\text{poly}}$ under the same assumption. Moreover, the gap $\dim_{\text{P}} - \mathcal{K}_{\text{poly}}$ can be made arbitrarily close to 1. The analogous non-robustness also holds for *strong* polynomial-time dimension, where lower asymptotic rates are replaced by upper asymptotic rates.

We also prove a partial converse: the existence of a polynomial-time samplable distribution supporting such dimension gaps implies the existence of infinitely-often one-way functions. This shows that the connection is not limited to deriving dimension gaps from cryptographic assumptions. Via the converse implication, dimension gaps over efficiently samplable sources lead to infinitely-often one-way functions.

Formally connecting one-way functions to the failure of robustness for these asymptotic measures of randomness requires arguments tailored to infinite sequences. The classical connections between compressibility, indistinguishability, and pseudorandomness in the finite-string setting [17, 38, 21] do not by themselves control information rates along infinitely many prefixes, or the success of a betting strategy along an infinite sequence.

The forward implication has to pass from asymptotic betting success on infinite sequences to finite-length distinguishers. A key step is an argument involving the Borel–Cantelli lemma, which isolates infinitely many lengths where the constructed source produces prefixes

on which the betting strategy has substantial gain. This is paired with a martingale estimate based on Kolmogorov's inequality, showing that comparable gains are unlikely under uniform randomness. The separation between these two behaviors is then turned into a pseudorandomness distinguisher.

The converse direction is technically different. Here the task is to show that an almost-sure dimension gap over an efficiently samplable source already carries cryptographic content. Assuming that infinitely-often one-way functions do not exist, one can approximate the probabilities of samplable distributions on typical inputs. The proof has to assemble these finite-prefix approximations into an efficient betting algorithm that works along the infinite sequence. This converts the absence of cryptographic hardness into a robustness statement for polynomial-time information density, and hence forces any such dimension gap to imply infinitely-often one-way functions.

In addition to resolving a longstanding open problem under the assumption that one-way functions exist, our results show that the robustness of polynomial-time information density is not merely a technical question internal to resource-bounded dimension. It is governed by the same phenomenon that underlies modern cryptography: the existence of efficiently samplable objects whose structure cannot be uniformly exposed by feasible computation. Thus the paper establishes a direct bridge between one-way functions and asymptotic information measures.

2 Background: Betting and Compression

Notation. Let Σ denote the binary alphabet $\{0,1\}$. Σ^n denotes the set of n-length strings and Σ^* denotes the set of all finite strings over Σ. For a finite string $w \in \Sigma^*$, $|w|$ denotes the length of w. 1^* denotes the set of all finite strings in the unary alphabet $\{1\}$. Σ^∞ denotes the *Cantor space*, or the set of all infinite strings over Σ. We use small letters w, x to represent finite strings and capital letters X, Y to represent infinite strings over Σ. For an infinite string $X \in \Sigma^\infty$, $X[i]$ denotes the ith bit of X and $X \upharpoonright n$ denotes the first n bits of X. For infinite string $X = X_1X_2X_3X_4\ldots$ and $m \geq n$, $X[n:m]$ denotes the the substring $X_nX_{n+1}X_{n+2}\ldots X_m$. For a finite string $w \in \Sigma^*$, $w[i]$, $w \upharpoonright n$ and $w[n:m]$ are defined similarly. λ denotes the empty string. $\mathbb{N}$ denotes the set of natural numbers and $\mathbb{Q}$ denotes the set of rationals. All the logarithms in the paper are taken to base 2 unless specified otherwise. For any function $f : \Sigma^\infty \to \Sigma^\infty$ and $\mathcal{S} \subseteq \Sigma^\infty$ let $f(\mathcal{S})$ denote $\{f(X) : X \in \mathcal{S}\}$.

For $w \in \Sigma^*$, C_w denotes the *cylinder set* of w, that is the set of all infinite sequences in Σ^∞ that begin with w. Let $\mathcal{B}(\Sigma^\infty)$ denote the Borel σ-algebra over Σ^∞ generated by the set of all cylinder sets $\{C_w : w \in \Sigma^*\}$. For two finite strings $x, y \in \Sigma^*$, $x.y$ denotes the concatenation of the strings x and y.

We use $\text{poly}(n)$ to denote the set of polynomial (time) functions $\bigcup_{c\in\mathbb{N}}\{n^c\}$. When the context is clear, we also use poly to denote $\text{poly}(n)$. We use U_n to denote the uniform probability distribution over Σ^n.

2.1 s-gales and Kolmogorov Complexity

***s*-gales** are real-valued betting strategies on infinite sequences. An s-gale may be viewed as a gambler that reads a sequence bit by bit and repeatedly reallocates its current capital between the two possible next bits. The gale d starts with initial capital 1 on the empty string. At the nth stage, after seeing a prefix $X_1X_2\ldots X_n$, the gale has capital $d(X_1X_2\ldots X_n)$ and places a bet on the next bit X_{n+1}. The rule of the game is that, for every finite string w, the capital assigned to the two possible extensions satisfies $2^s d(w) = d(w0) + d(w1)$. A gale d succeeds on the sequence $X \in \Sigma^\infty$ if it can make its capital arbitrarily large along the sequence, more precisely if $\limsup_{n\to\infty} d(X_1X_2\ldots X_n) = \infty$.

▶ **Definition 1** ([27, 28]). *For $s \in [0,\infty)$, an* s-supergale *is a function $d : \Sigma^* \to [0,\infty)$ such that $d(\lambda) < \infty$ and for every finite string $w \in \Sigma^*$, $d(w) \geq 2^{-s}(d(w0) + d(w1))$. An* s-gale *is a function $d : \Sigma^* \to [0,\infty)$ with $d(\lambda) < \infty$ for every finite string $w \in \Sigma^*$, $d(w) = 2^{-s}(d(w0) + d(w1))$. A* supermartingale *is a 1-supergale. A* martingale *is a 1-gale.*

Unless specified otherwise, for every s-supergale d, we assume that the initial capital $d(\lambda) = 1$.

▶ **Definition 2** ([27, 28],[1]). *The* success set *of an s-supergale d is $S^\infty(d) = \{ X \in \Sigma^\infty \mid \limsup_{n\to\infty} d(X \upharpoonright n) = \infty \}$. The* strong success set *of an s-supergale d is $S^\infty_{\text{str}}(d) = \{ X \in \Sigma^\infty \mid \liminf_{n\to\infty} d(X \upharpoonright n) = \infty \}$.*

For example, fix $s > 0$. The strategy that always bets all its capital on the next bit being 0 is given by $d(\lambda) = 1$, $d(w0) = 2^s d(w)$, and $d(w1) = 0$. This satisfies the s-gale condition. Along the sequence $000\cdots$, its capital after n steps is 2^{sn}, and hence it succeeds. On the other hand, a single bit 1 makes the capital drop to 0.

A more interesting example is obtained by betting according to a fixed bias. Let $0 < p < 1$, and define

$$d(w) = 2^{s|w|} p^{\#_0(w)} (1-p)^{\#_1(w)},$$

where $\#_0(w)$ and $\#_1(w)$ are the numbers of zeros and ones in w. Then $d(w0)+d(w1) = 2^s d(w)$, so d is an s-gale. If a sequence has limiting frequency p of zeros and $1-p$ of ones, then along its prefixes the exponential growth rate of this capital is $s - H(p)$, where $H(p)$ is the binary entropy. Thus, for every $s > H(p)$, this gale succeeds on such a biased sequence. This example illustrates how an s-gale can exploit statistical regularity rather than merely a fixed deterministic pattern.

When $s = 1$, the average capital after betting on $w0$ or $w1$ is equal to the previous capital $d(w)$. In this case the betting strategy is fair, and such s-gales are precisely martingales. When $s < 1$, the average capital after the bet is strictly smaller than $d(w)$. Thus the gambler is playing in an unfavorable market. This is often interpreted as "betting under inflation": unless the gambler detects structure in the sequence and bets accordingly, its capital tends to shrink. As s decreases, success requires increasingly strong regularities in the sequence.

The **Kolmogorov complexity** of a finite string x, denoted by $K(x)$, is the length of the shortest program that outputs x. That is, $K(x) = \min\{|\pi| : \mathcal{U}(\pi) = x\}$, where π is a program and $\mathcal{U}$ is the universal Turing machine. Any string x can be produced by a program that simply prints x, and therefore $K(x) \leq |x| + O(1)$. However, if the string contains regularity, there may be a much shorter program that outputs it. For instance, if all the even bits of the string are 0, then the program only needs to encode the bits at the odd indices and insert zeros in the even positions. In that case, $K(x)$ is at most about half the length of the string, up to additive constants.

▶ **Definition 3** (t-time-bounded Kolmogorov complexity [22, 24]). *Let t be a time-constructible function, and $x \in \Sigma^*$ be a finite binary string. The t-time bounded Kolmogorov complexity of x is $K_t(x) = \min\{|\Pi| \mid \Pi \in \Sigma^*$ and $\mathcal{U}(\Pi) = x$ in $t(|x|)$ steps$\}$, where $\mathcal{U}$ is any fixed efficient universal Turing machine.*

Since in the study of resource-bounded dimension we divide $K_t(x)$ by $|x|$, our results are unaffected by the choice between prefix-free Kolmogorov complexity and plain Kolmogorov complexity. We use plain Kolmogorov complexity in the rest of the paper.

2.2 Polynomial-time Dimension

Resource-bounded dimension is defined by placing resource bounds on the computation of the s-gale. Analogously, resource-bounded Kolmogorov complexity is defined by placing resource bounds on the programs that print a string. **Polynomial-time dimension** quantifies the rate of information in an infinite sequence, measured with respect to polynomial-time bounded computation. It is formulated using polynomial-time s-gales. An s-gale d wins on an infinite sequence X if $\limsup_{n\to\infty} d(X \upharpoonright n) = \infty$. The gale d is said to be polynomial-time computable if, for some $p(n) \in \mathrm{poly}(n)$, the value $d(w)$ can be computed in at most $p(n)$ time, where n is the length of w. Intuitively, $\dim_{\mathrm{P}}(X)$ is the infimum of the values of s for which there exists a polynomial-time s-gale that succeeds on X. Smaller values of s correspond to a more unfavorable betting environment. Thus, a low polynomial-time dimension means that some efficient betting strategy can exploit substantial regularity in the sequence, whereas high polynomial-time dimension means that the sequence resists such efficient betting.

On the other hand, in the *incompressibility approach*, we use the *time-bounded Kolmogorov complexity* to define a polynomial-time analogue of $\mathcal{K}$. For a given time bound $t(n)$, the ***t*-time bounded Kolmogorov complexity** $K_t(x)$ of a string x is the length of the shortest program that generates x in at most $t(|x|)$ time steps (see [24]).

For a given time bound $t(n)$, the quantity $\liminf_{n\to\infty} K_t(X \upharpoonright n)/n$ gives the asymptotic t-time-bounded rate of information in an infinite string X. The polynomial-time analogue of $\mathcal{K}$ is the infimum of this quantity over all polynomial-time bounds t.

Now, we define the asymptotic polynomial-time density of information of a subset $\mathcal{F} \subseteq \Sigma^\infty$.

▶ **Definition 4** ($\mathcal{K}_{\mathrm{poly}}$ and $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}$ [16, 36, 15]). *For any $\mathcal{F} \subseteq \Sigma^\infty$, define $\mathcal{K}_{\mathrm{poly}}(\mathcal{F}) = \inf_{t\in\mathrm{poly}} \sup_{X\in\mathcal{F}} \liminf_{n\to\infty} \frac{K_t(X\upharpoonright n)}{n}$ and $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(\mathcal{F}) = \inf_{t\in\mathrm{poly}} \sup_{X\in\mathcal{F}} \limsup_{n\to\infty} \frac{K_t(X\upharpoonright n)}{n}$.*

For individual sequences, we define $\mathcal{K}_{\mathrm{poly}}(X) = \mathcal{K}_{\mathrm{poly}}(\{X\})$ and $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(X) = \mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(\{X\})$. Note that $\mathcal{K}_{\mathrm{poly}}$ and $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}$ are equivalently defined in the following way.

▶ **Definition 5** ($\mathcal{K}_{\mathrm{poly}}$ and $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}$ [16, 36, 15]). *For any $X \in \Sigma^\infty$, define $\mathcal{K}_{\mathrm{poly}}(X) = \inf_{t\in\mathrm{poly}} \liminf_{n\to\infty} \frac{K_t(X\upharpoonright n)}{n}$ and $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(X) = \inf_{t\in\mathrm{poly}} \limsup_{n\to\infty} \frac{K_t(X\upharpoonright n)}{n}$.*

Now, we define time-bounded supergales. We first define $t(n)$-time computable s-gales.

▶ **Definition 6** ($t(n)$-time computability [27]). *An s-supergale $d : \Sigma^* \to [0,\infty)\cap\mathbb{Q}$ is $t(n)$-time computable if there exist a $O(t(n))$-time computable function $f : \Sigma^* \times 1^* \to \mathbb{Q}$ such that $|d(w) - f(w, 1^n)| \leq 2^{-n}$ for every $w \in \Sigma^*$ and $n \in \mathbb{N}$.*

Another notion of time-bounded computability is that of exact $t(n)$-time computability.

▶ **Definition 7** (Exact $t(n)$-time computability [27]). *An s-supergale $d : \Sigma^* \to [0,\infty) \cap \mathbb{Q}$ is exact $t(n)$-time computable if there exist a $O(t(n))$-time computable function $f : \Sigma^* \to \mathbb{Q}$ such that $d(w) = f(w)$ for every $w \in \Sigma^*$.*

Now, we define polynomial-time dimension and strong dimension.

▶ **Definition 8** (Polynomial-time dimension [27] and strong dimension [1, 36]). *The polynomial-time dimension of $\mathcal{F} \subseteq \Sigma^\infty$ is defined as*

$$\dim_{\mathrm{P}}(\mathcal{F}) = \inf\{s \mid (\exists k) \text{ there is an exact } n^k\text{-time computable } s\text{-gale } d \text{ such that } \mathcal{F} \subseteq S^\infty(d)\}.$$

For a sequence $X \in \Sigma^\infty$*, define* $\dim_{\mathrm{P}}(X) = \dim_{\mathrm{P}}(\{X\})$*. The* polynomial-time strong dimension $\mathrm{Dim}_{\mathrm{P}}(\mathcal{F})$ *of* $\mathcal{F} \subseteq \Sigma^\infty$ *is defined by replacing* S^∞ *by* S^∞_{str} *in the above expression. For a sequence* $X \in \Sigma^\infty$*, define* $\mathrm{Dim}_{\mathrm{P}}(X) = \mathrm{Dim}_{\mathrm{P}}(\{X\})$.

We now make an important remark. Polynomial-time dimension and strong dimension are often defined in terms of n^k-time computable s-gales that need not be exact computable. But these definitions are in fact equivalent. This is a direct consequence of the following lemma from [27] which is also useful in proving the main results in this paper.

▶ **Lemma 9** (Exact Computation Lemma [27]). *If there is a polynomial-time computable s-gale d such that $2^s \in \mathbb{Q}$, then there exists an exact polynomial-time computable s-gale $\tilde{d}$ such that $S^\infty(d) \subseteq S^\infty(\tilde{d})$.*

We will often use the terminology polynomial-time computable gales to refer to exact $t(n)$-time computable s-gales where $t(n) \in \mathrm{poly}(n)$. Similar comment applies in the case of exact polynomial-time computability and other notions related to gales such as martingales and supergales.

2.3 Robustness of Dimension

At the computability level, the relevant notions are $\mathcal{K}$, defined using time-unbounded Kolmogorov complexity $K(x)$, and dim, defined using lower semicomputable s-gales. Lutz [28] and Mayordomo [29] showed that the unbounded notions of $\mathcal{K}$ and dim are equivalent, hence establishing the robustness of *constructive* dimension.

PSPACE analogues of dim and $\mathcal{K}$ are defined by restricting the s-gales in the definition of dim to be polynomial-space computable and by using polynomial-space bounded Kolmogorov complexity in the definition of $\mathcal{K}$. Hitchcock and Vinodchandran [14, 16] showed that these notions of resource-bounded dimension coincide in the PSPACE setting. Thus polynomial-space dimension is robust in the same sense.

This leads to the following question: *Are the notions of polynomial-time dimension formulated using s-gales ($\dim_{\mathrm{P}}$) and time-bounded Kolmogorov complexity ($\mathcal{K}_{\mathrm{poly}}$) equivalent?* Hitchcock and Vinodchandran [16] showed that $\dim_{\mathrm{P}}$ is always greater than or equal to $\mathcal{K}_{\mathrm{poly}}$.

▶ **Theorem 10** ([14, 16]). *For every $\mathcal{F} \subseteq \Sigma^\infty$, $\mathcal{K}_{\mathrm{poly}}(\mathcal{F}) \leq \dim_{\mathrm{P}}(\mathcal{F})$.*

The question whether the reverse inequality holds has remained elusive. Hitchcock and Vinodchandran [14, 16] and later Stull in [36] posed the following open question:

▶ **Question 11** ([14, 16, 36]). *Is it true that, for every sequence $X \in \Sigma^\infty$, $\dim_{\mathrm{P}}(X) = \mathcal{K}_{\mathrm{poly}}(X)$?*

Polynomial-time strong dimension is a dual notion of polynomial-time dimension [1, 36]. As in the case of polynomial-time dimension, there exist two notions, one defined using s-gales and the other defined in terms of time-bounded Kolmogorov complexity. An s-gale d strongly succeeds on an infinite sequence X if $\liminf_{n\to\infty} d(X_1X_2\ldots X_n) = \infty$.

The strong dimension analogue of $\mathcal{K}_{\mathrm{poly}}$ is defined by replacing the lim inf in the definition of $\mathcal{K}_{\mathrm{poly}}$ with lim sup. The analogue of Theorem 10 also holds in this setting: $\mathrm{Dim}_{\mathrm{P}}$ is at least as large as $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}$. Stull in [36] posed the following question for the dual notion of strong dimension:

▶ **Question 12.** *Are the notions of polynomial-time strong dimension formulated using s-gales ($\mathrm{Dim}_{\mathrm{P}}$) and time-bounded Kolmogorov complexity ($\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}$) equivalent for every sequence $X \in \Sigma^\infty$?*

We answer both questions in the negative, under the standard cryptographic assumption that one-way functions exist.

2.4 Measure over Cantor Space

▶ **Definition 13** ([34]). *A function $\mu : \mathcal{M} \to [0, \infty]$, where $\mathcal{M} \subseteq P(\Sigma^\infty)$, is called a measure over $(\Sigma^\infty, \mathcal{M})$ if $\mu(\emptyset) = 0$ and μ is countably additive. That is, for any countable disjoint collection $\{E_k\}_{k=1}^\infty$ of measurable sets, $\mu\left(\bigcup_{k=1}^\infty E_k\right) = \sum_{k=1}^\infty \mu(E_k)$.*

We take $\mathcal{M}$ as the set of Borel Measurable sets. Note that $\mathcal{B} \subseteq \mathcal{M}$, where $\mathcal{B}$ is the Borel sigma algebra over Σ^∞, we omit $\mathcal{M}$ and say that μ is a measure over Σ^∞.

▶ **Definition 14.** *Let ν be a measure over Σ^∞. We say that ν is a probability distribution over Σ^∞ if it holds that $\nu(\Sigma^\infty) = 1$.*

Let ν be a probability distribution over Σ^∞. For every n, let ν_n denote the probability distribution induced by ν on Σ^n defined as $\nu_n(w) = \nu(C_w)$ for every $w \in \Sigma^*$.

Let Σ^∞ be the Cantor space. Now we define the uniform (Lebesgue) measure over the Cantor space [7, 31]. The uniform measure of a cylinder set C_w determined by a finite string w is defined as: $\mu(C_w) = 2^{-|w|}$. Using routine measure theoretic arguments, μ uniquely extends to a probability measure over $(\Sigma^\infty, \mathcal{B}(\Sigma^\infty))$ (see [2]).

2.5 One-way Functions and Pseudorandom Generators

One-way functions [6, 10, 23] are functions that are easy to compute but are hard to invert, except possibly on a negligible fraction of inputs. They are central in cryptography, since their existence is necessary for that of essential cryptographic primitives [17, 33, 12, 8, 30].

The following is the definition of one-way functions secure against uniform probabilistic polynomial-time adversaries.

▶ **Definition 15** (One-way functions [11, 37, 10]). *A function $f_n : \Sigma^* \to \Sigma^*$ is a one-way function (OWF) if there is a constant b such that f_n is computable in time n^b for sufficiently large n, and for every probabilistic polynomial-time algorithm A and every constant $c > 0$, $\Pr[A(f_n(U_n)) \in f_n^{-1}(f_n(U_n))] \leq \frac{1}{n^c}$, for all sufficiently large n, where the probability is taken over the choice of U_n and the internal randomness of algorithm A.*

To define pseudorandom generators, we first define computational indistinguishability.

▶ **Definition 16** (Computational Indistinguishability [11, 37]). *The ensembles of random variables $\{X_n\}_{n\in\mathbb{N}}$ and $\{Y_n\}_{n\in\mathbb{N}}$ are computationally indistinguishable if for every probabilistic polynomial-time algorithm T and every constant $c > 0$,*

$$|\Pr[T(X_n) = 1] - \Pr[T(Y_n) = 1]| \leq \frac{1}{n^c}$$

where the probabilities are taken over the distributions of either X_n or Y_n and the internal randomness of the algorithm T.

▶ **Definition 17** (Pseudorandom generators [11, 37, 10]). *A sequence of functions $\{G_n : \Sigma^{d(n)} \to \Sigma^n\}_{n\in\mathbb{N}}$ is a pseudorandom generator (PRG) if $d(n) < n$ for all n, there exists a uniform deterministic polynomial-time algorithm M such that $M(n, x) = G_n(x)$, and the ensembles $\{G_n(U_{d(n)})\}_{n\in\mathbb{N}}$ and $\{U_n\}_{n\in\mathbb{N}}$ are computationally indistinguishable.*

The theorem below states the equivalence of one-way functions and pseudorandom generators.

▶ **Theorem 18** (Equivalence theorem [17, 11, 10]). *The following are equivalent.*

1. *One-way functions exist.*
2. *There exist a pseudorandom generator with seed length $d(m) = m - 1$.*
3. *For every polynomial-time computable constant $\epsilon \in (0, 1)$, there exists a pseudorandom generator with seed length $d(m) = \epsilon \cdot m$.*

2.6 Efficiently Samplable Sources and Approximable Gales

We generalize the notion of polynomial-time samplable distributions [3] to probability distributions on the space of infinite sequences. This is the distributional setting in which our main duality theorem is stated: instead of considering arbitrary sequences alone, we also study typical outputs of efficiently samplable sources over Σ^∞.

Let ν be a probability measure over Σ^∞. For every n, let $\nu_n(w) = \nu(X \in \Sigma^\infty : w \sqsubseteq X)$[1] denote the probability distribution induced by ν on Σ^n. Now, we define polynomial-time samplable distributions on Σ^∞.

▶ **Definition 19.** *A probability distribution ν over Σ^∞ is polynomial-time samplable if there exists a probabilistic Turing machine M that uses $q(n)$ random bits, where q is a polynomial, such that for every n and $w \in \Sigma^n$, $\Pr_{r \sim \Sigma^{q(n)}}[M(1^n, r) = w] = \nu_n(w)$.*

An alternate way of defining polynomial-time samplable distributions on Σ^∞ is the following: $\nu = \{\nu_n\}$ is a *polynomial-time samplable distribution on* Σ^∞ if $\{\nu_n\}$ is a *polynomial-time samplable distribution* ([3]) such that for any $w \in \Sigma^n$, $\nu_n(w) = \nu_{n+1}(w.0) + \nu_{n+1}(w.1)$. The equivalence of these notions follows using routine measure theoretic arguments.

Primitives like one-way functions and pseudorandom generators are defined against *probabilistic* polynomial-time adversaries, whereas polynomial-time s-gales are *deterministic* betting strategies. To compare these two kinds of objects, we use a mild average-case evaluation notion for gales. The betting strategy itself remains a deterministic s-supergale, with the usual success condition along infinite sequences. The relaxation is only in how its capital function is accessed: on inputs drawn from the target samplable distribution, the capital is required to have an efficient randomized constant-factor approximation with high probability.

This is the natural interface for our distributional arguments. On the cryptographic side, pseudorandomness and probability-estimation results are inherently probabilistic and average-case over samples from a samplable distribution. On the dimension side, the object being analyzed is still a gale. Exact polynomial-time computable gales are included as a special case, since their values can be returned deterministically. Thus the notion below does not replace polynomial-time dimension. It is a technical strengthening used to formulate the almost-sure distributional separation and its converse.

This is in the spirit of the probabilistic approximation notions for martingales studied by Regan and Sivakumar [32], but we only need an inverse-polynomial average-case guarantee over ν_n: for each length n and every constant k, the estimator approximates $d(w)$ within a fixed constant factor on all but an n^{-k} fraction of samples $w \sim \nu_n$, and any approximation errors are allowed only on strings in support of ν_n.

▶ **Definition 20.** *Let $d : \Sigma^* \to [0, \infty) \cap \mathbb{Q}$ be an s-supergale and ν be any probability distribution over Σ^∞. d is $t(n)$-time ν-approximable if for every constant k there exist a probabilistic $t(n)$-time machine M and constant $c < 1$ such that for every n, $\{w \in \Sigma^n : M(w) \notin [c \cdot d(w), d(w)]\} \subseteq \mathrm{supp}(\nu_n)$ and $\nu_n\{w \in \Sigma^n : M(w) \notin [c \cdot d(w), d(w)]\} \leq n^{-k}$.*

[1] $\sqsubseteq$ denotes the prefix operator

Here $\mathrm{supp}(\nu_n) = \{w \in \Sigma^n : \nu_n(w) > 0\}$. The support condition prevents the approximation procedure from hiding errors on impossible prefixes. Equivalently, outside the support of the sampled prefix distribution, the estimator must still output a value within the specified multiplicative range, while on typical samples from the source it may fail only with inverse-polynomial probability.

3 Our Results

3.1 One-way functions and dimension gaps

Our main result gives a two-sided connection between one-way functions and dimension gaps over efficiently samplable sources. Assuming one-way functions, we construct a polynomial-time samplable distribution over Σ^∞ whose typical sequences have low polynomial-time Kolmogorov complexity rate but cannot be captured by low-dimensional polynomial-time betting strategies. Conversely, the existence of such a samplable source already implies infinitely-often one-way functions.

▶ **Theorem 21.** *In the following, (1) $\Longrightarrow$ (2) $\Longrightarrow$ (3):*

1. *One-way functions exist.*
2. *For every $s < 1/2$, there exists a polynomial-time samplable distribution ν over Σ^∞ such that:*
   a. *$\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(X) \le s$ for almost every $X \sim \nu$.*
   b. *For every $s' \in (s, 1/2)$ and every polynomial-time ν-approximable s'-supergale d, we have $\nu(S^\infty(d)) = 0$.*
3. *Infinitely-often one-way functions exist.*

Item (2a) says that, with ν-probability 1, the sampled sequence has small polynomial-time Kolmogorov complexity rate. In particular, $\mathcal{K}_{\mathrm{poly}}(X) \le s$ for ν-almost every $X \sim \nu$. The second part of Item (2) rules out success by low-dimensional polynomial-time ν-approximable supergales. Lemma 42 shows that, under the same assumption, this yields $\dim_{\mathrm{P}}(X) \ge 1/2$ for ν-almost every X. Since $s < 1/2$, this gives an almost-sure dimension gap over the samplable source.

It is important that the approximation notion in Item (2b) does not change the polynomial-time dimension appearing in the applications below. Every exact polynomial-time computable gale is polynomial-time ν-approximable, by returning its value deterministically. Thus Item (2b) rules out, in particular, ordinary polynomial-time betting strategies on positive-measure subsets of the samplable source. The approximability condition is used only to state the distributional theorem in a form compatible with pseudorandomness arguments and average-case probability-estimation results.

We prove Theorem 21 in two steps. First we show that one-way functions yield a polynomial-time samplable distribution exhibiting an almost-everywhere dimension gap between $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}$ and $\dim_{\mathrm{P}}$ (Lemma 25, giving (1)⇒(2)), and then we show that the existence of such a dimension-gap distribution yields infinitely-often one-way functions (Lemma 36, giving (2)⇒(3)).

3.2 Applications

Theorem 21 resolves the original robustness question for individual sequences, assuming one-way functions.

▶ **Theorem 22.** *If for all $X \in \Sigma^\infty$, $\dim_{\mathrm{P}}(X) = \mathcal{K}_{\mathrm{poly}}(X)$, then no one-way functions exist.*

Equivalently, assuming one-way functions, there are individual sequences X such that $\mathcal{K}_{\text{poly}}(X) < \dim_{\text{P}}(X)$. We extend this result to show that if one-way functions exist, then the distance between these quantities can be arbitrarily close to the maximum possible value of 1.

▶ **Theorem 23.** *If one-way functions exist, then for any $\epsilon > 0$, there exists $X \in \Sigma^\infty$ such that $\dim_{\text{P}}(X) - \mathcal{K}_{\text{poly}}(X) \geq 1 - \epsilon$.*

For polynomial-time strong dimension, we show that if one-way functions exist, then there exist sequences for which the gap between $\mathcal{K}^{\text{str}}_{\text{poly}}$ and Dim_{P} is arbitrarily close to 1.

▶ **Theorem 24.** *If one-way functions exist, then for any $\epsilon > 0$, there exists $X \in \Sigma^\infty$ such that $\text{Dim}_{\text{P}}(X) - \mathcal{K}^{\text{str}}_{\text{poly}}(X) \geq 1 - \epsilon$.*

Therefore, we show that if one-way functions exist, the answers to both parts of Open Question 3.71 from [36] are negative.

4 Proof Outline and Techniques

In this section we describe the main constructions and reductions behind our results. The emphasis is on how finite-length pseudorandomness arguments interact with asymptotic information-density notions over infinite sequences.

The main difficulty is that the two sides are formally quite different. Pseudorandomness is a finite-length indistinguishability notion against probabilistic polynomial-time tests, while dimension is an asymptotic notion defined by success of betting strategies along infinitely many prefixes of one sequence. The proof has to convert information in both directions: from asymptotic betting success to finite distinguishers, and from average-case probability estimation for samplable distributions to betting objects on infinite sequences.

4.1 From one-way functions to dimension gaps

We first show how one-way functions, through pseudorandom generators, yield efficiently samplable sources with an almost-everywhere dimension gap. Concretely, assuming one-way functions, for every $s < 1/2$ we construct a polynomial-time samplable distribution ν over Σ^∞ such that (i) $\mathcal{K}^{\text{str}}_{\text{poly}}(X) \leq s$ for ν-almost every X, and (ii) for every $s' \in (s, 1/2)$, no polynomial-time ν-approximable s'-supergale succeeds on a set of positive ν-measure.

▶ **Lemma 25.** *If one-way functions exist, then for every $s < 1/2$, there exist a polynomial-time samplable distribution ν over Σ^∞ such that:*

1. *$\mathcal{K}^{\text{str}}_{\text{poly}}(X) \leq s$ for almost every $X \sim \nu$.*
2. *For every $s' \in (s, 1/2)$ and any polynomial-time ν-approximable s'-supergale d, $\nu(S^\infty(d)) = 0$.*

Fix $s < 1/2$. Assume one-way functions exist, and choose a dyadic parameter $s_0 = 2^{-m}$ with $2s_0 < s$. Then there are pseudorandom generators $\{G_n\}_{n\in\mathbb{N}}$ running in time $t_G(n) \in \text{poly}(n)$ with constant stretch: for each n, $G_n : \Sigma^{s_0 n} \to \Sigma^n$. The choice of such an s_0 will give the stronger compression bound needed to obtain $\mathcal{K}^{\text{str}}_{\text{poly}}(X) \leq s$.

4.1.1 Construction of the PRG-induced source

We extend the family $\{G_n\}$ to a mapping on infinite sequences, $g : \Sigma^\infty \to \Sigma^\infty$, by applying the appropriate G_{2^i} blockwise to successive blocks of the input. Given a PRG $G_n : \Sigma^{s_0 n} \to \Sigma^n$ where $s_0 = 2^{-m}$ for some $m \in \mathbb{N}$, we construct a mapping g from the Cantor set to itself, by

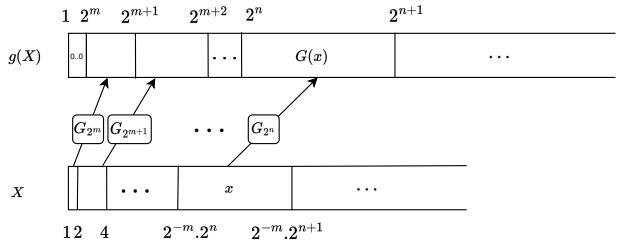

Figure 1 Illustration of the construction of $g(X)$. The first 2^m bits of $g(X)$ are 0. Thereafter, for every $n > m$, the block $X[s_0 \cdot 2^{n-1}, s_0 \cdot 2^n - 1]$ is mapped to $G_{2^{n-1}}(X[s_0 \cdot 2^{n-1}, s_0 \cdot 2^n - 1])$ in the output string $g(X)$.

using the family $\{G_n\}_{n\in\mathbb{N}}$ to map blocks within the input string to *longer* blocks within the output string. Given an input $X \in \Sigma^\infty$, $g(X)$ is constructed by applying G_n to successive blocks x of size $s_0 \cdot 2^n$ from X for all $n \in \mathbb{N}$. We first define a sequence of mappings g_k from Σ^k to Σ^*. These mappings preserve the prefix ordering among finite strings and hence we define $g(X)$ for $X \in \Sigma^\infty$ as the limit of $g_k(X \upharpoonright k)$.

▶ **Definition 26.** *Let $G_n : \Sigma^{s_0 n} \to \Sigma^n$ where $s_0 = 2^{-m}$ for some $m \in \mathbb{N}$ and let $k \in \mathbb{N}$. For $w \in \Sigma^k$, define $g_k(w)$ as follows. For any n satisfying any $m < n \leq \lfloor \log(k/s_0) \rfloor$ and $i \in \{2^{n-1}+1, 2^{n-1}+2, \ldots 2^n\}$, let $g_k(w)[i] = G_{2^{n-1}}(x)[i-2^{n-1}]$, where $x = w[s_0 \cdot 2^{n-1}, s_0 \cdot 2^n - 1]$. For $i \in \{1, 2, \ldots, 2^m\}$, we set $g_k(w)[i] = 0$.*

Note that $g_k(w)[2^{n-1}+1, 2^n] = G_{2^{n-1}}(w[s_0 \cdot 2^{n-1}, s_0 \cdot 2^n - 1])$. For $k \leq 2^m$, g_k maps any $w \in \Sigma^k$ to 0^{2^m}. Observe that the sequence of mappings $\langle g_k \rangle_{k\in\mathbb{N}}$ preserves the prefix order between strings. That is, If $w' \sqsubseteq w$, then $g_{|w'|}(w') \sqsubseteq g_{|w|}(w)$. Therefore, we define g as the limit of the mappings g_k as $k \to \infty$.

▶ **Definition 27.** *For every $X \in \Sigma^\infty$ let $g(X) = \cap_{n=1}^\infty C_{g(X\upharpoonright n)}$.*

Notice that for any $X \in \Sigma^\infty$ and $k \in \mathbb{N}$, $g_k(X \upharpoonright k) \sqsubseteq g(X)$. For convenience, we abuse the notation and use g to denote the mapping between infinite strings defined above or a mapping between finite strings defined as follows: $g(w) = g_{|w|}(w)$ for any $w \in \Sigma^*$. The intended meaning is clear from the context.

The mapping g induces a polynomial-time samplable distribution ν over Σ^∞. The sampling algorithm M for ν on input 1^n maps a random seed of length $s_0 \cdot 2^{\lceil \log_2(n) \rceil}$ using g to a string of length $2^{\lceil \log_2(n) \rceil}$, and thereafter trims the output to n bits. The number of random bits used by M on input 1^n is at most $2s_0 \cdot n$. Intuitively, because the sampler uses at most $2s_0 n$ random bits on input 1^n, those random bits, together with a fixed $O(1)$-bit description of the sampler, provide a short polynomial-time description of the output prefix. Thus, for ν-a.e. X, we obtain $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(X) \leq 2s_0 < s$. The formal complexity bound is given by the following lemma and corollary.

▶ **Lemma 28.** *For $s_0 = 2^{-m}$ for some $m > 1$, let $G_n : \Sigma^{s_0 n} \to \Sigma^n$ be a PRG that runs in time $t_G(n)$. Let $g : \Sigma^\infty \to \Sigma^\infty$ be the function constructed from G_n as in Definition 26. There exists a constant $c \in \mathbb{N}$ such that for all $X \in \Sigma^\infty$ and for all $n \in \mathbb{N}$, $K_{t_g}(g(X) \upharpoonright 2^n) \leq s_0 \cdot 2^n + c$, where $t_g(n) = t_G(n) \cdot n$.*

Proof. Consider the algorithm M which implements the mapping in Definition 26 as follows.

Algorithm 1 Algorithm M.

Input: A string w.
if $w = \lambda$ **then**
    Output λ
else
    Output 0^{2^m}
end if
for $i = m$ to $\lfloor \log(|w|2^m) \rfloor - 1$ **do**
    Output $G_{2^i}(w[2^{-m} \cdot 2^i, 2^{-m} \cdot 2^{i+1} - 1])$
end for

Since G_n runs in $t_G(n)$ time, it follows that M runs in $t_g(n) = t_G(n) \cdot n$ time. Also, for any $X \in \Sigma^\infty$ and $n \geq m$, M outputs the string $g(X) \upharpoonright 2^n$ on input $X \upharpoonright 2^{-m} \cdot 2^n = X \upharpoonright s_0 \cdot 2^n$. Therefore, it follows that $K_{t_g}(g(X) \upharpoonright 2^n) \leq s_0 \cdot 2^n + c$ where the constant c depends only on the length of any representation of M in the prefix language of the fixed universal Turing machine. ◀

We obtain the following corollary.

▶ **Corollary 29.** *For $s_0 = 2^{-m}$ for some $m > 1$, let $G_n : \Sigma^{s_0 n} \to \Sigma^n$ be a PRG that runs in time $t_G(n)$. Let $g : \Sigma^\infty \to \Sigma^\infty$ be the function constructed from G_n as in Definition 26. There exists a constant $c \in \mathbb{N}$ such that for all $X \in \Sigma^\infty$ and for all $i \in \mathbb{N}$, $K_{t_g}(g(X) \upharpoonright i) \leq 2s_0 \cdot i + 2\log(i) + c'$, where $t_g(n) = t_G(n)n$.*

Proof. From Lemma 28, $K_{t_g}(g(X) \upharpoonright 2^{\lceil log(i) \rceil}) \leq s_0 \cdot 2^{\lceil log(i) \rceil} + c'$. With $K_n(i)$ extra bits, we specify the index i at which $g(X) \upharpoonright 2^{\lceil log(i) \rceil}$ needs to be trimmed. Thus, we obtain a program that outputs $g(X) \upharpoonright i$ in $t_g(n)$-time. There is a trivial prefix-free program which given $2\log(i)$ bits of information, runs in linear time and prints i. Hence, the value of $K_n(i) \leq 2\log(i) + O(1)$. Since $2^{\lceil log(i) \rceil} \leq 2i$, there exists $c' > 0$ such that $K_{t_g}(g(X) \upharpoonright i) \leq 2s_0 \cdot i + K_n(i) + c \leq 2s_0 \cdot i + 2\log(i) + c'$. ◀

4.1.2 From betting gains to a finite-length distinguisher

Suppose toward a contradiction that there exist $s' \in (s, 1/2)$ and a polynomial-time ν-approximable s'-supergale d' with $\nu(S^\infty(d')) > 0$. Since $2s_0 < s < s'$, this is in particular a gale exponent above the compression rate obtained from the PRG-induced source. Using standard gale manipulations, we convert d' into a polynomial-time ν-approximable supermartingale $\tilde{d}$ that exhibits large multiplicative gains between dyadic checkpoints 2^{n-1} and 2^n infinitely often along every sequence in some positive-ν-measure set. This conversion is carried out in two stages, established in the following lemmas.

▶ **Lemma 30.** *For $s' \in [0, \infty)$ if $d' : \Sigma^* \to \mathbb{R}_{\geq 0}$ is a $t(n)$-time computable ν-approximable s'-supergale, then for any s'' satisfying $s' \leq s'' \leq 1$ and $2^{s''} \in \mathbb{Q}$, there exists an exact $t(n)poly(n)$-time ν-approximable supermartingale $\tilde{d} : \Sigma^* \to \mathbb{R}_{\geq 0}$ such that for any $X \in S^\infty(d')$,*

$$\limsup_{n \to \infty} 2^{-(1-s'')n} \tilde{d}(X \upharpoonright n) = \infty.$$

Proof. Let $s'' \geq s'$ such that $2^{s''} \in \mathbb{Q}$. We know that d' is a $t(n)$-time ν-approximable s''-supergale that succeeds on X (see Observation 4.4 from [27]). Let $\bar{d}$ be defined as $\bar{d}(w) = d'(w)2^{(1-s'')|w|}$. Note that as d' is ν-approximable, it follows that $\bar{d}$ is ν-approximable.

From Observation 3.2 in [28], it follows that $\bar{d}$ is a supermartingale such that,

$$\limsup_{n\to\infty} \frac{\bar{d}(X \upharpoonright n)}{2^{(1-s'')n}} = \infty.$$

Since $2^{s''}$ is rational, so is $2^{(1-s'')}$. Hence, $\bar{d}$ is an $t(n)poly(n)$-time ν-approximable supermartingale. ◀

▶ **Lemma 31.** *For $s' < 1/2$, let $d' : \Sigma^* \to \mathbb{R}_{\geq 0}$ be an $t(n)$-time ν-approximable s'-supergale. Let $\tilde{s}$ be such that $\tilde{s} > s'$, $2^{\tilde{s}} \in \mathbb{Q}$. Then, there exists an $t(n)poly(n)$-time ν-approximable supermartingale $\tilde{d} : \Sigma^* \to \mathbb{R}_{\geq 0}$ such that for any $X \in S^\infty(d')$, there exists infinitely many $n \in \mathbb{N}$ such that $\tilde{d}(X \upharpoonright 2^n) > 2^{(1-\tilde{s})2^{n-1}} \tilde{d}(X \upharpoonright 2^{n-1})$.*

Proof. Choose $s'' \in (s', 1/2)$ such that $s' < 2s' < 2s'' < \tilde{s}$ and $2^{s''} \in \mathbb{Q}$. Let $\tilde{d}$ be the $t(n)poly(n)$-time ν-approximable supermartingale from Lemma 30 such that

$$\limsup_{n\to\infty} \frac{\tilde{d}(X \upharpoonright n)}{2^{(1-s'')n}} = \infty.$$

Suppose, toward a contradiction, that for some $m > 0$ and every $n > m$,

$$\tilde{d}(X \upharpoonright 2^n) \leq 2^{(1-\tilde{s})2^{n-1}} \tilde{d}(X \upharpoonright 2^{n-1}).$$

Then, for any $n > m$ and $\ell \leq 2^n$,

$$\tilde{d}(X \upharpoonright (2^n + \ell)) \leq 2^\ell 2^{(1-\tilde{s})\sum_{i=m}^{n-1} 2^i} \tilde{d}(X \upharpoonright 2^m) = 2^\ell 2^{(1-\tilde{s})(2^n - 2^m)} \tilde{d}(X \upharpoonright 2^m).$$

If also $\tilde{d}(X \upharpoonright (2^n + \ell)) \geq 2^{(2^n+\ell)(1-s'')}$, then rearranging gives

$$2^{\ell s''} \geq \frac{2^{(1-\tilde{s})2^m}}{\tilde{d}(X \upharpoonright 2^m)} 2^{2^n(\tilde{s}-s'')}.$$

Since $\ell \leq 2^n$, we obtain

$$2^{2^n(\tilde{s}-2s'')} \leq \frac{\tilde{d}(X \upharpoonright 2^m)}{2^{(1-\tilde{s})2^m}}. \tag{1}$$

If there are infinitely many k such that $\tilde{d}(X \upharpoonright k) \geq 2^{(1-s'')k}$, then (1) holds for infinitely many n. But this is impossible for all large enough n, since $\tilde{s} > 2s''$. Therefore, for infinitely many n,

$$\tilde{d}(X \upharpoonright 2^n) > 2^{(1-\tilde{s})2^{n-1}} \tilde{d}(X \upharpoonright 2^{n-1}),$$

as required. ◀

Let M be a polynomial-time ν-approximator for $\tilde{d}$. We then define a polynomial-time algorithm A that, on input length 2^n, samples a random r, forms the corresponding prefix $w' = g(r) \upharpoonright 2^n$, and checks via M whether appending the input causes $\tilde{d}$ to jump by the required multiplicative factor.

4.1.3 The distinguisher algorithm

Let $\tilde{d}$ be the $t(n) \cdot poly(n)$-time ν-approximable martingale obtained from Lemma 31. Let M be the Turing machine that ν-approximates d. That is for all $n \in \mathbb{N}$, $\nu_n\{w \in \Sigma^n : M(w) \notin [\mathbf{c} \cdot d(w), d(w)]\} \leq n^{-k}$ where $\mathbf{c} \in \mathbb{Q}, k \in \mathbb{N}$ are constants such that $\mathbf{c} \leq 1$ and $k \geq 1$. We use M to build a distinguisher algorithm A that breaks the PRG $\{G_n\}$.

Algorithm 2 Algorithm A.

Input: A string w where $|w| = 2^n$
$r \leftarrow \text{random}(s_0 \cdot 2^n)$ ▷ Generate a random seed of length $s_0 \cdot 2^n$
for $i = m$ to $n-1$ **do**
    $v_i \leftarrow G_{2^i}(r[s_0 \cdot 2^i, s_0 \cdot 2^{i+1} - 1])$ ▷ Use r and G_{2^i} to get a PRG output of length 2^i
end for
$w' \leftarrow 0^{2^m} v_1 \dots v_n$ ▷ Concatenate all v_i
return 1 **if** $M(w'w) \geq \mathbf{c} \cdot 2^{(1-\tilde{s})|w|} \cdot M(w')$.

4.1.4 Performance on PRG outputs

A remaining subtlety is that the martingale guarantee is only *infinitely often* along each sequence in a positive-measure set. We upgrade this to a *noticeable fraction at infinitely many lengths* using a Borel–Cantelli argument, which yields infinitely many n for which a polynomially-large set of seeds r witnesses the required dyadic-block gain. At these lengths, the ν-approximation property of M ensures that A outputs 1 with inverse-polynomial probability on PRG outputs.

We first define the function f such that $f(X, n) = 1$ if $\tilde{d}$ has a sufficiently large gain in the n-th block of X, and $f(X, n) = 0$ otherwise.

▶ **Definition 32.** *Let $f : \Sigma^\infty \times \mathbb{N} \to \{0,1\}$ be defined by specifying $f(X,n) = 1$ if $\tilde{d}(X \upharpoonright 2^n) > 2^{(1-\tilde{s})2^n} \tilde{d}(X \upharpoonright 2^{n-1})$ and 0 otherwise.*

The following fact is a consequence of the Borel Cantelli Lemma [2].

▶ **Lemma 33.** *Let $f : \Sigma^\infty \times \mathbb{N} \to \{0,1\}$ and $\mathcal{S} \subseteq \Sigma^\infty$ such that $\nu(\mathcal{S}) > 0$. If for every $X \in \mathcal{S}$, there exist infinitely many $n \in \mathbb{N}$ such that $f(X,n) = 1$, then for any $c > 1$, there exist infinitely many $n \in \mathbb{N}$, such that $\nu(\{X : f(X,n) = 1\}) > n^{-c}$.*

Now, we apply the above lemma to the martingale $\tilde{d}$ from Lemma 30 to obtain the following. Recall that ν was defined at the start of this section as the distribution obtained by applying g to random seeds.

▶ **Lemma 34.** *Given $\tilde{d} : \Sigma^* \to \mathbb{R}_{\geq 0}$, if for all sequences $X \in \mathcal{S}$ where $\nu(\mathcal{S}) > 0$, there exists infinitely many $n \in \mathbb{N}$ such that $\tilde{d}(X \upharpoonright 2^n) > 2^{(1-\tilde{s})2^{n-1}} \tilde{d}(X \upharpoonright 2^{n-1})$, then it holds that for infinitely many n,*

$$\Pr_{x \sim \Sigma^{s_0 \cdot 2^n}}[\tilde{d}(g(x)) > 2^{(1-\tilde{s})2^n} \tilde{d}(g(x \upharpoonright s_0 \cdot 2^{n-1}))] \geq \frac{1}{n^2}. \tag{2}$$

This follows directly from Lemma 33. Indeed, by the hypothesis and the definition of f, every $X \in \mathcal{S}$ satisfies $f(X,n) = 1$ for infinitely many n. Since $\nu(\mathcal{S}) > 0$, Lemma 33 implies that this event has ν-measure at least n^{-c} for infinitely many n, for every $c > 1$. Unwinding the definition of f and using that ν is induced by applying g to uniformly random seeds gives the displayed probability bound; taking $c = 2$ completes the proof.

Now we analyze the performance of the algorithm on outputs of the PRG. Let $n+1$ be one of the lengths at which the condition in Lemma 34 holds. Let $w', w \in \Sigma^{2^n}$ such that $w = G_{2^n}(x)$ for some $x \in \Sigma^{s_0 2^n}$ and $w' = g(r)$ for some $r \in \Sigma^{s_0 2^n}$.

In order for the condition $M(w'w) \geq \mathbf{c} \cdot 2^{(1-\tilde{s})|w|} \cdot M(w')$ to hold, it suffices that $\tilde{d}(w'w) \geq 2^{(1-\tilde{s})|w|} \cdot \tilde{d}(w')$ and $M(w'w) \geq \mathbf{c} \cdot \tilde{d}(w'w)$ and $M(w) \leq \tilde{d}(w)$.

From Lemma 34, it follows that the first condition holds with probability at least $(n+1)^{-2}$ among x, r selected uniformly at random from $\Sigma^{s_0 \cdot 2^n} \times \Sigma^{s_0 \cdot 2^n}$ and taking $w = g(x), w' = g(r)$. Since $\tilde{d}$ is ν-approximable, for some $k \in \mathbb{N}$, on input $w \in \Sigma^{2^n}$, the computations of all $M(w)$ in Algorithm 2 outputs a value in $[\mathbf{c} \cdot \tilde{d}(w), \tilde{d}(w)]$ with probability at least $1 - 2^{-(kn-1)}$ according to the distribution ν_{2^n}. Note that the distribution according to ν_{2^n} corresponds to g applied to the uniform distribution on $2^{s_0 n}$.

Therefore it follows that for infinitely many n,

$$\Pr_{(x,r)\sim\Sigma^{s_0\cdot 2^n}\times\Sigma^{s_0\cdot 2^n}}[A(G_{2^n}(x), r) = 1] \geq \frac{1}{(n+1)^2} - \frac{1}{2^{kn}}.$$

Hence, taking $N = 2^n$, for infinitely many n,

$$\Pr_{x\sim\Sigma^{s_0\cdot N}}[A(G_N(x)) = 1] \geq \frac{1}{(\log N + 1)^2} - \frac{1}{N^k}. \tag{3}$$

4.1.5 Performance on uniformly random inputs

Finally, we show that A outputs 1 with exponentially small probability on a uniformly random input of the same length. This uses the Kolmogorov inequality for supermartingales to bound how many extensions can force a multiplicative jump of the required size, together with the fact that M fails to approximate $\tilde{d}$ only on a ν-small set.

▶ **Lemma 35** (Kolmogorov Inequality [27]). *Let $d : \Sigma^* \to \mathbb{R}_{\geq 0}$ be a supermartingale. For any $w' \in \Sigma^*$ and $n, c \in \mathbb{N}$, the number of strings $w \in \Sigma^n$ such that $d(w'y) \geq c \cdot d(w')$ for some $y \sqsubseteq w$ is less than or equal to $2^n/c$.*

We need an upper bound on the number of strings $w \in \Sigma^{2^n}$ and $r \in \Sigma^{s_0 2^n}$ such that $A(w, r) = 1$. This happens when $M(w'w) \geq \mathbf{c} \cdot 2^{(1-\tilde{s})|w|} \cdot M(w')$.

For any $n \in \mathbb{N}$, take any $r \in \Sigma^{s_0 \cdot 2^n}$, and let $w' = g(r)$. Using the Kolmogorov Inequality for Martingales (Lemma 35), the number of strings $w \in \Sigma^{2^n}$ such that $\tilde{d}(w'w) \geq \mathbf{c}^2 \cdot 2^{|w|(1-\tilde{s})}\tilde{d}(w')$ is less than $2^{|w|}/(\mathbf{c}^2 \cdot 2^{|w|(1-\tilde{s})})$.

For the remaining set of strings, we have that $\tilde{d}(w'w) < \mathbf{c}^2 \cdot 2^{|w|(1-\tilde{s})}\tilde{d}(w')$. If we have that $M(w'w) \leq \tilde{d}(w'w)$ and $M(w') \geq \mathbf{c} \cdot \tilde{d}(w')$, it follows that $A(w, r) = 0$.

We know that, $\nu\{w \in \Sigma^{2^n} : M(w) \notin [\mathbf{c} \cdot \tilde{d}(w), \tilde{d}(w)]\} \leq 2^{-nk}$ for some $k \in \mathbb{N}$. From this, it follows that $\Pr_{r\in\Sigma^{s_0\cdot N}}[M(w') < \mathbf{c} \cdot \tilde{d}(w')] \leq 2^{-nk}$.

Notice that $\{w \in \Sigma^j : M(w) \notin [\mathbf{c} \cdot \tilde{d}(w), \tilde{d}(w)]\} \subseteq \mathrm{supp}(\nu_j)$ for every j. From the block-wise definition of the mapping g, for any fixed $w' \in g(\Sigma^{2^n})$, we obtain that there are at most $2^{s_0 \cdot 2^n}$ strings in the set $\{w'w\}_{w\in\Sigma^{2^n}}$ contained in $\mathrm{supp}(\nu_{2^{n+1}})$. Therefore, for any fixed w', the number of strings $w \in \Sigma^{2^n}$ such that $M(w'w) \notin [\mathbf{c} \cdot \tilde{d}(w'w), \tilde{d}(w'w)]$ is at most $2^{s_0 \cdot 2^n}$. Therefore, we have that

$$\Pr_{x\sim\Sigma^N}\Pr_{r\in\Sigma^{s_0\cdot N}}[A(x, r) = 1] < \mathbf{c}^{-2} \cdot 2^{-N(1-\tilde{s})} + N^{-k} + 2^{-(1-s_0)N}.$$

Therefore, it follows that for any $n \in \mathbb{N}$,

$$\Pr_{x\sim\Sigma^N}[A(x) = 1] < \mathbf{c}^{-c} \cdot 2^{-N(1-\tilde{s})} + N^{-k} + 2^{-(1-s_0)N}.$$

Comparing the two cases yields that for infinitely many lengths, A distinguishes PRG outputs from uniform with non-negligible advantage, contradicting pseudorandomness. Hence $\nu(S^\infty(d')) = 0$ for every polynomial-time ν-approximable s'-supergale with $s' \in (s, 1/2)$.

4.1.6 Proof of Lemma 25

Proof. If one-way functions exist then there exists PRG $G_n : \Sigma^{s_0 n} \to \Sigma^n$ running in time $t_G(n) \in \mathrm{poly}(n)$ [Theorem 18]. Using $\{G_n\}$, we construct a polynomial-time samplable distribution ν over Σ^∞ as above. By Corollary 29 and the choice of s_0, we have $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(X) \leq 2s_0 < s$ for almost every $X \sim \nu$.

From the arguments in Sections 4.1.4 and 4.1.5, we obtain the following consequence. Suppose there exists some $s' \in (s, 1/2)$ and a polynomial-time ν-approximable s'-supergale d such that $\nu(S^\infty(d)) > 0$. Then there exists a distinguisher algorithm A running in time $t_A(n) \in \mathrm{poly}(n)$ such that, for infinitely many $N \in \mathbb{N}$ and for all $k \in \mathbb{N}$,

$$\Pr_{x \in \Sigma^{s_0 \cdot N}}[A(G_N(x)) = 1] - \Pr_{x \in \Sigma^N}[A(x) = 1] > \frac{1}{(\log N + 1)^2} - \frac{2}{N^k} - \frac{1}{\mathbf{c}^2 \cdot 2^{N(1-\tilde{s})}} - \frac{1}{2^{N(1-s_0)}}.$$

Let c be any constant such that $t_A(n) \leq n^c$ and for all large enough N,

$$\frac{1}{(\log N + 1)^2} - \frac{2}{N^k} - \frac{1}{\mathbf{c}^2 \cdot 2^{N(1-\tilde{s})}} - \frac{1}{2^{N(1-s_0)}} \geq \frac{1}{N^c}.$$

It follows that G_N is not a $(N^c, 1/N^c)$ PRG for infinitely many N. Therefore the family $\{G_n\}_{n \in \mathbb{N}}$ is not a PRG, contradicting the assumption that one-way functions exist. This completes the proof of the lemma. ◀

4.2 Infinitely-often one-way functions from dimension gaps

We now explain the reverse direction: an almost-everywhere dimension gap over an efficiently samplable source can be converted into infinitely-often one-way functions.

▶ **Lemma 36.** *If there exist an $s < 1$ and a polynomial-time samplable distribution ν over Σ^∞ such that:*

1. *$\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(X) \leq s$ for ν-almost every X.*
2. *There exists $\hat{s} \in (s, 1]$ such that for every $s' \in (s, \hat{s})$ and every polynomial-time ν-approximable s'-supergale d, we have $\nu(S^\infty(d)) = 0$.*

Then infinitely-often one-way functions exist.

Proof. Assume the hypothesis, and toward a contradiction assume that infinitely-often one-way functions do not exist. Fix reals $s < s' < s'' < s''' < \hat{s}$ with $2^{s'''} \in \mathbb{Q}$, and define

$$d(w) := 2^{s'''|w|}\, \nu(w).$$

It is straightforward that d is an s'''-supergale. The low-$\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}$ condition implies that with ν-probability close to 1, draws $X \sim \nu$ have many prefixes $X \upharpoonright n$ with small time-bounded description length (say $\leq s'n$ for all large n). For each n, there are at most $2^{s'n}$ such "typical" strings of length n. If all these typical strings had ν_n-mass $< 2^{-s''n}$ for all large n, then the total ν_n-mass of typical length-n strings would be at most $2^{s'n} \cdot 2^{-s''n} = 2^{-(s''-s')n}$, contradicting that typical strings carry almost all the mass. Therefore, with *positive* ν-probability, infinitely many n satisfy $\nu_n(X \upharpoonright n) \geq 2^{-s''n}$, and along those n we have $d(X \upharpoonright n) \geq 2^{(s'''-s'')n}$; hence $\nu(S^\infty(d)) > 0$.

We now formalize the positive-measure conclusion used above.

▶ **Lemma 37.** $\nu\{X \in \Sigma^\infty : \exists^\infty n \text{ such that } \nu_n(X \upharpoonright n) \geq 2^{-n \cdot s''}\} > 0$.

Notice that if $\nu_n(w) \geq 2^{-n \cdot s''}$ then $d(w) \geq 2^{n(s'''-s'')}$. Therefore from Lemma 37 we obtain that $\nu\{X \in \Sigma^\infty : \limsup_{n\to\infty} d(X \upharpoonright n) = \infty\} > 0$.

On the other hand, under the assumption that infinitely-often one-way functions do not exist, we invoke a distributional estimation theorem for polynomial-time samplable distributions. Distributional estimation results of this kind go back to Impagliazzo and Luby [20] and Impagliazzo and Levin [19]. Ilango, Ren, and Santhanam [18] give an algorithm that, for every polynomial-time samplable distribution ensemble $\mathcal{D} = \{\mathcal{D}_n\}$, estimates $\mathcal{D}_n(w)$ within a constant multiplicative factor on all but a $\mathcal{D}_n$-small exceptional set of samples $w \sim \mathcal{D}_n$. Nanashima and Hirahara [13] prove a substantially stronger form, giving a multiplicative $(1 \pm \delta)$ approximation (for arbitrarily small $\delta > 0$) on almost all samples from $\mathcal{D}_n$. Such distributional estimation results can be used to obtain efficient algorithms for universal extrapolation and Solomonoff's inductive inference. For our purposes in this paper, the constant-factor guarantee from [18] is sufficient, and we apply it to the particular samplable distribution $\nu_n(w) = \nu(C_w)$. Combining this estimator with a standard gale normalization step yields a polynomial-time ν-approximator for $\nu(C_w)$ on $\mathrm{supp}(\nu_n)$, and therefore for $d(w) = 2^{s'''|w|}\nu(C_w)$ (using $2^{s'''} \in \mathbb{Q}$). Thus d is a polynomial-time ν-approximable s'''-supergale with $\nu(S^\infty(d)) > 0$, contradicting item (2). Hence infinitely-often one-way functions must exist. The formal estimation result and the approximability argument are given next.

▶ **Theorem 38** ([18, 20, 19, 13])**.** *Assume that no infinitely-often one-way functions exist. Let $\mathcal{D} = \{\mathcal{D}_n\}$ be a polynomial-time samplable distribution and $q \geq 1$ be an arbitrary constant. Then, there exists a probabilistic polynomial-time algorithm $\mathcal{A}$ and constant $c < 1$ such that for all n,*

$$\Pr_{x\sim\mathcal{D}_n}[c \cdot \mathcal{D}_n(x) \leq \mathcal{A}(x) \leq \mathcal{D}_n(x)] \geq 1 - O\left(\frac{1}{n^q}\right).$$

▷ Claim 39. d is polynomial-time ν-approximable.

Proof. Let S be the machine that samples the distribution ν such that for every n, $\Pr_r[S(1^n, r) = w] = \nu_n(w)$ for every $w \in \Sigma^n$. Let c' be the constant such that S uses $n^{c'}$ random bits to sample a string of length n.

Assume that no infinitely-often one-way functions exist. Then, the function $f : \Sigma^* \to \Sigma^*$ defined as

$$f(x) = S(1^{|x|^{1/c'}}, x)$$

is not an infinitely-often weak one-way function. Hence for any $q \geq 1$ there exist an algorithm $\mathcal{I}$ such that for all n,

$$\Pr_{r\sim\Sigma^{n^{c'}}}[f(\mathcal{I}(f(r))) = f(r)] = \Pr_{w\sim\nu_n}[f(\mathcal{I}(w)) = w] \geq 1 - O\left(n^{-q}\right). \tag{4}$$

From our assumption that infinitely-often one-way functions do not exist and Theorem 38, we obtain that for any $q \geq 1$, there exists a probabilistic polynomial-time algorithm $\mathcal{A}$ and constant $c < 1$ such that for all n,

$$\Pr_{w\sim\nu_n}[c \cdot \nu_n(w) \leq \mathcal{A}(w) \leq \nu_n(w)] \geq 1 - O\left(n^{-q}\right). \tag{5}$$

Finally, we give the algorithm $\mathcal{M}$ that ν-approximates d. $\mathcal{M}$ on input $w \in \Sigma^n$ runs $\mathcal{I}$ on w. If $f(\mathcal{I}(w)) \neq w$, $\mathcal{M}$ outputs 0. Else, $\mathcal{M}$ runs $\mathcal{A}$ on w and outputs $2^{s'''|w|}\mathcal{A}(w)$. Since $2^{s'''} \in \mathbb{Q}$, $\mathcal{M}$ runs in polynomial time. For any w such that $\nu(w) = 0$ (i.e. $w \notin \mathrm{supp}(\nu_n)$), $\mathcal{I}$

will never succeed in finding a pre-image r such that $f(r) = w$ and hence $\mathcal{M}$ always outputs 0. Therefore for every n, $\{w : \mathcal{M}(w) \notin [c \cdot d(w), d(w)]\} \subseteq \text{supp}(\nu_n)$. Now, from (4) and (5) we obtain that,

$$\Pr_{x\sim\nu_n}[c \cdot d(x) \leq \mathcal{M}(x) \leq d(x)] \geq 1 - O\left(\frac{1}{n^q}\right) - O\left(\frac{1}{n^q}\right) \geq 1 - O\left(\frac{1}{n^q}\right).$$

Therefore for every n, $\nu\{w : \mathcal{M}(w) \notin [c \cdot d(w), d(w)]\} \leq O\left(n^{-q}\right)$. Since $\mathcal{A}$ runs in randomized polynomial time and q is arbitrary, $\mathcal{M}$ witnesses the fact that d is a polynomial-time ν-approximable s'''-gale. ◁

The claim shows that d is a polynomial-time ν-approximable s'''-supergale. Since $s''' < \hat{s}$ and $\nu(S^\infty(d)) > 0$, this contradicts the second item in the hypothesis. Therefore, infinitely-often one-way functions exist. ◀

4.3 Dimension gaps over sequences from one-way functions

Lemma 25 is a measure statement: under one-way functions it gives a samplable distribution ν on Σ^∞ for which typical sequences have low $\mathcal{K}^{\text{str}}_{\text{poly}}$, but every polynomial-time ν-approximable gale of exponent $< 1/2$ succeeds only on a ν-null set. We now indicate how this measure-theoretic gap yields an *individual* sequence with $\mathcal{K}^{\text{str}}_{\text{poly}}$ small but $\dim_{\text{P}}$ bounded away from it, and then how the same strategy can be pushed to obtain gaps arbitrarily close to 1.

▶ **Theorem 22.** *If for all $X \in \Sigma^\infty$, $\dim_{\text{P}}(X) = \mathcal{K}_{\text{poly}}(X)$, then no one-way functions exist.*

We first record the gale-combination construction needed to pass from pointwise polynomial-time gales, whose running-time exponents may vary with the sequence, to a single polynomial-time gale on a positive-measure set.

▶ **Lemma 40.** *For any time $t(n) \in \text{poly}(n)$, and $s > 0$ with $2^s \in \mathbb{Q}$, there exists an exact $t(n) \cdot n \cdot \log(n)$-time computable s-gale $\tilde{d}$ such that for all exact $t(n)$-time computable s-gales d, there exist a constant c such that for all $X \in \Sigma^\infty$ and $n \in \mathbb{N}$, $\tilde{d}(X \upharpoonright n) \geq c \cdot d(X \upharpoonright n)$.*

We now prove a stronger theorem. Theorem 22 follows from Theorem 41, since for all sequences $X \in \Sigma^\infty$, $\mathcal{K}_{\text{poly}}(X) \leq \mathcal{K}^{\text{str}}_{\text{poly}}(X)$.

▶ **Theorem 41.** *If one-way functions exist, then for every $s < 1/2$, there exist $X \in \Sigma^\infty$ such that $\mathcal{K}^{\text{str}}_{\text{poly}}(X) \leq s$ and $\dim_{\text{P}}(X) \geq 1/2$.*

Proof. Assume that one-way functions exist. From the proof of Lemma 25, we obtain that for every $s < 1/2$ there exist a polynomial-time samplable distribution ν over Σ^∞ and polynomial t such that:

1. The number of random bits used by the sampler for ν on input 1^n is at most sn.
2. For every $s' \in (s, 1/2)$ and any polynomial-time ν-approximable s'-supergale d, $\nu(S^\infty(d)) = 0$.

Consider the canonical closed full-measure support set $\mathcal{F} = \bigcap_{n\geq 1} \bigcup_{w\in\text{supp}(\nu_n)} C_w$. Now, $\cup_{w\in\text{supp}(\nu_n)} C_w$ is a finite union of cylinder sets in Σ^∞ and hence is a closed set. Since ν is a polynomial-time samplable probability distribution on Σ^∞, $\cup_{w\in\text{supp}(\nu_n)} C_w$ is a superset of $\cup_{w\in\text{supp}(\nu_{n+1})} C_w$ for every n. Since $\mathcal{F}$ is an intersection of a decreasing sequence of non-empty closed sets in the compact space Σ^∞, $\mathcal{F}$ is non-empty (see [35]). Since $\nu(\cup_{w\in\text{supp}(\nu_n)} C_w) = 1$ for every n, using the continuity of probability measures from above [2], we get $\nu(\mathcal{F}) = 1$. Since the number of random bits used by the sampler for ν on input 1^n is at most sn, $\mathcal{K}^{\text{str}}_{\text{poly}}(X) \leq s$ for every $X \in \mathcal{F}$.

For the sake of contradiction, assume that there exists $s' \in (s, 1/2)$ such that $\dim_{\mathrm{P}}(X) < s'$ for every $X \in \mathcal{F}$. So, for every $X \in \mathcal{F}$ there exists an exact computable s'-gale d'_X that runs in time $t_{d'_X}(n) \in \mathrm{poly}(n)$, such that d'_X succeeds on X. We group $\mathcal{F}$ according to a polynomial running-time exponent. Define

$$R_i = \left\{ X \in \mathcal{F} \;\middle|\; \text{there exists an } n^i\text{-time } s'\text{-gale } d \text{ such that } X \in S^\infty(d) \right\},$$

and let $S_i = R_i \setminus R_{i-1}$. Note that $\{S_i\}_{i\in\mathbb{N}}$ is a partition of $\mathcal{F}$ into countably many disjoint subsets. As $\sum_{i=1}^{\infty} \nu(S_i) = 1$, there exists an $k \in \mathbb{N}$ such that $\sum_{i=1}^{k} \nu(S_i) > 0$. Define $\mathcal{S} = \bigcup_{i=1}^{k} S_i$. On this positive-measure subset, all witnessing gales run within a common polynomial time bound. Using Lemma 40, there exists an exact polynomial-time computable s'-gale d that succeeds on all sequences in $\mathcal{S}$. Since d is polynomial-time computable, it is automatically polynomial-time ν-approximable. Now, since we know that $\nu(S^\infty(d)) \geq \nu(\mathcal{S}) > 0$, we obtain a contradiction to Lemma 25. Hence, it must be the case that there exists a sequence $X \in \mathcal{F}$ with $\dim_{\mathrm{P}}(X) > s'$. Since s' was arbitrary, the theorem follows. ◀

The same argument also gives an almost-sure version over the samplable source obtained from Lemma 25.

▶ **Lemma 42.** *If one-way functions exist then for some $s < 1/2$, there exist a polynomial-time samplable distribution ν over Σ^∞ such that:*

1. *The number of random bits used by the sampler for ν on input 1^n is at most sn.*
2. *For every $s' \in (s, 1/2)$ and polynomial-time ν-approximable s'-supergale d, $\nu(S^\infty(d)) = 0$.*
3. *$\nu\{X \in \Sigma^\infty : \mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(X) \leq s$ and $\dim_{\mathrm{P}}(X) \geq 1/2 > s\} = 1$.*

We now strengthen the conclusion by amplifying the gap. The above route naturally yields the threshold $1/2$ because the forward implication only rules out success of *ν-approximable* gales below $1/2$. To push the separation to $1 - \varepsilon$, we keep the same blueprint (construct a low-$\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}$ source and diagonalize against efficient betting strategies), but we modify the diagonalization so that it is carried out against *exact* computable gales. This avoids the accumulation of approximation slack, which becomes the bottleneck near dimension 1, and allows us to push the lower bound on $\dim_{\mathrm{P}}$ to $1 - \varepsilon$ while keeping $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}$ below ε.

▶ **Theorem 23.** *If one-way functions exist, then for any $\epsilon > 0$, there exists $X \in \Sigma^\infty$ such that $\dim_{\mathrm{P}}(X) - \mathcal{K}_{\mathrm{poly}}(X) \geq 1 - \epsilon$.*

We prove the following stronger statement independently since it does not follow directly using the techniques in the proofs of Lemma 25 and Theorem 41. The main obstacle is that techniques involving approximable gales introduce non-negligible approximation errors while trying to achieve gaps close to 1. In the proof of the below theorem we instead employ computable gales. Whether Lemma 25 can be strengthened to yield such a gap remains an open question.

▶ **Theorem 43.** *If one-way functions exist, then for every $\epsilon > 0$ there exist set $\mathcal{F}$ and a sequence X such that $\dim_{\mathrm{P}}(\mathcal{F}) - \mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(\mathcal{F}) \geq 1 - \epsilon$ and $\dim_{\mathrm{P}}(X) - \mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(X) \geq 1 - \epsilon$ respectively.*

The argument follows the same overall blueprint as the proof of Theorem 22: we use the PRG-induced mapping g to produce sequences with low $\mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}$, and then diagonalize against efficient betting strategies by converting a successful s'-gale into a martingale that must exhibit large multiplicative gains at dyadic checkpoints, which yields a distinguisher for the underlying PRG. The only substantive change is that, to obtain gaps arbitrarily close to

1, we carry out the diagonalization using exact polynomial-time computable gales rather than ν-approximable gales, so that no approximation slack accumulates when we test many intermediate prefixes. A similar argument yields the corresponding separation statement for sets, by applying the same support/compactness reduction and the same diagonalization idea at the level of collections rather than individual sequences.

We obtain the following corollary of Theorem 43. This result provides a strong negative answer to the open question posed by Stull in [36] under the assumption that one-way functions exist.

▶ **Corollary 44.** *If one-way functions exist then for every $\epsilon < 1/2$ there exists $X \in \Sigma^\infty$ such that $\mathcal{K}_{\mathrm{poly}}(X) \leq \mathcal{K}^{\mathrm{str}}_{\mathrm{poly}}(X) < \epsilon < 1 - \epsilon < \dim_{\mathrm{P}}(X) \leq \mathrm{Dim}_{\mathrm{P}}(X)$.*

5 Open Problems and Discussion

Our findings suggest several promising directions for future research. A key open question is whether weaker hardness assumptions, such as P $\neq$ NP, DistNP $\not\subseteq$ AvgP or DistNP $\not\subseteq$ AvgBPP, can be characterized in terms of separations of polynomial-time dimension, as defined using time-bounded s-gales and time-bounded Kolmogorov complexity in appropriate settings. Related work on time-bounded Kolmogorov complexity has also revealed connections with average-case hardness and one-way functions [25, 9]. Specifically, can these hardness assumptions be equivalently expressed through if-and-only-if statements involving polynomial-time dimension?

A different direction is to seek finite-length versions of these phenomena. Polynomial-time dimension is asymptotic, while the pseudorandomness assumptions used in this paper are finite-length indistinguishability assumptions. It would be interesting to define finite-length measures based on efficient online betting strategies, or equivalently log-loss prediction on n-bit samples, and compare them with finite-time Kolmogorov complexity rates. Can one obtain finite-length separation theorems between efficient betting and efficient compression that characterize one-way functions, average-case hardness, or other standard assumptions?

Another natural direction concerns extraction and dimension amplification. Standard randomness extractors transform weak finite sources into distributions close to uniform [37], while dimension measures asymptotic randomness rates along individual infinite sequences. Can seeded extractors, condensers, or related pseudorandomness objects be lifted to transformations that increase polynomial-time dimension for typical outputs of efficiently samplable infinite sources? A complementary question is whether cryptographic hardness can be used to construct efficiently samplable sources whose finite prefixes have substantial entropy, but whose polynomial-time dimension cannot be increased by these transformations.

Our results reveal a duality between the non-robustness of polynomial-time dimension and the existence of one-way functions. An interesting open question is whether notions of polynomial-time randomness, defined via betting algorithms and Kolmogorov incompressibility of prefixes (see [36] for more details), capture equivalent concepts of randomness. Polynomial-time betting algorithms that succeed on specific sequences do not necessarily provide guarantees on the rate of capital accumulation in general. Consequently, investigating the robustness of polynomial-time randomness and its potential connections to cryptographic and complexity-theoretic primitives may require fundamentally new approaches.

Recovering Planted Colorings in Sublinear Time

Weronika Wrzos-Kaminska
EPFL, Lausanne, Switzerland

Abstract

We study the problem of recovering a planted k-coloring in sublinear time. Given an expander G with a planted coloring, the goal is to efficiently construct a small-space data structure that allows consistent color queries: given a vertex v, the algorithm quickly returns the color of v according to the planted solution.

We work in the adversarial planted coloring model of David and Feige [STOC 2016], where an adversary chooses a d-regular spectral λ-expander G on n vertices and plants a balanced k-coloring by partitioning the vertices into k equal parts and deleting all edges within each part. This model generalizes the earlier random graph models studied by Blum and Spencer [J. Algorithms 1995] and Alon and Kahale [STOC 1994].

We give the first sublinear-time algorithm for recovering planted colorings in this model. In the adjacency list model, our algorithm has preprocessing time and space $\widetilde{O}\left(n^{1/2+O(1/\log(d/\lambda))}\right)$, and produces a data structure that answers color queries in time $\widetilde{O}\left(n^{1/2+O(1/\log(d/\lambda))}\right)$. With a high constant probability, the resulting labeling agrees with the planted coloring on all but an $O(\sqrt{\lambda/d})$ fraction of vertices, up to a permutation of the k colors.

Our algorithm gives sublinear time inner product access to the bottom eigenspace of the normalized adjacency matrix by using random walks, which allows us to adapt the classical spectral approach of Alon and Kahale in sublinear time.

1 Introduction

Graph coloring is a fundamental problem in theoretical computer science. In the k-coloring problem, the goal is to assign each vertex a color from $[k]$ so that adjacent vertices receive different colors. Finding k-colorings in graphs for $k \geq 3$ is among the first computational problems shown to be NP-hard [24, 18]. This has motivated extensive work on approximation algorithms and on identifying assumptions under which the problem can be solved efficiently [33, 5, 7, 6, 8, 1, 23, 27, 28, 2, 13, 3, 12, 25, 29, 26, 9, 20].

One influential line of work studies planted coloring models, where a hidden coloring is embedded into a graph, and the task is to recover (approximately) the planted solution. Blum and Spencer [6] and Alon and Kahale [1] considered random graph models with a planted k-coloring, and showed that polynomial-time spectral algorithms can recover the planted k-coloring with high probability. David and Feige [12] extended this to a more challenging adversarial setting, in which an adversary chooses an expander and plants a balanced k-coloring by deleting all edges within each color class. They showed that, even in this adversarial setting, the spectral approach of Alon and Kahale recovers the planted coloring on a 0.99 fraction of the vertices, while exact recovery is NP-hard.

While planted coloring models have been extensively studied in the polynomial-time regime, the question of *sublinear-time* recovery remains largely unexplored. This motivates the central question of this work:

Is it possible to recover a planted k-coloring in sublinear time?

Of course, any algorithm that explicitly outputs a coloring requires $\Omega(n)$ time simply to write down the labels. We therefore focus on constructing a *coloring oracle*: a small-space randomized data structure that quickly answers queries of the form "what color does vertex v have?". The oracle must be *consistent*, meaning that its answers agree with a single underlying assignment of colors (not necessarily a proper k-coloring), and *approximately correct*, meaning that the oracle disagrees with the planted coloring on only a small fraction of vertices, up to a permutation of colors (see Definition 8 for a formal definition of coloring oracle).

We consider a variant of the adversarial planted model of [12]. In this model, an adversary chooses a d-regular spectral λ-expander (i.e., eigenvalues of its adjacency matrix, other than the top eigenvalue d, have absolute value at most λ). The adversary also chooses a balanced partitioning of the vertices into k color classes, for a constant k. The planted instance is obtained by deleting all the monochromatic edges, i.e., all edges that have both endpoints in the same color class. Additionally, we require that the partitioning is chosen so that the degrees in the planted instance are balanced, in the sense that all vertices have degree $\Omega(d)$ after deleting the monochromatic edges (see Definition 6 for a formal definition of the input model).

A d-regular graph has $\lambda_1 = d$ and that the second largest eigenvalue in absolute value satisfies $\lambda = \Omega(\sqrt{d})$ [30]. Random d-regular graphs are essentially best possible spectral expanders, satisfying $\lambda = O(\sqrt{d})$ with high probability [14, 17, 16]. The adversarial planted coloring model therefore generalizes random planted models, in which the host graph is drawn at random and/or the planted partitioning is chosen uniformly at random.

Our contribution

We give the first sublinear-time algorithm for this planted coloring problem. Our result works in the adversarial planted model, and therefore also applies to the corresponding random planted models. Specifically, in the adversarial planted k-coloring model, we construct a coloring oracle with $\widetilde{O}(n^{1/2+O(1/\log(d/\lambda)}$ preprocessing time and space, where n is the number of vertices. The oracle answers each color query in $\widetilde{O}(n^{1/2+O(1/\log(d/\lambda))})$ time and, with a high constant probability, agrees with the planted coloring on at least a 0.99 fraction of the vertices.

▶ **Theorem 1.** *Let $k \geq 3$ be a constant, let c_k be a sufficiently small constant (depending on k), and let C_k be a sufficiently large constant (depending on k). For every $C_k < d < n$ and every $\lambda \leq c_k d$, there exists a randomized algorithm for the adversarial planted k-coloring model (Definition 6) that constructs a coloring oracle using $\widetilde{O}\big(n^{1/2+O(1/\log(d/\lambda))}\big)$ preprocessing time and space, where n denotes the number of vertices in the graph. For every query vertex v, the oracle outputs a color in $[k]$ in time $\widetilde{O}\big(n^{1/2+O(1/\log(d/\lambda))}\big)$, and its answers are consistent across queries. With probability at least 0.9, the oracle agrees with the planted coloring (up to a permutation of the colors) on all but at most $O\left(\sqrt{\frac{\lambda}{d}}n\right)$ vertices.*

In particular, the running time is $\approx n^{1/2+o(1)}$ when $\lambda/d = o(1)$. For dense graphs with $d = n^\delta$ and $\lambda = O(\sqrt{d})$ for a constant δ, the running time becomes $\widetilde{O}(n^{1/2})$. As in prior works on planted coloring, we treat the number of colors k as a constant.

Our algorithm may be viewed as a sublinear-time implementation of the classical spectral algorithm of [1]. The key technical ingredient is providing sublinear-time dot-product access to the bottom eigenspace of the adjacency matrix, which we achieve by adapting recent techniques from spectral clustering [22].

Related work on planted coloring

Blum and Spencer [6] and Alon and Kahale [1] studied the problem of planted k-coloring in random graphs, and showed that exact recovery is possible in polynomial time. [12] studied the role of randomness in the planted model, and showed that exact recovery is possible if the coloring is planted at random in an adversarial spectral expander, and that approximate recovery is possible even when the coloring is adversarial. [29] proved that approximate recovery is possible in low threshold rank graphs for pseudorandom colorings. Recently, [4, 9, 20] further considered the setting in which the coloring is planted in a one-sided expander or a low threshold rank graph.

Related work on sublinear spectral algorithms

Our techniques are closely related to work on sublinear spectral clustering [11, 10, 19, 32, 15, 22]. Most relevant to our work is [22], which uses a low-degree polynomial of the random walk matrix to provide access to the top eigenspace of the adjacency matrix under a clusterability assumption. Although this setting differs from ours (our graphs are not clusterable, and the signal lies in a different part of the spectrum), we adopt their general approach. [31] and [21] applied spectral techniques to approximate max-cut (and more generally max-2Lin) in sublinear time on expanders and clusterable graphs. The work of [31] also showed that testing whether an expander is 3-colorable versus far from 3-colorable requires $\Omega(n)$ time. We note that the hard instances in [31] are constant degree expanders with expansion $\phi = \Omega(1/d)$, whereas our results require stronger spectral expansion.

2 Technical Overview

Our algorithm can be viewed as a sublinear implementation of the spectral approaches of Alon and Kahale [1] and David and Feige [12]. These works show that planted colorings can be approximately recovered from the bottom eigenspace of the adjacency matrix. The main difficulty is that computing this exactly requires reading the whole graph and computing the eigenvectors.

Recent progress on sublinear spectral algorithms has focused on approximating inner products of spectral embeddings associated with the *top* eigenspace of a graph, typically under strong clusterability assumptions [19, 22]. Our main technical contribution is to extend this line of work to the setting of graph coloring by providing sublinear-time access to the *bottom* eigenspace of the adjacency matrix. While bottom eigenvectors have long played a central role in polynomial-time spectral algorithms, sublinear-time methods for accessing this part of the spectrum have remained largely undeveloped.

The spectral approach of [1] and [12]

We start by reviewing the classical approach of [1] and [12]. These works showed that an approximate coloring can be recovered from the bottom eigenspace of the adjacency matrix of the planted input graph. Specifically, the bottom $k-1$ eigenvalues of the normalized

adjacency matrix have value $-\frac{1}{k-1} \pm O(\sqrt{\lambda/d})$, while all remaining eigenvalues (except for the trivial top eigenvalue 1) are bounded in absolute value by $O(\sqrt{\lambda/d})$ [1]. The coloring can be approximately recovered from the spectral embedding in this bottom eigenspace.

▶ **Definition 2** (Spectral embedding). *Let $\bar{A} = D^{-1/2}AD^{-1/2}$ denote the normalized adjacency matrix of the input graph G', and let $U_{[k-1]} \in \mathbb{R}^{n\times(k-1)}$ denote the matrix whose columns are the bottom $k-1$ eigenvectors of $\bar{A}$. For every vertex $v \in V$, the spectral embedding of v, denoted $f_v \in \mathbb{R}^{k-1}$, is the v-th row of $U_{[k-1]}$, i.e.,*

$$f_v \coloneqq U_{[k-1]}^\top \mathbb{1}_v.$$

▶ Remark 3. The spectral embeddings f_v are not uniquely defined. However, the dot products $\langle f_u, f_v\rangle$, and hence also the Euclidean distances $\|f_u - f_v\|_2$, are uniquely defined (see Remark 17).

As shown in [12], spectral embeddings of vertices belonging to the same color class are close to each other, while spectral embeddings of vertices belonging to different color classes are far from each other. Specifically, for all but an $O(\lambda/d)$ fraction of vertices, the following holds[2]:

$$\|f_u - f_v\|_2^2 = \begin{cases} \leq \dfrac{k}{70n}, & \text{if } \chi(u) = \chi(v), \\ \geq \dfrac{k}{2n}, & \text{if } \chi(u) \neq \chi(v). \end{cases} \tag{1}$$

By Equation (1), approximate recovery of the planted coloring can be achieved using the following two steps:

1. Identify a set of *color representatives* $c_1 \in C_1, \ldots, c_k \in C_k$, i.e., one vertex from each color class.
2. Given a query vertex u, output the color of the closest color representative

$$\textsc{Color}(u) = \arg\min_{i\in[k]} \|f_u - f_{c_i}\|_2^2.$$

The main challenge is to perform this in sublinear time, without explicitly computing the full spectral embedding.

Spectral embeddings via polynomials

In order to approximate inner products $\langle f_u, f_v\rangle$ between spectral embeddings (and hence also the Euclidean distances), we will approximate the relevant projection matrix by a low-degree polynomial in the random walk matrix. The inner products can then be approximated by collision counting. This idea was used in [22] in the context of sublinear-time spectral clustering, and we adapt their general approach. Let $\bar{A} = U\Sigma U^\top$ denote the eigendecomposition of the normalized adjacency matrix $\bar{A}$. We are interested in approximating

$$\langle f_u, f_v\rangle = \mathbb{1}_u^\top U_{[k-1]} U_{[k-1]}^\top \mathbb{1}_v,$$

[1] [12] analyze the unnormalized adjacency matrix. Since our algorithm is based on random walks, it is more convenient for us to work with the normalized adjacency matrix. An analogous statement for the normalized adjacency matrix $\bar{A}$ follows by a similar argument (see Lemma 16).

[2] Equation (1) can be extracted from the analysis of [12] for embeddings of the *unnormalized* adjacency matrix, although it is not stated there explicitly in this form. We prove an analogous guarantee for the normalized adjacency matrix (see Lemma 20).

where $U_{[k-1]}U_{[k-1]}^\top$ is the projection onto the eigenspace corresponding to eigenvalues with value $\approx -1/(k-1)$. To this end, we seek a polynomial $p(x) = \sum_{t\geq 0} c_t x^t$ of the form $p(x) = x^t q(x)$, where $t = \Omega\left(\frac{\log n}{\log(d/\lambda)}\right)$, such that the coefficients c_t are small and the following properties hold:

- $p(x) \approx 1$ when $\left|x + \frac{1}{k-1}\right| \leq O\left(\sqrt{\frac{\lambda}{d}}\right)$, and
- $p(x) \approx 0$ when $|x| \leq O\left(\sqrt{\frac{\lambda}{d}}\right)$ or $x = 1$.

With such a polynomial, the matrix $p(\bar{A}) = Up(\Sigma)U^\top$ acts as an approximate projector onto the bottom $k-1$ eigenvectors. As a result,

$$\begin{aligned}\langle f_u, f_v\rangle &= \mathbb{1}_u^\top U_{[k-1]}U_{[k-1]}^\top \mathbb{1}_v \\ &\approx \mathbb{1}_u^\top U p(\Sigma)^2 U^\top \mathbb{1}_v = \langle p(\bar{A})\mathbb{1}_u, p(\bar{A})\mathbb{1}_v\rangle = \left\langle \sum_t c_t \bar{A}^t \mathbb{1}_u, \sum_t c_t \bar{A}^t \mathbb{1}_v \right\rangle \\ &= \sum_{t,t'} c_t c_{t'} \langle \bar{A}^t \mathbb{1}_u, \bar{A}^{t'} \mathbb{1}_v\rangle.\end{aligned}$$

Each inner product $\langle \bar{A}^t \mathbb{1}_u, \bar{A}^{t'} \mathbb{1}_v\rangle$ can be estimated efficiently using random walks. Indeed, let $M = AD^{-1}$ denote the random walk transition matrix. For $t = \Omega\left(\frac{\log n}{\log(d/\lambda)}\right)$, inner products of the form $\langle M^t \mathbb{1}_u, M^{t'} \mathbb{1}_v\rangle$ can be approximated using $\approx \sqrt{n}$ random walks via standard collision-counting arguments. Using the relation $\bar{A} = D^{-1/2}MD^{1/2}$, inner products involving powers of $\bar{A}$ can be approximated similarly.

It is crucial that the coefficients c_t of the polynomial p are small: each term $\langle \bar{A}^t \mathbb{1}_u, \bar{A}^{t'} \mathbb{1}_v\rangle$ must be estimated to precision inverse polynomial in $|c_t c_{t'}|$, and hence the overall running time depends polynomially on the size of coefficients.

[22] used a similar idea to cluster graphs. In their setting, the input graph is assumed to be clusterable, meaning that the top k eigenvalues lie in the interval $[1-\epsilon, 1]$ for some error parameter ϵ, while all remaining eigenvalues are bounded away from 1. The goal is to approximate embeddings in this *top* eigenspace of the graph, which they achieve by constructing a polynomial that approximates the indicator on $[1-\epsilon, 1]$.

A key challenge with adapting their construction to our setting is that the coefficients of their polynomial grows superpolynomially in their error parameter ϵ, and can be as large as $\approx (1/\epsilon)^{O(\log(1/\epsilon))} n^{O(\epsilon)}$. Since the running time depends polynomially on the coefficient size, the algorithm is sublinear only for relatively large values of ϵ.

In our setting, the relevant analogue of the error parameter is $\sqrt{\lambda/d}$, and a superpolynomial dependence on $\sqrt{d/\lambda}$ would lead to too large running times. For example, for random d-regular graphs with $d = n^{\Omega(1)}$, this would lead to running times that are superpolynomial in n.

To overcome this issue, we modify the polynomial construction of [22] and give a more careful analysis of the resulting polynomial. This gives a polynomial that approximates an indicator function around $-1/(k-1)$, while having coefficients with absolute at value most $n^{O(1/\log(d/\lambda))}$. In particular, the coefficient size, and hence the running time, decreases as λ/d decreases.

▶ **Theorem 4.** *Let $\delta, C > 0$ be constants. For every $\frac{10C\log n}{\log(d/\lambda)} \leq t \leq O\left(\frac{\log n}{\log(d/\lambda)}\right)$, there exists a polynomial p of the form $p(x) = x^t q(x)$, where q is a polynomial of degree $O(\sqrt{\lambda/d}\log n)$, such that the coefficients of p are bounded in absolute value by $n^{O\left(\frac{1}{\log(d/\lambda)}\right)}$, and*

1. *$|p(x) - 1| \leq \delta$ for $x \in \left[-\frac{1}{k-1} - C\sqrt{\frac{\lambda}{d}}, -\frac{1}{k-1} + C\sqrt{\frac{\lambda}{d}}\right]$*
2. *$|p(x)| \leq n^{-2}$ for $|x| \leq C\sqrt{\frac{\lambda}{d}}$.*

In fact, our proof establishes a more general result: for any constant $\alpha \in [-1, 1]$ with $\alpha \neq 0$ and any $0 < \epsilon \ll |\alpha|$, we construct a polynomial approximating an indicator on $[\alpha - \epsilon, \alpha + \epsilon]$ with similar coefficient bounds (see Theorem 28). The proof of Theorem 4 is presented in Section 5.4.

While this polynomial successfully maps the eigenvalues near $-1/(k-1)$ to values close to 1 and eigenvalues of size at most $\sqrt{\lambda/d}$ to values close to 0, it does not control the value of $p(1)$, which corresponds to the top eigenvalue. We handle this issue by explicitly removing the contribution of the top eigenvector. Since the top eigenvector of $\bar{A}$ is $e_1 = D^{1/2}\mathbb{1}/\sqrt{2m}$, its contribution can be computed exactly, and we can therefore apply the polynomial to the matrix $\bar{A} - e_1 e_1^\top$, in which the top eigenvalue has been shifted to zero.

The algorithms for approximating $\langle f_u, f_v \rangle$ (Algorithm 2) and $\|f_u - f_v\|_2^2$ (Algorithm 3) are presented in Section 4. Their guarantees (Lemma 10 and Lemma 11) are proved in Section 5.2.

Finding color representatives

Given access to pairwise distances between spectral embeddings, it remains to pick one representative vertex from each planted color class. The polynomial-time approach of [12] finds such representatives by repeatedly sampling k random vertices until exactly one comes from each class. However, their method for verifying whether a given sample is valid requires $\Omega(n)$ time, which is too costly in our setting. We instead sample $\Theta(k \log k)$ vertices and build a small "similarity graph" on the sample, connecting two sampled vertices when their embeddings are similar. This is similar to approaches used for clustering [11, 32].

The similarity graph decomposes into exactly k connected components (one per color class) with a high constant probability, so choosing one vertex from each component yields the required representatives. We present the algorithm for obtaining color representatives in Section 4.1.

3 Preliminaries and Notation

We start by formally defining the graph access model and the input model.

Graph access model. We work in the adjacency-list query model. In this model, an algorithm can perform neighbor queries, i.e., for the i-th neighbor of any vertex, and degree queries, i.e., for the degree of any vertex. We additionally assume that the number of edges m is given as part of the input to the algorithm.

▶ **Definition 5** (λ-expander). *Let $\lambda_1(A_G) \geq \lambda_2(A_G) \geq \cdots \geq \lambda_n(A_G)$ denote the eigenvalues of the unnormalized adjacency matrix A_G of a graph G. Say that G is a λ-expander if $\max\{|\lambda_2(A_G)|, |\lambda_n(A_G)|\} \leq \lambda$.*

▶ **Definition 6** (Adversarial planted k-coloring). *Let $k \geq 3$ be a constant. An adversary chooses an n-vertex d-regular λ-spectral expander $G = (V, E)$ together with a balanced partition $\mathcal{C} = (C_1, \ldots, C_k)$ of V, such that $|C_i| = n/k$ for all $i \in [k]$ and such that every vertex has at least $\Omega(d)$ neighbors outside its color class. The partition $\mathcal{C}$ defines a* planted k-coloring $\chi : V \to [k]$ *by setting $\chi(v) = i$ if $v \in C_i$.*

The planted instance is obtained by deleting all monochromatic edges from G. That is, let

$$E' \coloneqq \{(u, v) \in E : \chi(u) \neq \chi(v)\},$$

and let $G' = (V, E')$ denote the resulting k-colorable graph. We write $G' = P_{\mathcal{C}}(G)$ when G' is obtained this way from the graph G and the partition $\mathcal{C}$.

▶ Remark 7 (Model assumptions). The model above is almost identical to the planted adversarial model of [12], except that we impose the additional condition that every vertex has at least a small constant fraction of its neighbors outside of its own color class. This ensures that after deleting monochromatic edges, every vertex in G' has degree $\Omega(d)$. Since the typical degree in G' is $(1-\frac{1}{k})d$, this is a mild restriction that only rules out vertices that are almost isolated by the adversary. In particular, if the color classes are selected *at random* and $d = \Omega(\log n)$, then this holds with high probability. The purpose of this assumption is to ensure that the normalized adjacency matrix of G' has the required spectral properties. Our sublinear-time algorithm is based on random walks and therefore relies on spectral properties of the normalized adjacency matrix. In contrast, prior polynomial-time spectral algorithms for planted k-coloring work directly with the *unnormalized* adjacency matrix, and therefore do not need this additional balanced degree condition.

For simplicity of presentation, Definition 6 assumes that the planted coloring is exactly balanced, i.e., $|C_i| = n/k$ for all $i \in [k]$. Our results extend to approximately balanced planted colorings satisfying $|C_i|/|C_j| = O(1)$ for all $i, j \in [k]$. The exact balance assumption is consistent with the standard formulation in prior work (e.g., [6, 1, 12]).

Similar to prior work, we assume that $k = O(1)$, and suppress the dependency on k in the O-notation.

The goal is to construct a coloring oracle, as defined below.

▶ **Definition 8** (Coloring oracle). *A coloring oracle is a randomized data structure $\mathcal{O}$ that, given query access to a graph G' from the adversarial planted k-coloring model, provides consistent query access to a function $\textsc{Color} : V \to [k]$.*

We say that $\mathcal{O}$ defines an ε-approximate coloring if, with probability at least 0.9 over the random bits of $\mathcal{O}$, there exists a permutation $\pi : [k] \to [k]$ such that

$$|\{v \in V : \textsc{Color}(v) \neq \pi(\chi(v))\}| \leq \varepsilon n,$$

where χ is the planted coloring.

Notation

Given the input graph $G' = (V, E')$, we let m denote the number of edges $|E'|$. We write A for the unnormalized adjacency matrix of G' and D for the diagonal degree matrix. Write $\bar{A} = D^{-1/2}AD^{-1/2}$ for its normalized adjacency matrix, and write $M = AD^{-1}$ for the random walk matrix. Observe that $M = D^{1/2}\bar{A}D^{-1/2}$.

Let $\lambda_1(\bar{A}) \geq \lambda_2(\bar{A}) \geq \cdots \geq \lambda_n(\bar{A})$ denote the eigenvalues of $\bar{A}$, and let $e_1(\bar{A}), \ldots, e_n(\bar{A})$ denote a corresponding orthonormal basis of eigenvectors. When it is clear that we are talking about the matrix $\bar{A}$, we omit the dependence on $\bar{A}$ from the notation.

For a vertex $v \in V$, we write $\mathbb{1}_v \in \mathbb{R}^n$ for the indicator of v, i.e., the vector with entry 1 at index v and 0 everywhere else. Similarly, for a set $S \subseteq V$, we write $\mathbb{1}_S \in \mathbb{R}^n$ for the indicator vector of S. We use the notation $\mathbb{1} \in \mathbb{R}^n$ for the vector with all entries equal to 1.

▶ **Observation 9.** *$\bar{A}D^{1/2}\mathbb{1} = D^{1/2}\mathbb{1}$. In particular,*

$$e_1(\bar{A}) = \frac{D^{1/2}\mathbb{1}}{\|D^{1/2}\mathbb{1}\|_2} = \frac{D^{1/2}\mathbb{1}}{\sqrt{2m}} \qquad \text{and} \qquad \lambda_1(\bar{A}) = 1.$$

For a polynomial q, write $\deg(q)$ to denote the degree of q and $\max|\text{coeff}(q)|$ to denote the absolute value of the largest (in absolute value) coefficient of q.

We use $\widetilde{O}$ notation to suppress $\operatorname{polylog} n$ factors.

4 The Algorithm

In this section, we present the algorithm. The algorithm SpectralDotProduct (Algorithm 2) approximates inner products $\langle f_u, f_v \rangle$ of spectral embeddings. It runs $\approx \sqrt{n}$ random walks of various lengths starting from u and v, and then combines the resulting collision counts with the coefficients of the polynomial–p from Theorem 4.

To change from the random walk matrix $M = AD^{-1}$ to the normalized adjacency matrix $\bar{A} = D^{-1/2}MD^{1/2}$, we appropriately reweigh collisions according to the matrix $D^{-1/2}$. Finally, we subtract the term $\frac{1}{2m}$ in order to cancel out the contribution of the top eigenvalue.

Algorithm 1 RandomWalks(r, t, u).

Run r random walks of length t starting from u
Let $\hat{p}_u(v)$ be the fraction of random walks that end at v ▷ vector $\hat{p}_u$ has support at most r
return $\hat{p}_u$

Algorithm 2 SpectralDotProduct(u, v).

$t_{\min} \leftarrow O\left(\frac{\log n}{\log(d/\lambda)}\right)$ ▷ shortest random walk length
$t_\Delta \leftarrow O(\sqrt{\lambda/d}\log n)$ ▷ number of different walk lengths
$r \leftarrow \widetilde{O}\left(n^{1/2+O\left(\frac{1}{\log(d/\lambda)}\right)}\right)$ ▷ number of random walks
for $t = t_{\min}, \dots t_{\min} + t_\Delta$ **do**
    $\hat{p}_u^t \leftarrow$ RandomWalks(r, t, u) ▷ vector $\hat{p}_u^t$ has support at most r
    $\hat{p}_v^t \leftarrow$ RandomWalks(r, t, v) ▷ vector $\hat{p}_v^t$ has support at most r
end for
return $\sqrt{\deg(u)}\sqrt{\deg(v)}\sum_{t,t'} c_t c_{t'}\left(\left\langle D^{-1/2}\hat{p}_u^t, D^{-1/2}\hat{p}_v^{t'}\right\rangle - \frac{1}{2m}\right)$
▷ c_t is the coefficient of x^t in the polynomial $p(x)$ from Theorem 4

SpectralDotProduct has the following guarantee: outside a small deterministic set B of "bad" vertices, SpectralDotProduct(u, v) approximates $\langle f_u, f_v \rangle$ up to an additive error of $O(1/n)$. The set B is defined formally in Definition 19 and consists of vertices whose degree or spectral embedding is atypical relative to their planted color class. We bound the size of B in Lemma 20.

▶ **Lemma 10** (Correctness of SpectralDotProduct). *The procedure SpectralDotProduct (Algorithm 2) runs in time* $\widetilde{O}\left(n^{1/2+O\left(\frac{1}{\log(d/\lambda)}\right)}\right)$. *For every* $u, v \in V \setminus B$,

$$\Pr\left[\left|\textsc{SpectralDotProduct}(u, v) - \langle f_u, f_v \rangle\right| \le \frac{1}{80}\frac{k}{n}\right] \ge 0.9,$$

where the probability is over the internal randomness of SpectralDotProduct.

We prove the correctness guarantee of SpectralDotProduct (Lemma 10) in Section 5.2.

To compute distances $\|f_u - f_v\|_2^2$, we use the algorithm SpectralDistance (Algorithm 3). The algorithm boosts the success probability of SpectralDotProduct and approximates $\|f_u - f_v\|_2^2 = \|f_u\|_2^2 + \|f_v\|_2^2 - 2\langle f_u, f_v \rangle$ by approximating each of the terms.

Algorithm 3 SpectralDistance(u, v).

for $i = 1, \dots O(\log n)$ **do**
  $\|f_u\|^2_{\text{apx},i} \leftarrow$ SpectralDotProduct(u, u) ▷ Approximate $\|f_u\|_2^2$
  $\|f_v\|^2_{\text{apx},i} \leftarrow$ SpectralDotProduct(v, v) ▷ Approximate $\|f_v\|_2^2$
  $\langle f_u, f_v\rangle_{\text{apx},i} \leftarrow$ SpectralDotProduct(u, v) ▷ Approximate $\langle f_u, f_v\rangle$
  $\|f_u - f_v\|^2_{\text{apx},i} \leftarrow \|f_u\|^2_{\text{apx},i} + \|f_v\|^2_{\text{apx},i} - 2\langle f_u, f_v\rangle_{\text{apx},i}$
end for
return $\text{median}_i(\|f_u - f_v\|^2_{\text{apx},i})$

▶ **Lemma 11** (Correctness of SpectralDistance)**.** *The procedure SpectralDistance (Algorithm 3) runs in time* $\widetilde{O}\left(n^{1/2+O\left(\frac{1}{\log(d/\lambda)}\right)}\right)$*. With probability at least* $1 - n^{-100}$*,*

$$\left|\textsc{SpectralDistance}(u, v) - \|f_u - f_v\|_2^2\right| \le \frac{k}{20n} \qquad \text{for all } u, v \in V \setminus B,$$

where the probability is over the internal randomness of SpectralDistance.

As a corollary, SpectralDistance(u, v) can be used to determine if u and v belong to the same color class, for all $u, v \in V \setminus B$.

▶ **Corollary 12.** *With probability at least* $1 - n^{-100}$*, the following holds for all* $u, v \in V \setminus B$*:*

- *If* $\chi(u) = \chi(v)$*, then* SpectralDistance$(u, v) \le \frac{k}{4n}$*.*
- *If* $\chi(u) \neq \chi(v)$*, then* SpectralDistance$(u, v) \ge \frac{k}{2n}$*.*

We prove Lemma 11 and Corollary 12 in Section 5.3. In particular, Algorithm 3 can be used as a coloring oracle: given a set of color representatives $c_1, \dots, c_k$, where each c_i belongs to a different color class and none of them lies in the set of bad vertices B, one can answer each query u by assigning the color of its nearest neighbor among the c_i. Algorithm 4 does this.

Algorithm 4 Color$\left(u, \{c_i\}_{i\in[k]}\right)$.
Input: vertex u and set of color representatives $\{c_i\}_{i\in[k]}$ (see Definition 13)
Output: Index $i \in [k]$ such that $\chi(u) = \chi(c_i)$

return $\arg\min_{i\in[k]}$ SpectralDistance(u, c_i)

4.1 Obtaining color representatives

It remains to find a valid set of color representatives. The procedure FindRepresentatives (Algorithm 5) below achieves this. The algorithm samples $\Theta(k \log k)$ vertices uniformly at random, which ensures that, with high probability, we sample at least one vertex from each color class. The algorithm then constructs a "similarity graph" on the sampled vertices, connecting two sampled vertices if their distance is sufficiently small. By the clustering properties of the spectral embeddings (see Lemma 20), with a good probability, vertices from the same color class form a clique in this similarity graph, while vertices from different color classes are disconnected. Finally, the algorithm selects one arbitrary vertex from each connected component of the similarity graph and discards the rest. We show that, with probability at least 0.99, this procedure returns exactly one representative from each color class, yielding a valid set of representatives for use in the coloring oracle. Algorithm 5 is very similar to the preprocessing routines of [32] and [15].

Algorithm 5 FindRepresentatives.

$S \leftarrow$ Multiset of $10k \log k$ vertices sampled uniformly at random from V
$H \leftarrow (S, \emptyset)$ ▷ H will be the same-color graph on S (see definition in full version)
for all $u, v \in S$ **do**
  if SpectralDistance$(u, v) \leq \frac{k}{3n}$ **then**
    Add edge $\{u, v\}$ to H
  end if
end for
$i \leftarrow 1$
while $V(H) \neq \emptyset$ **do**
  Select arbitrary vertex u from $V(H)$ ▷ Select a representative of a color class
  $c_i \leftarrow u$
  $T_i \leftarrow \{u\} \cup N_H(u)$ ▷ The sampled vertices from the same color class as u
  $H \leftarrow H[V(H) \setminus T_i]$ ▷ Remove all vertices from the color class of u
  $i \leftarrow i + 1$
end while
return $c_1, c_2, \ldots$

▶ **Definition 13** (Color Representatives). *A set of vertices $\{c_i\}_{i \in [k]}$ is called a* set of color representatives *if the following conditions hold:*

1. *Every c_i is a good vertex (see Definition 19).*
2. *The vertices have distinct colors, i.e., $\chi(c_i) \neq \chi(c_j)$ for all $i \neq j$.*

▶ **Lemma 14** (Correctness of FindRepresentatives). *The procedure FindRepresentatives (Algorithm 5) runs in time $\widetilde{O}(n^{1/2+O(1/\log(d/\lambda))})$. With probability at least 0.99, it returns a set of k color representatives (as per Definition 13).*

The proof of Lemma 14 follows the analysis of the preprocessing procedure in [15], and is presented in the full version.

5 Analysis

In this section, we analyze the algorithms presented in Section 4 and prove the main result, Theorem 1. The section is organized as follows. In Section 5.1, we define the set B of bad vertices and bound its size. In Section 5.2, we prove Lemma 10, establishing the correctness of SpectralDotProduct. In Section 5.3, we prove Lemma 11 and Corollary 12, establishing the correctness of SpectralDistance. In Section 5.4 we construct the polynomial and prove Theorem 4. Finally, in Section 5.5 we combine everything to prove Theorem 1.

5.1 Properties of the input instance

We start by stating some of the key properties of the input instance G'. The proofs of these properties are included in the full version.

▶ **Observation 15.** *By the model assumption (Definition 6),* $\deg(v) = \Theta(d)$ *for all $v \in G'$ and $\Omega(nd) \leq m \leq nd$.*

▶ **Lemma 16** (Normalized version of Lemma C.4 in [12]). *Let G be a d-regular λ-expander, where $\lambda \le c_k d$ (for some constant c_k), and let $G' = P_{\mathcal{C}}(G)$ (as per Definition 6). Then*

1. *The eigenvalues of the normalized adjacency matrix $\bar{A}$ of G' have the following spectrum:*
   a. $\lambda_1(\bar{A}) = 1$
   b. $\left|\lambda_i(\bar{A}) + \frac{1}{k-1}\right| \le O\left(\sqrt{\frac{\lambda}{d}}\right)$ *for* $n-k+2 \le i \le n$.
   c. $|\lambda_i(\bar{A})| \le O\left(\sqrt{\frac{\lambda}{d}}\right)$ *for* $2 \le i \le n-k+1$
2. *For every $x \in \mathrm{span}(\{\mathbb{1}_{C_i}\}_{i\in[k]})$ with $\langle x, \mathbb{1}\rangle = 0$, there exists $x^* \in \mathrm{span}(\{e_i(G')\}_{i\in[n-k+2,n]})$ such that $\|D^{1/2}x - x^*\|_2^2 = O\left(\sqrt{\frac{\lambda}{d}}\right)\|D^{1/2}x\|_2^2$. Here $C_1, \dots C_k$ denotes the planted partition into color classes.*

[12] proves analogous guarantees to Lemma 16 for the eigenvalues and eigenvectors of the *unnormalized* adjacency matrix (see Lemma C.4 in [12]). Our proof of Lemma 16 is similar and is included in the full version.

▶ Remark 17. It follows from guarantee 1 in Lemma 16 that the space spanned by the bottom $k-1$ eigenvectors of $\bar{A}$ is uniquely defined, i.e., the choice of $U_{[k-1]}$ is unique up to multiplication by an orthogonal matrix $R \in \mathbb{R}^{(k-1)\times(k-1)}$ on the right.

While the choice of f_v for $v \in V$ is not unique, the dot product between the spectral embedding of $u \in V$ and $v \in V$ is well defined, since for every orthogonal $R \in \mathbb{R}^{(k-1)\times(k-1)}$ one has

$$\langle R^\top f_u, R^\top f_v\rangle = (R^\top f_u)^\top (R^\top f_v) = f_u^\top R R^\top f_v = \langle f_u, f_v\rangle.$$

A useful property of the spectral embeddings is that they concentrate around their color class center.

▶ **Definition 18** (Color class center). *For each color class $C_i \in \mathcal{C}$, let μ_i denote the* color class center

$$\mu_i \coloneqq \frac{1}{|C_i|}\sum_{v\in C_i} f_v = \frac{1}{|C_i|} U_{[k-1]}^\top \mathbb{1}_{C_i}.$$

We define a set of *good* vertices consisting of those vertices that are close to their own color class center, far from other color class centers, and whose degree is close to the "typical" value $\frac{d(k-1)}{k}$.

▶ **Definition 19** (Good vertex). *Say that a vertex $v \in C_i$ is* good *if*

1. $\frac{d(k-1)}{k}\left(1 - \sqrt{\frac{\lambda}{d}}\right) \le \deg(v) \le \frac{d(k-1)}{k}\left(1 + \sqrt{\frac{\lambda}{d}}\right)$, *and*
2. $\|f_v - \mu_i\|_2^2 \le \frac{0.05k}{n}$, *and*
3. *for all $j \ne i$, $\|f_v - \mu_j\|_2^2 \ge \frac{k}{n}$.*

Say that the vertex is bad otherwise. Let $B \subseteq V$ denote the set of bad vertices.

We will show that the oracle is correct on all good vertices. Observe that the set B of bad vertices is deterministic once the input graph and planted coloring are fixed. It consists of vertices whose degree or spectral embedding is atypical relative to their planted color class.

▶ **Lemma 20.** *Let B be the set of bad vertices (as per Definition 19). Then*

$$|B| \le O\left(\sqrt{\frac{\lambda}{d}} \cdot n\right).$$

A similar bound for vertices with bad spectral properties was proved in [12]. While their bound is similar, the definition of "bad" vertices in [12] differs slightly from ours. The proof of Lemma 20 is included in the full version.

Additionally, we will use the fact that the ℓ_2 norm of good vertices is not too large.

▶ **Lemma 21.** *If v is good (as per Definition 19), then*

$$\|f_v\|_2^2 = O\left(\frac{1}{n}\right).$$

The proof of Lemma 21 is presented in the full version.

5.2 Analysis of SpectralDotProduct (Proof of Lemma 10)

In this section, we prove the correctness guarantee of SpectralDotProduct, namely Lemma 10. Recall that we wish to apply the polynomial from Theorem 4 to the normalized adjacency matrix $\bar{A}$ in order to approximate the projection $U_{[k-1]}U_{[k-1]}^\top$. However, since Theorem 4 does not provide any guarantees for $p(1)$, we need to shift the top eigenvalue. Therefore, it will be convenient for the analysis to consider the matrix $\bar{A} - e_1 e_1^\top$.

▶ **Definition 22.** *Let*

$$\bar{A}_\star = \bar{A} - e_1 e_1^\top.$$

We start by showing that $\mathbb{1}_u^\top p(\bar{A}_\star)^2 \mathbb{1}_v$ approximates the inner product $\langle f_u, f_v\rangle$. Later, in Claim 27, we will show the output of Algorithm 2 approximates $\mathbb{1}_u^\top p(\bar{A}_\star)^2 \mathbb{1}_v$.

▶ **Lemma 23.** *Let $\delta > 0$ be a sufficiently small constant, let p be the polynomial from Theorem 4 (applied with the parameter δ), and let B be the set of bad vertices from Definition 19. For every $u, v \in V \setminus B$,*

$$\left|\mathbb{1}_u^\top p(\bar{A}_\star)^2 \mathbb{1}_v - \langle f_u, f_v\rangle\right| \le \frac{1}{160}\frac{k}{n}.$$

Proof. The high-level idea is to decompose the matrix $\bar{A}_\star$ according to its spectrum. We separate it into two parts: one corresponding to the bottom $k-1$ eigenvalues, and one corresponding to the remaining $n-k+1$ eigenvalues. By Lemma 16, the bottom $k-1$ eigenvalues are all close to $-1/(k-1)$. Applying the polynomial p to this part therefore "boosts" these eigenvalues up to (approximately) 1, so this part closely approximates the spectral projection $U_{[k-1]}U_{[k-1]}^\top$. On the other hand, the remaining $n-k+1$ eigenvalues have absolute value at most $O(\sqrt{\lambda/d})$ (again by Lemma 16). The polynomial p maps these values close to zero, so the error introduced by this part is small.

We now do this more formally. Let $\bar{A}_\star = U\Sigma^\star U^\top$ denote the eigendecomposition of $\bar{A}_\star$, where $\Sigma^\star = \mathrm{diag}(0, \lambda_2, \lambda_3, \ldots, \lambda_n)$. Observe that $\bar{A}$ and $\bar{A}_\star$ share the same eigenbasis, so the matrix $U_{[k-1]}$ from Definition 2 is the matrix consisting of the last $k-1$ columns of U.

We write $\Sigma^\star_{[k-1]}$ for the $(k-1)\times(k-1)$ diagonal matrix consisting of the bottom $k-1$ diagonal entries of $\Sigma^\star$, and $\Sigma^\star_{\mathrm{top}}$ for the $(n-k+1)\times(n-k+1)$ diagonal matrix consisting of the remaining (top) entries. We let U_{top} denote the matrix formed by the first $n-k+1$ columns of U.

With this notation, we can decompose

$$p(\bar{A}_\star)^2 = Up(\Sigma^\star)^2U^\top = U_{[k-1]}p(\Sigma^\star_{[k-1]})^2U_{[k-1]}^\top \;+\; U_{\mathrm{top}}p(\Sigma^\star_{\mathrm{top}})^2U_{\mathrm{top}}^\top. \tag{2}$$

Recalling from Definition 2 that $\langle f_u, f_v\rangle = \mathbb{1}_u^\top U_{[k-1]} U_{[k-1]}^\top \mathbb{1}_v$, we can bound the error by decomposing $p(\bar{A}_\star)^2$ into the two terms in Equation (2):

$$\begin{aligned}
&\left|\mathbb{1}_u^\top p(\bar{A}_\star)^2 \mathbb{1}_v - \langle f_u, f_v\rangle\right| \\
&= \left|\mathbb{1}_u^\top U p(\Sigma^\star)^2 U^\top \mathbb{1}_v - \mathbb{1}_u^\top U_{[k-1]} U_{[k-1]}^\top \mathbb{1}_v\right| \\
&= \left|\mathbb{1}_u^\top U_{[k-1]} p(\Sigma^\star_{[k-1]})^2 U_{[k-1]}^\top \mathbb{1}_v + \mathbb{1}_u^\top U_{\text{top}} p(\Sigma^\star_{\text{top}})^2 U_{\text{top}}^\top \mathbb{1}_v - \mathbb{1}_u^\top U_{[k-1]} U_{[k-1]}^\top \mathbb{1}_v\right| \\
&= \left|\mathbb{1}_u^\top U_{[k-1]} \left(p(\Sigma^\star_{[k-1]})^2 - I_{k-1}\right) U_{[k-1]}^\top \mathbb{1}_v + \mathbb{1}_u^\top U_{\text{top}} p(\Sigma^\star_{\text{top}})^2 U_{\text{top}}^\top \mathbb{1}_v\right| \\
&\le \left|f_u^\top \left(p(\Sigma^\star_{[k-1]})^2 - I_{k-1}\right)\ f_v\right| + \left|\mathbb{1}_u^\top U_{\text{top}} p\left(\Sigma^\star_{\text{top}}\right)^2 U_{\text{top}}^\top \mathbb{1}_v\right|.
\end{aligned} \tag{3}$$

Here the second equality follows by Equation (2), and the last inequality follows by the triangle inequality and the identity $f_u = U_{[k-1]}^\top \mathbb{1}_u$.

We now bound the first summand in Equation (3). By Lemma 16 and the definition of $\Sigma^\star_{[k-1]}$, the matrix $\Sigma^\star_{[k-1]}$ is a diagonal matrix with entries in $\left[-\frac{1}{k-1} - O\left(\sqrt{\frac{\lambda}{d}}\right), -\frac{1}{k-1} + O\left(\sqrt{\frac{\lambda}{d}}\right)\right]$. Therefore, by Theorem 4, $p(\Sigma^\star_{[k-1]})^2$ is a diagonal matrix with entries in $[1-3\delta, 1+3\delta]$. Hence, $\left\|p(\Sigma^\star_{[k-1]})^2 - I_{k-1}\right\|_2 \le 3\delta$, so

$$\left|f_u^\top (p(\Sigma^\star_{[k-1]})^2 - I_{k-1})\ f_v\right| \le \|f_u\|_2 \left\|\left(p(\Sigma^\star_{[k-1]})^2 - I_{k-1}\right) f_v\right\|_2 \le 3\delta \|f_u\|_2 \|f_v\|_2 \le \frac{1}{320n}, \tag{4}$$

where the last inequality follows by Lemma 21 and the assumption that δ is a sufficiently small constant.

We now bound the second summand in Equation (3). The matrix $U_{\text{top}} p(\Sigma^\star_{\text{top}})^2 U_{\text{top}}^\top$ is positive semidefinite, and therefore

$$\begin{aligned}
\left|\mathbb{1}_u^\top U_{\text{top}} p(\Sigma^\star_{\text{top}})^2 U_{\text{top}}^\top\ \mathbb{1}_v\right| &\le \mathbb{1}_u^\top U_{\text{top}} p(\Sigma^\star_{\text{top}})^2 U_{\text{top}}^\top \mathbb{1}_u + \mathbb{1}_v^\top U_{\text{top}} p(\Sigma^\star_{\text{top}})^2 U_{\text{top}}^\top \mathbb{1}_v \\
&\le \left\|p\left(\Sigma^\star_{\text{top}}\right)^2\right\|_2 \left\|U_{\text{top}}^\top \mathbb{1}_u\right\|_2^2 + \left\|p\left(\Sigma^\star_{\text{top}}\right)^2\right\|_2 \left\|U_{\text{top}}^\top \mathbb{1}_v\right\|_2^2 \\
&\le 2\left\|p\left(\Sigma^\star_{\text{top}}\right)^2\right\|_2,
\end{aligned}$$

where the last inequality uses that $\left\|U_{\text{top}}^\top \mathbb{1}_w\right\|_2^2 \le \|U^\top \mathbb{1}_w\|_2^2 = \|\mathbb{1}_w\|_2^2 = 1$ for all $w \in V$.

By Lemma 16 and the definition of $\Sigma^\star_{\text{top}}$, the matrix $\Sigma^\star_{\text{top}}$ is a diagonal matrix with entries bounded in absolute value by $O(\sqrt{\lambda/d})$ Therefore, by Theorem 4, $\left\|p\left(\Sigma^\star_{\text{top}}\right)^2\right\|_2 \le n^{-2}$. So the second summand in Equation (3) can be bounded as

$$\left|\mathbb{1}_u^\top U_{\text{top}} p(\Sigma^\star_{\text{top}})^2 U_{\text{top}}^\top\ \mathbb{1}_v\right| \le 2\left\|p\left(\Sigma^\star_{\text{top}}\right)^2\right\|_2 \le 2n^{-2} \le \frac{1}{320n}. \tag{5}$$

Combining Equation (3), Equation (4) and Equation (5) gives the claim. ◀

The following lemma shows that the quantity computed by Algorithm 2 has expected value $\mathbb{1}_u^\top p(\bar{A}_\star)^2 \mathbb{1}_v = \sum_{t,t'} c_t c_{t'} \langle \bar{A}_\star^t \mathbb{1}_u, \bar{A}_\star^{t'} \mathbb{1}_v\rangle$.

▶ **Lemma 24.** *For every $u, v \in V$,*

$$\sqrt{\deg(u)}\sqrt{\deg(v)}\left(\langle D^{-1/2} M^t \mathbb{1}_u, D^{-1/2} M^{t'} \mathbb{1}_v\rangle - \frac{1}{2m}\right) = \langle \bar{A}_\star^t \mathbb{1}_u, \bar{A}_\star^{t'} \mathbb{1}_v\rangle.$$

Proof. We start by relating the left-hand side to $\langle \bar{A}^t \mathbb{1}_u, \bar{A}^{t'} \mathbb{1}_v \rangle$. From the definition of $M = AD^{-1}$ and $\bar{A} = D^{-1/2}AD^{-1/2}$, for every t, it holds that $M^t = D^{1/2}\bar{A}^t D^{-1/2}$. Therefore,

$$\begin{aligned}
&\langle D^{-1/2}M^t \mathbb{1}_u, D^{-1/2}M^{t'} \mathbb{1}_v \rangle = \mathbb{1}_u^\top \left(M^t\right)^\top D^{-1} M^{t'} \mathbb{1}_v \\
&= \mathbb{1}_u^\top D^{-1/2} (\bar{A}^t)^\top D^{1/2} D^{-1} D^{1/2} A^{t'} D^{-1/2} \mathbb{1}_v = \left(D^{-1/2}\mathbb{1}_u\right)^\top (\bar{A}^t)^\top A^{t'} D^{-1/2} \mathbb{1}_v \\
&= \frac{\langle \bar{A}^t \mathbb{1}_u, \bar{A}^{t'} \mathbb{1}_v \rangle}{\sqrt{\deg(u)}\sqrt{\deg(v)}}.
\end{aligned} \tag{6}$$

Next, we relate this to $\langle \bar{A}_\star^t \mathbb{1}_u, \bar{A}_\star^{t'} \mathbb{1}_v \rangle$. Recall from Observation 9 that $e_1 = \frac{D^{1/2}\mathbb{1}}{\sqrt{2m}}$. Since $\bar{A}e_1 = e_1$, we have $\bar{A}_\star^t = (\bar{A} - e_1 e_1^\top)^t = \bar{A}^t - e_1 e_1^\top$ for every $t \geq 1$. Therefore,

$$\begin{aligned}
\left\langle \bar{A}_\star^t \mathbb{1}_u, \bar{A}_\star^{t'} \mathbb{1}_v \right\rangle &= \left\langle \bar{A}^t \mathbb{1}_u, \bar{A}^{t'} \mathbb{1}_v \right\rangle - \langle e_1, \mathbb{1}_u \rangle \langle e_1, \mathbb{1}_v \rangle \\
&= \left\langle \bar{A}^t \mathbb{1}_u, \bar{A}^{t'} \mathbb{1}_v \right\rangle - \frac{\langle \mathbb{1}_u, D^{1/2}\mathbb{1} \rangle \langle \mathbb{1}_v, D^{1/2}\mathbb{1} \rangle}{2m} \\
&= \left\langle \bar{A}^t \mathbb{1}_u, \bar{A}^{t'} \mathbb{1}_v \right\rangle - \frac{\sqrt{\deg(u)}\sqrt{\deg(v)}}{2m}.
\end{aligned} \tag{7}$$

Combining Equation (6) and Equation (7) gives the lemma. ◀

To prove Lemma 10, we need to argue that we can estimate the quantity $\sqrt{\deg(u)}\sqrt{\deg(v)} \sum_{t,t'} c_t c_{t'} \left(\left\langle D^{-1/2}M^t \mathbb{1}_u, D^{-1/2}M^{t'} \mathbb{1}_v \right\rangle - \frac{1}{2m} \right)$ to a sufficiently high precision. We will argue this on a term-by-term basis, using the collision counting result stated in Lemma 25.

▶ **Lemma 25** (Weighted Collision Counting)**.** *Let p, q be two distributions $p, q \in \mathbb{R}^n$, let $\xi \in (0,1)$ be the desired precision and let $\zeta \in (0,1)$ be the desired failure probability. Let $w_1, \dots w_n \in (0, w_{\max}]$ and let $W = diag(w_1, \dots w_n)$. One can estimate $p^\top W q$ up to precision $\xi \cdot w_{\max}(\|p\|_2^2 + \|q\|_2^2)$ with success probability $1 - \zeta$ using $r = 5\xi^{-2}\zeta^{-1}(\|p\|_2^2 + \|q\|_2^2)^{-1/2}$ samples from each of p and q. That is, it is possible to compute $\hat{z} \in \mathbb{R}$ such that*

$$\Pr\left[|p^\top W q - \hat{z}| > \xi \cdot w_{\max}\left(\|p\|_2^2 + \|q\|_2^2\right)\right] \leq \zeta.$$

The proof of Lemma 25 is a standard collision counting argument, and is included in the full version.

We will apply Lemma 25 to the distributions $p = M^t \mathbb{1}_u$ and $q = M^{t'} \mathbb{1}_v$, and the weight matrix $W = D^{-1}$. Since both the error and the sample complexity in Lemma 25 depend on $\|p\|_2 = \|M^t \mathbb{1}_u\|_2$, we need to bound the norm $\|M^t \mathbb{1}_u\|_2$ for $u \in V \setminus B$. This is achieved by Lemma 26 below.

▶ **Lemma 26.** *Let C be a sufficiently large constant, and let $t \geq \frac{C \log n}{\log(d/\lambda)}$. Then for every $u \in V \setminus B$,*

$$\|\bar{A}^t \mathbb{1}_u\|_2^2 = \Theta\left(\frac{1}{n}\right) \qquad \textit{and} \qquad \|M^t \mathbb{1}_u\|_2^2 = \Theta\left(\frac{1}{n}\right).$$

Proof. Recall that $1 = \lambda_1 \geq \dots \geq \lambda_n$ denotes the eigenvalues of $\bar{A}$, and $e_1, \dots e_n$ denotes the corresponding eigenvectors. We have

$$\|\bar{A}^t \mathbb{1}_u\|_2^2 = \sum_{i=1}^n \lambda_i^{2t} \langle \mathbb{1}_u, e_i \rangle^2 = \frac{\langle \mathbb{1}_u, D^{1/2}\mathbb{1} \rangle^2}{2m} + \sum_{i=2}^n \lambda_i^{2t} \langle \mathbb{1}_u, e_i \rangle^2 = \frac{\deg(u)}{2m} + \sum_{i=2}^n \lambda_i^{2t} \langle \mathbb{1}_u, e_i \rangle^2 \tag{8}$$

where the second transition uses $\lambda_1 = 1$ and $e_1 = \frac{D^{1/2}\mathbb{1}}{\sqrt{2m}}$, and the last transition uses $\langle \mathbb{1}_u, D^{1/2}\mathbb{1}\rangle^2 = \deg(u)$. By Observation 15, $m = O(nd)$ and by the model assumption (Definition 6), $\deg(u) = \Omega(d)$. Since every term in Equation (8) is non-negative, this gives $\|\bar{A}^t\mathbb{1}_u\|_2^2 \geq \frac{\deg(u)}{2m} = \Omega\left(\frac{1}{n}\right)$.

We now prove that $\|\bar{A}^t\mathbb{1}_u\|_2^2 = O(1/n)$. By Lemma 16, for every $i \in [2, n-k+1]$, $|\lambda_i| \leq C'\sqrt{\lambda/d}$, for some constant C'. By the assumption that C is sufficiently large, we can assume that $t \geq \frac{C\log n}{\log(d/\lambda)} \geq \frac{\log n}{\log(\sqrt{d/\lambda}/C')}$. This gives $\lambda_i^{2t} \leq \left(C'\sqrt{\lambda/d}\right)^{2t} \leq n^{-2}$. Substituting this into Equation (8) gives

$$\begin{aligned}
\|\bar{A}^t\mathbb{1}_u\|_2^2 &= \frac{\deg(u)}{2m} + \sum_{i=2}^{n-k+1}\lambda_i^{2t}\langle \mathbb{1}_u, e_i\rangle^2 + \sum_{i=n-k+2}^{n}\lambda_i^{2t}\langle \mathbb{1}_u, e_i\rangle^2 \\
&\leq \frac{\deg(u)}{2m} + \frac{1}{n^2}\sum_{i=2}^{n-2}\langle \mathbb{1}_u, e_i\rangle^2 + \sum_{i=n-k+2}^{n}\lambda_i^{2t}\langle \mathbb{1}_u, e_i\rangle^2 \\
&\leq \frac{\deg(u)}{2m} + \frac{1}{n^2}\|\mathbb{1}_u\|_2^2 + \|f_u\|_2^2 \\
&= O\left(\frac{1}{n}\right).
\end{aligned}$$

Here, the last transition uses that $\|f_u\|_2^2 = O(1/n)$ by Lemma 21, since $u \in V \setminus B$, and that $\deg(u) \leq d$ and $m = \Omega(nd)$, by Observation 15.

The guarantee on $\|M^t\mathbb{1}_u\|_2^2$ follows from $M^t\mathbb{1}_u = D^{1/2}\bar{A}^tD^{-1/2}\mathbb{1}_u$, together with the assumption that $\deg(v) = \Theta(d)$ for all $v \in V$ (see Observation 15). ◀

We are now ready to prove the correctness of SpectralDotProduct(Lemma 10).

Proof of Lemma 10. Let C be a sufficiently large constant, let $\delta > 0$ be a sufficiently small constant. Let $t_{\min} \coloneqq \frac{10C\log n}{\log(d/\lambda)}$, and let $p(x) = x^{t_{\min}}q(x)$ be the polynomial from Theorem 4 applied with parameters δ, C and $t = t_{\min}$. Let $t_\Delta = \deg q = O\left(\sqrt{\lambda/d}\log n\right)$. For a sufficiently large constant κ, let

$$r = \kappa\sqrt{n}\cdot(\max|\mathrm{coeff}(p)|)^4(t_\Delta+1)^6. \tag{9}$$

By Theorem 4, $\max|\mathrm{coeff}(p)| = n^{O\left(\frac{1}{\log(d/\lambda)}\right)}$, so $r = \widetilde{O}\left(\sqrt{n}\cdot n^{O\left(\frac{1}{\log(d/\lambda)}\right)}\right)$.

We now show that with probability at least 0.9, the quantity computed by the algorithm approximates $\sum_{t,t'} c_t, c_{t'}\langle \bar{A}_\star\mathbb{1}_u, \bar{A}_\star\mathbb{1}_v\rangle = \langle p(\bar{A}_\star)\mathbb{1}_u, p(\bar{A}_\star)\mathbb{1}_v\rangle$ to a high precision.

▷ Claim 27. With probability at least 0.9, it holds that

$$\left|\sqrt{\deg(u)}\sqrt{\deg(v)}\sum_{t,t'}c_tc_{t'}\left(\left\langle D^{-1/2}\hat{p}_u^t, D^{-1/2}\hat{p}_v^{t'}\right\rangle - \frac{1}{2m}\right) - \langle p(\bar{A}_\star)\mathbb{1}_u, p(\bar{A}_\star)\mathbb{1}_v\rangle\right| \leq \frac{1}{160}\frac{k}{n}.$$

Proof. Fix $t, t' \in [t_{\min}, t_{\min}+t_\Delta]$. Set $p = M^t\mathbb{1}_u$, $q = M^{t'}\mathbb{1}_v$ and $W = D^{-1}$ in Lemma 25. Then $p^\top Wq = \langle D^{-1/2}M^t\mathbb{1}_u, D^{-1/2}M^{t'}\mathbb{1}_v\rangle$ and $\|p\|_2^2 + \|q\|_2^2 = \|M^t\mathbb{1}_u\|_2^2 + \|M^{t'}\mathbb{1}_v\|_2^2 = \Theta(1/n)$, where the last equality follows by Lemma 26. Therefore, applying Lemma 25 with $w_{\max} = O(1/d)$, $\zeta = \frac{0.1}{(t_\Delta+1)^2}$, $\xi = \frac{\gamma}{c_tc_{t'}(t_\Delta+1)^2}$ for a sufficiently small constant γ, and r as in Equation (9), we get that with probability at least $1 - \frac{0.1}{(t_\Delta+1)^2}$, it holds that

$$\left|\left\langle D^{-1/2}\hat{p}_u^t, D^{-1/2}\hat{p}_v^{t'}\right\rangle - \langle D^{-1/2}M^t\mathbb{1}_u, D^{-1/2}M^{t'}\mathbb{1}_v\rangle\right| \leq \frac{1}{160|c_t||c_{t'}|(t_\Delta+1)^2}\cdot\frac{k}{dn}$$

By taking a union bound over the $(t_\Delta+1)^2$ possible pairs of $t,t' \in [t_{\min}, t_{\min}+t_\Delta]$, we get

$$\Pr\left[\left|\sum_{t,t'} c_t c_{t'}\left(\left\langle D^{-1/2}\hat{p}_u^t, D^{-1/2}\hat{p}_v^{t'}\right\rangle - \langle D^{-1/2}M^t\mathbb{1}_u, D^{-1/2}M^{t'}\mathbb{1}_v\rangle\right)\right| \le \frac{k}{160dn}\right] \ge 0.9. \quad (10)$$

From Lemma 24, we have

$$\begin{aligned}
&\sum_{t,t'} c_t c_{t'}\left(\left\langle D^{-1/2}\hat{p}_u^t, D^{-1/2}\hat{p}_v^{t'}\right\rangle - \langle D^{-1/2}M^t\mathbb{1}_u, D^{-1/2}M^{t'}\mathbb{1}_v\rangle\right)\\
=&\sum_{t,t'} c_t c_{t'}\left(\left\langle D^{-1/2}\hat{p}_u^t, D^{-1/2}\hat{p}_v^{t'}\right\rangle - \frac{1}{2m}\right) - \sum_{t,t'} c_t c_{t'}\left(\langle D^{-1/2}M^t\mathbb{1}_u, D^{-1/2}M^{t'}\mathbb{1}_v\rangle - \frac{1}{2m}\right)\\
=&\sum_{t,t'} c_t c_{t'}\left(\left\langle D^{-1/2}\hat{p}_u^t, D^{-1/2}\hat{p}_v^{t'}\right\rangle - \frac{1}{2m}\right) - \frac{1}{\sqrt{\deg(u)}\sqrt{\deg(v)}}\sum_{t,t'} c_t c_{t'}\langle \bar{A}_\star^t\mathbb{1}_u, \bar{A}_\star^{t'}\mathbb{1}_v\rangle\\
=&\sum_{t,t'} c_t c_{t'}\left(\left\langle D^{-1/2}\hat{p}_u^t, D^{-1/2}\hat{p}_v^{t'}\right\rangle - \frac{1}{2m}\right) - \frac{1}{\sqrt{\deg(u)}\sqrt{\deg(v)}}\langle p(\bar{A}_\star)\mathbb{1}_u, p(\bar{A}_\star)\mathbb{1}_v\rangle.
\end{aligned}$$

Combining with Equation (10) gives the claim. ◁

Finally, by Lemma 23, since $u,v \in V\setminus B$, we have

$$\left|\langle p(\bar{A}_\star)\mathbb{1}_u, p(\bar{A}_\star)\mathbb{1}_v\rangle - \langle f_u, f_v\rangle\right| \le \frac{1}{160}\frac{k}{n}. \quad (11)$$

Combining Claim 27 and Equation (11) gives

$$\Pr\left[\left|\textsc{SpectralDotProduct}(u,v) - \langle f_u, f_v\rangle\right| \le \frac{1}{80}\frac{k}{n}\right] \ge 0.9.$$

Running time. The running time of SpectralDotProduct is dominated by the $2(t_\Delta+1) = \widetilde{O}(1)$ calls to RandomWalks (Algorithm 1) in lines 5-6, and the $(t_\Delta+1)^2 = \widetilde{O}(1)$ inner product computations in line 8. Each call to RandomWalks$(r,t,\cdot)$ takes time $O(t\cdot r) = \widetilde{O}(r)$ and returns a vector $\hat{p}_u^t$ of support at most r. Then, each of the inner product computations $\langle D^{-1/2}\hat{p}_u^t, D^{-1/2}\hat{p}_v^{t'}\rangle$ in line 8 can be performed in time

$$O\left(\min\left\{|\mathrm{supp}(D^{-1/2}\hat{p}_u^t)|, |\mathrm{supp}(D^{-1/2}\hat{p}_v^{t'})|\right\}\right) = O(r)$$

by computing $\sum_{w\in\mathrm{supp}(\hat{p}_u^t)\cap\mathrm{supp}(\hat{p}_v^{t'})}\hat{p}_u^t(w)\hat{p}_v^{t'}(w)/\deg(w)$. So the overall running time is $\widetilde{O}(r) = \widetilde{O}\left(n^{1/2+O\left(\frac{1}{\log(d/\lambda)}\right)}\right)$. ◀

5.3 Analysis of SpectralDistance (Proof of Lemma 11 and Corollary 12)

In this section, we prove Lemma 11 and Corollary 12. We start by proving Lemma 11.

Proof of Lemma 11. Let $i_{\max} = 5\cdot 10^6 \log n$ denote the number of iterations in SpectralDistance (Algorithm 3). Let $u,v \in V\setminus B$. For every $i \in [1, i_{\max}]$, each of the calls to SpectralDotProduct in lines 2, 3, 4 succeeds with probability at least 0.9. Therefore, by Lemma 10 and the union bound, with probability at least 0.7, it holds that

$$\begin{aligned}
&\left|\|f_u - f_v\|^2_{\mathrm{apx},i} - \|f_u - f_v\|_2^2\right| \\
&\quad = \left|\left(\|f_u\|^2_{\mathrm{apx},i} + \|f_v\|^2_{\mathrm{apx},i} - 2\langle f_u, f_v\rangle_{\mathrm{apx},i}\right) - \left(\|f_u\|_2^2 + \|f_v\|_2^2 - 2\langle f_u, f_v\rangle\right)\right| \\
&\quad \le \left|\|f_u\|^2_{\mathrm{apx},i} - \|f_u\|_2^2\right| + \left|\|f_v\|^2_{\mathrm{apx},i} - \|f_v\|_2^2\right| + 2\left|\langle f_u, f_v\rangle_{\mathrm{apx},i} - \langle f_u, f_v\rangle\right| \\
&\quad \le \frac{k}{80n} + \frac{k}{80n} + \frac{2k}{80n} = \frac{k}{20n}.
\end{aligned}$$

Therefore, by a Chernoff bound, for each pair $u, v \in V \setminus B$,

$$\Pr\left[\left|\underset{i\in[1,i_{\max}]}{\mathrm{median}}\left(\|f_u - f_v\|^2_{\mathrm{apx},i}\right) - \|f_u - f_v\|_2^2\right| \ge \frac{k}{20n}\right] \le \exp(-0.00025 i_{\max}) \le n^{-102},$$

where the last inequality follows from the setting $i_{\max} = 5 \cdot 10^6 \log n$. Taking a union bound over all possible pairs of $u, v \in V \setminus B$ (of which there are at most n^2) gives the required guarantee.

Running time. By Lemma 10, each call to SpectralDotProduct takes time $\widetilde{O}\left(n^{1/2+O\left(\frac{1}{\log(d/\lambda)}\right)}\right)$. Since the total number of calls to SpectralDotProduct is $O(\log n) = \widetilde{O}(1)$, we get the claimed running time. ◀

Next, we prove Corollary 12.

Proof of Corollary 12. Condition on the event that for all $u, v \in V \setminus B$,

$$\left|\textsc{SpectralDistance}(u, v) - \|f_u - f_v\|_2^2\right| \le \frac{k}{20n}. \tag{12}$$

By Lemma 11, this happens with probability at least $1 - n^{-100}$. Suppose that $\chi(u) = \chi(v) = i$. Then by the triangle inequality and Definition 19,

$$\|f_u - f_v\|_2 \le \|f_u - \mu_i\|_2 + \|f_v - \mu_i\|_2 \le 2 \cdot \sqrt{\frac{0.05k}{n}} = \sqrt{\frac{0.2k}{n}}. \tag{13}$$

By Equations (12) and (13), we get

$$\begin{aligned}
&\textsc{SpectralDistance}(u, v) \le \left|\textsc{SpectralDistance}(u, v) - \|f_u - f_v\|_2^2\right| + \|f_u - f_v\|_2^2 \\
&\le \frac{0.05k}{n} + \frac{0.2k}{n} = \frac{k}{4n}.
\end{aligned}$$

Suppose instead that $\chi(u) = i \neq \chi(v)$. Then by the triangle inequality and Definition 19,

$$\|f_u - f_v\|_2 \ge \|f_v - \mu_i\|_2 - \|f_u - \mu_i\|_2 \ge \sqrt{\frac{k}{n}} - \sqrt{\frac{0.05k}{n}} \ge \sqrt{\frac{0.56k}{n}}. \tag{14}$$

By Equation (12) and (14) we get

$$\begin{aligned}
&\textsc{SpectralDistance}(u, v) \ge \|f_u - f_v\|_2^2 - \left|\textsc{SpectralDistance}(u, v) - \|f_u - f_v\|_2^2\right| \\
&\ge \frac{0.56k}{n} - \frac{0.05k}{n} > \frac{k}{2n}.
\end{aligned}$$

◀

5.4 Construction of the polynomial (Proof of Theorem 4)

In this section, we prove Theorem 4. More generally, we prove:

▶ **Theorem 28.** *Let $\alpha \in [-1,1]$ be a non-zero constant (independent of n), and let $\delta > 0$. For every $\epsilon > 0$ smaller than a sufficiently small constant (depending on $|\alpha|$ and δ), and every $\frac{10\log n}{\log(1/\epsilon)} \le t \le O\left(\frac{\log n}{\log(1/\epsilon)}\right)$, there exists a polynomial p of the form*

$$p(x) = x^t q(x)$$

where q is a polynomial of degree $O(\epsilon \log n)$ such that the coefficients of p are bounded in absolute value by $n^{O_{\alpha,\delta}\left(\frac{1}{\log(1/\epsilon)}\right)}$ and

1. *$|p(x) - 1| \le \delta$ for $x \in [\alpha - \epsilon, \alpha + \epsilon]$*
2. *$|p(x)| \le n^{-2}$ for $|x| \le \epsilon$.*

As a corollary of Theorem 28, we obtain Theorem 4.

Proof of Theorem 4. Immediate from Theorem 28 by setting $\alpha = \frac{-1}{(k-1)}$ and $\epsilon = C\sqrt{\lambda/d}$. ◀

For the rest of the section, we prove Theorem 28. Our polynomial builds on the polynomial construction from [22], and we use the following two results.

▶ **Theorem 29** (Theorem A.2 in [22])**.** *Let $t \ge 2$, $\epsilon \in (0, 0.1]$, $d \ge 10\epsilon t$, and let*

$$P(x) = \sum_{v=0}^{d} T_v(x) c_{v,\epsilon,t}$$

be the polynomial obtained by taking the first $d+1$ terms of the Chebyshev expansion of $(1-\epsilon x)^{-t}$ on $[-1,1]$, where T_v denotes the polynomial given by $T_v(\cos\theta) = \cos(v\theta)$. Then

- *$\max_{v \le d} |c_{v,\epsilon,t}| \le 2^{O(\epsilon t)}$, and*
- *$\sup_{x\in[-1,1]} |P(x) - (1-\epsilon x)^{-t}| = O(de^{-d})$.*

▷ Claim 30 (Claim A.3 in [22]). There exists an absolute constant C such that for every $\epsilon, t > 0$ and every $d \ge 10\epsilon t$, the maximum coefficient of the polynomial $P\left(\frac{1-x}{\epsilon}\right)$ is bounded in absolute value by $(1/\epsilon)^{C\cdot d}$, where $P(y)$ denotes the degree d polynomial from Theorem 29.

Proof of Theorem 28. The main idea is to split the proof into the two cases $\epsilon \lesssim |\alpha|/\log n$, in which case the polynomial $p(x) = (x/\alpha)^t$ is already enough, and the case $\epsilon \gtrsim |\alpha|/\log n$, in which case we will use the polynomial from Theorem 29.

To keep the coefficients small enough in the first case, we choose $t \approx \frac{\log n}{\log(1/\epsilon)}$ rather than $t \approx \log n$, as in [22]. We then analyze the second case more carefully for this choice of t, instead of relying directly on the analysis in [22].

First, we need to set up some parameters. Let C_{29} denote the hidden universal constant in Theorem 29 such that $\sup_{x\in[-1,1]} |P(x) - (1-\epsilon x)^{-t}| \le C_{29} de^{-d}$ for all ϵ. Suppose that ϵ satisfies

$$\log(1/\epsilon) \ge \frac{\log(C_{29}/\delta)}{\delta} \tag{15}$$

(this holds by the assumption that ϵ is smaller than a sufficiently small constant). Let $\tau \ge 10$ be the constant such that

$$t = \frac{\tau \log n}{\log(1/\epsilon)}.$$

Additionally, define the constant

$$\kappa := \frac{\log(C_{29}/\delta)}{4\tau} \leq \frac{\log(C_{29}/\delta)}{40}. \tag{16}$$

We now split the proof into the two cases $\epsilon \leq \frac{\kappa|\alpha|}{\log n}$ or $\epsilon > \frac{\kappa|\alpha|}{\log n}$.

Case 1. Suppose $\epsilon \leq \frac{\kappa|\alpha|}{\log n}$. Let $p(x) = \frac{x^t}{\alpha^t}$. Then clearly p is of the right form, and the only non-zero coefficient of p is bounded in absolute value by

$$\left(\frac{1}{|\alpha|}\right)^t = \left(\frac{1}{|\alpha|}\right)^{\frac{\tau \log n}{\log(1/\epsilon)}} = n^{\frac{\tau \log(1/\alpha)}{\log(1/\epsilon)}} = n^{O_\alpha\left(\frac{1}{\log(1/\epsilon)}\right)},$$

by the assumption that $t = \frac{\tau \log n}{\log(1/\epsilon)}$ for some constant τ.

We now verify Condition 1. By the assumption $\epsilon \leq \frac{\kappa|\alpha|}{\log n}$, we have

$$\begin{aligned}
\frac{4\epsilon t}{|\alpha|} &= \frac{4\tau\epsilon \log n}{|\alpha| \log(1/\epsilon)} && \text{by the definition of } \tau \\
&\leq \frac{4\tau\kappa}{\log(1/\epsilon)} && \text{by the assumption } \epsilon \leq \frac{\kappa|\alpha|}{\log n} \\
&\leq \delta && \text{by Equation (16) and Equation (15).}
\end{aligned}$$

Therefore,

$$\max_{x \in [\alpha-\epsilon, \alpha+\epsilon]} |p(x) - 1| = \max_{x \in [\alpha-\epsilon, \alpha+\epsilon]} \left| \left(\frac{x}{\alpha}\right)^t - 1 \right| \leq \exp\left(\frac{2t\epsilon}{|\alpha|}\right) - 1 \leq \frac{4t\epsilon}{|\alpha|} \leq \delta.$$

Next, we verify Condition 2. We have

$$\max_{x \in [-\epsilon, \epsilon]} |p(x)| = \max_{x \in [-\epsilon, \epsilon]} \left| \left(\frac{x}{\alpha}\right)^t \right| = \left(\frac{\epsilon}{|\alpha|}\right)^t \leq \exp\left(-t \log(|\alpha|/\epsilon\right) \leq n^{-2},$$

where the third transition uses the assumption $t \geq \frac{10 \log n}{\log(1/\epsilon)}$, and the last transition holds for n sufficiently large, using the assumption α is a constant independent of n.

Case 2. Suppose $\epsilon \geq \frac{\kappa|\alpha|}{\log n}$. Let $P(x)$ be the polynomial from Theorem 29 applied with error parameter $\epsilon/|\alpha|$ and $d = \frac{10 \log(1/\epsilon)\epsilon t}{|\alpha|} = \frac{10\tau\epsilon \log n}{|\alpha|} = O_\alpha(\epsilon \log n)$, and let $p(x) := \left(\frac{x}{\alpha}\right)^t P\left(\frac{1 - \frac{x}{\alpha}}{\frac{\epsilon}{|\alpha|}}\right)$. We start by bounding the coefficients of $p(x)$. By Claim 30 and the setting of d, the coefficients of the polynomial $q(x) := x^t P\left(\frac{1-x}{\frac{\epsilon}{|\alpha|}}\right)$ are bounded in absolute value by $(|\alpha|/\epsilon)^{C_{30} \cdot d} = n^{O_\alpha(\epsilon \log(1/\epsilon))} = n^{O_\alpha(1/\log(1/\epsilon))}$, where C_{30} denotes the universal constant from Claim 30. Since $p(x) = q(x/\alpha)$, the coefficients of p are bounded in absolute value by

$$\begin{aligned}
\max |\text{coeff}(p)| &\leq \left(\frac{1}{|\alpha|}\right)^{\deg p} \cdot \max |\text{coeff}(q)| = \left(\frac{1}{|\alpha|}\right)^{t+d} n^{O_\alpha\left(\frac{1}{\log(1/\epsilon)}\right)} \\
&\leq \left(\frac{1}{|\alpha|}\right)^{\frac{\tau \log n}{\log(1/\epsilon)} + \frac{10\tau\epsilon \log n}{|\alpha|}} n^{O_\alpha\left(\frac{1}{\log(1/\epsilon)}\right)} = n^{O_\alpha\left(\frac{1}{\log(1/\epsilon)}\right)},
\end{aligned}$$

as required. We now prove that Condition 1 holds. We have

$$\begin{aligned}
&\max_{x\in[\alpha-\epsilon,\alpha+\epsilon]} |p(x)-1| \\
&= \max_{x\in[\alpha-\epsilon,\alpha+\epsilon]} \left|\left(\frac{x}{\alpha}\right)^t P\left(\frac{1-x/\alpha}{\epsilon/|\alpha|}\right) - 1\right| \\
&\le \left(1+\frac{\epsilon}{|\alpha|}\right)^t \max_{x\in[\alpha-\epsilon,\alpha+\epsilon]} \left|P\left(\frac{1-x/\alpha}{\epsilon/|\alpha|}\right) - \left(\frac{x}{\alpha}\right)^{-t}\right| \\
&\le C_{29}\cdot\left(1+\frac{\epsilon}{|\alpha|}\right)^t de^{-d} && \text{by Theorem 29} \\
&\le C_{29}\cdot\exp\left(\frac{\epsilon t}{|\alpha|}\right)\exp\left(-\frac{d}{2}\right) && \text{since } x\le e^{x/2} \text{ and } 1+x\le e^x \\
&= C_{29}\cdot\exp\left(\frac{\epsilon t}{|\alpha|} - 5\log(1/\epsilon)\frac{\epsilon}{|\alpha|}t\right) && \text{by the setting } d = 10\log(1/\epsilon)\epsilon t/|\alpha| \\
&\le C_{29}\cdot\exp\left(-4\log(1/\epsilon)\frac{\epsilon}{|\alpha|}t\right) \\
&\le C_{29}\exp\left(-4\kappa\tau\right) && \text{by } t=\frac{\tau\log n}{\log(1/\epsilon)} \text{ and } \epsilon\ge\frac{\kappa|\alpha|}{\log n} \\
&= \delta && \text{by setting } \kappa \text{ (16).}
\end{aligned}$$

We now prove Condition 2. Since p has at most $(d+1)$ non-zero coefficients, we have

$$\begin{aligned}
&\max_{x\in[-\epsilon,\epsilon]} |p(x)| \le \epsilon^t\cdot(d+1)\cdot\max|\mathrm{coeff}(p)| \\
&\le \epsilon^{10\log n/\log(1/\epsilon)}\cdot O\left(\epsilon\log n/|\alpha|\right)\cdot n^{O_\alpha(1/\log(1/\epsilon))} \le n^{-10}\cdot n\cdot n^{O_\alpha(1/\log(1/\epsilon))} \le n^{-2},
\end{aligned}$$

where the last inequality uses that ϵ is smaller than a sufficiently small constant depending on α, so we can assume that the value of the exponent $O_\alpha(1/\log(1/\epsilon))$ is at most 7. ◀

5.5 Putting everything together (Proof of Theorem 1)

We now combine Theorem 4, Lemma 11, Corollary 12 and Lemma 20 to obtain Theorem 1.

Proof of Theorem 1. The oracle runs the preprocessing algorithm FindRepresentatives (Algorithm 5) to obtain a set of k color representatives $\{c_i\}_{i\in[k]}$. Then, for every query u, the oracle returns $\textsc{Color}(u,\{c_i\}_{i\in[k]})$.

Let B be the set of bad vertices from Definition 19. We now show that with probability at least 0.9, the oracle is correct on all vertices in $V\setminus B$.

By Lemma 14, with probability at least 0.99, the output of FindRepresentatives is a valid set of color representatives (as per Definition 13). Claim 31 below shows that conditioned on the success of FindRepresentatives, the oracle $\textsc{Color}(v,\{c_i\}_{i\in[k]})$ returns the correct color (up to a permutation of colors) for every $v\in V\setminus B$:

▷ Claim 31. Suppose that $\{c_i\}_{i\in[k]}$ is a set of color representatives (as per Definition 13). Let π be the permutation such that $\pi(\chi(c_i))=i$ for every $i\in[k]$. Then with probability at least $1-n^{-100}$, for all $v\in V\setminus B$,

$$\textsc{Color}(v,\{c_i\}_{i\in[k]}) = \pi(\chi(v)).$$

Proof. Let $v \in V \setminus B$, and let c_i be the color representative such that $\chi(c_i) = \chi(v)$. Since $\{c_j\}_{j\in[k]}$ is a set of color representatives, by Definition 13, every c_j belongs to a different color class, and $c_j \in V \setminus B$ for all $j \in [k]$. Therefore, by Corollary 12,

$$\textsc{SpectralDistance}(v, c_i) \leq \frac{k}{4n}$$

and for all $j \neq i$,

$$\textsc{SpectralDistance}(v, c_j) \geq \frac{k}{2n}.$$

In particular, $\arg\min_j \textsc{SpectralDistance}(v, c_j) = i$. By definition of the permutation π, we have $i = \pi(\chi(c_i)) = \pi(\chi(v))$, so Color returns $\pi(\chi(v))$ as claimed. ◁

Taking a union bound over the success of FindRepresentatives and Claim 31, we get that with probability at least $0.99 - n^{-100} \geq 0.9$, every vertex in $V \setminus B$ is colored correctly (up to a permutation of the colors). In that case, by Lemma 20,

$$|\{v : \textsc{Color}(v, \{c_i\}_{i\in[k]}) \neq \pi(\chi(v))\}| \leq |B| \leq O\left(\sqrt{\frac{\lambda}{d}} \cdot n\right).$$

Running time. The preprocessing stage runs FindRepresentatives (Algorithm 5). By Lemma 14, this has running time $\widetilde{O}\big(n^{1/2+O(1/\log(d/\lambda))}\big)$.

Each query is answered by Color (Algorithm 4), which calls SpectralDistance (Algorithm 3) $k = O(1)$ times. By Lemma 11, this takes time $\widetilde{O}\big(n^{1/2+O(1/\log(d/\lambda))}\big)$. ◀

One-Sided-Error Parameterized Reductions for the Minimum Distance and Shortest Vector Problems*

Abstract

It is notoriously difficult to obtain deterministic reductions for the Minimum Distance Problem (MDP) and the Shortest Vector Problem (SVP). Under two-sided-error randomized reductions, Bennett, Cheraghchi, Guruswami, and Ribeiro (STOC 2023) proved parameterized hardness of approximation for these problems. We partially derandomize their reductions and present one-sided-error randomized reductions: MDP is W[1]-hard to approximate within an arbitrary constant factor under FPT many-one one-sided-error randomized reductions; For every fixed $p \geq 1$, SVP in the ℓ_p norm is W[1]-hard to approximate within an arbitrary constant factor below $2^{1/p}$.

We demonstrate the usefulness of one-sided-error randomized reductions by showing that they can be conditionally derandomized when the target problem has an OR function. Under a standard hardness-vs-randomness assumption, namely a plausible lower-bound assumption against nondeterministic circuits, we prove a general theorem formalizing this derandomization. Here, an OR function combines several instances into one instance that preserves their disjunction. We construct such OR functions for the relevant MDP and SVP gap problems, and thereby obtain deterministic W[1]-hardness for approximating MDP over every fixed finite field within every constant factor, and for approximating SVP in ℓ_p norms for every fixed integer p within every factor below $2^{1/p}$. Applying the same framework to Micciancio's one-sided-error randomized reduction (ToC 2012) yields, under the same circuit lower-bound assumption, deterministic polynomial-time NP-hardness of approximating Euclidean SVP within every constant factor.

1 Introduction

As fundamental computational problems on codes and lattices, the Minimum Distance Problem (MDP) and the Shortest Vector Problem (SVP) have long been studied. In the gap version, γ-GapMDP$_q$ asks whether a linear code over $\mathbb{F}_q$ has a nonzero codeword of Hamming weight at most k, or whether every nonzero codeword has weight larger than γk. Similarly, γ-GapSVP$_p$ asks whether an integer lattice has a nonzero vector of ℓ_p norm at most d, or whether every nonzero vector has norm larger than γd. For further background, see surveys and standard textbooks [3, 31, 35, 41].

For MDP, Dumer, Micciancio, and Sudan [18] proved randomized NP-hardness for every constant approximation factor. Cheng and Wan [13] derandomized this result, Austrin and Khot [5] and Micciancio [34] gave simpler deterministic reductions. For SVP, van Emde Boas [39] proved NP-hardness of the decision version in the ℓ_∞ norm and conjectured hardness in the Euclidean norm. Ajtai [4] proved randomized NP-hardness of Euclidean SVP. Subsequent work by Khot [27, 28], Haviv and Regev [23], Micciancio [32, 33], and Bennett and Peikert [9] established stronger randomized hardness results for GapSVP$_p$ in several norms and approximation regimes. More recently, Hecht and Safra [24], Hair and Sahai [22, 21], and Wan [40] obtained deterministic hardness results for SVP in finite ℓ_p norms.

Parameterized complexity emerged as a systematic framework in the late 1980s and early 1990s, mainly through the work of Downey and Fellows [15, 16, 17], building on earlier work with Langston; see also [14]. In this framework, the running time of an algorithm is measured not only as a function of the input length n, but also as a function of an additional parameter k. A parameterized problem is *fixed-parameter tractable* if it can be solved in time $f(k) \cdot n^{O(1)}$ for some computable function f. The class of such problems is denoted by FPT. The standard hardness notion used to rule out fixed-parameter tractability is W[1]-hardness, which plays a role analogous to NP-hardness in classical complexity theory. For γ-GapMDP$_q$ and γ-GapSVP$_p$, one of the natural parameters is the distance threshold. Bhattacharyya, Bonnet, Egri, Ghoshal, Karthik C. S., Lin, Manurangsi, and Marx [11] proved that γ-GapMDP$_2$ is W[1]-hard under randomized reductions for every constant $\gamma \geq 1$. They also proved that, for every fixed $p > 1$, γ-GapSVP$_p$ is W[1]-hard for every $\gamma \in [1, (1/2 + 1/2^p)^{-1/p})$, again under randomized reductions. Bennett, Cheraghchi, Guruswami, and Ribeiro [7] extended these parameterized hardness results to GapMDP$_q$ over every fixed finite field and to GapSVP$_p$ in finite ℓ_p norms. More precisely, for every fixed $p > 1$, they proved W[1]-hardness for every constant approximation factor $\gamma \geq 1$. For the remaining case $p = 1$, they proved W[1]-hardness for every $\gamma \in [1, 2)$. Except for binary MDP in [11], these parameterized reductions have two-sided error. In the classical setting, randomized reductions with one-sided error were already used by Micciancio [32, 33] and Bennett and Peikert [9]; Wan [40] subsequently derandomized this line for approximation factors $\gamma \in [1, 2^{1/p})$.

1.1 Our Results

Our first contribution is to strengthen the parameterized hardness reductions of Bennett, Cheraghchi, Guruswami, and Ribeiro [7] from two-sided error to one-sided error.

Our first theorem proves this for γ-GapMDP$_q$ over every fixed finite field, without losing their hardness [7] for every constant approximation factor.

▶ **Theorem 1.** *For every fixed prime power $q \geq 2$ and every constant $\gamma \geq 1$, γ-GapMDP$_q$ is* W[1]*-hard under randomized* FPT *many-one reductions with one-sided error.*

Our second theorem proves the corresponding statement for γ-GapSVP$_p$ in the range $\gamma < 2^{1/p}$.

▶ **Theorem 2.** *For any fixed $p \in [1, \infty)$ and constant $\gamma \in [1, 2^{1/p})$, γ-GapSVP$_p$ is* W[1]*-hard under randomized* FPT *many-one reductions with one-sided error.*

In the classical setting, Micciancio [33] viewed his randomized reduction with one-sided error for the NP-hardness of γ-GapSVP$_2$ as a *partial derandomization*. Following this terminology, Theorems 1 and 2 can be viewed as a partial derandomization of the randomized parameterized hardness reductions of MDP and SVP.

The significance of one-sidedness is that it provides a route to removing the remaining randomness under standard hardness-vs-randomness assumptions. Our second contribution is to show that, for MDP and SVP, the randomized hardness results with one-sided error above can be converted into deterministic hardness results under a standard circuit lower-bound assumption. We assume that there exists an $\varepsilon > 0$ such that

$$\mathsf{E} := \mathsf{DTIME}(2^{O(n)}) \not\subseteq i.o.\text{-}\mathrm{NSIZE}(2^{\varepsilon n}).$$

Here, $\mathrm{NSIZE}(s(n))$ denotes the class of languages decidable by nondeterministic circuits of size $O(s(n))$, and i.o. stands for "infinitely often". Under this assumption, we show in Section 4 that suitable one-sided-error randomized reductions to promise problems with OR functions can be made deterministic. An OR function combines a finite list of instances into a single instance that is YES if at least one input is YES, and is NO if all inputs are NO. In the parameterized setting, we additionally require the output parameter to be bounded by a computable function of the largest input parameter.

To apply this framework to MDP and SVP, we show that the relevant gap problems have the required OR functions.

▶ **Proposition 3** (Informal; see Lemmas 36–38)**.** *Let $\gamma \geq 1$ be a constant. The following hold.*

1. *For every fixed prime power $q \geq 2$, γ-GapMDP_q, parameterized by the distance threshold, has an FPT OR function.*
2. *For every fixed $p \geq 1$, γ-GapSVP_p has a polynomial-time OR function. Moreover, when parameterized by the distance threshold, γ-GapSVP_p has an FPT OR function.*

Combining the general derandomization framework with the OR functions for MDP and SVP yields the following deterministic hardness results. They show that one-sidedness is not merely a stronger error guarantee.

▶ **Theorem 4.** *Assume that there exists an $\varepsilon > 0$ such that*

$$\mathsf{E} \not\subseteq i.o.\text{-}\mathrm{NSIZE}(2^{\varepsilon n}).$$

Then, for every fixed prime power $q \geq 2$ and constant $\gamma \geq 1$, γ-GapMDP_q is $\mathsf{W}[1]$-hard under deterministic FPT many-one reductions.

▶ **Theorem 5.** *Assume that there exists an $\varepsilon > 0$ such that*

$$\mathsf{E} \not\subseteq i.o.\text{-}\mathrm{NSIZE}(2^{\varepsilon n}).$$

For every fixed integer $p \geq 1$ and constant $\gamma \in [1, 2^{1/p})$, γ-GapSVP_p is $\mathsf{W}[1]$-hard under deterministic FPT many-one reductions.[1]

Finally, the conditional derandomization principle also applies to the classical, non-parameterized setting. Starting from Micciancio's randomized hardness result with one-sided error for γ-GapSVP_2 [33], we obtain a deterministic hardness result under the same circuit lower-bound assumption.

▶ **Theorem 6.** *Assume that there exists an $\varepsilon > 0$ such that*

$$\mathsf{E} \not\subseteq i.o.\text{-}\mathrm{NSIZE}(2^{\varepsilon n}).$$

Then, for every fixed constant $\gamma \geq 1$, γ-GapSVP_2 is NP-hard under deterministic polynomial-time many-one reductions.

[1] More generally, the result holds for every fixed $p \geq 1$ such that the language of pairs $(\mathbf{B}, d)$, where $\mathbf{B} \in \mathbb{Z}^{m \times n}$ is a lattice basis, $d \in \mathbb{Z}_{>0}$, and there exists $\boldsymbol{z} \in \mathbb{Z}^n \setminus \{\mathbf{0}\}$ with $\|\mathbf{B}\boldsymbol{z}\|_p \leq d$, belongs to NP.

Compared with Wan's unconditional deterministic polynomial-time many-one hardness result for $1 \leq \gamma < \sqrt{2}$ [40], Theorem 6 extends the approximation range to every constant $\gamma \geq 1$, at the cost of the circuit lower-bound assumption above.

1.2 Technical Overview

The reductions follow Khot's approach [27] used by Bennett, Cheraghchi, Guruswami, and Ribeiro [7]. In that approach, a locally dense object is combined with an inhomogeneous instance, and a random sparsification step is used to make the output homogeneous. The random step has two roles: in YES instances, it should preserve at least one good vector; in NO instances, it should rule out annoying short vectors.

For MDP, we keep the random linear map used for the YES case, but add a deterministic checking block. The block is built from a BCH parity-check matrix $\mathbf{P}$ and a syndrome amplification map $\mathbf{E}$. Every nonzero vector of Hamming weight at most the relevant threshold has a nonzero syndrome under $\mathbf{P}$, and $\mathbf{E}$ expands any nonzero syndrome into more than the allowed number of nonzero coordinates. Thus every potential short vector in a NO instance is ruled out deterministically.

For SVP, the checking block is analogous. We choose a prime q, use a Reed–Solomon parity-check matrix modulo q, and lift it to the integers. A large scaling factor forces any nonzero syndrome in the checking block to have norm above the soundness threshold. The proof then separates possible short lattice vectors according to the coefficient of the target vector and shows that all cases are impossible in NO instances, independently of the remaining randomness.

For the conditional hardness of MDP and SVP, we assume that there exists an $\varepsilon > 0$ such that

$$\mathsf{E} \not\subseteq i.o.\text{-NSIZE}(2^{\varepsilon n}).$$

By the hardness-vs-randomness results of Impagliazzo and Wigderson [26], Klivans and van Melkebeek [29], and Shaltiel and Umans [38], this assumption gives logarithmic-seed pseudorandom generators against polynomial-size nonadaptive SAT-oracle circuits. For a fixed input, let $\phi(r)$ be the predicate that the random tape r makes the randomized reduction output a YES instance. On YES inputs, completeness gives $\Pr[\phi(r) = 1] \geq 2/3$. For the MDP and SVP instances used in our conditional applications, the YES language of the target problem belongs to NP. Thus the success predicate ϕ can be represented by the SAT oracle circuits considered above. The generator obtained from the circuit lower bound has logarithmic seed length and guarantees that, whenever such a predicate ϕ accepts at least a $2/3$ fraction of random tapes, there is a seed σ such that $\phi(G(\sigma)) = 1$. Hence it suffices to enumerate all seeds of G, run the reduction using the corresponding tapes $G(\sigma)$, and combine the outputs by an OR function. On NO inputs, every tape gives a NO instance since the reduction has a one-sided error. For promise problems, an OR function maps a tuple of instances to a single instance that is YES if at least one input is YES, and is NO if all inputs are NO.

1.3 Related Work

Fine-grained hardness of lattice problems and related problems has been studied under assumptions such as ETH, SETH, Gap-ETH, and Gap-SETH. Relevant results include hardness for SVP by Aggarwal and Stephens-Davidowitz [2], hardness for Bounded Distance Decoding (BDD) in ℓ_p norms by Bennett and Peikert [8], improved bounds for BDD and

SVP by Bennett, Peikert, and Tang [10], lower bounds for parameterized Nearest Codeword Problem (NCP) and related problems by Li, Lin, and Liu [30], consequences for parameterized MDP, Closest Vector Problem (CVP), and SVP via earlier gap-preserving reductions [11, 7], and recent ETH-based hardness results for CVP, SVP, and BDD by Aggarwal, Gupta, Morolia, and Zhang [1]. Several of the lattice hardness results cited above use locally dense lattice gadgets, sparsification, or both, but the specific gadgets and reductions in those works differ from ours.

Hittmeir [25] proved deterministic fine-grained hardness results for GapSVP_p in a different parameterized setting, where p is part of the input and also serves as the parameter. In contrast, in this paper p is fixed and the distance threshold is the parameter.

OR functions and related combining reductions have appeared in other contexts. Chang and Kadin [12] studied polynomial-time OR functions for languages, and Ball, Boyle, Degwekar, Deshpande, Rosen, Vaikuntanathan, and Vasudevan [6] studied lossy reductions that combine several input instances according to a Boolean function.

There is also an earlier conditional route to deterministic hardness for SVP: Micciancio [32] proved deterministic many-one NP-hardness of approximating SVP under a number-theoretic conjecture on the distribution of square-free smooth numbers.

1.4 Open Problems

Our results leave several natural open questions. Can the assumption $\mathsf{E} \not\subseteq i.o.\text{-NSIZE}(2^{\varepsilon n})$ for some $\varepsilon > 0$ be removed from Theorems 4 and 5? For SVP, Theorem 2 gives randomized $\mathsf{W}[1]$-hardness with one-sided error for $\gamma < 2^{1/p}$, whereas Bennett, Cheraghchi, Guruswami, and Ribeiro [7] obtained randomized hardness with two-sided error for every constant factor for fixed $p > 1$; can their entire approximation range be made one-sided error? For the Euclidean norm, Wan [40] proved deterministic polynomial-time NP-hardness of γ-GapSVP_2 for every constant $1 \le \gamma < \sqrt{2}$; can deterministic polynomial-time many-one hardness be extended to every constant $\gamma \ge \sqrt{2}$?

2 Preliminaries

2.1 Notations

All vectors are column vectors unless stated otherwise. For a positive integer N, we write $[N] := \{1, \dots, N\}$. We write $\mathbb{Z}_{>0}$ for the set of positive integers. For a finite set S, its cardinality is denoted by $|S|$; for a string x, its bit length is denoted by $|x|$. We use $\langle x_1, \dots, x_t \rangle$ for a standard polynomial-time computable encoding of a tuple. Unless explicitly indicated otherwise, logarithms are base 2; $\log_q$ denotes logarithm with base q. We use $\mathrm{poly}(\cdot)$ for an unspecified polynomial and allow constants hidden in $O(\cdot)$ to depend on fixed constants such as p and q, and on γ whenever γ is fixed throughout the statement. We write U_n for the uniform distribution over $\{0,1\}^n$.

For a map $f\colon X \to Y$ and subset $S \subseteq X$, we write $f(S) := \{f(x) : x \in S\} \subseteq Y$ for the image of S under f. For a set S in an abelian group and an element a, we write $S - a := \{s - a : s \in S\}$.

For $\boldsymbol{x} = (x_1, \dots, x_m)$, its support is $\mathrm{supp}(\boldsymbol{x}) := \{i \in [m] : x_i \neq 0\}$. For vectors over either $\mathbb{F}_q$ or $\mathbb{Z}$, we write $\|\boldsymbol{x}\|_0 := |\mathrm{supp}(\boldsymbol{x})|$. For $\boldsymbol{x} \in \mathbb{R}^m$ and $p \in [1, \infty)$, we write $\|\boldsymbol{x}\|_p := (\sum_{i=1}^m |x_i|^p)^{1/p}$, and $\|\boldsymbol{x}\|_\infty := \max_i |x_i|$. The Hamming distance between two vectors over $\mathbb{F}_q$ is $\|\boldsymbol{x} - \boldsymbol{y}\|_0$. For $r \ge 0$, define the Hamming ball over $\mathbb{F}_q^m$ by $B_{q,m}(r) := \{\boldsymbol{x} \in \mathbb{F}_q^m : \|\boldsymbol{x}\|_0 \le r\}$ and the ℓ_p ball in $\mathbb{R}^m$ by $\mathcal{B}_p^m(r) := \{\boldsymbol{x} \in \mathbb{R}^m : \|\boldsymbol{x}\|_p \le r\}$. When integer vectors are intended, we use $\mathcal{B}_p^m(r) \cap \mathbb{Z}^m$ implicitly.

2.2 Probability Theory

We use a standard consequence of Chebyshev's inequality.

▶ **Lemma 7.** *Let $X_1, \ldots, X_N$ be pairwise independent random variables over $\{0,1\}$ such that $\Pr[X_i = 1] = p > 0$ for $i = 1, \ldots, N$. Then, it holds that*

$$\Pr[\forall i \in [N], X_i = 0] \leq \frac{1}{pN}.$$

2.3 Promise Problems and Reductions

A promise problem is a pair $\Pi = (\Pi_{\text{YES}}, \Pi_{\text{NO}})$ of disjoint languages. A parameterized promise problem is such a pair whose instances are pairs (x, k), where $k \in \mathbb{N}$ is the parameter. For details on promise problems and parameterized complexity, see the survey by Goldreich [19] and the textbooks by Downey and Fellows [17, 16, 15].

Some reductions used are randomized. They are required to preserve NO instances for every choice of randomness, while YES instances need only be mapped correctly with constant probability.

▶ **Definition 8** (Randomized many-one reductions with one-sided error)**.** *Let $\Pi = (\Pi_{\text{YES}}, \Pi_{\text{NO}})$ and $\Pi' = (\Pi'_{\text{YES}}, \Pi'_{\text{NO}})$ be promise problems. A randomized polynomial-time algorithm R is called a randomized many-one reduction with one-sided error from Π to Π' if, on every input x, it outputs a single instance $R(x; r)$ in the input format of Π', and the following hold:*
1. *if $x \in \Pi_{\text{YES}}$, then $\Pr_r[R(x; r) \in \Pi'_{\text{YES}}] \geq 2/3$;*
2. *if $x \in \Pi_{\text{NO}}$, then $\Pr_r[R(x; r) \in \Pi'_{\text{NO}}] = 1$.*

In particular, for YES inputs we allow unsuccessful random strings to produce outputs outside the promise of Π'.

For parameterized problems, we also require that the running time be fixed-parameter tractable and that the output parameter depend only on the input parameter. This gives the parameterized analogue of the preceding randomized reduction.

▶ **Definition 9** (Randomized FPT many-one reductions with one-sided error)**.** *Let $\Pi = (\Pi_{\text{YES}}, \Pi_{\text{NO}})$ and $\Pi' = (\Pi'_{\text{YES}}, \Pi'_{\text{NO}})$ be parameterized promise problems. A randomized algorithm R is called a randomized* FPT *many-one reduction with one-sided error from Π to Π' if there exist a computable function T, a computable function g, and a constant $c > 0$ such that, on input (x, k), the algorithm runs in time at most $T(k) \cdot |x|^c$, outputs a pair (x', k'), and satisfies*
1. *$k' \leq g(k)$;*
2. *if $(x, k) \in \Pi_{\text{YES}}$, then $\Pr[(x', k') \in \Pi'_{\text{YES}}] \geq 2/3$;*
3. *if $(x, k) \in \Pi_{\text{NO}}$, then $\Pr[(x', k') \in \Pi'_{\text{NO}}] = 1$.*

▶ Remark 10. With respect to the fixed encoding of tuples, the running-time bounds

$$T(k) \cdot |x|^c \qquad \text{and} \qquad T'(k) \cdot |\langle x, k \rangle|^c$$

are equivalent up to replacing T by another computable function of k. Therefore, in Definition 9 (and deterministic FPT many-one reduction), one may measure the polynomial factor using either $|x|$ or $|\langle x, k \rangle|$.

We assume that all random choices are implemented using a fixed-length random tape whose length is computable within the stated running-time bound. Standard bounded rejection sampling is used when necessary, and its arbitrarily small loss is absorbed into the completeness probability.

2.4 Coding Problems

For a matrix $\mathbf{G} \in \mathbb{F}_q^{m \times n}$, the linear code generated by the columns of $\mathbf{G}$ is $\mathcal{C} = \mathcal{C}(\mathbf{G}) := \{\mathbf{G}\boldsymbol{x} : \boldsymbol{x} \in \mathbb{F}_q^n\} \subseteq \mathbb{F}_q^m$. The minimum distance of a nonzero linear code $\mathcal{C} \subseteq \mathbb{F}_q^m$ is $\lambda(\mathcal{C}) := \min_{\boldsymbol{c} \in \mathcal{C} \setminus \{\mathbf{0}\}} \|\boldsymbol{c}\|_0$. We use the convention $\lambda(\{\mathbf{0}\}) := +\infty$. For a target vector $\boldsymbol{t} \in \mathbb{F}_q^m$, we write $\mathrm{dist}(\mathcal{C}, \boldsymbol{t}) := \min_{\boldsymbol{c} \in \mathcal{C}} \|\boldsymbol{c} - \boldsymbol{t}\|_0$.

The Minimum Distance Problem (MDP) asks for the Hamming weight of the shortest nonzero codeword in a given linear code. In this paper we use its gap version, where one distinguishes codes of minimum distance at most k from those of minimum distance greater than γk.

▶ **Definition 11** (γ-GapMDP$_q$, [18]). *For $\gamma \geq 1$ and a prime power $q \geq 2$, the (parameterized) promise problem γ-approximate Minimum Distance Problem over $\mathbb{F}_q$ (γ-GapMDP$_q$) is defined as follows. Instances are pairs $(\mathbf{G}, k)$, where $\mathbf{G} \in \mathbb{F}_q^{m \times n}$ is a generator matrix of $\mathcal{C}(\mathbf{G})$, and $k \in \mathbb{Z}_{>0}$ is a distance parameter such that*

1. *$(\mathbf{G}, k)$ is a YES instance if $\lambda(\mathcal{C}(\mathbf{G})) \leq k$;*
2. *$(\mathbf{G}, k)$ is a NO instance if $\lambda(\mathcal{C}(\mathbf{G})) > \gamma k$.*

The parameter of interest is k.

The Nearest Codeword Problem (NCP) is the inhomogeneous analogue of MDP: given a target vector, it asks whether some codeword is close to the target. We will use NCP as the starting point for reductions to MDP.

▶ **Definition 12** (γ-GapNCP$_q$, [18]). *For $\gamma \geq 1$ and a prime power $q \geq 2$, the (parameterized) promise problem γ-approximate Nearest Codeword Problem over $\mathbb{F}_q$ (γ-GapNCP$_q$) is defined as follows. Instances are tuples $(\mathbf{G}, \boldsymbol{t}, k)$, where $\mathbf{G} \in \mathbb{F}_q^{m \times n}$ is a generator matrix of $\mathcal{C}(\mathbf{G})$, $\boldsymbol{t} \in \mathbb{F}_q^m$ is a target vector, and $k \in \mathbb{Z}_{>0}$ is a distance parameter such that*

1. *$(\mathbf{G}, \boldsymbol{t}, k)$ is a YES instance if $\mathrm{dist}(\mathcal{C}(\mathbf{G}), \boldsymbol{t}) \leq k$;*
2. *$(\mathbf{G}, \boldsymbol{t}, k)$ is a NO instance if $\mathrm{dist}(\mathcal{C}(\mathbf{G}), \boldsymbol{t}) > \gamma k$.*

The parameter of interest is k.

The next theorem states the W[1]-hardness of γ-GapNCP$_q$. We will use this result later in the reduction to γ-GapMDP$_q$.

▶ **Theorem 13** ([11, Theorem 5.1, adapted] and [7, Theorem 2.7]). *For any real number $\gamma \geq 1$ and any prime power $q \geq 2$, γ-GapNCP$_q$ is W[1]-hard.*

2.5 Lattice Problems

We now turn to the lattice problems considered in the paper. The lattice analogues of the above coding problems are measured with respect to ℓ_p norms.

For a matrix $\mathbf{B} \in \mathbb{Z}^{m \times n}$, the lattice generated by the columns of $\mathbf{B}$ is $\mathcal{L} = \mathcal{L}(\mathbf{B}) := \{\mathbf{B}\boldsymbol{z} : \boldsymbol{z} \in \mathbb{Z}^n\} \subseteq \mathbb{Z}^m$; that is, $\mathcal{L}(\mathbf{B})$ consists of all integer linear combinations of the columns of $\mathbf{B}$. If the columns of $\mathbf{B}$ are linearly independent, then $\mathbf{B}$ is called a lattice basis of $\mathcal{L}(\mathbf{B})$. For $p \in [1, \infty]$, the ℓ_p length of a shortest nonzero lattice vector is $\lambda_1^{(p)}(\mathcal{L}) := \min_{\boldsymbol{v} \in \mathcal{L} \setminus \{\mathbf{0}\}} \|\boldsymbol{v}\|_p$. For a target vector $\boldsymbol{t} \in \mathbb{R}^m$, we write $\mathrm{dist}_p(\mathcal{L}, \boldsymbol{t}) := \min_{\boldsymbol{v} \in \mathcal{L}} \|\boldsymbol{v} - \boldsymbol{t}\|_p$.

One of the central problems on lattices is the Shortest Vector Problem (SVP), which is to find a shortest non-zero vector in a given lattice. In this paper, we study the promise problem version of the Shortest Vector Problem, which is defined as follows:

▶ **Definition 14** (γ-GapSVP$_p$, [20]). *For $p \geq 1$ and $\gamma \geq 1$, the (parameterized) promise problem γ-approximate Shortest Vector Problem (γ-GapSVP$_p$) is defined as follows. Instances are pairs $(\mathbf{B}, d)$, where $\mathbf{B} \in \mathbb{Z}^{m \times n}$ is a lattice basis of $\mathcal{L}(\mathbf{B})$, and $d \in \mathbb{Z}_{>0}$ is a distance parameter such that*

1. $(\mathbf{B}, d)$ *is a YES instance if* $\lambda_1^{(p)}(\mathcal{L}(\mathbf{B})) \le d$;
2. $(\mathbf{B}, d)$ *is a NO instance if* $\lambda_1^{(p)}(\mathcal{L}(\mathbf{B})) > \gamma d$.

The parameter of interest is d.

We will also use the following classical NP-hardness result for approximate SVP for ℓ_2 norm. This theorem is the non-parameterized hardness input for the deterministic hardness result later in the paper.

▶ **Theorem 15** ([33, Corollary 6.3]). *For any constant* $\gamma \ge 1$, γ-GapSVP$_2$ *is* NP*-hard under randomized many-one reductions with one-sided error.*

The Closest Vector Problem (CVP) is the inhomogeneous analogue of SVP: given a lattice and a target vector, it asks whether the target is close to some lattice vector. For the reduction to GapSVP, we use the following gap variant, whose NO instances require all lattice vectors to be far from every nonzero integer multiple of the target vector.

▶ **Definition 16** (γ-GapCVP$_p$, [7]). *For* $p \ge 1$ *and* $\gamma \ge 1$, *the (parameterized) promise problem* γ*-approximate Closest Vector Problem (*γ-GapCVP$_p$*) is defined as follows. Instances are tuples* $(\mathbf{B}, \boldsymbol{t}, d)$, *where* $\mathbf{B} \in \mathbb{Z}^{m \times n}$ *is a lattice basis of* $\mathcal{L}(\mathbf{B})$, $\boldsymbol{t} \in \mathbb{Z}^m$ *is a target vector, and* $d \in \mathbb{Z}_{>0}$ *is a distance parameter such that*

1. $(\mathbf{B}, \boldsymbol{t}, d)$ *is a YES instance if* $\mathrm{dist}_p(\mathcal{L}(\mathbf{B}), \boldsymbol{t}) \le d$;
2. $(\mathbf{B}, \boldsymbol{t}, d)$ *is a NO instance if* $\mathrm{dist}_p(\mathcal{L}(\mathbf{B}), w\boldsymbol{t}) > \gamma d$ *for all* $w \in \mathbb{Z} \setminus \{0\}$.

The parameter of interest is d.

The following theorem provides the parameterized hardness of this CVP variant. It will be combined with our randomized reduction from CVP to SVP.

▶ **Theorem 17** ([11, Theorem 7.2] and [7, Theorem 2.11]). *For any real numbers* $\gamma \ge 1$ *and* $p \ge 1$, γ-GapCVP$_p$ *is* W[1]*-hard under deterministic* FPT *many-one reductions.*

▶ Remark 18. In [11], the NO instance condition for γ-GapCVP$_p$ is stated as $\mathrm{dist}_p(\mathcal{L}(\mathbf{B}), \boldsymbol{t}) > \gamma d$, but their proof in fact shows that $\mathrm{dist}_p(\mathcal{L}(\mathbf{B}), w\boldsymbol{t}) > \gamma d$ for every nonzero integer $w \in \mathbb{Z} \setminus \{0\}$.

2.6 OR functions

An OR function is a deterministic map that, given a finite tuple of strings, outputs one instance of the same promise problem, with the guarantee that it outputs YES if at least one input is a YES instance and outputs NO if all inputs are NO instances.

▶ **Definition 19** (OR functions of a promise problem). *A promise problem* Π *has a polynomial-time OR function if there is a deterministic polynomial-time algorithm* C *such that, for every tuple* $(x_1, \ldots, x_t)$, *if some* $x_i \in \Pi_{\mathrm{YES}}$, *then* $C(x_1, \ldots, x_t) \in \Pi_{\mathrm{YES}}$, *and if all* $x_i \in \Pi_{\mathrm{NO}}$, *then* $C(x_1, \ldots, x_t) \in \Pi_{\mathrm{NO}}$.

▶ **Definition 20** (FPT OR functions of a parameterized promise problem). *A parameterized promise problem* Π *has an* FPT *OR function if there is a deterministic algorithm* C *and computable functions* T, g *such that, on input* $((x_1, k_1), \ldots, (x_t, k_t))$, *the algorithm runs in time* $T(\kappa)N^{O(1)}$, *where* $\kappa = \max_i k_i$ *and* $N = \sum_i |\langle x_i, k_i \rangle|$, *outputs* (y, ℓ) *with* $\ell \le g(\kappa)$, *and satisfies the same YES/NO OR guarantee as above.*

2.7 Circuits and Pseudorandom Generators

Finally, we recall the circuit classes and pseudorandom generators used in the derandomization argument. A nondeterministic circuit is a Boolean circuit with additional nondeterministic input wires; it accepts an input if some assignment to these wires makes the circuit output 1. For a function $s\colon \mathbb{N} \to \mathbb{N}$, $\mathrm{NSIZE}(s(n))$ denotes the class of languages decided by families of nondeterministic circuits of size $O(s(n))$. We write $L \in i.o.\text{-}\mathrm{NSIZE}(s(n))$ if, for infinitely many input lengths n, there is a nondeterministic circuit C_n of size $O(s(n))$ such that for every $x \in \{0,1\}^n$, C_n accepts x if and only if $x \in L$.

We also use nonadaptive SAT-oracle circuits. We write $\mathrm{SIZE}_{\|}^{\mathsf{SAT}}(s(n))$ for languages decided by families of nonadaptive SAT-oracle circuits of size $O(s(n))$. Nonadaptive means that on every path from an input gate to the output gate there is at most one oracle gate.

▶ **Definition 21** (SAT-circuitizable success predicates). *Let R be a randomized FPT many-one reduction from a parameterized promise problem Π to Π'. We say that R has SAT-circuitizable success predicates if there is a polynomial P such that, for every promised input (x,k), if μ is the number of random bits used by R, $m = |\langle x,k\rangle| + \mu$, and*

$$\phi_{x,k}(r) = 1 \iff R((x,k);r) \in \Pi'_{\mathrm{YES}},$$

then $\phi_{x,k}$ is computable by a circuit in $\mathrm{SIZE}_{\|}^{\mathsf{SAT}}(P(m))$. Extra bits of $r \in \{0,1\}^m$ are ignored.

A pseudorandom generator stretches a short seed into a longer string that is indistinguishable from a uniform random string for a specified class of Boolean circuits.

▶ **Definition 22** (Pseudorandom generators against circuit classes). *Let $\mathcal{C} = \{\mathcal{C}_n\}_{n\geq 1}$ be a family of Boolean circuit classes. A family of functions $G_n : \{0,1\}^{m(n)} \to \{0,1\}^n$ is an $\varepsilon(n)$-PRG for $\mathcal{C}$ if, for every sufficiently large n and every Boolean function $D \in \mathcal{C}_n$,*

$$\left| \Pr_{y \leftarrow U_n}[D(y) = 1] - \Pr_{\sigma \leftarrow U_{m(n)}}[D(G_n(\sigma)) = 1] \right| \leq \varepsilon(n).$$

The next theorem is the derandomization tool used in the paper. Under an exponential circuit lower bound for $\mathsf{E} := \mathsf{DTIME}(2^{O(n)})$ against nondeterministic circuits, it gives logarithmic-seed PRGs that fool polynomial-size nonadaptive SAT-oracle circuits.[2]

▶ **Theorem 23** ([26, 29, 38], see also Theorem 2.8 in [37]). *Assume that there exists an $\varepsilon > 0$ such that $\mathsf{E} \not\subseteq i.o.\text{-}\mathrm{NSIZE}(2^{\varepsilon n})$. Then, for every constant $c > 1$, there exists a constant $a > 1$ such that, for all sufficiently large n, there is a $1/n^c$-PRG*

$$G_n : \{0,1\}^{a \log n} \to \{0,1\}^n$$

for $\mathrm{SIZE}_{\|}^{\mathsf{SAT}}(n^c)$, and G_n is computable in time $\mathrm{poly}(n^c)$.

3 W[1]-hardness with One-Sided Error

In this section, we will show that γ-GapMDP_q and γ-GapSVP_p are $\mathsf{W}[1]$-hard under randomized FPT reductions with one-sided error. As in the prior work [7], this reduction is based on locally dense codes/lattices constructed from BCH and Reed–Solomon codes, together with sparsification; however, by additionally incorporating a gadget based on the minimum distance of the locally dense codes/lattices, it achieves one-sided error.

Locally dense codes and locally dense lattices are defined as follows.

[2] In the proof of Theorem 35, the PRG is used only through the following consequence: if $\phi \in \mathrm{SIZE}_{\|}^{\mathsf{SAT}}(m^c)$ satisfies $\Pr_{r \leftarrow U_m}[\phi(r) = 1] \geq 2/3$, then some pseudorandom output $G_m(\sigma)$ satisfies $\phi(G_m(\sigma)) = 1$. Thus an efficiently enumerable polynomial-size hitting set for the same predicates would suffice.

▶ **Definition 24** (Locally dense codes, [7]). *Fix a real number $\alpha \in (0,1)$, positive integers d, N, m, n, and a prime power q. A (q, α, d, N, m, n)-*locally dense code *is specified by a generator matrix $\mathbf{A} \in \mathbb{F}_q^{m \times n}$ and a target vector $\boldsymbol{s} \in \mathbb{F}_q^m$ with the following properties:*

- $\lambda(\mathcal{C}(\mathbf{A})) > d$.
- $|(\mathcal{C}(\mathbf{A}) - \boldsymbol{s}) \cap B_{q,m}(\alpha d)| \geq N$.

▶ **Definition 25** (Locally dense lattices, [7]). *Fix real numbers $\alpha \in (0,1)$ and $p \geq 1$ and positive integers d, N, m, n. A (p, α, d, N, m, n)-*locally dense lattice *is specified by a basis $\mathbf{A} \in \mathbb{Z}^{m \times n}$ and a target vector $\boldsymbol{s} \in \mathbb{Z}^m$ with the following properties:*

- $\lambda_1^{(p)}(\mathcal{L}(\mathbf{A})) > d$.
- $\left|(\mathcal{L}(\mathbf{A}) - \boldsymbol{s}) \cap \mathcal{B}_p^m(\alpha d)\right| \geq N$.

▶ **Lemma 26.** *Let $T \subseteq \mathbb{F}_q^M \setminus \{0\}$ be a set of pairwise linearly independent vectors, and let $\mathbf{R} \in \mathbb{F}_q^{h \times M}$ be uniformly random. For every $\boldsymbol{a} \in \mathbb{F}_q^h$,*

$$\Pr_{\mathbf{R}}[\exists \boldsymbol{w} \in T : \mathbf{R}\boldsymbol{w} = \boldsymbol{a}] \geq 1 - \frac{q^h}{|T|}.$$

Proof. For each $\boldsymbol{w} \in T$, the indicator of the event $\mathbf{R}\boldsymbol{w} = \boldsymbol{a}$ has expectation q^{-h}. Pairwise linear independence of the vectors in T implies pairwise independence of these indicators. The claim follows from Lemma 7. ◀

3.1 W[1]-hardness of γ-GapMDP$_q$ with One-Sided Error

We will show the W[1]-hardness of GapMDP by giving a randomized FPT reduction with one-sided error from GapNCP to GapMDP.

For this, we use properties of BCH codes.

▶ **Theorem 27** (q-ary BCH codes, [7]). *Fix a prime power q. Then, given integers $m' = q^r - 1$ and $1 \leq d \leq m'$ for some integer r, it is possible to construct in time* poly(m′) *a generator matrix $\mathbf{G}_{\mathrm{BCH}} \in \mathbb{F}_q^{m' \times n'}$ such that $\mathcal{C}_{\mathrm{BCH}} = \mathcal{C}(\mathbf{G}_{\mathrm{BCH}}) \subseteq \mathbb{F}_q^{m'}$ has minimum distance at least d and co-dimension*

$$m' - n' \leq \lceil (d-1)(1 - 1/q) \rceil \log_q(m' + 1).$$

Bennett, Cheraghchi, Guruswami, and Ribeiro [7] constructed the following locally dense code using the BCH code from Theorem 27.

▶ **Theorem 28** ([7, Theorem 3.3]). *Fix a prime power $q \geq 2$ and set $\gamma = 4q$. There exists a randomized algorithm which, given positive integers m and $k \leq m$, runs in time* poly(m) *and outputs with probability at least 0.99 a $(q, \alpha, d, N, m', n')$-locally dense code $(\mathbf{A}, \boldsymbol{s})$, where*

$$m', n' \leq \mathrm{poly}(m),$$
$$d = \gamma k = 4qk,$$
$$\alpha = 1 - \frac{1}{2q},$$
$$N = \frac{(qm)^{2d}}{100},$$

provided that m is sufficiently large compared to q. Moreover, $\lambda(\mathcal{C}(\mathbf{A})) > d$ with probability 1.

In addition to these locally dense codes, by using a random matrix and the parity-check matrix of a BCH code, we obtain a randomized FPT reduction with one-sided error.

▶ **Theorem 29.** *For a fixed prime power $q \geq 2$ and real numbers $\gamma := 4q$ and $\gamma' := \gamma/(\gamma-1) = 4q/(4q-1)$, there exists a randomized* FPT *many-one reduction with one-sided error from γ-GapNCP$_q$ to γ'-GapMDP$_q$.*

Proof. We use the following equivalent formulation of $4q$-GapNCP$_q$. An instance $(\mathbf{G}, \boldsymbol{t}, k)$ consists of a matrix $\mathbf{G} \in \mathbb{F}_q^{m \times n}$, a target $\boldsymbol{t} \in \mathbb{F}_q^m$, and an integer $k \geq 1$. In the NO case we are promised that

$$\operatorname{dist}(\mathcal{C}(\mathbf{G}), \beta \boldsymbol{t}) > 4qk \qquad \text{for every } \beta \in \mathbb{F}_q \setminus \{0\}.$$

This is equivalent to the usual definition because, for every $\beta \in \mathbb{F}_q \setminus \{0\}$,

$$\operatorname{dist}(\mathcal{C}(\mathbf{G}), \beta \boldsymbol{t}) = \min_{\boldsymbol{c} \in \mathcal{C}(\mathbf{G})} \|\boldsymbol{c} - \beta \boldsymbol{t}\|_0 = \min_{\boldsymbol{c}' \in \mathcal{C}(\mathbf{G})} \|\beta \boldsymbol{c}' - \beta \boldsymbol{t}\|_0 = \min_{\boldsymbol{c}' \in \mathcal{C}(\mathbf{G})} \|\boldsymbol{c}' - \boldsymbol{t}\|_0 = \operatorname{dist}(\mathcal{C}(\mathbf{G}), \boldsymbol{t}),$$

since $\mathcal{C}(\mathbf{G})$ is closed under multiplication by nonzero field elements and $\|\beta \boldsymbol{v}\|_0 = \|\boldsymbol{v}\|_0$ for all $\boldsymbol{v} \in \mathbb{F}_q^m$.

By a standard preprocessing, we may assume $1 \leq k \leq m$ and that m is sufficiently large compared with the fixed field size q. Indeed, if $k > m$, the input is automatically a YES instance, and if m is bounded by a constant depending only on q, the instance can be solved exactly by brute-force search. In these exceptional cases we output a fixed YES or NO instance of γ'-GapMDP$_q$ accordingly.

We first describe the reduction. Set $d := \gamma k$, $\alpha := 1 - 1/(2q)$, and $k' := k + \alpha d = (4q-1)k$. By Theorem 28, in randomized polynomial time on input (m, k) we obtain, with probability at least 0.99, a $(q, \alpha, d, N, m', n')$-locally dense code $(\mathbf{A}, \boldsymbol{s})$, where $m', n' \leq \operatorname{poly}(m)$ and $N = (qm)^{2d}/100$. Moreover, Theorem 28 guarantees that $\lambda(\mathcal{C}(\mathbf{A})) > d$ with probability 1. Define

$$\mathcal{S} := (\mathcal{C}(\mathbf{A}) - \boldsymbol{s}) \cap B_{q,m'}(\alpha d).$$

Then, with probability at least 0.99, we have $|\mathcal{S}| \geq (qm)^{2d}/100$. Next define

$$\widehat{m} := \min \left\{ q^r - 1 : q^r - 1 \geq \max\{m, d+1\} \right\}.$$

By Theorem 27 applied with block length $\widehat{m}$ and distance parameter $d+1$, there is a q-ary BCH code of length $\widehat{m}$ and minimum distance at least $d+1$ whose co-dimension h satisfies

$$h \leq \lceil d(1-1/q) \rceil \log_q(\widehat{m}+1) = d(1-1/q) \log_q(\widehat{m}+1).$$

The equality holds because $d(1-1/q) = 4(q-1)k$ is an integer. Let $\mathbf{H}_P \in \mathbb{F}_q^{h \times \widehat{m}}$ be a parity-check matrix of this BCH code. Let $\mathbf{P} \in \mathbb{F}_q^{h \times m}$ be the matrix consisting of the first m columns of $\mathbf{H}_P$. Then every nonzero vector $\boldsymbol{u} \in \mathbb{F}_q^m$ with $\|\boldsymbol{u}\|_0 \leq d$ satisfies $\mathbf{P}\boldsymbol{u} \neq 0$. Indeed, if $\mathbf{P}\boldsymbol{u} = 0$, then the vector obtained from $\boldsymbol{u}$ by padding $\widehat{m} - m$ zeros would be a nonzero codeword of the BCH code checked by $\mathbf{H}_P$ of ℓ_0-norm at most d, contradicting its minimum distance at least $d+1$. Define the linear map

$$\mathbf{E} : \mathbb{F}_q^h \to \mathbb{F}_q^{(d+1)h}$$

by

$$\mathbf{E}(a_1, \ldots, a_h) := (a_1 \mathbf{1}_{d+1}, \ldots, a_h \mathbf{1}_{d+1}),$$

where $\mathbf{1}_{d+1}$ is the all-ones vector of length $d+1$. Then every nonzero $\boldsymbol{a} \in \mathbb{F}_q^h$ satisfies $\|\mathbf{E}\boldsymbol{a}\|_0 \geq d+1$. Finally, sample $\mathbf{R} \in \mathbb{F}_q^{h \times m'}$ uniformly at random, and output the code generated by

$$\mathbf{G}' := \begin{pmatrix} \mathbf{G} & \mathbf{0} & -\boldsymbol{t} \\ \mathbf{0} & \mathbf{A} & -\boldsymbol{s} \\ \mathbf{EPG} & \mathbf{ERA} & -\mathbf{E}(\mathbf{P}\boldsymbol{t} + \mathbf{R}\boldsymbol{s}) \end{pmatrix}$$

together with the parameter k'. Equivalently, for every $(\boldsymbol{x}, \boldsymbol{y}, \beta) \in \mathbb{F}_q^{n+n'+1}$, the corresponding codeword is $\boldsymbol{c}(\boldsymbol{x}, \boldsymbol{y}, \beta) = \big(\boldsymbol{u}, \boldsymbol{w}, \mathbf{E}(\mathbf{P}\boldsymbol{u} + \mathbf{R}\boldsymbol{w})\big)$, where $\boldsymbol{u} := \mathbf{G}\boldsymbol{x} - \beta\boldsymbol{t}$ and $\boldsymbol{w} := \mathbf{A}\boldsymbol{y} - \beta\boldsymbol{s}$.

We now verify that this is an FPT reduction. By Theorem 28, we have $m', n' \leq \mathrm{poly}(m)$. Also $\widehat{m} \leq q(\max\{m, d+1\} + 1) = O_q(m)$ because $k \leq m$ and hence $d = 4qk \leq 4qm$. Therefore $h = O_q(k \log m)$, the output length is polynomial in the input size, and the output parameter is $k' = (4q-1)k$. Hence the reduction runs in time $f(k) \cdot \mathrm{poly}(|\mathbf{G}| + |\boldsymbol{t}|)$ and maps k to $O(k)$.

It remains to prove completeness and soundness.

Completeness. Assume that $(\mathbf{G}, \boldsymbol{t}, k)$ is a YES instance of $4q$-GapNCP$_q$. Then there exists $\boldsymbol{x}' \in \mathbb{F}_q^n$ such that $\|\mathbf{G}\boldsymbol{x}' - \boldsymbol{t}\|_0 \leq k$. Let $\boldsymbol{u}' := \mathbf{G}\boldsymbol{x}' - \boldsymbol{t}$ and $\boldsymbol{a} := -\mathbf{P}\boldsymbol{u}' \in \mathbb{F}_q^h$. Condition on the event that $(\mathbf{A}, \boldsymbol{s})$ is locally dense, equivalently that $|\mathcal{S}| \geq (qm)^{2d}/100$. This event has probability at least 0.99.

Choose a subset $\mathcal{T} \subseteq \mathcal{S} \setminus \{\mathbf{0}\}$ containing exactly one representative from each one-dimensional subspace that intersects $\mathcal{S} \setminus \{\mathbf{0}\}$ nontrivially. Then distinct elements of $\mathcal{T}$ are pairwise linearly independent. Moreover, on the event under consideration, $|\mathcal{S}| \geq (qm)^{2d}/100 \geq 2$, where the last inequality follows from the preprocessing. Hence

$$|\mathcal{T}| \geq \frac{|\mathcal{S}| - 1}{q - 1} \geq \frac{|\mathcal{S}|}{2q} \geq \frac{(qm)^{2d}}{200q}.$$

By Lemma 26, the probability that no $\boldsymbol{w} \in \mathcal{T}$ satisfies $\mathbf{R}\boldsymbol{w} = \boldsymbol{a}$ is at most $q^h/|\mathcal{T}|$. The BCH codimension bound gives

$$q^h \leq (\widehat{m} + 1)^{d(1-1/q)} \leq \big(q(4q+3)m\big)^d,$$

and our preprocessing ensures

$$\frac{q^h}{|\mathcal{T}|} \leq 200q \left(\frac{4q+3}{qm}\right)^d \leq 0.01.$$

Hence, conditioned on the event that $(\mathbf{A}, \boldsymbol{s})$ is locally dense, with probability at least 0.99 over $\mathbf{R}$ there exists $\boldsymbol{w} \in \mathcal{T} \subseteq \mathcal{S} \setminus \{\mathbf{0}\}$ such that $\mathbf{R}\boldsymbol{w} = -\mathbf{P}\boldsymbol{u}'$.

Fix such a $\boldsymbol{w}$. Since $\boldsymbol{w} \in \mathcal{S} \subseteq \mathcal{C}(\mathbf{A}) - \boldsymbol{s}$, there exists $\boldsymbol{y} \in \mathbb{F}_q^{n'}$ such that $\boldsymbol{w} = \mathbf{A}\boldsymbol{y} - \boldsymbol{s}$ and $\|\boldsymbol{w}\|_0 \leq \alpha d$. Then $\mathbf{P}\boldsymbol{u}' + \mathbf{R}\boldsymbol{w} = 0$, and therefore $\boldsymbol{c}(\boldsymbol{x}', \boldsymbol{y}, 1) = (\boldsymbol{u}', \boldsymbol{w}, 0)$. It follows that

$$\|\boldsymbol{c}(\boldsymbol{x}', \boldsymbol{y}, 1)\|_0 \leq \|\boldsymbol{u}'\|_0 + \|\boldsymbol{w}\|_0 \leq k + \alpha d = k'.$$

Thus the output instance is a YES instance of γ'-GapMDP$_q$.

Since the event that $(\mathbf{A}, \boldsymbol{s})$ is locally dense has probability at least 0.99 and, conditioned on that event, the probability over $\mathbf{R}$ that some $\boldsymbol{w} \in \mathcal{T}$ satisfies $\mathbf{R}\boldsymbol{w} = -\mathbf{P}\boldsymbol{u}'$ is at least 0.99, we conclude that

$$\Pr[\text{output is a YES instance of } \gamma'\text{-GapMDP}_q] \geq 0.99 \cdot 0.99 > 2/3.$$

Soundness. Assume that $(\mathbf{G}, \boldsymbol{t}, k)$ is a NO instance of $4q$-GapNCP$_q$. We show that for every realization of $(\mathbf{A}, \boldsymbol{s})$ produced above and every choice of $\mathbf{R}$, the output is a NO instance of γ'-GapMDP$_q$.

Let $\boldsymbol{c} = \boldsymbol{c}(\boldsymbol{x}, \boldsymbol{y}, \beta) \in \mathcal{C}(\mathbf{G}') \setminus \{0\}$ be an arbitrary nonzero codeword. Suppose toward a contradiction that $\|\boldsymbol{c}\|_0 \le d$. Writing $\boldsymbol{c} = \big(\boldsymbol{u}, \boldsymbol{w}, \mathbf{E}(\mathbf{P}\boldsymbol{u} + \mathbf{R}\boldsymbol{w})\big)$, where $\boldsymbol{u} = \mathbf{G}\boldsymbol{x} - \beta\boldsymbol{t}$ and $\boldsymbol{w} = \mathbf{A}\boldsymbol{y} - \beta\boldsymbol{s}$, we get $\|\boldsymbol{u}\|_0 + \|\boldsymbol{w}\|_0 \le d$.

We first show that $\beta = 0$. If $\beta \neq 0$, then by the NO promise for $4q$-GapNCP$_q$, $\|\boldsymbol{u}\|_0 = \|\mathbf{G}\boldsymbol{x} - \beta\boldsymbol{t}\|_0 > 4qk = d$, contradicting $\|\boldsymbol{u}\|_0 + \|\boldsymbol{w}\|_0 \le d$.

Thus $\beta = 0$. We next show that $\boldsymbol{w} = 0$. If $\boldsymbol{w} \neq 0$, then $\boldsymbol{w} = \mathbf{A}\boldsymbol{y}$ is a nonzero codeword of $\mathcal{C}(\mathbf{A})$, and hence $\|\boldsymbol{w}\|_0 \ge \lambda(\mathcal{C}(\mathbf{A})) > d$, again contradicting $\|\boldsymbol{u}\|_0 + \|\boldsymbol{w}\|_0 \le d$.

Therefore $\beta = 0$ and $\boldsymbol{w} = 0$, so $\boldsymbol{c} = \big(\boldsymbol{u}, 0, \mathbf{E}(\mathbf{P}\boldsymbol{u})\big)$ with $\boldsymbol{u} = \mathbf{G}\boldsymbol{x}$. Since $\boldsymbol{c} \neq 0$, we must have $\boldsymbol{u} \neq 0$. Also $\|\boldsymbol{u}\|_0 \le d$, so by the defining property of $\mathbf{P}$, $\mathbf{P}\boldsymbol{u} \neq 0$. Hence $\|\mathbf{E}(\mathbf{P}\boldsymbol{u})\|_0 \ge d + 1$, which implies $\|\boldsymbol{c}\|_0 \ge d + 1$, contradicting $\|\boldsymbol{c}\|_0 \le d$. This contradiction proves that every nonzero codeword of $\mathcal{C}(\mathbf{G}')$ has ℓ_0-norm strictly larger than d. Therefore $\lambda(\mathcal{C}(\mathbf{G}')) > d$.

Finally, since $d = \gamma' k'$, we obtain $\lambda(\mathcal{C}(\mathbf{G}')) > \gamma' k'$, so the output is a NO instance of γ'-GapMDP$_q$. This holds for every realization of $(\mathbf{A}, \boldsymbol{s})$ and every choice of $\mathbf{R}$, and thus the reduction has one-sided error. ◀

To amplify to an arbitrary approximation constant factor, we use the following well-known fact.

▶ **Fact 30.** *For any two linear codes $\mathcal{C}(\mathbf{G}_1)$ and $\mathcal{C}(\mathbf{G}_2)$ with $\mathbf{G}_1 \in \mathbb{F}_q^{m_1 \times n_1}$, $\mathbf{G}_2 \in \mathbb{F}_q^{m_2 \times n_2}$, and minimum distances $\lambda(\mathcal{C}(\mathbf{G}_1)) = d_1$, $\lambda(\mathcal{C}(\mathbf{G}_2)) = d_2$, we have*

$$\lambda(\mathcal{C}(\mathbf{G}_1 \otimes \mathbf{G}_2)) = d_1 \cdot d_2,$$

where $\mathbf{G}_1 \otimes \mathbf{G}_2 \in \mathbb{F}_q^{m_1 m_2 \times n_1 n_2}$ is the Kronecker product of $\mathbf{G}_1$ and $\mathbf{G}_2$.

By combining the above claims, we obtain the desired proof.

Proof of Theorem 1. By Theorems 13 and 29, the problem

$$\gamma_0\text{-GapMDP}_q \qquad \text{with} \qquad \gamma_0 := \frac{4q}{4q-1} > 1$$

is W[1]-hard under randomized FPT many-one reductions with one-sided error.

Fix an integer $c \ge 1$. Given an instance $(\mathbf{G}, k)$ of γ_0-GapMDP$_q$, map it to $(\mathbf{G}^{\otimes c}, k^c)$, where $\mathbf{G}^{\otimes c}$ denotes the c-fold Kronecker product of $\mathbf{G}$ with itself. By Fact 30, $\lambda(\mathcal{C}(\mathbf{G}^{\otimes c})) = \lambda(\mathcal{C}(\mathbf{G}))^c$. Hence, if $(\mathbf{G}, k)$ is a YES instance, then

$$\lambda(\mathcal{C}(\mathbf{G}^{\otimes c})) \le k^c,$$

so $(\mathbf{G}^{\otimes c}, k^c)$ is a YES instance of γ_0^c-GapMDP$_q$. If $(\mathbf{G}, k)$ is a NO instance, then

$$\lambda(\mathcal{C}(\mathbf{G}^{\otimes c})) > (\gamma_0 k)^c = \gamma_0^c k^c,$$

so $(\mathbf{G}^{\otimes c}, k^c)$ is a NO instance of γ_0^c-GapMDP$_q$. Because c is a constant, this is a deterministic FPT many-one reduction. Therefore, for every integer $c \ge 1$, the problem γ_0^c-GapMDP$_q$ is W[1]-hard under randomized FPT many-one reductions with one-sided error.

Now let $\gamma \ge 1$ be arbitrary. Choose c so that $\gamma_0^c \ge \gamma$. Every YES instance of γ_0^c-GapMDP$_q$ is also a YES instance of γ-GapMDP$_q$, and every NO instance of γ_0^c-GapMDP$_q$ is also a NO instance of γ-GapMDP$_q$. Hence the identity map is a deterministic FPT many-one reduction from γ_0^c-GapMDP$_q$ to γ-GapMDP$_q$. Therefore γ-GapMDP$_q$ is W[1]-hard under randomized FPT many-one reductions with one-sided error. ◀

3.2 W[1]-hardness of γ-GapSVP$_p$ with One-Sided Error

In this section, we prove a randomized FPT reduction with one-sided error from CVP to SVP using ideas similar to those for the hardness of MDP.

▶ **Lemma 31** (Reed–Solomon codes, [36]). *Let q be a prime and let m, r be integers with $1 \le r \le m < q$. Then one can construct in time* $\mathrm{poly(m, \log q)}$ *a matrix $\mathbf{P} \in \mathbb{F}_q^{r\times m}$ such that every nonzero vector $\boldsymbol{u} \in \mathbb{F}_q^m$ with $\|\boldsymbol{u}\|_0 \le r$ satisfies $\mathbf{P}\boldsymbol{u} \neq 0$.*

Proof. Take the standard $r \times m$ Vandermonde parity-check matrix of a Reed–Solomon code over $\mathbb{F}_q$. Any set of at most r columns is linearly independent, so no nonzero vector of Hamming weight at most r lies in its kernel. This construction is deterministic and polynomial time. ◀

The following theorem gives a randomized algorithm for constructing locally dense lattices based on Reed–Solomon codes.

▶ **Theorem 32** ([7, Theorem 4.3]). *Fix real numbers $p \ge 1$ and $\gamma' \in [1, 2^{1/p})$. Let*

$$\varepsilon = (\gamma')^{-p} - \frac{1}{2} > 0,\ \gamma = \left\lceil \max\left(\frac{12}{\varepsilon}, \frac{1}{(1+\varepsilon/2)^{1/p}-1}\right)\right\rceil,\ \alpha = \left(\frac{1}{(\gamma')^p} - \frac{2}{\gamma^p}\right)^{1/p}.$$

Then there exists a randomized algorithm which, on input positive integers m and d, runs in time poly(m, d) and outputs with probability at least 0.99 a $(p, \alpha, \gamma d, N, m', n')$-locally dense lattice $(\mathbf{A}, \boldsymbol{s})$, where

$$m', n' \le \mathit{poly}(m, d),\ N = (2m(1+\gamma d))^{3(\gamma d)^p},$$

provided that m is sufficiently large compared to p. Moreover, $\lambda_1^{(p)}(\mathcal{L}(\mathbf{A})) > \gamma d$ with probability 1.

As in the case of MDP, by using a random matrix and the parity-check matrix of a Reed–Solomon code, we obtain a randomized FPT reduction with one-sided error.

▶ **Theorem 33.** *Fix a real number $p \ge 1$ and a rational constant $\gamma' \in [1, 2^{1/p})$. Define*

$$\varepsilon = (\gamma')^{-p} - \frac{1}{2} > 0 \ \text{ and } \ \gamma = \left\lceil \max\left(\frac{12}{\varepsilon}, \frac{1}{(1+\varepsilon/2)^{1/p}-1}\right)\right\rceil.$$

Then there exists a randomized FPT *many-one reduction with one-sided error from γ-*GapCVP$_p$ *to γ'-*GapSVP$_p$.

Proof. Let $(\mathbf{B}, \boldsymbol{t}, d)$ be an instance of γ-GapCVP$_p$ with $\mathbf{B} \in \mathbb{Z}^{m\times n}$, $\boldsymbol{t} \in \mathbb{Z}^m$, and $d \in \mathbb{Z}_{>0}$.

By padding $\mathbf{B}$ and $\boldsymbol{t}$ with zero rows, if necessary, we may assume that m is sufficiently large compared with p, so that Theorem 32 applies. This padding preserves $\mathrm{dist}_p(\mathcal{L}(\mathbf{B}), a\boldsymbol{t})$ for every $a \in \mathbb{Z}$ and leaves the parameter d unchanged.

Write $\gamma' = s_0/t_0$ in lowest terms with $s_0, t_0 \in \mathbb{Z}_{>0}$. Set

$$\alpha := \left(\frac{1}{(\gamma')^p} - \frac{2}{\gamma^p}\right)^{1/p},\ r := \min\{m, \lceil(\gamma d)^p\rceil\},\ L := s_0,\ d' := \gamma t_0 d = L\frac{\gamma}{\gamma'}d \in \mathbb{Z}_{>0}.$$

By Theorem 32, in randomized time $\mathrm{poly}(m, d)$ on input (m, d) we obtain, with probability at least 0.99, a $(p, \alpha, \gamma d, N, m', n')$-locally dense lattice $(\mathbf{A}, \boldsymbol{s})$, where

$$N = (2m(1+\gamma d))^{3(\gamma d)^p},\ m', n' \le \mathrm{poly}(m, d), \ \text{ and } \ \lambda_1^{(p)}(\mathcal{L}(\mathbf{A})) > \gamma d.$$

Next, choose a prime q satisfying

$$2\max\{m, \gamma d\} < q \leq 4\max\{m, \gamma d\}.$$

By Bertrand's postulate and primality testing, such a prime can be found deterministically in time $\mathrm{poly}(m, d)$. If $\lceil (\gamma d)^p \rceil \geq m$, let $\mathbf{P} := I_m \in \mathbb{F}_q^{m \times m}$. Otherwise, apply Lemma 31 with parameters (q, m, r) to obtain $\mathbf{P} \in \mathbb{F}_q^{r \times m}$ such that every nonzero vector $\boldsymbol{u} \in \mathbb{F}_q^m$ with $\|\boldsymbol{u}\|_0 \leq r$ satisfies $\mathbf{P}\boldsymbol{u} \neq 0$. Let $\widehat{\mathbf{P}} \in \mathbb{Z}^{r \times m}$ be the canonical integer lift of $\mathbf{P}$ whose entries lie in $\{0, 1, \ldots, q-1\}$. Define the reduction modulo q maps

$$\pi_m : \mathbb{Z}^m \to \mathbb{F}_q^m, \qquad \pi_m(\boldsymbol{u}) = \boldsymbol{u} \bmod q,$$
$$\pi_{m'} : \mathbb{Z}^{m'} \to \mathbb{F}_q^{m'}, \qquad \pi_{m'}(\boldsymbol{w}) = \boldsymbol{w} \bmod q.$$

Observe that every nonzero $\boldsymbol{u} \in \mathbb{Z}^m$ with $\|\boldsymbol{u}\|_p \leq \gamma d$ satisfies $\mathbf{P}\pi_m(\boldsymbol{u}) \neq 0$. Indeed, $|u_i| \leq \|\boldsymbol{u}\|_p \leq \gamma d < q/2$ for every coordinate, so $\pi_m(\boldsymbol{u}) \neq 0$. Moreover,

$$\|\pi_m(\boldsymbol{u})\|_0 \leq \|\boldsymbol{u}\|_0 \leq \|\boldsymbol{u}\|_p^p \leq (\gamma d)^p \leq r$$

if $r < m$, while if $r = m$ then $\mathbf{P} = I_m$ and the claim is immediate. Now sample $\mathbf{R} \in \mathbb{F}_q^{r \times m'}$ uniformly at random, let $\widehat{\mathbf{R}} \in \mathbb{Z}^{r \times m'}$ be its canonical integer lift. More precisely, $\mathbf{R}$ is obtained by sampling the entries independently and uniformly at random from $\mathbb{F}_q$. Define the lattice basis

$$\mathbf{B}' := \begin{pmatrix} \mathbf{B} & \mathbf{0}_{m \times n'} & -\boldsymbol{t} & \mathbf{0}_{m \times r} \\ \mathbf{0}_{m' \times n} & \mathbf{A} & -\boldsymbol{s} & \mathbf{0}_{m' \times r} \\ \mathbf{0}_{1 \times n} & \mathbf{0}_{1 \times n'} & 1 & \mathbf{0}_{1 \times r} \\ \beta\widehat{\mathbf{P}}\mathbf{B} & \beta\widehat{\mathbf{R}}\mathbf{A} & -\beta(\widehat{\mathbf{P}}\boldsymbol{t} + \widehat{\mathbf{R}}\boldsymbol{s}) & \beta q \mathbf{I}_r \end{pmatrix}, \qquad \beta := \gamma d + 1.$$

And set $\widehat{\mathbf{B}} := L\mathbf{B}'$. Output the lattice basis $\widehat{\mathbf{B}}$ together with the threshold d'. Equivalently, for every $(\boldsymbol{x}, \boldsymbol{y}, a, \boldsymbol{z}) \in \mathbb{Z}^{n+n'+1+r}$, the corresponding lattice vector is

$$\boldsymbol{c}(\boldsymbol{x}, \boldsymbol{y}, a, \boldsymbol{z}) = \big(\boldsymbol{u}, \boldsymbol{w}, a, \beta(\widehat{\mathbf{P}}\boldsymbol{u} + \widehat{\mathbf{R}}\boldsymbol{w} + q\boldsymbol{z})\big),$$

where $\boldsymbol{u} := \mathbf{B}\boldsymbol{x} - a\boldsymbol{t}$ and $\boldsymbol{w} := \mathbf{A}\boldsymbol{y} - a\boldsymbol{s}$. This is the output instance of γ'-GapSVP$_p$.

We now verify that this is an FPT reduction. Since $m', n' \leq \mathrm{poly}(m, d)$ and $r \leq \lceil (\gamma d)^p \rceil$, the output basis has size polynomial in the input size, and the output parameter is $d' = \gamma t_0 d = O(d)$, because γ and t_0 are constants depending only on the fixed target factor γ'. Hence the reduction runs in time $f(d) \cdot \mathrm{poly}(|\mathbf{B}| + |\boldsymbol{t}|)$ and maps d to $O(d)$.

It remains to prove completeness and soundness.

Completeness. Assume that $(\mathbf{B}, \boldsymbol{t}, d)$ is a YES instance of γ-GapCVP$_p$. Then there exists $\boldsymbol{x}' \in \mathbb{Z}^n$ such that $\|\mathbf{B}\boldsymbol{x}' - \boldsymbol{t}\|_p \leq d$. Let

$$\boldsymbol{u}' := \mathbf{B}\boldsymbol{x}' - \boldsymbol{t}, \qquad \boldsymbol{a} := -\mathbf{P}\pi_m(\boldsymbol{u}') \in \mathbb{F}_q^r.$$

Define

$$\mathcal{W}_s := (\mathcal{L}(\mathbf{A}) - \boldsymbol{s}) \cap \mathcal{B}_p^{m'}(\alpha\gamma d).$$

Then, with probability at least 0.99, we have $|\mathcal{W}_s| \geq N$. Because every $\boldsymbol{w} \in \mathcal{W}_s$ has $\|\boldsymbol{w}\|_p \leq \alpha\gamma d < q/2$, the map $\pi_{m'}$ is injective on $\mathcal{W}_s$, and $\pi_{m'}(\boldsymbol{w}) \neq 0$ whenever $\boldsymbol{w} \neq 0$.

Choose $\mathcal{T} \subseteq \mathcal{W}_s \setminus \{\mathbf{0}\}$ so that $\pi_{m'}(\mathcal{T})$ contains exactly one representative from each one-dimensional subspace of $\mathbb{F}_q^{m'}$ that intersects $\pi_{m'}(\mathcal{W}_s \setminus \{\mathbf{0}\})$. Then $\pi_{m'}(\mathcal{T})$ is pairwise linearly independent and, since $|\mathcal{W}_s| \geq N$ and $N \geq q$,

$$|\mathcal{T}| \geq \frac{|\mathcal{W}_s| - 1}{q - 1} \geq \frac{N}{q}.$$

By Lemma 26, the probability that no $\boldsymbol{w} \in \mathcal{T}$ satisfies

$$\mathbf{R}\pi_{m'}(\boldsymbol{w}) = -\mathbf{P}\pi_m(\boldsymbol{u}') \tag{1}$$

is at most $q^r/|\mathcal{T}| \leq q^{r+1}/N$. With $M := 2m(1 + \gamma d)$, the choices of q, r, N give

$$\frac{q^{r+1}}{N} \leq \frac{(2M)^{(\gamma d)^p + 2}}{M^{3(\gamma d)^p}} < 0.01.$$

Thus, conditioned on the locally dense lattice event, with probability at least 0.99 over $\mathbf{R}$ there exists $\boldsymbol{w} \in \mathcal{T} \subseteq \mathcal{W}_s$ satisfying Equation (1).

Fix such a vector $\boldsymbol{w}$. Since $\boldsymbol{w} \in \mathcal{W}_s \subseteq \mathcal{L}(\mathbf{A}) - \boldsymbol{s}$, there exists $\boldsymbol{y} \in \mathbb{Z}^{n'}$ such that $\boldsymbol{w} = \mathbf{A}\boldsymbol{y} - \boldsymbol{s}$ and $\|\boldsymbol{w}\|_p \leq \alpha\gamma d$. Since $\widehat{\mathbf{P}}\boldsymbol{u}' + \widehat{\mathbf{R}}\boldsymbol{w} = 0 \pmod q$, this implies that there exists $\boldsymbol{z} \in \mathbb{Z}^r$ such that

$$\widehat{\mathbf{P}}\boldsymbol{u}' + \widehat{\mathbf{R}}\boldsymbol{w} + q\boldsymbol{z} = 0.$$

Hence $\boldsymbol{c}(\boldsymbol{x}', \boldsymbol{y}, 1, \boldsymbol{z}) = (\boldsymbol{u}', \boldsymbol{w}, 1, \mathbf{0}_r)$. Its ℓ_p norm satisfies

$$\begin{aligned}
\|\boldsymbol{c}(\boldsymbol{x}', \boldsymbol{y}, 1, \boldsymbol{z})\|_p^p &= \|\boldsymbol{u}'\|_p^p + \|\boldsymbol{w}\|_p^p + 1 \\
&\leq d^p + (\alpha\gamma d)^p + 1 \\
&\leq 2d^p + \alpha^p\gamma^p d^p \\
&= (2 + \alpha^p\gamma^p)\, d^p \\
&= \left(\frac{\gamma}{\gamma'}\right)^p d^p,
\end{aligned}$$

where the last equality uses the definition of α. Hence

$$\|\boldsymbol{c}(\boldsymbol{x}', \boldsymbol{y}, 1, \boldsymbol{z})\|_p \leq \frac{\gamma}{\gamma'} d.$$

Therefore the nonzero vector $L\boldsymbol{c}(\boldsymbol{x}', \boldsymbol{y}, 1, \boldsymbol{z}) \in \mathcal{L}(\widehat{\mathbf{B}})$ satisfies

$$\|L\boldsymbol{c}(\boldsymbol{x}', \boldsymbol{y}, 1, \boldsymbol{z})\|_p \leq L\frac{\gamma}{\gamma'} d = d'.$$

Thus the output instance is a YES instance of γ'-GapSVP$_p$. Since the event that $(\mathbf{A}, \boldsymbol{s})$ is $(p, \alpha, \gamma d, N, m', n')$-locally dense lattice has probability at least 0.99 and, conditioned on that event, the probability over $\mathbf{R}$ that some $\boldsymbol{w} \in \mathcal{W}_s$ satisfies the congruence in Equation (1) is at least 0.99, we conclude that

$$\Pr[\text{output is a YES instance of } \gamma'\text{-GapSVP}_p] \geq 0.99 \cdot 0.99 > \frac{2}{3}.$$

Soundness. Assume that $(\mathbf{B}, \boldsymbol{t}, d)$ is a NO instance of γ-GapCVP$_p$. We first show that, regardless of the choice of $\mathbf{R}$, every nonzero vector of $\mathcal{L}(\mathbf{B}')$ has ℓ_p norm strictly larger than γd. Let $\boldsymbol{c} = \boldsymbol{c}(\boldsymbol{x}, \boldsymbol{y}, a, \boldsymbol{z}) \in \mathcal{L}(\mathbf{B}') \setminus \{0\}$ be an arbitrary nonzero lattice vector. Suppose toward a contradiction that $\|\boldsymbol{c}\|_p \le \gamma d$. Writing

$$\boldsymbol{c} = \big(\boldsymbol{u}, \boldsymbol{w}, a, \beta(\widehat{\mathbf{P}}\boldsymbol{u} + \widehat{\mathbf{R}}\boldsymbol{w} + q\boldsymbol{z})\big),$$

where $\boldsymbol{u} = \mathbf{B}\boldsymbol{x} - a\boldsymbol{t}$ and $\boldsymbol{w} = \mathbf{A}\boldsymbol{y} - a\boldsymbol{s}$, we get

$$\|\boldsymbol{u}\|_p^p + \|\boldsymbol{w}\|_p^p + |a|^p \le (\gamma d)^p.$$

In particular, if $a \neq 0$, then by the NO promise for γ-GapCVP$_p$,

$$\|\boldsymbol{u}\|_p = \|\mathbf{B}\boldsymbol{x} - a\boldsymbol{t}\|_p > \gamma d,$$

a contradiction. Hence $a = 0$. If now $\boldsymbol{w} \neq 0$, then because $\lambda_1^{(p)}(\mathcal{L}(\mathbf{A})) > \gamma d$, we get $\|\boldsymbol{w}\|_p > \gamma d$, again a contradiction. Therefore $a = 0$ and $\boldsymbol{w} = 0$. So every short vector must be of the form

$$\boldsymbol{c}(\boldsymbol{x}, \boldsymbol{y}, a, \boldsymbol{z}) = (\boldsymbol{u}, 0, 0, \beta(\widehat{\mathbf{P}}\boldsymbol{u} + q\boldsymbol{z})).$$

If $\boldsymbol{u} = 0$, then since $\boldsymbol{c} \neq 0$, $\boldsymbol{z} \neq 0$. Hence

$$\|\boldsymbol{c}(\boldsymbol{x}, \boldsymbol{y}, a, \boldsymbol{z})\|_p \ge \beta q > \gamma d,$$

a contradiction. So we may assume $\boldsymbol{u} \neq 0$. Since $\|\boldsymbol{u}\|_p \le \gamma d$, property of $\mathbf{P}$ implies $\mathbf{P}\pi_m(\boldsymbol{u}) \neq 0$. Equivalently,

$$\widehat{\mathbf{P}}\boldsymbol{u} + q\boldsymbol{z} \neq 0 \qquad \text{for every } \boldsymbol{z} \in \mathbb{Z}^r.$$

Therefore the last block of $\boldsymbol{c}(\boldsymbol{x}, \boldsymbol{y}, a, \boldsymbol{z})$ is nonzero, so

$$\|\boldsymbol{c}(\boldsymbol{x}, \boldsymbol{y}, a, \boldsymbol{z})\|_p \ge \beta > \gamma d,$$

a contradiction. We conclude that every nonzero vector of $\mathcal{L}(\mathbf{B}')$ has ℓ_p norm strictly larger than γd. Since $\mathcal{L}(\widehat{\mathbf{B}}) = L\mathcal{L}(\mathbf{B}')$, every nonzero vector of $\mathcal{L}(\widehat{\mathbf{B}})$ has ℓ_p norm strictly larger than $L\gamma d = \gamma' d'$. Therefore the output is a NO instance of γ'-GapSVP$_p$. This holds for every pair $(\mathbf{A}, \boldsymbol{s})$ from Theorem 32 and every choice of $\mathbf{R}$, and thus the reduction has one-sided error. ◀

From the above, we immediately obtain Theorem 2.

Proof of Theorem 2. Let $\gamma \in [1, 2^{1/p})$ be the target approximation factor. Choose any rational number η such that $\gamma < \eta < 2^{1/p}$. By Theorems 17 and 33, the problem η-GapSVP$_p$ is W[1]-hard under randomized FPT many-one reductions with one-sided error.

Now observe that every YES instance of η-GapSVP$_p$ is also a YES instance of γ-GapSVP$_p$, and every NO instance of η-GapSVP$_p$ is also a NO instance of γ-GapSVP$_p$, because $\eta > \gamma$. Hence any algorithm for γ-GapSVP$_p$ would also solve η-GapSVP$_p$ on the same input.

Therefore γ-GapSVP$_p$ is W[1]-hard under randomized FPT many-one reductions with one-sided error. ◀

4 Deterministic Hardness under the Circuit Lower Bound

In this section, we describe the derandomization principle used later. The proof is the same in the ordinary and parameterized settings: enumerate a small hitting set of random tapes, run the randomized reduction with one-sided error on all of them, and combine the outputs by an OR function.

▶ **Theorem 34.** *Assume that there exists an $\varepsilon > 0$ such that*

$$\mathsf{E} \not\subseteq i.o.\text{-NSIZE}(2^{\varepsilon n}).$$

Let Π and Π' be promise problems. Suppose that
1. *Π is NP-hard under deterministic polynomial-time many-one reductions;*
2. *$\Pi'_{\mathrm{YES}} \in \mathsf{NP}$;*
3. *Π' has a polynomial-time OR function;*
4. *there exists a randomized many-one reduction with one-sided error from Π to Π'.*

Then Π' is NP-hard under deterministic polynomial-time many-one reductions.

Proof sketch. Let R be the randomized reduction. For a fixed input x, let $\phi_x(r) = 1$ iff $R(x; r) \in \Pi'_{\mathrm{YES}}$. Since $\Pi'_{\mathrm{YES}} \in \mathsf{NP}$, after hardwiring x, the predicate ϕ_x is computable by a polynomial-size nonadaptive SAT-oracle circuit: compute $R(x; r)$, reduce membership in Π'_{YES} to SAT, and ask one oracle query.

On YES inputs, completeness gives $\Pr_r[\phi_x(r) = 1] \geq 2/3$. By Theorem 23, the corresponding hitting set contains a tape r with $\phi_x(r) = 1$, once the combined input-and-randomness length is large enough. For the finitely many smaller lengths, enumerate all random tapes. The deterministic reduction runs R on all tapes in the chosen list and combines the resulting instances by the polynomial-time OR function. Completeness follows because one output is YES. Soundness follows because, on NO inputs, one-sidedness ensures that every tape produces a NO instance. Composing with the deterministic hardness reduction to Π proves the theorem. ◀

▶ **Theorem 35.** *Assume that there exists an $\varepsilon > 0$ such that*

$$\mathsf{E} \not\subseteq i.o.\text{-NSIZE}(2^{\varepsilon n}).$$

Let Π and Π' be parameterized promise problems. Suppose that
1. *Π is $\mathsf{W}[1]$-hard under deterministic FPT many-one reductions;*
2. *Π' has an FPT OR function;*
3. *there exists a randomized FPT many-one reduction with one-sided error $R : \Pi \to \Pi'$;*
4. *R has SAT-circuitizable success predicates.*

Then Π' is $\mathsf{W}[1]$-hard under deterministic FPT many-one reductions.

Proof. Let R be the randomized reduction with one-sided error and let C be an FPT OR function for Π'. By the SAT-circuitizability assumption, there is a polynomial P such that every success predicate

$$\phi_{x,k}(r) = 1 \iff R((x, k); r) \in \Pi'_{\mathrm{YES}}$$

is in $\mathrm{SIZE}^{\mathsf{SAT}}_{\|}(P(m))$, where $m = |\langle x, k\rangle| + \mu$ and μ is the number of random bits used by R. Choose a constant c with $P(m) \leq m^c$ for all sufficiently large m, and take the hitting sets $H_m := \{G_m(\sigma) : \sigma \in \{0,1\}^{a \log m}\}$ from Theorem 23. Increase the threshold m_0 if necessary so that the theorem applies for all $m \geq m_0$.

The deterministic reduction is as follows. On input (x, k), compute $m = |\langle x, k\rangle| + \mu$. If $m < m_0$, list all 2^μ random tapes; this is only a constant-size list because m_0 is fixed. If $m \geq m_0$, enumerate H_m. Run R on (x, k) using each listed tape, and apply the FPT OR function C to all resulting outputs.

The running time is FPT: the hitting set has size $m^{O(1)}$, each call to R takes $T(k)|x|^{O(1)}$ time, and the OR function is called on a tuple whose maximum parameter is bounded by the parameter bound of R. Hence the output parameter is bounded by a computable function of k.

If $(x, k) \in \Pi_{\mathrm{YES}}$, then $\Pr_r[\phi_{x,k}(r) = 1] \geq 2/3$. In the small case, the list contains a successful tape; in the large case, the hitting set hits the accepting set of $\phi_{x,k}$. Thus at least one input to C is a YES instance, and the output is YES. If $(x, k) \in \Pi_{\mathrm{NO}}$, then soundness of R says that every tape gives a NO instance of Π', and the OR function outputs NO. Therefore we have a deterministic FPT many-one reduction from Π to Π', and the claimed hardness follows from item (1). ◀

5 Conditional Hardness of MDP and SVP

We now construct the OR functions needed in Theorems 34 and 35 and apply the derandomization theorem to MDP and SVP.

5.1 OR functions

▶ **Lemma 36.** *Let $q \geq 2$ be a prime power, and let $\gamma \geq 1$ be a constant. Then γ-GapMDP$_q$, parameterized by the distance threshold, has an FPT OR function.*

Proof. Given a tuple of strings, discard all syntactically invalid strings and keep the valid instances $(\mathbf{G}_i, k_i)$. If none remain, output any fixed NO instance. Let $\kappa = \max_i k_i$, $K = \mathrm{lcm}(1, \ldots, \kappa)$, and $c_i = K/k_i$. Let $\widetilde{\mathbf{G}}_i$ be obtained from $\mathbf{G}_i$ by repeating each row c_i times, and output the block-diagonal generator matrix

$$\mathbf{G}_{\mathrm{out}} = \mathrm{diag}(\widetilde{\mathbf{G}}_1, \ldots, \widetilde{\mathbf{G}}_s) \quad \text{with threshold } K.$$

Repeating rows multiplies the minimum distance by c_i, and the minimum distance of a block-diagonal code is the minimum of the block minimum distances. Hence

$$\lambda(\mathcal{C}(\mathbf{G}_{\mathrm{out}})) = \min_i c_i \lambda(\mathcal{C}(\mathbf{G}_i)).$$

Thus a YES input block gives distance at most K, while if all retained inputs are NO then every block has distance larger than γK. The output threshold K depends only on κ, and the construction runs in time $T(\kappa)N^{O(1)}$. This is an FPT OR function. ◀

▶ **Lemma 37.** *Let $p \in [1, \infty)$ and let $\gamma \geq 1$ be a constant. Then γ-GapSVP$_p$ has a polynomial-time OR function.*

Proof. Keep the valid instances $(\mathbf{B}_i, d_i)$ with $d_i \geq 1$, and output a fixed NO instance if none remain. Set $D = \prod_i d_i$, $c_i = D/d_i$, and $\widetilde{\mathbf{B}}_i = c_i \mathbf{B}_i$. Output

$$\mathbf{B}_{\mathrm{out}} = \mathrm{diag}(\widetilde{\mathbf{B}}_1, \ldots, \widetilde{\mathbf{B}}_s) \quad \text{with threshold } D.$$

Scaling a basis by c_i scales $\lambda_1^{(p)}$ by c_i, and a block-diagonal lattice has shortest-vector length equal to the minimum over blocks. Therefore

$$\lambda_1^{(p)}(\mathcal{L}(\mathbf{B}_{\mathrm{out}})) = \min_i c_i \lambda_1^{(p)}(\mathcal{L}(\mathbf{B}_i)).$$

The OR guarantee follows exactly as above. The bit length of D is at most the sum of the bit lengths of the input thresholds, so the construction is polynomial time. ◀

▶ **Lemma 38.** *Let $p \in [1, \infty)$ and let $\gamma \geq 1$ be a constant. Then γ-GapSVP$_p$, parameterized by the threshold, has an FPT OR function.*

Proof. Use the same block-diagonal construction as in Lemma 37, but replace $D = \prod_i d_i$ by $D = \mathrm{lcm}(1, \ldots, \kappa)$, where $\kappa = \max_i d_i$. Then D depends only on the largest input parameter, and the same distance calculation proves the OR guarantee. The construction runs in time $T(\kappa)N^{O(1)}$, and the output parameter is D. ◀

5.2 Applications

We will use the following lemma to verify item (4) in Theorem 35.

▶ **Lemma 39.** *Let R be a randomized* FPT *many-one reduction from Π to Π'. Suppose that, after padding the random tape with ignored bits, its length μ on input (x, k) is at least the running-time bound of R on that input, and set $m = |\langle x, k\rangle| + \mu$. If $\Pi'_{\mathrm{YES}} \in$ NP, then R has SAT-circuitizable success predicates.*

Proof. For fixed (x, k), view the success predicate as a function of $r \in \{0,1\}^m$, where only the first μ bits are used as the random tape. Since the running time, and hence the output length, is at most $\mu \leq m$, compute $R((x, k); r)$ by a polynomial-size circuit. Then compose with a polynomial-time reduction from Π'_{YES} to SAT, and finally make one SAT-oracle query. ◀

Therefore, the desired claims follow.

Proof of Theorem 4. Fix q and γ. We apply Theorem 35 to the randomized reduction with one-sided error underlying Theorem 1; equivalently, the source is the W[1]-hard problem $4q$-GapNCP$_q$ from Theorem 13, followed by the constant number of tensorings needed to reach the target approximation factor. The target γ-GapMDP$_q$ has an FPT OR function by Lemma 36.

The YES language of γ-GapMDP$_q$ is in NP. The concrete reduction can be padded with ignored random bits so that the random tape length is at least its FPT running-time bound. Hence Lemma 39 gives SAT-circuitizable success predicates. All hypotheses of Theorem 35 hold, so γ-GapMDP$_q$ is W[1]-hard under deterministic FPT many-one reductions. ◀

Proof of Theorem 6. Fix $\gamma \geq 1$. By Theorem 15, there is a randomized polynomial-time reduction with one-sided error from an NP-hard language to γ-GapSVP$_2$. The YES language of γ-GapSVP$_2$ is in NP. By Lemma 37, γ-GapSVP$_2$ has a polynomial-time OR function. Therefore Theorem 34 applies and yields deterministic polynomial-time NP-hardness. ◀

Proof of Theorem 5. Fix an integer $p \geq 1$ and $\gamma < 2^{1/p}$. Choose a rational η with $\gamma < \eta < 2^{1/p}$. It is enough to prove deterministic W[1]-hardness of η-GapSVP$_p$, since the identity map reduces η-GapSVP$_p$ to γ-GapSVP$_p$ on promised instances.

By Theorem 2, η-GapSVP$_p$ is W[1]-hard under randomized FPT many-one reductions with one-sided error; specifically, the source is the W[1]-hard Γ-GapCVP$_p$ from Theorem 17, where Γ is the source approximation factor in Theorem 33. The target has an FPT OR function by Lemma 38.

Since p is fixed, the YES language of η-GapSVP$_p$ is in NP. The reduction in Theorem 33 can be padded with ignored random bits so that the random tape length is at least its FPT running-time bound. By Lemma 39, it has SAT-circuitizable success predicates. Applying Theorem 35 gives deterministic FPT hardness of η-GapSVP$_p$, and hence of γ-GapSVP$_p$. ◀

Abstract

It is well known that the spectral gap of the down-up walk over an n-partite simplicial complex (also known as Glauber dynamics) cannot be better than $O(1/n)$ due to natural obstructions such as coboundaries. We study an alternative random walk over partite simplicial complexes known as the sequential sweep or the systematic scan Glauber dynamics: Whereas the down-up walk at each step selects a random coordinate and updates it based on the remaining coordinates, the sequential sweep goes through each of the coordinates one by one in a deterministic order and applies the same update operation. It is natural, thus, to compare n-steps of the down-up walk with a single step of the sequential sweep. Interestingly, while the spectral gap of the n-th power of the down-up walk is still bounded from above by a constant, under a strong enough local spectral assumption (in the sense of Gur, Lifschitz, Liu, STOC 2022) we can show that the spectral gap of this walk can be arbitrarily close to 1. We also study other isoperimetric inequalities for these walks, and show that under the assumptions of local entropy contraction (related to the considerations of Gur, Lifschitz, Liu), these walks satisfy an entropy contraction inequality. Concretely, we generalize a result of Lubetzky, Lubotzky, and Parzanchevski (Journal of the EMS) about the rapid mixing of sequential sweep in Ramanujan complexes to suitable high dimensional expanders.

1 Introduction

Let Ω be a finite set of n-tuples, i.e. $\Omega \subset U_1 \times U_2 \times \cdots \times U_n$, where each U_i is a finite set. Given a tuple $\omega \in \Omega$, for each $i \in [n]$, the i-th update operation $\mathsf{update}_i(\omega)$ returns a uniformly random tuple from Ω that is conditioned to agree with ω everywhere except for the i-th coordinate, i.e.

$$\Pr_{\omega' \sim \Omega}[\mathsf{update}_i(\omega) = \omega'] = \Pr_{\omega' \sim \Omega}\left[\omega' \,\middle|\, \omega_j = \omega'_j \ \text{ for all } \ j \in [n] \setminus i\right].$$

The main object of study in this paper will be the random walk called sequential sweep $\mathsf{P}_{\mathtt{seq}}$ on the collection Ω, otherwise known as the systematic scan Glauber dynamics[1] on Ω: A single step of this dynamics moves between tuples by applying the n update operations in sequential fashion, i.e. writing $\omega^{(t)}$ for the tuple visited by this dynamics at step t, $\omega^{(t+1)}$ is the result of the following random update operations,

$$\omega^{(t+1)} = (\mathsf{update}_n \circ \mathsf{update}_{n-1} \circ \cdots \circ \mathsf{update}_1)(\omega^{(t)}) = \mathsf{update}_n(\mathsf{update}_{n-1}(\cdots(\mathsf{update}_1(\omega^{(t)})))).$$

It is easy to see that the stationary distribution for this random walk is the uniform distribution on Ω.

It is instructive to compare $\mathsf{P}_{\mathtt{seq}}$ with the the down-up walk $\mathsf{P}_{\mathtt{gd}}$ on Ω also known as the Glauber dynamics, which moves between tuples by first sampling a random coordinate $i \in [n]$ and then applying the operation $\mathsf{update}_i(\bullet)$. In other words, $\mathsf{P}_{\mathtt{seq}}$ can be thought as simulating n successive steps of $\mathsf{P}_{\mathtt{gd}}$ in which we condition the coordinate that is updated at the i-th step to be i for all $i \in [n]$.

1.1 HDX, Spectral Independence, and ε-products

We recall the notion of local-spectral expansion in (partite) simplicial complexes introduced in [40, 23, 42, 51, 22, 4]. A (finite) simplicial complex of rank n is a collection of subsets of size at most n of a finite set U, i.e. $X \subset \binom{U}{\leq n}$, which is closed under containment. X is called partite, if we can partition U into n disjoint subsets $U_1, \ldots, U_n$ such that any set from X of size n contains a unique element from each U_i – the sets U_i are called the sides of the simplicial complex. In particular, each $\omega \in X$ with $|\omega| = n$ can be treated as a tuple $(\omega_1, \ldots, \omega_n)$ where $\omega_i \in U_i$. We will write $X^{(i)} = \{\omega \in X : |\omega| = i\}$. We will also write $\omega_S = (\omega_s)_{s \in S}$ for all $\omega \in X^{(n)}$.

The local structures in X, are described by its links. For a face $\alpha \in X$, we describe the weighted graph $G^{(\alpha)} = (V_\alpha, E_\alpha, w_\alpha)$ as follows. We have,

$$V_\alpha = \{u \in U : \alpha \cup u \in X\} \text{ and } E_\alpha = \left\{uv \in \binom{U}{2} : \alpha \cup \{u,v\} \in X\right\}.$$

Every edge uv is assigned a weight based on the number of subsets in X of size n that contain $\alpha \cup \{u, v\}$, i.e.

$$w_\alpha(uv) = |\{\omega \in X : |\omega| = n, \omega \supset \alpha \cup \{u,v\}\}|.$$

Writing $G^{(\alpha)}$ for the random walk matrix of $G^{(\alpha)}$ also, we observe that $\lambda_2(G^{(\alpha)})$ measures an amortized notion of the correlation between the vertices in V_α. Formally, we say that the simplicial complex X is a $\vec{\gamma} = (\gamma_0, \ldots, \gamma_{n-2})$-local spectral expander if for each $\alpha \in X$ with $|\alpha| \leq n-2$, we have $\lambda_2(G^{(\alpha)}) \leq \gamma_{|\alpha|}$. When $n = 2$, this notion is equivalent to the usual notion of a spectral expander, [37, 44].

For our purposes an alternative but related notion of high-dimensional expansion introduced in [34, 21] will be more useful to consider. Whereas, we have said that $\lambda_2(G^{(\alpha)})$ measures an amortized notion of the correlation between vertices in V_α, we will be more interested in measuring a worst case notion of the correlation between the vertices in V_α which come from pre-specified parts U_i and U_j. Formally, we are interested in the second eigenvalue of the following bipartite graph $G_{i,j}^{(\alpha)} = (V_{ij}^{(\alpha)}, E_{ij}^{(\alpha)}, w_{ij}^{(\alpha)})$ for each $\alpha \in X$ such

[1] More precisely, n steps of the systematic scan dynamics is the walk we call sequential sweep here.

that $|\alpha \cap U_i| = |\alpha \cap U_j| = 0$. In words, α can be thought as an assignment to a subset of coordinates $S \subset [n]$, such that $\{i,j\} \notin S$. Here,

$$V_{ij}^{(\alpha)} = \{u \in U_i \cup U_j : \alpha \cup u \in X\} \quad \text{and} \quad E_{ij}^{(\alpha)} = \{uv : u \in U_i, v \in U_j, \alpha \cup \{u,v\} \in X\}.$$

Similarly, we assign each edge uv a weight between the number of subsets in X of size n containing $\alpha \cup \{u,v\}$, i.e.

$$w_{ij}^{(\alpha)}(uv) = \left|\left\{\omega \in X^{(n)} : |\omega| = n, \omega_S = \alpha, \omega_i = u, \omega_j = v\right\}\right|,$$

where we have assumed that α to be a tuple with coordinates in $S \subset [n]$, $u \in U_i$, and $v \in V_j$. We will call the simplicial complex $\underline{\vec{\varepsilon} = (\varepsilon_0, \ldots, \varepsilon_{n-2})\text{-product}}$ if for all α and i,j we have $\lambda_2(G_{i,j}^{(\alpha)}) \le \varepsilon_{|\alpha|}$. We observe, that the quantity $\lambda_2(G_{i,j}^{(\alpha)}) \le \varepsilon_{|\alpha|}$ quantifies the correlation between the i-th and j-th coordinate on an n-tuple drawn from X conditioned on agreeing with α. We say X is completely ε-product if it is $\vec{\varepsilon} = (\varepsilon_i)_{i=0}^{n-2}$-product where $\varepsilon_i \le \varepsilon$ for all $i = 0, \ldots, n-2$.

In [34] this definition was used in proving hypercontractive estimates for the noise operator over simplicial complexes and in [21], it was used in the context of agreement testing. We recall, that every strong enough local partite expander is also $\vec{\varepsilon}$-product [21, Corollary 7.6]:

▶ **Theorem 1.** *Let X be an n-partite simplicial complex. If X is a $\vec{\gamma}$-local spectral expander with $\gamma_{n-2} \le \frac{\varepsilon}{(n-2)\varepsilon+1}$, then X is also completely ε-product.*

And also, recall the following rudimentary remark

▶ Remark 2. [2] Let X be an n-partite simplicial complex. If X is a $\vec{\gamma}$-local spectral expander with $\gamma_i \le \frac{\varepsilon_i}{n-i-1}$, then X is also $(\varepsilon_0, \ldots, \varepsilon_{n-2})$-product.

More generally, we will consider the following bipartite graphs $G_{I,J}^{(\alpha)} = (V_{I,J}^{(\alpha)}, E_{I,J}^{(\alpha)}, w_{I,J}^{(\alpha)})$ given $\alpha \in X$, and disjoint sets I and J such that $|\alpha \cap U_k| = 0$ for all $k \in I \cup J$. Similarly, we are thinking of α as a partial assignment to a subset of the coordinates of an n-tuple which do not assign anything to the coordinates in I or J. Here,

$$V_{I,J} = \left\{\omega_I \in \prod_{i \in I} U_i : \alpha \cup \omega_I \in X\right\} \cup \left\{\omega_J \in \prod_{j \in J} U_j : \alpha \cup \omega_J \in X\right\},$$

and

$$E_{I,J} = \left\{\omega_I \omega_J : \omega_I \in \prod_{i \in I}, \omega_J \in \prod_{j \in I}, \alpha \cup \omega_I \cup \omega_J \in X\right\},$$

and assign a weight on each edge $\omega_I \omega_J \in E_{I,J}$ based on the number of subsets in X of size n that contain $\alpha \cup \{u,v\}$, i.e.

$$w_{I,J}^{(\alpha)}(\omega_I \omega_J) = \left|\left\{\bar{\omega} \in X^{(n)} : \bar{\omega}_S = \alpha, \bar{\omega}_I = \omega_I, \bar{\omega}_S = \omega_S\right\}\right|.$$

where we have assumed α to be a partial assignment to the coordinates in S. Similarly to before, $\lambda_2(G_{I,J}^{(\alpha)})$ is a measure of correlation between the coordinates on I and the coordinates in J.

In [21, 34], the following bound is shown,

▶ **Theorem 3.** *If X is an n-partite simplicial complex with parts $U_1, \ldots, U_n$ which is $\vec{\varepsilon}$-product (where $\varepsilon_i \le \varepsilon$ for all $i = 0, \ldots, n-2$), then for all α satisfying $|\alpha \cap U_k| = 0$ for $k \in I \cup J$, we have $\lambda_2(G_{I,J}^{(\alpha)})^2 \le |I||J| \cdot \varepsilon^2$.*

[2] We will prove this observation formally.

1.2 Results and Techniques

Let X be an n-partite simplicial complex. We write,

$$\varepsilon^{I\to J} := \varepsilon_X^{I\to J} = \max\Big\{\lambda_2(G_{I,J}^{(\alpha)}) : \alpha \text{ is an assignment to the coordinates in } [n]\setminus(I\cup J)\Big\}.$$

In particular, $\varepsilon^{I\to J}$ quantifies the maximum correlation between the coordinates in I and J from an n-tuple drawn from X given any assignment α to the coordinates in $(I\cup J)^c$.

We have,

▶ **Theorem 4** (Informal Version of Theorem 25). *Let X be an n-partite simplicial complex. We have,*

$$\sigma_2(\mathsf{P}_{\mathsf{seq}})^2 \le 1 - \prod_{j=2}^{n}(1-(\varepsilon^{[j-1]\to j})^2),$$

where $\sigma_2(\bullet)$ denotes the second largest singular value of $\bullet$.

In particular, writing $\mathsf{gap}(\bullet) = 1-\sigma_2(\bullet)$, we have

$$\mathsf{gap}(\mathsf{P}_{\mathsf{seq}}) \ge 1 - \sqrt{1-\prod_{j=2}^{n}(1-(\varepsilon^{[j-1]\to j})^2)}.$$

We also give an improved version of Theorem 3,

▶ **Theorem 5** (Simplified Version of Theorem 30). *Let (X,π) be an n-partite simplicial complex where π is $\vec{\varepsilon}$-product. For any assignment α to $S\subset[n]$ such that $S\cap[j]=\varnothing$, we have,*

$$\sigma_2(G^{(\alpha)}_{\{j\},[j-1]})^2 \le 1 - \prod_{q=0}^{j-2}(1-\varepsilon^2_{|\alpha|+q})$$

In particular, we have

$$(\varepsilon^{j\to[j-1]})^2 \le 1 - \prod_{q=0}^{j-1}(1-\varepsilon^2_{n-j+q})$$

In the full version of our paper, we study the expansion parameters $\varepsilon^{j\to[j-1]}$ in Ramanujan complexes of thickness p. We summarize our results for these complexes below in the following theorem.[3]

▶ **Theorem 6.** *Let X be a Ramanujan complex of thickness p and dimension $(d-1)$. We have,*

$$\Big(\varepsilon^{[0,j-1]\to j}\Big)^2 = \frac{1}{p+1}\big(1-\Theta\big(p^{-j}\big)\big) \quad \text{and} \quad \Big(\varepsilon^{[0,\ldots,d-2]\to d-1}\Big)^2 = \frac{1}{p+1}\cdot\big(1-\Theta\big(p^{-j}\big)\big) \tag{1}$$

for all $j=1,\ldots,d-2$. Consequently,

$$\sigma_2\big(\mathsf{P}_{\mathsf{seq}}\big)^2 \le \frac{d+1}{p} - O\left(\frac{d^2}{p^2}\right)$$

where N is the number of vertices in X.

[3] Recall that a Ramanujan complex of dimension $d-1$ is a d-partite simplicial complex where the colors are named from 0 to $d-1$.

We note that the expansion parameters in Equation (1) are computed exactly and they do not suffer the co-dimension dependent blowups from Theorem 5, which would replace the RHS of the expansion parameters in Equation (1) with *roughly* $(j-1)/p$ and $(d-1)/(p+1)$, compare with Theorem 3. While our techniques fall short of recovering the optimal mixing results of [46], we hope our techniques will find further applications in the study of *spectral* expansion of Ramanujan complexes. We note that our spectral bound does not follow from the spectral techniques of [46] as this work concerns itself with spectral radii of non-backtracking operators, which in our context do not neatly translate into a bound on the singular values.

We note that Theorem 4 is proven using geometric considerations. For each $I \subset [n]$, we define the subspace $\mathcal{U}_I \subset \mathbb{R}^{X^{(n)}}$ as

$$\mathcal{U}_I = \operatorname{span}\Big\{ \boldsymbol{f} \in \mathbb{R}^{X^{(n)}} : \boldsymbol{f}(\omega) = \boldsymbol{f}(\bar{\omega}) \ \text{ for all } \ \omega, \bar{\omega} \in X^{(n)} \text{ such that } \omega_{[n]\setminus I} = \bar{\omega}_{[n]\setminus I} \Big\}$$

and we will write $\mathsf{Q}_I = \mathrm{Proj}(\mathcal{U}_I)$ for the orthogonal projection to $\mathcal{U}_I$. It is well known that $\mathsf{P}_{\mathtt{seq}} = \mathsf{Q}_{\{1\}} \cdots \mathsf{Q}_{\{n\}}$, e.g. see [6]. We recall that the cosine between two subspaces $\mathcal{U}, \mathcal{V} \in \mathbb{R}^{X^{(n)}}$ is defined as,

$$\cos(\mathcal{U}, \mathcal{V}) = \max\big\{ \langle \boldsymbol{u}, \boldsymbol{v} \rangle_\pi : \boldsymbol{u} \in \mathcal{U} \cap (\mathcal{U} \cap \mathcal{V})^\perp, \boldsymbol{v} \in (\mathcal{U} \cap \mathcal{V})^\perp, \|\boldsymbol{u}\|_\pi = \|\boldsymbol{v}\|_\pi = 1 \big\},$$

Similarly, $\sin^2(\mathcal{U}, \mathcal{V}) = 1 - \cos^2(\mathcal{U}, \mathcal{V})$. Now, we can follow in the footsteps of [6], who has proven estimates on the spectral gap of the sequential sweep in the Gaussian setting, by appealing to the following theorem:

▶ **Theorem 7** ([59]). *Let $\mathsf{Q}_1, \ldots, \mathsf{Q}_p \in \mathbb{R}^{\Omega \times \Omega}$ be projection operators to sub-spaces $\mathcal{U}_1, \ldots, \mathcal{U}_p$. Set $\mathcal{V}_j = \bigcap_{i=1}^{j} \mathcal{U}_i$. Writing $\mathsf{Q}_\star$ for the projection to $\mathcal{V}_p$, we have*

$$\|\mathsf{Q}_1 \cdots \mathsf{Q}_p \boldsymbol{f} - \mathsf{Q}_\star \boldsymbol{f}\|^2 \le \left(1 - \prod_{j=2}^{p} \sin^2(\mathcal{U}_j, \mathcal{V}_{j-1}) \right) \cdot \|\boldsymbol{f} - \mathsf{Q}_\star \boldsymbol{f}\|^2.$$

Now, Theorem 4 follows from the following geometric interpretation of $\varepsilon^{I \to J}$:

▶ **Theorem 8** (Informal Version of Theorem 29 and Proposition 27). *Let X be an n-partite simplicial complex $I, J \subset [n]$ such that $I \cap J = \varnothing$. Under suitable assumptions,*

$$\cos(\mathcal{U}_I, \mathcal{U}_J) \le \varepsilon^{I \to J} \quad \text{and} \quad \bigcap_{i \in I} \mathcal{U}_i = \mathcal{U}_I.$$

We also show an analog of Theorem 4 for contraction in relative entropy: We recall that the KL-divergence between the distributions μ and π is defined as $\mathcal{D}(\mu \parallel \pi) = \mathbb{E}_{x \sim \pi} \left[\frac{\mu(x)}{\pi(x)} \log \frac{\mu(x)}{\pi(x)} \right]$. The entropy contraction factor $\mathsf{ec}(\mathsf{P})$ of the random walk operator $\mathsf{P} \in \mathbb{R}^{V \times V}$ with stationary measure π is defined as,

$$\mathsf{ec}(\mathsf{P}) = 1 - \kappa(\mathsf{P}) \ \text{ where } \ \kappa(\mathsf{P}) = \sup\left\{ \frac{\mathcal{D}(\mu \mathsf{P} \parallel \pi)}{\mathcal{D}(\mu \parallel \pi)} : \mu \text{ is a probability distribution on } V \right\}.$$

We define the following entropy contraction parameters,

$$\eta^{I \to J} = 1 - \kappa^{I \to J} \ \text{ where } \ \kappa^{I \to J} = \sup\left\{ \frac{\mathcal{D}(\mu \cdot G^{(\alpha)}_{I,J} \parallel \pi^{(\alpha)}_J)}{\mathcal{D}(\mu \parallel \pi^{(\alpha)}_I)} : \alpha \in X[(I \cup J)^c] \text{ and } \mu \in \triangle_{X_\alpha[I]} \right\}$$

where we have overloaded the notation $G^{(\alpha)}_{I,J}$ to mean the random walk from the part of $V^{(\alpha)}_{I,J}$ that describes the transition from assignments of I to assignments of J, and $\pi^{(\alpha)}_I$ and $\pi^{(\alpha)}_J$ are uniform distributions the assignments of I and assignments of J respectively.

In the full version of our paper, we prove

▶ **Theorem 9.** *Let X be an n-partite simplicial complex. Then,*

$$\mathsf{ec}(\mathsf{P}_{\mathsf{seq}}) \geq \prod_{j=1}^{n-1} \eta^{[j+1,n]\to j}. \tag{2}$$

In particular, writing π for the uniform distribution on $X^{(n)}$ we have

$$\mathcal{D}(\mu \mathsf{P}_{\mathsf{seq}} \parallel \pi) \leq (1 - \mathsf{ec}(\mathsf{P}_{\mathsf{seq}})) \cdot \mathcal{D}(\mu \parallel \pi).$$

The proof of Theorem 9 follows from an inductive argument. Our key observation is that conditional on the 1-st coordinate equalling any given value x, the distribution of $\mu\mathsf{P}_{\mathsf{seq}}$ on the remaining coordinates in $[2,\ldots,n]$ can be thought as the distribution resulting from a sequential sweep in a smaller complex X_x with faces $(\omega_2,\ldots,\omega_n)$ such that $(x,\omega_2,\ldots,\omega_n)$ is a facet of X. The proof is then completed using the well-known Garland method [30] and the chain-rule for KL divergences. There is one interesting *twist*: usually the Garland method considers the localizations of functions, which need not be normalized. Applying the Garland method to distributions, requires understanding how the *localized/pinned* distributions interplay with the graphs $G^{(\alpha)}_{I,J}$. To the best of our knowledge, this is where our proofs differ from existing *local-to-global* arguments of [4, 17, 33, 5]. We hope our proof techniques will find more applications in the future.

We note that both $\mathsf{ec}(\mathsf{P}_{\mathsf{seq}})$ and $\mathsf{gap}(\mathsf{P}_{\mathsf{seq}})$ are useful tools for bounding the mixing time $T(\mathsf{P}_{\mathsf{seq}})$ of the random walk $\mathsf{P}_{\mathsf{seq}}$, i.e. the number of steps one needs to take to come within small, say 0.01, distance of the uniform distribution. We have,

$$T(\mathsf{P}_{\mathsf{seq}}) \lesssim \left\lceil \frac{\log\big(|X^{(n)}|\big)}{\log\big(1/\sigma_2(\mathsf{P}_{\mathsf{seq}})\big)} \right\rceil \lesssim \left\lceil \frac{\log(|X^{(n)}|)}{\mathsf{gap}(\mathsf{P}_{\mathsf{seq}})} \right\rceil,$$

$$T(\mathsf{P}_{\mathsf{seq}}) \lesssim \left\lceil \frac{\log\log(|X^{(n)}|)}{\log(1/(1-\mathsf{ec}(\mathsf{P}_{\mathsf{seq}})))} \right\rceil \lesssim \left\lceil \frac{\log\log\big(|X^{(n)}|\big)}{\mathsf{ec}(\mathsf{P}_{\mathsf{seq}})} \right\rceil$$

When $\mathsf{gap}(\mathsf{P}_{\mathsf{seq}})$ and $\mathsf{ec}(\mathsf{P}_{\mathsf{seq}})$ tend to 1, the first bound in each inequality is significantly sharper than the second. However, as they get closer and closer to 0, the latter inequalities are essentially lossless. In particular, when $\mathsf{gap}(\mathsf{P}_{\mathsf{seq}})$ and $\mathsf{ec}(\mathsf{P}_{\mathsf{seq}})$ are of the same order, the bounds one obtains through $\mathsf{ec}(\mathsf{P}_{\mathsf{seq}})$ are typically much sharper, though typically this constant is much more troublesome to bound.

▶ Remark 10. We note that our proof technique for Theorem 9 is general enough to prove contraction estimates for $\mathsf{P}_{\mathsf{seq}}$ with respect to general Φ-divergences, $\mathcal{D}_\Phi(\mu \parallel \pi) = \mathbb{E}_{\omega\sim\pi}\left[\Phi\left(\frac{\mu(\omega)}{\pi(\omega)}\right)\right]$ for convex Φ, assuming that $G^{(\alpha)}_{[j+1,n],\{j\}}$ contract Φ-divergences. In particular, we could give an alternative proof for Theorem 4 by setting $\Phi(t) = (t-1)^2$ and adapting the proof of Theorem 9.[4] We will refrain from taking this route and carrying this out explicitly, as we believe that proving Theorem 4 through Theorem 7 better highlights the geometric nature of this result. We refer to [16, 14, 56] for more information on Φ-divergences and the closely related Φ-entropies, and inequalities for Φ-divergence contraction called *generalized* data-processing inequalities.

[4] This would correspond to the so-called χ^2-divergence. The bound by which a random walk contracts the χ^2 divergence is well understood to correspond to the (square of the) second singular value.

1.3 Related Work

A similar proof strategy in proving a spectral gap bound for the sequential sweep in the Gaussian setting was employed by [6] – there he shows that the cosine of the angle between subspaces can be bounded in terms of the covariance matrix of the underlying Gaussian distribution, which is where our analysis diverges from his. We rely on the Garland method [30] to bound these values, which has been a staple in high-dimensional expansion literature, e.g. [51, 52, 42, 22, 4, 53, 54]. In particular, there is a non-trivial overlap between our techniques and the ones employed in [49, 50, 53, 54, 31]. Similar considerations about angles between subspaces have also been investigated in the context of Kazhdan constants and the property (T), e.g. [43, 27, 39].

Our work is close in spirit to [46] which study a non-stuttering version of the sequential sweep $\mathsf{P}_{\mathtt{seq}}$ in Ramanujan complexes, called the geodesic flow. The main result of [46] is that for these geodesic flows on Ramanujan complexes, the total-variation mixing time is as small as possible up to an additive logarithmic constant. Namely, a k-regular flow on n states achieves ϵ-mixing after only $\log_k(n) + O(\log\log(n))$ steps. In fact, this result holds for a larger class of walks on so-called *Ramanujan digraphs* [55]. While we cannot recover this result, our results hold in much greater generality without assumption of Ramanujanness, and also show that in suitable high-dimensional expanders the sequential sweep improves upon down-up walks.

As already mentioned a significant amount of work has been done in investigating the mixing properties of the down-up walk $\mathsf{P}_{\mathtt{gd}}$ from considerations of high-dimensional expansion. See for example, [40, 23, 42, 22, 4] for works investigating local-spectral expansion (and variants) to get a bound on $\mathtt{gap}(\mathsf{P}_{\mathtt{gd}})$. Most of the concrete applications of these results rely on the spectral independence framework of [9, 28, 17] – we refer to the excellent lecture notes [60] and the references therein for more on this subject. Similarly, the works of [19, 33, 18, 7, 8] explore bounding $\mathtt{ec}(\mathsf{P}_{\mathtt{gd}})$ based on considerations of local entropy contraction. Our bound on $\mathtt{ec}(\mathsf{P}_{\mathtt{seq}})$ is proven using similar ideas. There has also been some work in connecting these concepts to classical Markov Chain techniques such as path coupling [1, 15], see e.g. [45, 12].

The random walks $G^{(\alpha)}_{I,J}$ that we have considered have also been studied in the works [21, 34], with applications in hypercontractivity and agreement testing. They are a natural generalization of swap-walks which have been studied in [3, 21]. Their study have found applications in approximation algorithms for constraint satisfaction problems [3], agreement testing [21], coding theory [2, 38], and hypercontractivity [10, 11, 34].

Although the sequential sweep $\mathsf{P}_{\mathtt{seq}}$ is a very natural random sampling algorithm considerably less is known about it and the results apply only in restricted and specialized settings, e.g. [20, 25, 35, 26]. These results show mixing by considering what is known as the Dobrushin matrix [24] whose entries give pessimistic estimates on the worst case dependencies between the coordinates. In [36, 57] the impact of the order of the vertices for $\mathsf{P}_{\mathtt{seq}}$ was studied and shown that the mixing time of the walk crucially depends on the order of the vertices. The relation between the relaxation time of $\mathsf{P}_{\mathtt{seq}}$ and $\mathsf{P}_{\mathtt{gd}}$ (with a given order) was also subject of investigation in [32]. We refer the readers to the papers mentioned here and the references therein for more on the topic of scan order and mixing time.

The sequence of updated coordinates in $\mathsf{P}_{\mathtt{seq}}$ can be thought as the set of vertices visited by a (deterministic) walk on the directed cyle $C_n = ([n], E)$ initiated from the vertex 1. It is now a natural idea to replace the directed circle with an arbitrary graph $G = ([n], E)$ and picking the updated vertices by means of a random walk on $[n]$. [5] shows that if G is a two-sided spectral expander, the mixing time of this new walk is comparable to the mixing time of $\mathsf{P}_{\mathtt{gd}}$ under mild assumptions. Their techniques fall short of establishing a mixing

time for the sequential sweep in blackbox fashion since the directed cycle has no two-sided expansion. However, we observe that their result essentially translates an $O(n \log n)$ mixing time for $\mathsf{P}_{\mathtt{gd}}$ into an $O(\frac{n \log n}{1-\lambda(G)})$ mixing time for this new-walk. Observing that this mixing time is roughly the cover time[5] of the graph G, suggesting that a tighter analysis could perhaps establish an $O(1)$-mixing time[6] for our sweep[7].

Finally, we mention the work [29], which proves worst case comparison theorems between the sequential sweep $\mathsf{P}_{\mathtt{seq}}$ and the Glauber dynamics $\mathsf{P}_{\mathtt{gd}}$, which shows that $\mathtt{gap}(\mathsf{P}_{\mathtt{seq}}) = \Omega(n^{-1}) \cdot \mathtt{gap}(\mathsf{P}_{\mathtt{gd}})$. They further give examples of complexes in which this bound is tight. We note that our focus in this work are complexes where $\mathtt{gap}(\mathsf{P}_{\mathtt{seq}})$ is significantly better than $\mathtt{gap}(\mathsf{P}_{\mathtt{gd}})$, thus our result can be thought as complementary to their result.

2 Preliminaries

2.1 Linear Algebra

Vectors and Inner Products

Given $\boldsymbol{f}, \boldsymbol{g} \in \mathbb{R}^V$, and a measure π on V such that $\pi(x) > 0$ for all $x \in V$, we use the notations $\langle \boldsymbol{f}, \boldsymbol{g} \rangle_\pi$ and $\|\boldsymbol{f}\|_\pi$ to denote the inner-product and the norm with respect to the distribution π, i.e.

$$\langle \boldsymbol{f}, \boldsymbol{g} \rangle_\pi = \mathop{\mathbb{E}}_{x \sim \pi} \boldsymbol{f}(x)\boldsymbol{g}(x) = \sum_{x \in V} \pi(x) \cdot \boldsymbol{f}(x)\boldsymbol{g}(x) \quad \text{and} \quad \|\boldsymbol{f}\|_\pi^2 = \langle \boldsymbol{f}, \boldsymbol{f} \rangle_\pi. \tag{3}$$

Matrices and Eigenvalues

In this section, we will recall some results concerning eigenvalues and eigenvectors of matrices.

We will call a matrix $\mathsf{B} \in \mathbb{R}^{U \times V}$ row-stochastic if all entries of B are non-negative and all rows of B sum up to 1, i.e.

$$\text{for all } u \in U, v \in V \quad \mathsf{B}(u, v) \geq 0 \quad \text{and} \quad \mathsf{B}\mathbf{1} = \mathbf{1}.$$

The adjoint of the operator $\mathsf{B} \in \mathbb{R}^{U \times V}$, with respect to the inner-products defined by the measures π_U and π_V on U and V, is the operator $\mathsf{B}^* \in \mathbb{R}^{V \times U}$ satisfying

$$\langle \boldsymbol{f}, \mathsf{B}\boldsymbol{g} \rangle_{\pi_U} = \langle \mathsf{B}^* \boldsymbol{f}, \boldsymbol{g} \rangle_{\pi_V} \quad \text{for all } \boldsymbol{f} \in \mathbb{R}^U, \boldsymbol{g} \in \mathbb{R}^V.$$

If $U = V$ and $\pi_U = \pi_V$, the operator B is called self-adjoint when $\mathsf{B}^* = \mathsf{B}$. If B is a row-stochastic matrix, we will call B^* the time-reversal of B with respect to π_U, π_V and say that B is reversible if $\mathsf{B} = \mathsf{B}^*$. It is well known that the operator $\mathsf{B}^* \in \mathbb{R}^{V \times U}$ is uniquely determined by the choice of $\mathsf{B} \in \mathbb{R}^{U \times V}$ and the inner-products defined by π_U and π_V (see e.g. [58, p. 318]),

▶ **Proposition 11.** *Let $\mathsf{B} \in \mathbb{R}^{U \times V}$ be arbitrary. We write B^* for the adjoint operator to B with respect to the inner-products defined by the distributions π_U and π_V. Then,*

$$\mathsf{B}^*(y, x) = \mathsf{B}(x, y) \cdot \frac{\pi_U(x)}{\pi_V(y)} \quad \textit{for all} \quad x \in U, y \in V.$$

[5] The number of steps following which the random is expected to have visited all the vertices after being initialized from an arbitrary vertex.
[6] i.e. $O(n)$ update steps
[7] where we observe that the cover time of the directed cycle is n, which would correspond to a single sweep

We also recall the following standard fact which is an immediate consequence of Proposition 11,

▶ **Proposition 12.** *If* $\mathsf{B} \in \mathbb{R}^{U,V}$ *is a row-stochastic matrix satisfying* $\pi_U \mathsf{B} = \pi_V$*, then the adjoint matrix* B^* *with respect to* π_U, π_V *is also row-stochastic and satisfies* $\pi_V \mathsf{B}^* = \pi_U$*.*

Throughout this paper, we will often deal with operators which are not self-adjoint, and therefore we will need to deal with singular values. Given an operator $\mathsf{B} \in \mathbb{R}^{V \times U}$ we will write $\sigma_i(\mathsf{B})$ for the i-th largest singular value of B, i.e. we have $\sigma_i(\mathsf{B}) = \sqrt{\lambda_i(\mathsf{B}^*\mathsf{B})}$.[8] This expression is well-defined since $\mathsf{B}^*\mathsf{B}$ is positive-semi definite and therefore $\lambda_i(\mathsf{B}^*\mathsf{B}) \geq 0$. We recall the following facts,

▶ **Proposition 13.** *Let* $\mathsf{B} \in \mathbb{R}^{U \times V}$ *be a row-stochastic matrix satisfying* $\pi_U \mathsf{B} = \pi_V$*. Then,*

1. $\sigma_1(\mathsf{B}) = 1$,
2. $\sigma_2(\mathsf{B}) =$
   $\max\left\{\langle \boldsymbol{f}, \mathsf{B}\boldsymbol{g}\rangle_{\pi_U} : \boldsymbol{f} \in \mathbb{R}^U, \boldsymbol{g} \in \mathbb{R}^V, \|\boldsymbol{f}\|_{\pi_U} = \|\boldsymbol{g}\|_{\pi_V} = 1, \langle \boldsymbol{f}, \mathbf{1}_U\rangle_{\pi_U} = \langle \boldsymbol{g}, \mathbf{1}_V\rangle_{\pi_V} = 0\right\}$.
3. $\sigma_2(\mathsf{B}) = \max\left\{\frac{\|(\mathsf{B}-\mathbf{1}_U\pi_V)\boldsymbol{f}\|_{\pi_U}}{\|\boldsymbol{f}-\mathbf{1}_V\pi_V\boldsymbol{f}\|_{\pi_V}} : \boldsymbol{f} \in \mathbb{R}^V, \|\boldsymbol{f} - \mathbf{1}_V\pi_V\boldsymbol{f}\|_{\pi_V} \neq 0\right\}$

A matrix $\mathsf{Q} \in \mathbb{R}^{V \times V}$ is called an orthogonal projection with respect to π if it is self adjoint with respect to π, i.e. $\mathsf{Q} = \mathsf{Q}^*$ and it satisfies the equation $\mathsf{Q}^2 = \mathsf{Q}$. We will say that Q is the orthogonal projection operator to a subspace $\mathcal{U} \subset \mathbb{R}^V$ if the image $\mathrm{im}(\mathsf{Q}) = \mathsf{Q}\mathbb{R}^V$ equals $\mathcal{U}$.

Finally, we will recall some results concerning the angles between subspaces and products of projection matrices. Let $\mathcal{U}, \mathcal{V} \subset \mathbb{R}^\Omega$ equipped with the inner-product π. The cosine of the angle between $\mathcal{U}$ and $\mathcal{V}$ is defined to be,

$$\cos(\mathcal{U}, \mathcal{V}) = \max\left\{\langle \boldsymbol{u}, \boldsymbol{v}\rangle_\pi : \boldsymbol{u} \in \mathcal{U} \cap (\mathcal{U} \cap \mathcal{V})^\perp, \boldsymbol{v} \in (\mathcal{U} \cap \mathcal{V})^\perp, \|\boldsymbol{u}\|_\pi = \|\boldsymbol{v}\|_\pi = 1\right\}, \tag{4}$$

▶ **Theorem 14** ([59])**.** *Let* $\mathsf{Q}_1, \ldots, \mathsf{Q}_p \in \mathbb{R}^{\Omega \times \Omega}$ *be projection operators to sub-spaces* $\mathcal{U}_1, \ldots, \mathcal{U}_p$*. Set* $\mathcal{V}_j = \bigcap_{i=1}^j \mathcal{U}_i$*. Writing* $\mathsf{Q}_\star$ *for the projection to* $\mathcal{V}_p$*, we have*

$$\|\mathsf{Q}_1 \cdots \mathsf{Q}_p \boldsymbol{f} - \mathsf{Q}_\star \boldsymbol{f}\|_\pi^2 \leq \left(1 - \prod_{j=2}^{p} \sin^2(\mathcal{U}_j, \mathcal{V}_{j-1})\right) \cdot \|\boldsymbol{f} - \mathsf{Q}_\star \boldsymbol{f}\|_\pi^2$$

where $\sin^2(\mathcal{U}, \mathcal{V}) = 1 - \cos^2(\mathcal{U}, \mathcal{V})$*.*

2.2 Probability Distributions and Relative Entropy

Let Ω be a finite set. We will write $\triangle_\Omega$ for the probability simplex with vertices Ω, i.e.

$$\triangle_\Omega := \left\{\mu : \Omega \to \mathbb{R}_{\geq 0} : \sum_{\omega \in \Omega} \mu(\omega) = 1\right\}.$$

We will adopt the convention of treating elements of $\mu \in \triangle_\Omega$ as row-vectors. For $\mu \in \triangle_\Omega$, we will write $\mathrm{supp}(\mu) = \{\omega \in \Omega : \mu(\omega) > 0\}$ for the support of μ. Throughout the paper, Ω (or X) will always be a set of n-tuples for some $n \geq 1$, i.e. there exists a finite sequence of sets $\Omega_1, \ldots, \Omega_n$ such that $\Omega \subset \Omega_1 \times \cdots \times \Omega_n$. Given a set $S \subset [n]$, we will write $\Omega[S]$ for the projection of Ω to the coordinates in S, i.e.

[8] Crucially, the i-th singular value always depends on the choice of the measures which define the adjoint matrix. We will mostly deal with row-stochastic matrices that satisfy $\pi_U \mathsf{B} = \pi_V$ for some choice of distributions π_U, π_V. The adjoint matrix B^* is then defined with respect to these distributions.

$$\Omega[S] = \{(\omega_s)_{s\in S} : (\omega_1, \ldots, \omega_n) \in \Omega\}.$$

The S-marginal distribution of $\mu \in \Omega$ is defined by,

$$\mu_S(\omega_S) = \sum_{\bar{\omega}\in\Omega[S^c]} \mu(\omega_S \oplus \bar{\omega}) \quad \text{for all} \quad \omega_S \in \Omega[S], \tag{5}$$

where $S^c = [n] \setminus S$.

Let $\omega_S \in \Omega_S$. We will write Ω_{ω_S} and $\mu^{(\omega_S)}$ for the ω_S-pinning of Ω and μ_S, where

$$\Omega_{\omega_S} = \{\bar{\omega} \in \Omega[S^c] : \omega_S \oplus \bar{\omega} \in \Omega\} \quad \text{and} \quad \mu^{(\omega_S)}(\bar{\omega}) = \frac{\mu(\omega_S \oplus \bar{\omega})}{\sum_{\tilde{\omega}\in\Omega[S^c]} \mu(\omega_S \oplus \tilde{\omega})}, \tag{6}$$

for all $\omega_S \in \Omega[S]$. The following relation between the S-marginal μ_S and ω_S-pinning is immediate from the definitions. Let, $S, T \subset [n]$ such that $S \cap T = \varnothing$,

$$\mu(\omega_S \oplus \omega_T) = \mu_S(\omega_S) \cdot \mu_T^{(\omega_S)}(\omega_T) \tag{7}$$

We note that the statement of Equation (7) is a simple consequence of the law of conditional probability (Bayes' rule).

The Kullback-Leibler divergence $\mathcal{D}(\mu \parallel \nu)$ between distributions $\mu, \nu \in \triangle_\Omega$ is defined as,

$$\mathcal{D}(\mu \parallel \nu) = \mathop{\mathbb{E}}_{x\sim\nu}\left[\frac{\mu(x)}{\nu(x)} \log \frac{\mu(x)}{\nu(x)}\right] \tag{KL divergence}$$

where we have adopted the convention $0/0 = 1$ and assumed $\mathrm{supp}(\mu) \subset \mathrm{supp}(\nu)$.

It is a well-known fact that $\mathcal{D}(\bullet \parallel \bullet)$ is monotone-decreasing under the application of a row-stochastic matrix,

▶ **Lemma 15** (Data Processing Inequality). *Let $\mathsf{M} \in \mathbb{R}^{\Omega\times\Omega'}$ be any row-stochastic operator. Then, for any pair of distributions $\mu, \nu \in \Delta_\Omega$ we have,*

$$\mathcal{D}(\mu\mathsf{M} \parallel \nu\mathsf{M}) \leq \mathcal{D}(\mu \parallel \nu).$$

We also recall the following consequence of the chain-rule for the KL divergence,

▶ **Lemma 16.** *Let $n \geq 0$ finite sets $\Omega_1, \ldots, \Omega_n$ be given. Suppose the set $\Omega \subset \Omega_1 \times \cdots \times \Omega_n$ and the distribution $\mu \in \triangle_\Omega$ are arbitrary. Then, writing $S^c = [n] \setminus S$, we have*

$$\mathcal{D}(\mu \parallel \nu) = \mathcal{D}(\mu_S \parallel \nu_S) + \mathop{\mathbb{E}}_{\omega_S\sim\mu_S} \mathcal{D}(\mu_{S^c}^{(\omega_S)} \parallel \nu_{S^c}^{(\omega_S)}).$$

2.3 Random Walks and Mixing Times

The mixing time $T(\varepsilon, \mathsf{P})$ of the random walk operator $\mathsf{P} \in \mathbb{R}^{V\times V}$ is defined to be the least time step where the distribution of the random walk is ε-close to the stationary distribution π of P in the ℓ_1 distance, i.e. $\pi^{(t)}$ for the distribution of the random walk after t-steps, we have

$$T(\varepsilon, \mathsf{P}) = \min\Big\{t \in \mathbb{N}_{\geq 0} : \|\pi^{(t)} - \pi\|_{\ell_1} \leq \varepsilon\Big\}.$$

We will write $\mathsf{A}(x, \bullet)$ for the x-th row of the matrix A. Recalling that the distribution of the random walk P starting from x after t steps is given by $\pi^{(t)} = \mathsf{P}^t(x, \bullet)$, we formally define

$$T(\varepsilon, \mathsf{P}) = \min\big\{t \in \mathbb{N}_{\geq 0} : \|\mathsf{P}^t(x, \bullet) - \pi^\top\|_{\ell_1} \leq \varepsilon \text{ for all } x \in V\big\}. \tag{mixing time}$$

We define the spectral gap $\mathsf{gap}(\mathsf{P})$ of the random walk $\mathsf{P} \in \mathbb{R}^{\Omega\times\Omega}$ with stationary distribution π as,

$$\mathsf{gap}(\mathsf{P}) = 1 - \sigma_2(\mathsf{P}) \qquad \text{(spectral gap)}$$

The following mixing time bound is well-known, see for example [48, Proposition 1.12].

▶ **Theorem 17** (Spectral Mixing Time Bound). *Let $\mathsf{P} \in \mathbb{R}^{V\times V}$ be a random walk matrix P with stationary distribution π. One has,*

$$T(\varepsilon,\mathsf{P}) \le \left\lceil \frac{\log\left(\left(\varepsilon\cdot\sqrt{\min_{x\in V}\pi(x)}\right)^{-1}\right)}{\log(1/\sigma_2(\mathsf{P}))} \right\rceil \le \left\lceil \frac{\log\left(\left(\varepsilon\cdot\sqrt{\min_{x\in V}\pi(x)}\right)^{-1}\right)}{\mathsf{gap}(\mathsf{P})} \right\rceil$$

where $\mathsf{gap}(\mathsf{P})$ is the spectral gap of the operator P.

The entropy contraction factor $\mathsf{ec}(\mathsf{P})$ of the random walk operator P with stationary measure π is defined as,

$$\mathsf{ec}(\mathsf{P}) = 1-\kappa(\mathsf{P}) \ \text{ where } \ \kappa(\mathsf{P}) = \sup\left\{ \frac{\mathcal{D}(\mu\mathsf{P} \parallel \pi)}{\mathcal{D}(\mu \parallel \pi)} : \mu \in \triangle_\Omega \right\} \qquad \text{(entropy contraction factor)}$$

Then, the following estimate can be used to bound the mixing time, see for example [13, Lemma 2.4],

▶ **Theorem 18.** *Let $\mathsf{P} \in \mathbb{R}^{V\times V}$ be a random walk operator P with stationary distribution π. One has,*

$$T(\varepsilon,\mathsf{P}) \le \frac{C}{\mathsf{ec}(\mathsf{P})} \cdot \log\log \frac{1}{\varepsilon\cdot\min_{x\in V}\pi(x)},$$

where $\mathsf{ec}(\mathsf{P})$ is the entropy contraction factor of P and C is a universal constant independent of (P,π).

2.4 (Partite) Simplicial Complexes

A simplicial complex is a downward closed collection of subsets of a finite set U. Formally, $X \subset 2^U$ and whenever $\beta \in X$ for all $\alpha \subset \beta$ we have $\alpha \in X$. The rank of a face α is $|\alpha|$. Given some j, we will adopt the notation $X^{(j)}$ to refer to the collection faces of X of rank j and the notation $X^{(\le j)}$ to refer to the collection of faces of X of rank at most j, i.e.

$$X^{(j)} := X \cap \binom{U}{j} \ \text{ and } \ X^{(\le j)} := \bigcup_{i=0}^{j} X^{(i)}.$$

We say X is a simplicial complex of rank n if the largest rank of any face $\alpha \in X$ is n. We note that by definition $X^{(0)} = \{\varnothing\}$.

We say that a simplicial complex X of rank n is pure, if any face $\alpha \in X^{(j)}$ for any $j < n$ is contained in another face $\beta \in X^{(n)}$. Equivalently, in a pure simplicial complex the only inclusion maximal faces are those of maximal rank. In this article, we will only deal with pure simplicial complexes.

A rank-n pure simplicial complex X is called n-partite if we can partition $X^{(1)}$ into disjoint sets $X[1],\dots,X[n]$ such that

$$\text{for all } \beta \in X^{(n)} \text{ and for all } i = 1,\dots,n \ \text{ we have } \ |\beta \cap X[i]| = 1. \qquad (n\text{-partiteness})$$

We will call the sets $X[1], \ldots, X[n]$ the sides of the complex X. Equivalently, every element of a rank-n face $\beta \in X[n]$ comes from a distinct side $X[i]$. We observe that a bipartite graph is a 2-partite simplicial complex.

To keep our nomenclature simple, we will simply refer to a pure n-partite simplicial complex of rank n as an n-partite simplicial complex, i.e. we will not consider n-partite complexes which are not pure.

For a face $\alpha \in X$ we introduce the notation, $\mathrm{type}(\alpha) = \{i \in [n] : \alpha \cap X[i] \neq \varnothing\}$ for the type of the face α, i.e. the collection of sides of X that α intersects.

For any $i \in [n]$ and $\beta \in X^{(n)}$ we will write $\beta_i \in X^{(1)}$ for the unique element of β satisfying $\{\beta_i\} = \beta \cap X[i]$. We will refer to β_i as the i-th coordinate of β. We will also write $\beta_T = \{\beta_t : t \in T\}$ for all $T \subset [n]$. We extend this notation to arbitrary faces $\alpha \in X$ and $T \subset \mathrm{type}(\alpha)$. In keeping with the view that a face $\alpha \in X$ with $\mathrm{type}(\alpha) = \{t_1, \ldots, t_k\}$ can be represented as a tuple $(a_{t_1}, \cdots, a_{t_k})$, we will favour the notation $\alpha \oplus \alpha'$ to denote the union of two faces $\alpha, \alpha' \in X$ with $\mathrm{type}(\alpha) \cap \mathrm{type}(\alpha') = \varnothing$ over the usual notation $\alpha \cup \alpha'$.

We observe that for facets $\beta \in X^{(n)}$, i.e. faces of maximal rank, we have $\mathrm{type}(\beta) = [n]$. Given, $\alpha \in X$ we recall that the link X_α is defined as,

$$X_\alpha = \{(\beta \setminus \alpha) \in X : \beta \in X, \beta \supset \alpha\}.$$

The following observation is immediate,

▶ **Lemma 19.** *Let X be an n-partite simplicial complex with sides $X[1], \ldots, X[n]$ and $\alpha \in X^{(j)}$ for some $j \in [0, n]$. Then, the simplicial complex X_α is an $(n-j)$-partite simplicial complex with sides $X_\alpha[j] := X[j] \cap X_\alpha^{(1)}$ for $j \in [n] \setminus \mathrm{type}(\alpha)$.*

For $T \subset [n]$, we will also introduce the notation $X[T]$ to refer to all faces of X of type T, i.e. $X[T] = \{\alpha \in X : \mathrm{type}(\alpha) = T\}$.

2.5 Weighted Simplicial Complexes

A weighted simplicial complex (X, π) of rank n is a pure simplicial complex of rank n where $\pi := \pi_n$ is a probablity distribution on $X^{(n)}$ with full support, i.e. $\pi \in \triangle_{X^{(n)}}$ and $\mathrm{supp}(\pi) = X^{(n)}$. For $j \in [0, n-1]$, we inductively define the probability distributions $\pi_j : X^{(j)} \to \mathbb{R}$ as

$$\pi_j(\alpha) = \frac{1}{j+1} \sum_{\substack{\beta \in X[j+1], \\ \beta \subset \alpha}} \pi_{j+1}(\beta). \tag{8}$$

Following repeated applications of Equation (8), we obtain the following well-known result (see, e.g. [4, Proposition 2.3.1])

▶ **Proposition 20.** *Let (X, π) be a simplicial complex of rank n. For all $0 \leq j \leq k \leq n$ and $\alpha \in X^{(j)}$, one has*

$$\pi_j(\alpha) = \frac{1}{\binom{k}{j}} \sum_{\substack{\beta \supset \alpha, \\ \beta \in X^{(k)}}} \pi_k(\beta).$$

Similarly, given a face $\alpha \in X^{(j)}$, we define the distribution $\pi^{(\alpha)}$ on $X_\alpha^{(n-j)}$ by conditioning π on the containment of α. Consequently, we have

▶ **Proposition 21.** *Let (X, π) be a simplicial complex of rank n. Let $\alpha \in X^{(j)}$ and $\tau \in X_\alpha^{(\ell)}$ be faces for some $0 \leq \ell \leq j \leq n$. Then,*

$$\pi_l^{(\alpha)}(\tau) = \frac{\pi_{j+\ell}(\alpha \cup \tau)}{\binom{j+\ell}{\ell} \cdot \pi_j(\alpha)}.$$

When (X,π) is an n-partite weighted simplicial complex, for any $T\subset[n]$, we will define π_T as the marginal distribution of π on the coordinates in T according to Equation (5), i.e.

$$\pi_T(\omega_T)=\sum_{\bar\omega\in X[T^c]}\pi(\omega_T\oplus\bar\omega).$$

Similarly, given any $\omega_T\in X[T]$, we define the weighting $\pi^{(\omega_T)}$ on $(X_{\omega_T},\pi^{(\omega_T)})$ according to Equation (6). Thus,

$$\pi^{(\omega_T)}(\bar\omega)=\Pr_{\omega'\sim\pi}[\omega'_{T^c}=\bar\omega\mid\omega'_T=\bar\omega]=\frac{\pi(\omega_T\oplus\bar\omega)}{\pi_T(\omega_T)}\quad\text{for all}\quad\bar\omega\in X[T^c].$$

2.6 Update Operators and the Sequential Sweep

Let (X,π) be a pure, n-partite simplicial complex of rank n. We define the update operators $\mathsf{Q}_1,\dots,\mathsf{Q}_n\in\mathbb{R}^{X^{(n)}\times X^{(n)}}$ as follows,

$$\mathsf{Q}_i(\omega,\omega')=\Pr_{\bar\omega\sim\pi}\left[\bar\omega=\omega'\mid\bar\omega\supset\omega_{[n]\setminus i}\right]=\pi_{\{i\}}^{(\omega_{[n]\setminus i})}(\omega'_i).\tag{9}$$

Thus, Q_i can be thought as describing the random walk which makes a transition from $\omega\in X^{(n)}$ to a random state $\omega'\in X^{(n)}$ by only re-sampling the i-th coordinate from the distribution π without changing the remaining coordinates, $\omega_{[n]\setminus i}$.

Given an ordering $\vec{s}=(s(1),\dots,s(n))$ of $[n]$, we define the sequential sweep $\mathsf{P}_{\mathsf{seq}}^{(\vec{s})}$ as the random walk operator $\mathsf{P}_{\mathsf{seq}}^{(\vec{s})}:=\mathsf{Q}_{s(1)}\cdots\mathsf{Q}_{s(n)}$, which updates the coordinates $s(1),\dots,s(n)$ sequentially one after the other. When $\vec{s}=(1,\dots,n)$, i.e. $\vec{s}$ is the canonical order of $[n]$, we will simply write $\mathsf{P}_{\mathsf{seq}}:=\mathsf{P}_{\mathsf{seq}}^{(\vec{s})}$. We note that the weighting π of the simplicial complex is stationary for $\mathsf{P}_{\mathsf{seq}}$, since $\pi\mathsf{Q}_i=\pi$ for all $i=1,\dots,n$. Thus, $\pi\mathsf{P}_{\mathsf{seq}}=\pi$.

Notice that we have, $\mathsf{P}_{\mathsf{seq}}^*=(\mathsf{Q}_1\cdots\mathsf{Q}_n)^*=\mathsf{Q}_n^*\cdots\mathsf{Q}_1^*=\mathsf{Q}_n\cdots\mathsf{Q}_1$. In particular the random-walk $\mathsf{P}_{\mathsf{seq}}$ is not necessarily reversible!

It has already been observed in [6, 53], that the update operators Q_i are orthogonal projections.

▶ **Proposition 22.** *For all $i=1,\dots,n$ the operator Q_i is an orthogonal projection to the subspace,*

$$\mathcal{U}_i=\operatorname{span}\{\boldsymbol{u}_\alpha:\alpha\in X[1,\cdots,i-1,i+1,\cdots,n]\},$$

where $\boldsymbol{u}_\alpha(\omega)=\mathbf{1}[\omega\supset\alpha]$.

2.7 Colored Random Walks on Partite Simplicial Complexes

It will also be important to recall the colored random walks, introduced in [21, 34]. Let $\alpha\in X$ be any given face of an n-partite weighted simplicial complex. Let $I,J\subset[n]\setminus\operatorname{type}(\alpha)$ be two disjoint sets, i.e. $I\cap J=\varnothing$. We define the (I,J) colored random walk $\mathsf{C}_\alpha^{I\to J}\in\mathbb{R}^{X_\alpha[I]\times X_\alpha[J]}$ from $X_\alpha[I]$ to $X_\alpha[J]$ by setting

$$\mathsf{C}_\alpha^{I\to J}(\tau_I,\tau_J)=\pi_J^{(\alpha\oplus\tau_I)}(\tau_J)=\Pr_{\omega\sim\pi}[\omega_J=\tau_J\mid\omega_I=\tau_I,\omega_{\operatorname{type}(\alpha)}=\alpha]\tag{10}$$

for all $\tau_I\in X_\alpha[I]$ and $\tau_J\in X_\alpha[J]$.

Let $I, J \subset [n]$ be two subsets satisfying $I \cap J = \varnothing$. Suppose for some $\alpha \in X[(I \cup J)^c]$ the marginal distributions $\pi_I^{(\alpha)}$ and $\pi_J^{(\alpha)}$ are independent, i.e. we have

$$\pi_{I\cup J}^{(\alpha)}(\tau_I \oplus \tau_J) = \pi_I^{(\alpha)}(\tau_I) \cdot \pi_J^{(\alpha)}(\tau_J) \text{ for all } \tau_I \in X_\alpha[I], \tau_J \in X_\alpha[J].$$

It is easy to see, that in this case $\mathsf{C}_\alpha^{I\to J} = \mathbf{1}\pi_J^{(\alpha)}$. In particular, we have[9]

$$\sigma_2(\mathsf{C}_\alpha^{I\to J}) = \sigma_2(\mathbf{1}\pi_J^{(\alpha)}) = 0 \text{ and } \mathcal{D}(\mu\mathsf{C}_\alpha^{I\to J} \parallel \nu\mathsf{C}_\alpha^{I\to J}) = \mathcal{D}(\pi_J^{(\alpha)} \parallel \pi_J^{(\alpha)}) = 0,$$

for all $\mu, \nu \in \triangle_{X_\alpha[I]}$. We will consider relaxations of both statements to consider the proximity of $\pi_I^{(\alpha)}$ and $\pi_J^{(\alpha)}$ to being product distributions. Thus, the (I, J) variance contraction parameter $\varepsilon^{I\to J}$ is defined as,

$$\varepsilon^{I\to J} := \varepsilon_{(X,\pi)}^{I\to J} = \max_{\alpha\in X[(I\cup J)^c]} \sigma_2\big(\mathsf{C}_\alpha^{I\to J}\big) \tag{11}$$

We also define, the related (I, J) entropy contraction parameter

$$\eta^{I\to J} = 1-\kappa^{I\to J} \;;\; \kappa^{I\to J} = \sup\left\{ \frac{\mathcal{D}(\mu\mathsf{C}_\alpha^{I\to J} \parallel \pi_J^{(\alpha)})}{\mathcal{D}(\mu \parallel \pi_I^{(\alpha)})} : \alpha \in X[(I \cup J)^c] \text{ and } \mu \in \triangle_{X_\alpha[I]} \right\} \tag{12}$$

$\vec{\varepsilon}$-product distributions and $\varepsilon^{I\to J}$

When dealing with the colored random walks $\mathsf{C}_\alpha^{I\to J}$ an alternative notion of high-dimensional expansion introduced in [34] proves more convenient: Let (X, π) be an n-partite simplicial complex with parts $X[1], \cdots, X[n]$. The distribution π is called ε-product if,

$$\sigma_2(\mathsf{C}_\varnothing^{i\to j}) \le \varepsilon \text{ for all } i, j \in [n] \text{ where } i \neq j.$$

We extend this definition in the following manner: Let $\vec{\varepsilon} = (\varepsilon_0, \ldots, \varepsilon_{n-2})$ and (X, π) be an arbitrary n-partite simplicial complex. We say the distribution π is $\vec{\varepsilon}$-product if for all $\alpha \in X^{(\le n-2)}$ we have,

$$\sigma_2(\mathsf{C}_\alpha^{i\to j}) \le \varepsilon_{|\alpha|} \text{ for all } i, j \in [n] \setminus \alpha \text{ where } i \neq j.$$

Equivalently, π is $\vec{\varepsilon}$-product if and only if $\pi^{(\alpha)}$ is $\varepsilon_{|\alpha|}$-product for all $\alpha \in X^{(\le n-2)}$. We recall the following result of [21, Claim 7.10],

▶ **Proposition 23.** *Let (X, π) be an n-partite simplicial complex in which every link G_α is connected – equivalently, (X, π) is a one-sided $\vec{\gamma}$-local spectral expander where $\gamma_i < 1$ for all i. Then, the bipartite graph $G_{\{i\},\{j\}}$ described by $\mathsf{C}_\alpha^{i\to j}$ is connected. In particular, there exists a vector $\vec{\varepsilon} = (\varepsilon_i)_{i=0}^{n-2}$ such that $\varepsilon_i < 1$ for all i, for which the distribution π is $\vec{\varepsilon}$-product.*

They also prove the following down-trickling result, [21, Corollary 7.6]

▶ **Theorem 24.** *Let (X, π) be an n-partite simplicial complex all of whose links are connected. Suppose $\gamma_{n-2}(X, \pi) \le \frac{\varepsilon}{(n-2)\varepsilon+1}$. Then, for every $\alpha \in X^{(k)}$ and every $i, j \in [n] \setminus \mathrm{type}(\alpha)$, we have $\sigma_2(\mathsf{C}_\alpha^{i\to j}) \le \frac{\varepsilon}{k\varepsilon+1}$.*

[9] the first equality is the consequence of $\mathsf{C}_\alpha^{I\to J}$ being a rank one matrix

3 A Spectral Gap Bound for $\mathsf{P}_{\mathsf{seq}}$

Our main theorem in this section will be,

▶ **Theorem 25.** *Let (X,π) be an n-partite simplicial complex, $\vec{s}=(s(1),\dots,s(n))$ be any ordering of $[n]$, and the parameters $\varepsilon^{I\to J}$ be defined as in Equation (11) for all $I,J\subset[n]$ with $I\cap J=\varnothing$. Then,*

$$\sigma(\mathsf{P}_{\mathsf{seq}}^{(\vec{s})})^2 \le 1-\prod_{j=2}^{n}\Big(1-(\varepsilon^{s([j-1])\to s(j)})^2\Big),$$

where we have written $S(A)=\{s(a):a\in S\}$. Equivalently,

$$\mathsf{gap}(\mathsf{P}_{\mathsf{seq}}^{(\vec{s})}) \ge 1-\sqrt{1-\prod_{j=2}^{n}\big(1-(\varepsilon^{s([j-1])\to s(j)})^2\big)}.$$

In particular, if π is $\vec{\varepsilon}$-product, we have

$$\sigma(\mathsf{P}_{\mathsf{seq}}^{(\vec{s})})^2 \le 1-\prod_{j=2}^{n}\prod_{p=0}^{j-2}(1-\varepsilon_p^2).$$

Equivalently,

$$\mathsf{gap}(\mathsf{P}_{\mathsf{seq}}^{(\vec{s})}) \ge 1-\sqrt{1-\prod_{j=2}^{n}\prod_{p=0}^{j-2}(1-\varepsilon_p)^2}$$

In conjunction with Theorem 24, Theorem 25 immediately implies the following

▶ **Corollary 26.** *Let (X,π) be a link-connected n-partite simplicial complex that is a $\vec{\gamma}$-local spectral expander with $\gamma_i\le\varepsilon/(n-1-i)$ (i.e. π $\vec{\varepsilon}$-product, with $\varepsilon_i\le\varepsilon$), then*

$$\sigma_2(\mathsf{P}_{\mathsf{seq}})\le\frac{n\cdot\varepsilon}{\sqrt{2}} \quad \textit{and} \quad \mathsf{gap}(\mathsf{P}_{\mathsf{seq}})\ge 1-\frac{n\cdot\varepsilon}{\sqrt{2}}.$$

If we have $\gamma_{n-2}\le\frac{\varepsilon}{2n}$ and all links of (X,π) are connected, then

$$\sigma_2(\mathsf{P}_{\mathsf{seq}})\le\frac{\varepsilon}{\sqrt{2}} \quad \textit{and} \quad \mathsf{gap}(\mathsf{P}_{\mathsf{seq}})\ge 1-\frac{\varepsilon}{\sqrt{2}}.$$

For the second statement we note that Theorem 24 implies that we are completely ε/n product assuming $\gamma_{n-2}\le\varepsilon/2n$. In particular, the ε in the statement of Theorem 24 and the ε above differ by a factor of n. The above corollary shows that for constant n, having constant local spectral expansion guarentees that $\mathsf{gap}(\mathsf{P}_{\mathsf{seq}})$ is close to 1 – thus it allows us to conclude that $\mathsf{P}_{\mathsf{seq}}$ mixes rapidly in the complexes of [47, 41].

We will prove Theorem 25 using Theorem 14. To be able apply Theorem 14, we will need some preparatory work:

1. For all $T\subset[n]$, we will characterize the intersections $\bigcap_{t\in T}\mathcal{U}_t$, where $\mathcal{U}_t$ are as defined in Proposition 22, i.e. $\mathcal{U}_t=\mathrm{im}(\mathsf{Q}_t)$. This will be done in Proposition 27.
2. We will get a bound on $\sin^2(\mathcal{U}_p,\bigcap_{t\in T}\mathcal{U}_t)$ for all $p\in[n]$ and $T\subset[n]\setminus p$ in terms of the parameters $\varepsilon^{I\to J}$, defined in Equation (11). This will be done in Theorem 29.
3. We will get a bound on the parameters $\varepsilon^{I\to J}$ under the assumption that π is $\vec{\varepsilon}$-product. This will be done in Theorem 30.

We state these results now.

▶ **Proposition 27.** *For (X,π) a weighted and link-connected n-partite simplicial complex. Let $\mathcal{U}_1,\dots,\mathcal{U}_n$ be as defined in Proposition 22. For all $T\subset[n]$, we define*

$$\mathcal{U}_T := \operatorname{span}\{\boldsymbol{u}_\alpha : \alpha\in X[T^c]\}.$$

Then, $\mathcal{U}_T=\bigcap_{t\in T}\mathcal{U}_t$.

▶ Remark 28. We have,

$$\mathcal{U}_I=\operatorname{span}\Big\{\boldsymbol{f}\in\mathbb{R}^{X^{(n)}} : \boldsymbol{f}(\omega)=\boldsymbol{f}(\bar\omega) \text{ for all } \omega,\bar\omega\in X^{(n)} \text{ such that } \omega_{[n]\setminus I}=\bar\omega_{[n]\setminus I}\Big\}.$$

In particular, $\mathcal{U}_I$ is the space of vectors $\boldsymbol{f}\in\mathbb{R}^{X^{(n)}}$ whose entries are completely determined by the coordinates in $[n]\setminus I$.

We note that a special case of this result was already proven in [53, Proposition 3.6]. We will present a proof for Proposition 27, in Section 3.2.

Then, we show the geometric interpretation for the quantities $\varepsilon^{I\to J}$ as follows,

▶ **Theorem 29.** *Let (X,π) be an n-partite simplicial complex. Let $I,J\subset[n]$ be any pair of disjoint sets, i.e. $I\cap J=\varnothing$.*

Then, $\cos(\mathcal{U}_I,\mathcal{U}_J)\le\varepsilon^{I\to J}$, where the subspaces $\mathcal{U}_I,\mathcal{U}_J$ are as defined in Proposition 27 and the parameters $\varepsilon^{I\to J}$ are as defined in Equation (11).

We will prove Theorem 29 in Section 3.3.

Finally, we state our bound on the parameters $\varepsilon^{I\to J}$,

▶ **Theorem 30.** *Let (X,π) be an n-partite simplicial complex where π is $\vec{\varepsilon}$-product. We have,*

$$\sigma_2(\mathsf{C}_\alpha^{I\to J})^2\le 1-\prod_{p=0}^{|I|-1}\prod_{q=0}^{|J|-1}(1-\varepsilon^2_{|\alpha|+p+q}) \quad \textit{and thus} \quad (\varepsilon^{I\to J})^2\le 1-\prod_{p=0}^{|I|-1}\prod_{j=0}^{|J|-1}(1-\varepsilon^2_{n-|I|-|J|+p+q}) \tag{13}$$

▶ Remark 31. Notice that the RHS of Equation (13) is always strictly smaller than 1 provided that π is $\vec{\varepsilon}$-product with $\varepsilon_i<1$ for all $i=0,\dots,n-2$. By Proposition 23, this is always the case assuming all the links in (X,π) are connected.

We will present the proof for Theorem 30 in Section 3.1.

The proof of Theorem 25 is now immediate from Theorem 14.

3.1 Proof of Theorem 30

Proof of Theorem 30. If $|I|=|J|=1$, then the RHS of Equation (13) equals $\varepsilon_{|\alpha|}$ and thus the statement follows since π is $\vec{\varepsilon}$-product. Suppose without loss of generality, that $\alpha=\varnothing$ and $|I|\ge 2$ where we have some fixed element $i\in I$. Write,

$$\sigma := \max_{x\in X[i]}\sigma_2\Big(\mathsf{C}_x^{(I\setminus i)\to J}\Big). \tag{14}$$

Let $\boldsymbol{F}\in X[J]\to\mathbb{R}$ satisfy $\|\boldsymbol{F}\|_{\pi_J}=1$, $\langle\boldsymbol{F},\mathbf{1}\rangle_{\pi_J}=0$, and $\|\mathsf{C}_\varnothing^{I\to J}\boldsymbol{F}\|_{\pi_I}=\sigma_2(\mathsf{C}_\varnothing^{I\to J})$.

Then,

$$\begin{aligned}
\sigma_2\left(\mathsf{C}_{\varnothing}^{I\to J}\right)^2 = \left\|\mathsf{C}_{\varnothing}^{I\to J}\boldsymbol{F}\right\|_{\pi_I}^2 &= \mathop{\mathbb{E}}_{\alpha_I\sim\pi_I}\left(\mathop{\mathbb{E}}_{\alpha_J\sim\pi_J^{(\alpha_I)}}\boldsymbol{F}(\alpha_J)\right)^2,\\
&= \mathop{\mathbb{E}}_{x\sim\pi_{\{i\}}}\mathop{\mathbb{E}}_{\alpha'\sim\pi_{I\setminus i}^{(x)}}\left(\mathop{\mathbb{E}}_{\alpha_J\sim\pi_J^{(x\oplus\alpha')}}\boldsymbol{F}(\alpha_J)\right)^2,\\
&= \mathop{\mathbb{E}}_{x\sim\pi_{\{i\}}}\left\|\mathsf{C}_x^{(I\setminus i)\to J}\boldsymbol{F}_x\right\|_{\pi_{I\setminus i}^{(x)}}^2,\\
&\le \mathop{\mathbb{E}}_{x\sim\pi_{\{i\}}}\left[\left\|\boldsymbol{F}_x^{\mathbf{1}}\right\|_{\pi_J^{(x)}}^2 + \sigma_2(\mathsf{C}_x^{(I\setminus i)\to J})^2\cdot\left\|\boldsymbol{F}_x^{\perp\mathbf{1}}\right\|_{\pi_J^{(x)}}^2\right],\\
&= \sigma^2 + (1-\sigma^2)\cdot\mathop{\mathbb{E}}_{x\sim\pi_{\{i\}}}\|\boldsymbol{F}_x^{\mathbf{1}}\|_{\pi_J^{(x)}}^2
\end{aligned}$$

where $\boldsymbol{F}_x^{\mathbf{1}} = \mathbf{1}\cdot\mathbb{E}_\alpha\,\boldsymbol{F}_x(\alpha_{J\setminus i})$. We note now for each $i\in X[i]$,

$$\left\|\boldsymbol{F}_x^{\mathbf{1}}\right\|_{\pi_J}^2 = \left(\mathop{\mathbb{E}}_{\alpha_J\sim\pi_J^{(x)}}\boldsymbol{F}(\alpha_J)\right)^2 = [\mathsf{C}_{\varnothing}^{i\to J}\boldsymbol{F}](x)^2.$$

Thus, using that $\langle\boldsymbol{F},\mathbf{1}\rangle_{\pi_J}=0$,

$$\mathop{\mathbb{E}}_{x\sim\pi_{\{1\}}}\left\|\boldsymbol{F}_x^{\mathbf{1}}\right\|_{\pi_J}^2 = \|\mathsf{C}_{\varnothing}^{i\to J}\boldsymbol{F}\|_{\pi_{\{i\}}}^2 \le \sigma_2\left(\mathsf{C}_{\varnothing}^{i\to J}\right)^2.$$

Thus,

$$\begin{aligned}
\sigma_2\left(\mathsf{C}_{\varnothing}^{I\to J}\right)^2 &\le 1-(1-\sigma^2)(1-\sigma_2(\mathsf{C}_{\varnothing}^{i\to J})^2),\\
&= 1-\left(1-\sigma_2\left(\mathsf{C}_{x^\star}^{I\setminus i\to J}\right)^2\right)\left(1-\sigma_2\left(\mathsf{C}_{\varnothing}^{i\to J}\right)^2\right).
\end{aligned}\tag{15}$$

where $x^\star = \arg\max_{x\in X[i]}\sigma_2(\mathsf{C}_x^{I\setminus i\to J})$.

Now, we first assume $J=\{j\}$ and $I=\{i_1,\dots,i_\ell\}$, applying Equation (15) recursively, we obtain

$$\sigma_2(\mathsf{C}_{\varnothing}^{I\to\{j\}}) \le 1-(1-\sigma_2(\mathsf{C}_{\varnothing}^{i_1\to j})^2)\prod_{p=k}^{\ell}\left(1-\sigma_2\left(\mathsf{C}_{x_{i_1}\oplus\cdots\oplus x_{i_{p-1}}}^{i_p\to\{j\}}\right)^2\right),$$

where

$$x_{i_1}=x^\star,\quad \omega(p)=x_{i_1}\oplus\cdots x_{i_{p-1}},\quad\text{and}\quad x_p=\arg\max_{x\in X_{\omega(p)}[i_p]}\sigma_2\left(\mathsf{C}_{x_{i_1}\oplus\cdots\oplus x_{i_{p-1}}\oplus x}^{I\setminus\{i_1,\dots,i_p\}\to\{j\}}\right),$$

In particular using the $\vec{\varepsilon}$-product assumption,

$$\sigma_2(\mathsf{C}_{\varnothing}^{I\to j})^2 \le 1-\prod_{p=0}^{|I|-1}(1-\varepsilon_p^2).$$

Now, by using $\mathsf{C}_{\varnothing}^{J\to i}=\left(\mathsf{C}_{\varnothing}^{i\to J}\right)^*$ and that $\sigma_2(\mathsf{B})=\sigma_2(\mathsf{B}^*)$ we have by the above

$$\sigma_2(\mathsf{C}_{\varnothing}^{i\to J})^2 \le 1-\prod_{p=0}^{|J|-1}(1-\varepsilon_p^2).\tag{16}$$

Similarly, inserting Equation (16) inside Equation (15), we obtain

$$\sigma_2\big(\mathsf{C}_{\varnothing}^{I\to J}\big)^2 \le 1 - \prod_{p=0}^{|J|-1}(1-\varepsilon_p^2)\cdot\left(1-\sigma_2\Big(\mathsf{C}_{x^\star}^{I\setminus i\to J}\Big)^2\right). \tag{17}$$

Suppose $I=\{i_1,\dots,i_\ell\}$ write $x_{i_1}=x^\star$ and

$$\omega(q)=x_{i_1}\oplus\cdots x_{i_{q-1}},\quad\text{and}\quad x_q=\arg\max_{x\in X_{\omega(q)}[i_q]}\sigma_2\Big(\mathsf{C}_{\omega(q)\oplus x}^{I\setminus\{i_1,\dots,i_p\}\to J}\Big),$$

Applying Equation (17) repeatedly, we obtain

$$\sigma_2(\mathsf{C}_{\varnothing}^{I\to J})^2 \le 1-\left(\prod_{p=0}^{|J|-1}(1-\varepsilon_p^2)\right)\cdot\prod_{q=1}^{|I|-1}\left(1-\sigma_2\Big(\mathsf{C}_{x_{i_1}\oplus\cdots\oplus x_{i_q}}^{i_{q+1}\to J}\Big)^2\right). \tag{18}$$

By Equation (16), we have

$$\sigma_2\Big(\mathsf{C}_{x_{i_1}\oplus\cdots\oplus x_{i_q}}^{i_{q+1}\to J}\Big)^2 \le 1-\prod_{p=0}^{|J|-1}(1-\varepsilon_{q+p}^2)$$

And inserting this in Equation (18), we obtain

$$\begin{aligned}\sigma_2\big(\mathsf{C}_{\varnothing}^{I\to J}\big)^2 &\le 1-\left(\prod_{p=0}^{|J|-1}(1-\varepsilon_p^2)\right)\cdot\left(\prod_{p=0}^{|J|-1}(1-\varepsilon_{p+1}^2)\right)\cdots\left(\prod_{p=0}^{|J|-1}(1-\varepsilon_{p+|I|-1}^2)\right),\\ &= 1-\prod_{q=0}^{|I|-1}\prod_{p=0}^{|I|-1}(1-\varepsilon_{p+q}^2).\end{aligned}$$

◀

3.2 Proof of Proposition 27

Proof of Proposition 27. We proceed by induction on the number of elements in T. For $|T|=1$, the statement is clear. Thus, we assume that

$$\mathcal{U}_T=\bigcap_{t\in T}\mathcal{U}_t\quad\text{for all}\quad T\quad\text{with}\quad |T|=\ell.$$

Let $t\in[n]\setminus T$, and consider $T\cup\{t\}$. First, fix any $\alpha\in X[[n]\setminus(T\cup t)]$. Then, note

$$\boldsymbol{u}_\alpha=\sum_{\substack{\beta\in X[[n]\setminus T],\\ \beta\supset\alpha}}\boldsymbol{u}_\beta=\sum_{\substack{\beta'\in X[1,\dots,t-1,t+1,\dots,n],\\ \beta'\supset\alpha}}\boldsymbol{u}_{\beta'}.$$

Thus, indeed: $\operatorname{span}\{\boldsymbol{u}_\alpha:\alpha\in X[[n]\setminus(T\cup t)]\}=\mathcal{U}_{T\cup t}\subset\mathcal{U}_T\cap\mathcal{U}_t$.

To show the reverse inclusion, we recall that a function $\boldsymbol{f}\in\mathbb{R}^{X^{(n)}}$ is in $\mathcal{U}_A$ if and only if we have

$$\boldsymbol{f}(\omega_A\oplus\omega_{[n]\setminus A})=\boldsymbol{f}(\tilde{\omega}_A\oplus\omega_{[n]\setminus A})$$

for all $\omega_A,\tilde{\omega}_A\in X[A]$ and $\omega_{[n]\setminus A}\in X[[n]\setminus A]$ such that $\omega_A\oplus\omega_{[n]\setminus A},\tilde{\omega}_A\oplus\omega_{[n]\setminus A}\in X^{(n)}$.

i.e. the value of $\boldsymbol{f}$ is determined only by the coordinates in $[n]\setminus A$ (qv. Remark 28).

Suppose $\boldsymbol{f} \in \mathcal{U}_T \cap \mathcal{U}_t$. We want to prove,

$$\boldsymbol{f}(\omega_t \oplus \omega_T \oplus \omega_{[n]\setminus(T\cup t)}) = \boldsymbol{f}(\tilde{\omega}_t \oplus \tilde{\omega}_T \oplus \omega_{[n]\setminus(T\cup t)}), \tag{19}$$

for all $\omega_t, \tilde{\omega}_t \in X[t]$, $\omega_T, \tilde{\omega}_T \in X[T]$ and $\omega_{[n]\setminus(T\cup t)} \in X[(T\cup t)^c]$ such that $\omega_t \oplus \omega_T \oplus \omega_{(T\cup t)^c}, \tilde{\omega}_t \oplus \tilde{\omega}_T \oplus \omega_{(T\cup t)^c} \in X^{(n)}$.

Since $\boldsymbol{f} \in \mathcal{U}_t$, we have,

$$\boldsymbol{f}(\omega_t \oplus \omega_T \oplus \omega_{[n]\setminus(T\cup t)}) = \boldsymbol{f}(\tilde{\omega}_t \oplus \omega_T \oplus \omega_{[n]\setminus(T\cup t)})$$

for all $\omega_t, \tilde{\omega}_t \in X[t]$, $\omega_T \in X[T]$, and $\omega_{[n]\setminus(T\cup t)} \in X[[n]\setminus(T\cup t)]$ such that $\omega_t \oplus \omega_T \oplus \omega_{[n]\setminus(T\cup t)}, \tilde{\omega}_t \oplus \omega_T \oplus \omega_{[n]\setminus(T\cup t)} \in X^{(n)}$. Similarly, since $\boldsymbol{f} \in \mathcal{U}_T$, we have,

$$\boldsymbol{f}(\omega_t \oplus \omega_T \oplus \omega_{[n]\setminus(T\cup t)}) = \boldsymbol{f}(\omega_t \oplus \tilde{\omega}_T \oplus \omega_{[n]\setminus(T\cup t)})$$

for all $\omega_t \in X[t]$, $\omega_T, \tilde{\omega}_T \in X[T]$, and $\omega_{[n]\setminus(T\cup t)} \in X[[n]\setminus(T\cup t)]$ such that $\omega_t \oplus \omega_T \oplus \omega_{[n]\setminus(T\cup t)}, \omega_t \oplus \tilde{\omega}_T \oplus \omega_{[n]\setminus(T\cup t)} \in X^{(n)}$. Fixing $\omega_{[n]\setminus(T\cup t)}$, this means that Equation (19) is satisfied by any pair $(\omega_t \oplus \omega_T, \tilde{\omega}_t \oplus \tilde{\omega}_T)$ which is connected by an edge in the line graph[10] $L(G_{t,T}^{(\omega_{[n]\setminus(T\cup t)})})$, where $G_{t,T}^{(\omega_{[n]\setminus(T\cup t)})}$ is the graph underlying $\mathsf{C}_{\omega_{[n]\setminus(T\cup t)}}^{t\to T}$. By Remark 31, since the links of (X,π) are connected, so is the graph $G_{t,T}^{(\omega_{[n]\setminus(T\cup t)})}$ for any $\omega_{[n]\setminus(T\cup t)} \in X[[n]\setminus(T\cup t)]$. In particular, the graph $L(G_{t,T}^{(\omega_{[n]\setminus(T\cup t)})})$ is connected, meaning any pair of $\omega_t \oplus \omega_T, \tilde{\omega}_t \oplus \tilde{\omega}_T \in X_{\omega_{[n]\setminus(T\cup t)}}[T\cup t]$ are connected by a path and therefore satisfy Equation (19). This allows us to conclude $\boldsymbol{f} \in \mathcal{U}_{T\cup t}$. ◀

3.3 Proof of Theorem 29

Proof. By Proposition 27 we have $\mathcal{U}_I \cap \mathcal{U}_J = \mathcal{U}_{I\cup J}$ and by Equation (4) we have,

$$\cos(\mathcal{U}_I, \mathcal{U}_J) = \max\left\{\langle \boldsymbol{h}, \boldsymbol{g}\rangle_\pi : \|\boldsymbol{h}\|_\pi = \|\boldsymbol{g}\|_\pi = 1 \text{ and } \boldsymbol{g} \in \mathcal{U}_I \cap \mathcal{U}_{I\cup J}^\perp, \boldsymbol{h} \in \mathcal{U}_J \cap \mathcal{U}_{I\cup J}^\perp\right\}. \tag{20}$$

Now, let $\boldsymbol{h}$ and $\boldsymbol{g}$ be the optimizers of the formula in Equation (20). For convenience we introduce the functions $\boldsymbol{G} : X[[n]\setminus I] \to \mathbb{R}$ and $\boldsymbol{H} : X[[n]\setminus J] \to \mathbb{R}$ where,

$$\begin{aligned}\boldsymbol{h} &:= \sum_{\alpha \in X[[n]\setminus J]} \boldsymbol{H}(\alpha)\cdot \boldsymbol{u}_\alpha,\\ \boldsymbol{g} &:= \sum_{\bar{\alpha} \in X[[n]\setminus I]} \boldsymbol{G}(\bar{\alpha})\cdot \boldsymbol{u}_{\bar{\alpha}}.\end{aligned}$$

where the vectors $\boldsymbol{u}_\bullet$ are as defined in Proposition 22, i.e. $\boldsymbol{u}_\tau(\omega) = \mathbf{1}[\omega \supset \tau]$ for all $\tau \in X$. We observe that both $\boldsymbol{H}$ and $\boldsymbol{G}$ have the same norm as $\boldsymbol{h}$ and $\boldsymbol{g}$ respectively.

▷ Claim 32. We have,

$$\|\boldsymbol{H}\|_{\pi_{[n]\setminus J}} = \|\boldsymbol{G}\|_{\pi_{[n]\setminus I}} = 1.$$

Proof. Since the proofs are identical, we only prove the statement for $\boldsymbol{H}$. By the orthogonality of the collection $\boldsymbol{u}_\bullet$ we have,

$$\|\boldsymbol{h}\|_\pi^2 = \sum_{\alpha \in X[[n]\setminus J]} \boldsymbol{H}^2(\alpha)\cdot \|\boldsymbol{u}_\alpha\|_\pi^2.$$

[10] The line graph $L(G)$ of a simple graph G is the graph $L(G) = (E, E')$ where $ef \in E'$ if $|e\cap f| = 1$, i.e. there is an edge $ef \in E'$ for any pair of distinct edges sharing an end point.

Notice, for any $\alpha \in X[[n] \setminus J]$,

$$\|\boldsymbol{u}_\alpha\|_\pi^2 = \sum_{\substack{\beta \in X^{(n)}, \\ \beta \supset \alpha}} \pi(\beta) = \pi_{[n]\setminus J}(\alpha),$$

where we have used the definition of $\pi_{[n]\setminus J}$, i.e. Equation (5) for this equality.

In particular,

$$\|\boldsymbol{h}\|_\pi^2 = \sum_{\alpha \in X[[n]\setminus J]} \boldsymbol{H}(\alpha)^2 \cdot \pi_{[n]\setminus J}(\alpha) = \|\boldsymbol{H}\|_{\pi_{[n]\setminus J}}.$$

Since $\boldsymbol{h}$ is picked as an optimizer to Equation (20), we have $\|\boldsymbol{H}\|_{\pi_{[n]\setminus J}} = 1$. ◁

Then, note

$$\begin{aligned}\langle \boldsymbol{h}, \boldsymbol{g}\rangle_\pi &= \sum_{\alpha \in X[[n]\setminus J]} \sum_{\bar\alpha \in X[[n]\setminus I]} \boldsymbol{H}(\alpha)\boldsymbol{G}(\bar\alpha) \cdot \langle \boldsymbol{u}_\alpha, \boldsymbol{u}_{\bar\alpha}\rangle_\pi, \\ &= \sum_{\alpha \in X[[n]\setminus J]} \sum_{\bar\alpha \in X[[n]\setminus I]} \boldsymbol{H}(\alpha)\boldsymbol{G}(\bar\alpha) \cdot \pi_n(\alpha \wedge \bar\alpha).\end{aligned}$$

where we define $\alpha \wedge \bar\alpha$ as $\perp$[11] if there exists some $\ell \in [n] \setminus (I \cup J)$ such that $\alpha_\ell \neq (\bar\alpha)_\ell$ and otherwise we have,

$$(\alpha \wedge \bar\alpha)_i = \begin{cases} \alpha_i & \text{if } i \in I, \\ \bar\alpha_i & \text{if } i \in J, \\ \alpha_i = (\bar\alpha)_i & \text{if } i \in [n] \setminus (I \cup J) \end{cases}$$

In particular, since the $(\alpha, \bar\alpha)$-term is only non-$\perp$ when α and $\bar\alpha$ agree on the coordinates $[n]\setminus(I\cup J)$, we can localize this sum at the intersections $\tilde\alpha \in X[[n]\setminus(I\cup J)]$. In particular, writing $\boldsymbol{H}_{\tilde\alpha}(\alpha_I) = \boldsymbol{H}(\tilde\alpha \oplus \alpha_I)$ and $\boldsymbol{G}_{\tilde\alpha}(\alpha_J) = \boldsymbol{G}(\tilde\alpha \oplus \alpha_J)$ for $\alpha_I \in X_{\tilde\alpha}[I]$ and $\alpha_J \in X_{\tilde\alpha}[J]$, we have

$$\begin{aligned}\langle \boldsymbol{h}, \boldsymbol{g}\rangle_\pi &= \sum_{\alpha \in X[[n]\setminus J]} \sum_{\bar\alpha \in X[\tilde\alpha \in X[[n]\setminus I]]} \boldsymbol{H}(\alpha)\boldsymbol{G}(\bar\alpha) \cdot \pi_n(\alpha \wedge \bar\alpha), \\ &= \sum_{\tilde\alpha \in X[[n]\setminus(I\cup J)]} \left(\sum_{\alpha_I \in X_{\tilde\alpha}[I]} \sum_{\alpha_J \in X_{\tilde\alpha}[J]} \boldsymbol{H}_{\tilde\alpha}(\alpha_I)\boldsymbol{G}_{\tilde\alpha}(\alpha_J)\pi(\alpha_I \oplus \alpha_J \oplus \tilde\alpha) \right), \\ &=^{\blacklozenge} \sum_{\tilde\alpha \in X[[n]\setminus(I\cup J)]} \pi_{[n]\setminus(I\cup J)}(\tilde\alpha) \cdot \left(\sum_{\alpha_J \in X_{\tilde\alpha}[J]} \sum_{\alpha_I \in X_{\tilde\alpha}[I]} \boldsymbol{H}_{\tilde\alpha}(\alpha_I)\boldsymbol{G}_{\tilde\alpha}(\alpha_J) \cdot \pi^{(\tilde\alpha)}_{I\cup J}(\alpha_I \oplus \alpha_J). \right), \\ &= \mathop{\mathbb{E}}_{\tilde\alpha \sim \pi_{[n]\setminus(I\cup J)}} \left\langle \boldsymbol{H}_{\tilde\alpha}, \mathsf{C}_{\tilde\alpha}^{J\to I} \boldsymbol{G}_{\tilde\alpha} \right\rangle_{\pi_I^{\tilde\alpha}} \end{aligned} \tag{21}$$

where we have used Equation (7) to get the equality marked by ($\blacklozenge$). To conclude, we observe that both $\boldsymbol{G}_{\tilde\alpha}$ and $\boldsymbol{H}_{\tilde\alpha}$ are perpendicular to the constant functions.

▷ Claim 33. For all $\tilde\alpha \in X[[n] \setminus (I \cup J)]$ we have,

$$\langle \boldsymbol{H}_{\tilde\alpha}, \mathbf{1}\rangle_{\pi_I^{(\tilde\alpha)}} = \langle \boldsymbol{G}_{\tilde\alpha}, \mathbf{1}\rangle_{\pi_J^{(\tilde\alpha)}} = 0.$$

▷ Claim 34. For any $S, T \subset [n]$ with $S \cap T = \varnothing$ and $\boldsymbol{F} : X[S \cup T] \to \mathbb{R}$, we have

$$\|\boldsymbol{F}\|_{S\cup T}^2 = \mathop{\mathbb{E}}_{\alpha \sim \pi_T} \|\boldsymbol{F}_\alpha\|^2_{\pi_S^{(\alpha)}}.$$

[11] in particular, $\pi(\alpha \wedge \bar\alpha) = 0$

Thus, we can continue upper-bounding Equation (21) as follows,

$$\begin{aligned}\langle \boldsymbol{h}, \boldsymbol{g}\rangle_\pi &\le \mathop{\mathbb{E}}_{\tilde\alpha\sim\pi_{[n]\setminus(I\cup J)}}\left[\sigma_2\left(\mathsf{C}_{\tilde\alpha}^{J\to I}\right)\cdot\|\boldsymbol{H}_{\tilde\alpha}\|_{\pi_I^{(\tilde\alpha)}}\cdot\|\boldsymbol{G}_{\tilde\alpha}\|_{\pi_J^{(\tilde\alpha)}}\right],\\ &\le \mathop{\mathbb{E}}_{\tilde\alpha\sim\pi_{[n]\setminus(I\cup J)}}\left[\sigma_2\left(\mathsf{C}_{\tilde\alpha}^{J\to I}\right)\cdot\frac{\|\boldsymbol{H}_{\tilde\alpha}\|^2_{\pi_I^{(\tilde\alpha)}}+\|\boldsymbol{G}_{\tilde\alpha}\|^2_{\pi_I^{(\tilde\alpha)}}}{2}\right],\\ &\le \varepsilon^{J\to I}.\end{aligned}$$

We now present the proofs of Claim 33 and Claim 34.

Proof of Claim 33. Let $\tilde\alpha\in X[[n]\setminus(I\cup J)]$ be fixed. Since the proofs will be identical we will only prove the statement for $\boldsymbol{H}_{\tilde\alpha}$. Since $\boldsymbol{h}$ is picked as an optimizer to Equation (20), we have $\langle \boldsymbol{h}, \boldsymbol{u}_{\tilde\alpha}\rangle_\pi = 0$. We also have,

$$\langle \boldsymbol{u}_{\tilde\alpha}, \boldsymbol{h}\rangle_\pi = \sum_{\alpha\in X[[n]\setminus J]}\boldsymbol{H}(\alpha)\cdot\langle \boldsymbol{u}_{\tilde\alpha}, \boldsymbol{u}_\alpha\rangle_\pi = \sum_{\alpha\in X[[n]\setminus J]}\boldsymbol{H}(\alpha)\cdot\langle \mathbf{1}, \boldsymbol{u}_\alpha\rangle_\pi\cdot\mathbf{1}[\alpha\supset\tilde\alpha],$$

where we have used that $\mathrm{supp}(\boldsymbol{u}_\alpha)\subset\mathrm{supp}(\boldsymbol{u}_{\tilde\alpha})$ whenever $\tilde\alpha\subset\alpha$. Thus, using $\langle \mathbf{1}, \boldsymbol{u}_\alpha\rangle_\pi = \pi_{[n]\setminus J}(\alpha)$ we can simplify the above into

$$0 = \sum_{\substack{\alpha\in X[[n]\setminus J],\\ \alpha\supset\tilde\alpha}}\boldsymbol{H}(\alpha)\cdot\pi_{[n]\setminus J}(\alpha).$$

Every $\alpha\in X[[n]\setminus J]$ satisfying $\alpha\supset\tilde\alpha$ can be written as $\alpha=\tilde\alpha\oplus\alpha_I$ for a unique choice of $\alpha_I\in X_{\tilde\alpha}[I]$. Thus, using $\boldsymbol{H}(\tilde\alpha\oplus\alpha_I)=\boldsymbol{H}_{\tilde\alpha}(\alpha_I)$, we obtain

$$0 = \sum_{\alpha_I\in X_{\tilde\alpha}[I]}\boldsymbol{H}_{\tilde\alpha}(\alpha_I)\cdot\pi_{[n]\setminus J}(\tilde\alpha\oplus\alpha_I) = \pi_{[n]\setminus(I\cup J)}(\tilde\alpha)\cdot\sum_{\alpha_I\in X_{\tilde\alpha}[I]}\boldsymbol{H}_{\tilde\alpha}(\alpha_I)\cdot\pi_I^{(\tilde\alpha)}(\alpha_I),$$

where the last inequality is through Equation (7). The theorem then follows by noting that the term on the RHS is a multiple of $\langle \boldsymbol{H}_{\tilde\alpha}, \mathbf{1}\rangle_{\pi_I^{(\tilde\alpha)}}$. ◁

Proof Claim 34. We have,

$$\begin{aligned}\|\boldsymbol{F}\|^2_{\pi_{S\cup T}} &= \sum_{\alpha\in X[S\cup T]}\boldsymbol{F}(\alpha)^2\cdot\pi_{S\cup T}(\alpha),\\ &= \sum_{\alpha\in X[S\cup T]}\pi_S(\alpha_S)\pi_T^{(\alpha_S)}(\alpha_T)\boldsymbol{F}_{\alpha_S}(\alpha_T)^2,\\ &= \mathop{\mathbb{E}}_{\alpha_S\sim\pi_S}\|\boldsymbol{F}_{\alpha_S}\|^2_{\pi_T^{(\alpha_S)}}\end{aligned}$$

where we have used Equation (7) to obtain the second equality. ◁

An Elementary Proof of the First LP Bound on the Rate of Binary Codes

Nati Linial

Elyassaf Loyfer
School of Computer Science and Engineering, Hebrew University, Jerusalem, Israel

Abstract

The asymptotic rate vs. distance problem is a long-standing fundamental problem in coding theory. The best upper bound to date was given in 1977, and has since received numerous proofs and interpretations. Here we provide a new, elementary proof of this bound that is based on counting walks in the Hamming cube.

1 Introduction

A binary code of length n is a subset $C \subset \mathbb{F}_2^n$. Its distance is the smallest Hamming distance among all pairs of code words, $\mathrm{dist}(C) := \min_{x \neq y \in C} |x + y|$. A fundamental problem in coding theory is to find the largest possible size, $A(n, d)$, of a code of length n and distance d:

$$A(n, d) := \max\{|C| : C \subset \mathbb{F}_2^n,\ \mathrm{dist}(C) \geq d\}$$

The asymptotic version of this question, the *rate vs. distance problem*, seeks the largest possible rate $R(C) := n^{-1} \log_2(|C|)$, where the distance is linear in n:

$$\mathcal{R}(\delta) := \limsup_{n \to \infty} \{R(C) \colon C \subset \mathbb{F}_2^n,\ \mathrm{dist}(C) \geq \lfloor \delta n \rfloor\}$$

It is known that $\mathcal{R}(0) = 1$, and $\mathcal{R}(\delta) = 0$ for all $\delta \geq 1/2$. The exact value of $\mathcal{R}(\delta)$ remains unknown for all $\delta \in (0, 1/2)$.

The best and only lower bound, $\mathcal{R}(\delta) \geq 1 - H(\delta)$, is due to Gilbert [7] and Varshamov [13]. Here and throughout, $H(\cdot)$ is the binary entropy function.

The best upper bound that we have on $\mathcal{R}(\delta)$ for a large range of δ is the *first linear programming (LP) bound*.[1] Due to McEliece, Rodemich, Rumsey and Welch (MRRW, [9]), this bound states that:

[1] MRRW [9] also proved a second LP bound which improves upon the first for $\delta \in (0, 0.273)$. Because this paper focuses exclusively on the first LP bound, we omit the statement of the second.

▶ **Theorem 1** (The first LP bound [9]). *$\mathcal{R}(\delta) \le H(1/2 - \sqrt{\delta(1-\delta)})$ for every $0 \le \delta \le 1/2$.*

These bounds are based on a linear program due to Delsarte [4], the optimum of which is an upper bound on $A(n,d)$. Although this maximum is still unknown, upper bounds on $A(n,d)$ can be derived by passing to the LP dual and constructing a dual feasible solution.

Numerous works have constructed dual feasible solutions [9, 6, 10, 11, 12, 2, 1], yet all lead to the same asymptotic bound. Interestingly, we observe that not only do all these works reach the same bound, but also construct the same dual feasible solution. They differ, however, in proof techniques, and introduce new insight or generalizations to other metric spaces.

Can we achieve a better bound by designing a different solution? This question motivated the current work. It led us to identify the common pattern underlying previous approaches and develop a slightly more general template for dual solutions. Based on this template, we build a new family of solutions which, while different from previous constructions, yields the same asymptotic upper bound stated in Theorem 1.

Although our new construction does not improve upon Theorem 1, it offers potential insights into the nature of the bound. First, exploring alternate constructions may either lead to improved solutions or clarify the inherent limitations of the Delsarte–MRRW framework. Furthermore, while recent LP/SDP hierarchies offer stronger relaxations to the rate-distance problem ([3, 8]), they have struggled to yield concrete bounds due to their complexity. By constructing an explicit dual solution that relies on different machinery than its predecessors, our walk-based combinatorial approach may prove more adaptable to these advanced hierarchies. Second, our proof technique establishes a connection between bounds on binary codes and small sets with large expansion properties, which can possibly lead to mutual benefits. Third, the main part of our proof is a simple counting argument, which allows for a complete and transparent exposition of the bound, with no technical details omitted. Nonetheless, the proof necessarily includes a non-elementary component common to all previous approaches, detailed in Section 3.

Organization of the paper: Section 2 introduces notation, provides necessary background in Fourier analysis, and recalls Delsarte's LP for binary codes. In Section 3, we introduce the general template for dual feasible solutions and demonstrate how previous works can be seen as implementations of this template. In Section 4, we construct the new solutions. In Appendix A, we state and prove some standard results for completeness.

2 Preliminaries

The Hamming cube. As usual, the Hamming cube is the graph whose vertex set is $\mathbb{F}_2^n$, where adjacency means having Hamming distance one. We denote the adjacency matrix of the cube by $A_H \in \{0,1\}^{\mathbb{F}_2^n \times \mathbb{F}_2^n}$. The j-th *level* of the cube, for $0 \le j \le n$, is the set of vertices of Hamming weight j. We denote by $L_j \colon \mathbb{F}_2^n \to \{0,1\}$ the indicator of the j-th level.

Binary codes. A binary code is a subset $C \subset \mathbb{F}_2^n$. The minimal distance of a code, denoted $\mathrm{dist}(C)$, is determined by the minimum Hamming distance between distinct codewords:

$$\mathrm{dist}(C) \coloneqq \min\{|x-y| \colon x,y \in C \wedge x \neq y\}$$

Analysis of Boolean functions. Let $f, g : \mathbb{F}_2^n \to \mathbb{R}$ be real functions on the cube. We define their inner product w.r.t. the uniform measure,

$$\langle f, g \rangle := 2^{-n} \sum_{x \in \mathbb{F}_2^n} f(x)g(x)$$

Convolution between f and g is defined by

$$(f * g)(x) := 2^{-n} \sum_{y \in \mathbb{F}_2^n} f(y)g(x+y)$$

To every $x \in \mathbb{F}_2^n$ there corresponds a *Fourier character* $\chi_x : \mathbb{F}_2^n \to \mathbb{R}$ that is defined via $\chi_x(y) = (-1)^{\langle x,y \rangle}$. The set of characters $\{\chi_x\}_{x \in \mathbb{F}_2^n}$ forms an orthonormal basis of the space of real functions on the Hamming cube. The Fourier transform of f is denoted $\mathcal{F}[f]$ or $\widehat{f}$ in short, and defined by

$$\widehat{f}(x) := \langle \chi_x, f \rangle = 2^{-n} \sum_{y \in \mathbb{F}_2^n} (-1)^{\langle x,y \rangle} f(y)$$

In Fourier space, operators are defined with normalization factor of 1, and we denote them explicitly with a subscript $\mathcal{F}$, e.g.

$$\langle \widehat{f}, \widehat{g} \rangle_{\mathcal{F}} = \sum_{x \in \mathbb{F}_2^n} \widehat{f}(x) \cdot \widehat{g}(x)$$
$$(\widehat{f} *_{\mathcal{F}} \widehat{g})(x) = \sum_{y \in \mathbb{F}_2^n} \widehat{f}(y)\widehat{g}(y+x)$$

The Fourier transform is its own inverse, up to normalization:

$$f(x) = \mathcal{F}^{-1}[\widehat{f}](x) = \langle \chi_x, \widehat{f} \rangle_{\mathcal{F}} = \sum_{y \in \mathbb{F}_2^n} \chi_x(y)\widehat{f}(y)$$

Parseval's theorem states that $\langle f, g \rangle = \langle \widehat{f}, \widehat{g} \rangle_{\mathcal{F}}$.
The convolution theorem states that $\widehat{f * g} = \widehat{f} \cdot \widehat{g}$.

Krawtchouk polynomials. The Krawtchouk polynomials $\{K_0, \ldots, K_n\}$ are a family of polynomials orthogonal with respect to the binomial probability measure,

$$\sum_{i=0}^{n} 2^{-n} \binom{n}{i} K_j(i)K_k(i) = \begin{cases} \binom{n}{j} & j = k \\ 0 & \text{otherwise} \end{cases}$$

The j-th Krawtchouk can be defined by the sum

$$K_j(t) = \sum_{k=0}^{n} (-1)^k \binom{t}{k} \binom{n-t}{j-k}, \qquad t \in \mathbb{R}$$

In particular, $K_0(t) = 1$ and $K_1(t) = n - 2t$.

2.1 Delsarte's LP

Here we recall Delsarte's LP for binary codes. Although we only require the dual LP, we start with the primal as it better suits the exposition. In his original work [4], Delsarte formulated the LP via association schemes, which readily generalizes to other spaces, e.g. fixed-weight codes or spherical codes. For binary codes with the Hamming distance, the LP can be developed completely through Fourier analysis, as we choose to do here.

Delsarte's LP for binary codes can be stated as follows. Inequalities on functions are defined pointwise.

$$\begin{aligned} \max \quad & \sum_{x \in \mathbb{F}_2^n} f(x) \\ \text{s.t.} \quad & f \colon \mathbb{F}_2^n \to \mathbb{R} \\ & f(0) = 1 && \text{(normalization)} \\ & f \geq 0 && \text{(non-negativity)} \\ & \widehat{f} \geq 0 && \text{(Fourier)} \\ & f(x) = 0 \text{ if } 1 \leq |x| \leq d-1 && \text{(distance)} \end{aligned} \tag{1}$$

▶ **Proposition 2.** *The optimum of Delsarte's LP is an upper bound to $A(n,d)$.*

Proof. The proof is by constructing a feasible solution to (1) whose value is $A(n,d)$. Consider a binary code $C \subset \mathbb{F}_2^n$ of length n, minimal distance $\operatorname{dist}(C) \geq d$, and maximum cardinality, $|C| = A(n,d)$. Let $\mathbb{1}_C : \mathbb{F}_2^n \to \mathbb{R}$ be its indicator function, and let $f_C \coloneqq \frac{2^n}{|C|} \mathbb{1}_C * \mathbb{1}_C$. It is not hard to verify that f_C satisfies the normalization and non-negativity constraints. The Fourier constraints are a consequence of the convolution theorem, as $\mathcal{F}[\mathbb{1}_C * \mathbb{1}_C] = \widehat{\mathbb{1}}_C^2 \geq 0$. The distance constraints follow from the distance property of the code, $\operatorname{dist}(C) \geq d$. Finally, the value of this solution is $\sum_{x \in \mathbb{F}_2^n} f_C(x) = |C|$ which is by assumption $A(n,d)$. ◀

Passing to the LP dual,

$$\begin{aligned} \text{min.} \quad & g(0)/\widehat{g}(0) \\ \text{s.t.} \quad & g \colon \mathbb{F}_2^n \to \mathbb{R} \\ & \widehat{g}(0) > 0 && \text{(normalization)} \\ & \widehat{g} \geq 0 && \text{(Fourier)} \\ & g(x) \leq 0 \text{ if } |x| \geq d && \text{(distance)} \end{aligned} \tag{2}$$

Note that to turn the minimization problem (2) into an honest LP we can just require that $\widehat{g}(0) = 1$.

The dual can be derived by standard LP methods. For completeness we include a proof of weak duality.

▶ **Proposition 3.** *If $g : \mathbb{F}_2^n \to \mathbb{R}$ is feasible for (2), then*

$$A(n,d) \leq g(0)/\widehat{g}(0) \tag{3}$$

Proof. Let $g \colon \mathbb{F}_2^n \to \mathbb{R}$ be feasible as in the proposition's statement, and let $f \colon \mathbb{F}_2^n \to \mathbb{R}$ be an optimal solution to (1). By Proposition 2,

$$\widehat{g}(0) \cdot A(n,d) \leq \widehat{g}(0) \cdot \sum_x f(x) = 2^n \widehat{g}(0) \cdot \widehat{f}(0)$$

Since both $\widehat{f}$ and $\widehat{g}$ are non-negative,

$$\widehat{g}(0) \cdot \widehat{f}(0) \leq \sum_{x \in \mathbb{F}_2^n} \widehat{g}(x) \cdot \widehat{f}(x) = \langle \widehat{g}, \widehat{f} \rangle_{\mathcal{F}}$$

Using Parseval's inequality, we have

$$\langle \widehat{g}, \widehat{f} \rangle_{\mathcal{F}} = \langle g, f \rangle = 2^{-n} \sum_x f(x)g(x)$$

If $1 \leq |x| \leq d-1$ then $f(x) = 0$. If $|x| \geq d$ then $f(x) \geq 0$ while $g(x) \leq 0$. Hence,

$$2^{-n} \sum_x f(x)g(x) \leq 2^{-n} f(0)g(0)$$

Recalling that $f(0) = 1$ and $\widehat{g}(0) > 0$, we conclude that $A(n,d) \leq g(0)/\widehat{g}(0)$. ◀

3 A recipe for dual solutions

We next describe a general framework that yields feasible solutions to (2). The idea is to decouple the two families of constraints: first handle the distance constraints and then the Fourier constraints. We then demonstrate how previous works fit into this framework by implementing a dual solution similar to [9, 6, 10, 11, 12, 2, 1]. Finally, we remark shortly on the proof techniques used in prior works.

▶ **Proposition 4.** *Let $\phi, \Gamma : \mathbb{F}_2^n \to \mathbb{R}$ such that*

1. *$\phi(0) > 0$ and $\phi(x) \leq 0$ whenever $|x| \geq d$,*
2. *The nonzero function Γ satisfies*

$$\widehat{\Gamma} \geq 0, \ \widehat{\phi} *_{\mathcal{F}} \widehat{\Gamma} \geq \widehat{\Gamma}$$

Take $g := \phi \cdot \Gamma^2$. Then, g is feasible for (2), and

$$g(0)/\widehat{g}(0) \leq \phi(0) \cdot |\mathrm{supp}(\widehat{\Gamma})|$$

where $\mathrm{supp}(\widehat{\Gamma})$ is the support of $\widehat{\Gamma}$.

Combined with Proposition 3, Proposition 4 gives an upper bound to $A(n,d)$ in terms of $\phi(0)$ and the support size of $\widehat{\Gamma}$.

Note that this method involves only $\widehat{\Gamma}$ with no direct reference to Γ.

Proof. Let ϕ, Γ and g as above. Indeed, such g is non-positive on levels $d, d+1, \ldots, n$ of the cube, and, by the convolution theorem, $\widehat{g} \geq \widehat{\Gamma} *_{\mathcal{F}} \widehat{\Gamma} \geq 0$. In particular, $\widehat{g}(0) \geq \|\widehat{\Gamma}\|_2^2 > 0$. Hence, g is feasible for (2).

In spirit of [10], we derive an upper bound on $A(n,d)$ in terms of the support size of $\widehat{\Gamma}$. Start with an upper bound on $g(0)$:

$$g(0) = \phi(0) \cdot \Gamma^2(0) = \phi(0) \cdot \left(\sum_{x \in \mathbb{F}_2^n} \widehat{\Gamma}(x) \right)^2$$

Let $S \subset \mathbb{F}_2^n$ be the support of $\widehat{\Gamma}$ and let $\mathbb{1}_S$ be its indicator. Then $\sum_{x \in \mathbb{F}_2^n} \widehat{\Gamma}(x) = \langle \widehat{\Gamma}, \mathbb{1}_S \rangle_{\mathcal{F}}$. By Cauchy-Schwarz,

$$\langle \widehat{\Gamma}, \mathbb{1}_S \rangle_{\mathcal{F}} \leq \left(\langle \widehat{\Gamma}, \widehat{\Gamma} \rangle_{\mathcal{F}} \cdot \langle \mathbb{1}_S, \mathbb{1}_S \rangle_{\mathcal{F}} \right)^{1/2} = \left(\langle \widehat{\Gamma}, \widehat{\Gamma} \rangle_{\mathcal{F}} \cdot |\mathrm{supp}(\widehat{\Gamma})| \right)^{1/2}$$

On the other hand,

$$\widehat{g}(0) \geq (\widehat{\Gamma} *_{\mathcal{F}} \widehat{\Gamma})(0) = \sum_{x \in \mathbb{F}_2^n} \widehat{\Gamma}^2(x) = \langle \widehat{\Gamma}, \widehat{\Gamma} \rangle_{\mathcal{F}}$$

Dividing $g(0)/\widehat{g}(0)$, we get the desired result. ◀

3.1 The MRRW solution

The MRRW construction, and subsequent works, can be described by choosing

- $\phi(x) = 2(d - |x|)$, and
- $\widehat{\Gamma} = f_r$, where f_r is the principal eigenfunction of the adjacency matrix $A_{B(r)}$ of the Hamming ball with radius $r = n/2 - \sqrt{d(n-d)}$ (a more detailed definition is given below).

We turn to give the details in a language close to that of [10]. At the end of this section we remark on the different techniques used by previous authors to obtain this solution.

Let $\phi(x) = 2(d - |x|)$. It can be expressed with Krawtchouk polynomials,

$$\phi(x) = 2(d - |x|) = (n - 2|x|) - (n - 2d) = K_1(|x|) - K_1(d)$$

The Fourier transform of the linear Krawtchouk K_1 is the level-1 indicator L_1, (Proposition 8),

$$\widehat{K_1}(|x|) = L_1(x) = \begin{cases} 1 & |x| = 1 \\ 0 & \text{otherwise} \end{cases}$$

By the convolution theorem,

$$\widehat{\phi \cdot \Gamma}(x) = \widehat{\phi} *_{\mathcal{F}} \widehat{\Gamma} = L_1 *_{\mathcal{F}} \widehat{\Gamma} - K_1(d) \cdot \widehat{\Gamma}$$

The operator "$L_1 *_{\mathcal{F}}$" has a nice interpretation: it is equivalent to multiplication by the adjacency matrix A_H of the Hamming cube (see Proposition 9). The conditions on Γ from Proposition 4 can be expressed as

$$\begin{aligned} &\text{minimize} && |\mathrm{supp}(\widehat{\Gamma})| \\ &\text{s.t.} && \Gamma \neq 0, \quad \widehat{\Gamma} \geq 0, \quad A_H \widehat{\Gamma} \geq (1 + K_1(d)) \cdot \widehat{\Gamma} \end{aligned} \tag{4}$$

The problem is now reduced to finding an approximate eigenfunction of A_H with eigenvalue at least $n - 2d + 1$ and small support. The best known choice is to take $\widehat{\Gamma}$ as the principal eigenfunction of the adjacency matrix restricted to the Hamming ball of radius r.

Let $A_{B(r)} \in \{0,1\}^{\mathbb{F}_2^n \times \mathbb{F}_2^n}$ be the adjacency matrix of the Hamming ball of radius $0 \leq r \leq n$,

$$A_{B(r)}(x,y) = \begin{cases} 1 & |x|, |y| \leq r \wedge |x + y| = 1 \\ 0 & \text{otherwise} \end{cases}$$

We now state facts regarding the operator $A_{B(r)}$, without proof. These facts are compiled from [9, 6, 10, 11, 12, 2, 1], where proofs can be found. The largest eigenvalue of $A_{B(r)}$ is equal to the first root of the r-th Krawtchouk polynomial, and its value is $2\sqrt{r(n-r)} + o(n)$. Let f_r be the corresponding eigenfunction. Then f_r is non-negative and supported on $B(r)$, thus its support size is at most $\sum_{j=0}^{r} \binom{n}{r} = 2^{nH(r/n)+o(n)}$.

Choose $\widehat{\Gamma} = f_r$, for some r to be determined later. Since A_H has only non-negative entries, $A_H f_r \geq 2\sqrt{r(n-r)} \cdot f_r$, element-wise. Consequently, the choice $\widehat{\Gamma} = f_r$ satisfies (4) if

$$2\sqrt{r(n-r)} \geq n - 2d + 1 \tag{5}$$

hence

$$A(n,d) \leq \phi(0) \cdot |\mathrm{supp}(f_r)| \leq 2^{nH(r/n)+o(n)}$$

The first LP bound, Theorem 1, is obtained by optimizing r.

In [9], f_r is obtained using Christoffel-Darboux formula. The problem (4) is equivalent to the Faber-Krahn maximizer in [6]. In [10], f_r is obtained directly by solving a recurrence relation. In [2, 1], a function close to f_r is found by spectral and functional tools. In [5], they use the Rayleigh quotient to prove existence of a feasible solution to (4) supported on levels $[r - \sqrt{n}, r]$ of the Boolean hypercube, for r satisfying (5).

4 A new family of solutions to Delsarte's dual LP

In this section we present our proof, which is cast in the pattern described in the previous section.

The main idea is as follows. By choosing a slightly more involved ϕ than in prior work, we can dramatically simplify $\widehat{\Gamma}$, reducing it to the indicator of a set. The sets of interest are small, and have the property that a random walk, started inside the set, has a high probability of returning to it. This is captured in Proposition 5. The symmetry of the Hamming cube suggests the level sets as natural candidates for such subsets. In Proposition 6 we count the walks between levels of the cube. Finally, we derive the first LP bound (Theorem 1) from Proposition 5 and Proposition 6.

A walk of length m on the cube is a sequence of vertices $(x_1, x_2, \ldots, x_m) \in (\mathbb{F}_2^n)^m$, where every two consecutive vertices are neighbors, $|x_i + x_{i+1}| = 1$, for $i = 1, \ldots, m-1$.

▶ **Proposition 5.** *Let $n, d \in \mathbb{N}$ such that $d \leq n/2$. Let $m \in \mathbb{N}$ and let $S \subset \mathbb{F}_2^n$ be a set of vertices such that for any $x \in S$, the number of length-m walks starting at x and ending in S is at least $(n-2d)^m + 1$. Then,*

$$A(n,d) \leq n^m \cdot |S|$$

Proof. We choose ϕ and Γ to satisfy Proposition 4 and derive the bound. Define

$$\phi_m(x) = (n - 2|x|)^m - (n-2d)^m$$

and let $\widehat{\Gamma} = \mathbb{1}_S$, the indicator function of the set S. Observe that

1. $\phi_m(0) > 0$ and $\phi_m(x) \leq 0$ for $|x| \geq d$.
2. $\widehat{\Gamma} \neq 0$, $\widehat{\Gamma} \geq 0$.

It remains to show that $\widehat{\phi}_m *_{\mathcal{F}} \widehat{\Gamma} \geq \widehat{\Gamma}$. The Fourier transform of $(n-2|x|)^m = K_1^m(x)$ is the m-wise convolution of L_1, the level-1 indictor (see Proposition 8),

$$\mathcal{F}[K_1^m] = \widehat{K}_1 *_{\mathcal{F}} \ldots *_{\mathcal{F}} \widehat{K}_1 = L_1 *_{\mathcal{F}} \ldots *_{\mathcal{F}} L_1$$

Convolution with the level-1 indictor is equivalent to multiplying by the adjacency matrix of the Hamming cube A_H (see Proposition 9). Namely,

$$\widehat{\phi}_m *_{\mathcal{F}} \widehat{\Gamma} = A_H^m \cdot \widehat{\Gamma} - (n-2d)^m \widehat{\Gamma}$$

Hence the remaining condition $\widehat{\phi}_m *_{\mathcal{F}} \widehat{\Gamma} \geq \widehat{\Gamma}$ is equivalent to

$$(A_H^m \cdot \mathbb{1}_S)(x) \geq ((n-2d)^m + 1)\mathbb{1}_S(x) \qquad \forall x \in \mathbb{F}_2^n \tag{6}$$

Let $x \in \mathbb{F}_2^n$. The left-hand side counts walks that start at x and end in S,

$$(A_H^m \mathbb{1}_S)(x) = \sum_{y \in \mathbb{F}_2^n} A_H^m(x,y)\mathbb{1}_S(y) = \sum_{y \in S} A_H^m(x,y)$$

the last expression sums the number of length-m paths between x and y, for every $y \in S$.

If $x \notin S$, then the left-hand side of (6) is non-negative while the right-hand side is 0. If $x \in S$, the number of walks from x to S exceeds $((n-2d)^m+1)$, by assumption. Hence (6) holds for every $x \in \mathbb{F}_2^n$, and ϕ_m, Γ satisfy Proposition 4.

Finally, $\phi_m(0) = n^m - (n-2d)^m \leq n^m$, and the support size of $\mathbb{1}_S$ is $|S|$. By Proposition 4, $A(n,d) \leq n^m \cdot |S|$. ◀

▶ **Proposition 6.** *Let $j, r, m \in \mathbb{N}$ such that $m = o(\sqrt{r})$ and $r \leq n/2$. Let $P_{r,m,j}$ be the number of walks that start at some vertex x in level r and end at any vertex in level j. Then,*

1. *If $m + r + j = 1 \pmod 2$ or $m < |r - j|$ then $P_{r,m,j} = 0$.*
2. *Otherwise,*

$$P_{r,m,j} = \binom{m}{(m-r+j)/2}(n-r)^{(m+r-j)/2} r^{(m-r+j)/2}(1+O(m/r))^m$$

Proof. A vertex in level k has $n-k$ neighbors in level $k+1$, and k neighbors at level $k-1$. The walk takes m steps and thus contained in levels $r-m, \ldots, r+m$, so from every vertex encountered during the walk there are $n - r + O(m)$ ways to go up one level and $r + O(m)$ ways to go down one level.

If the walk terminates at level j, it takes in total $(m+r-j)/2$ steps up and $(m-r+j)/2$ steps down. There are $\binom{m}{(m-r+j)/2}$ ways to choose the order of the up/down steps, $n-r+O(m)$ options for each "up" step and $r + O(m)$ options for each "down" step, so in total

$$\binom{m}{(m-r+j)/2}(n-r+O(m))^{(m+r-j)/2}(r+O(m))^{(m-r+j)/2}$$ ◀

▶ **Corollary 7.** *Let $1 \leq d \leq n/2$ be integers. Then $A(n,d) \leq 2^{nH(1/2-\sqrt{d/n(1-d/n)})+o(n)}$.*

Proof. Let m be odd, $m = \omega_n(1)$ and $m = o(\sqrt{n})$. Let $r = n/2 - \sqrt{d(n-d)}$ and let $S = \{r-1 \leq |x| \leq r\}$. It suffices to show that S has sufficiently many returning walks. Let $x \in S$. If $|x| = r$, by Proposition 6, the number of length-m walks from x to level r is 0, and to level $r-1$ it is

$$P_{r,m,r-1} = \binom{m}{(m-1)/2}\sqrt{((n-r)r)^m \frac{n-r}{r}}(1+O(m/r))^m$$

Using the well known approximation for binomial coefficients, $\binom{n}{k} = 2^{nH(k/n)-O(\log n)}$, we obtain

$$((A_H^m \mathbb{1}_S)(x))^{1/m} \geq 2\sqrt{r(n-r)} + O(m)$$

By our choice of r, this is greater than $((n-2d)^m+1)^{1/m}$. The proof for $x \in S$ with $|x| = r-1$ is similar. ◀

Theorem 1 follows directly from the above corollary.

A Supplementary proofs

▶ **Proposition 8.** *Let K_j be the j-th Krawtchouk polynomial,*

$$K_j(t) = \sum_{k=0}^{n} (-1)^k \binom{t}{k}\binom{n-t}{j-k}$$

and let $L_j(x) = \mathbb{1}_{|x|=j}$ be the indicator function of the j-level of the Hamming cube. Then,

$$\widehat{K_j} = L_j$$

Proof. It is easier to apply the Fourier transform to L_j, and recall that Fourier transform is its own inverse up to normalization, $\mathcal{F}^{-1}[\mathcal{F}[f]] = 2^n \mathcal{F}[\mathcal{F}[f]] = f$, for every $f\colon \mathbb{F}_2^n \to \mathbb{R}$.

Indeed, let $x \in \mathbb{F}_2^n$ with $|x| = t$. Then,

$$2^n \widehat{L}_j(x) = \sum_{y\in\mathbb{F}_2^n} L_j(y)\chi_x(y) = \sum_{|y|=j} (-1)^{\langle x,y\rangle}$$

where $\langle x, y\rangle = \sum_{i=1}^n x_i y_i$. We group elements by the value of $\langle x, y\rangle$:

$$\sum_{|y|=j} (-1)^{\langle x,y\rangle} = \sum_{k=0}^{n} \sum_{\substack{y\in\mathbb{F}_2^n:\\ |y|=j\\ \langle y,x\rangle=k}} (-1)^k$$

The term $(-1)^k$ does not depend on y anymore, so it remains to count $|\{y \in \mathbb{F}_2^n \colon |y| = j \langle y, x\rangle = k\}|$. If $\langle x, y\rangle = k$, there are $\binom{|x|}{k} = \binom{t}{k}$ options to choose the bits of y that intersect with x, and $\binom{n-|x|}{|y|-k} = \binom{n-t}{j-k}$ options to choose the bits of y outside the support of x. Hence

$$2^n \widehat{L}_j(x) = \sum_{k=0}^{n} (-1)^k \binom{t}{k} \binom{n-t}{j-k}$$ ◀

▶ **Proposition 9.** *Let $f \colon \mathbb{F}_2^n \to \mathbb{R}$, then $\widehat{K_1} *_{\mathcal{F}} f = A_H \cdot f$, where A_H is the adjacency matrix of the Hamming cube.*

Proof. By Proposition 8, $\widehat{K}_1 *_{\mathcal{F}} f = L_1 *_{\mathcal{F}} f$. By definition,

$$(\widehat{K}_1 *_{\mathcal{F}} f)(x) = (L_1 *_{\mathcal{F}} f)(x) = \sum_{y \in \mathbb{F}_2^n} L_1(x+y) f(y) = \sum_{y \in \mathbb{F}_2^n \colon |x+y|=1} f(y)$$

The condition $|x + y| = 1$ is the adjacency condition between vertices x, y in the Hamming cube, hence the last sum is equal $(A_H f)(x)$. ◀

Ultra-Sparse Expanders and the Free Method

Abstract

In this paper we ask how much expansion one can retain with almost no edges beyond connectivity. Concretely, for graphs of average degree $2+\varepsilon$, what is the "Ramanujan bound" – how does spectral expansion scale with ε? We compare five ultra–sparse graph models – including the configuration model, subdivision of regular expanders, and the union of a cycle with a partial matching – and analyze each under the normalized or unnormalized notions of expansion. In the normalized setting, we prove bounds that are essentially optimal, determining the correct asymptotic dependence on ε. Our results extend to expansion in general irregular graphs.

For some models we prove rigorous bounds – primarily via finite free probability – while others remain beyond our current techniques. To bridge this gap, we introduce the *Free Method*, which produces quantitative predictions without proving existence – analogous to the probabilistic method, which certifies existence without providing an explicit construction. These predictions align with experiments. We expect the free method to be useful more broadly in graph-theoretic settings.

1 Introduction

Expanders are sparse, highly connected graphs whose expansion allows them, up to some error, to behave like complete graphs at far lower cost. They have been studied for decades, with constructions ranging from combinatorial [31, 5, 4] and group-theoretic [20, 25] to analytic [22]. Their applications include coding theory [33, 2, 36], computational complexity [17, 13, 30], and more. For background, see [16], Chapter 4 of [37], or [35].

We study the optimal expansion when the edge budget is barely above connectivity. Specifically, for graphs of average degree $2+\varepsilon$, what is the "Ramanujan bound" – how does spectral expansion depend on ε? Such *ultra-sparse* graphs are necessarily irregular, as are many graphs arising in applications, including sparse codes [21, 32]. We therefore consider both normalized and unnormalized (adjacency-based) expansion.

Let G be an undirected graph on n vertices with adjacency matrix A and eigenvalues $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$. We call λ_2 the *one-sided spectral expansion*, $\lambda_1 - \lambda_2$ the *one-sided spectral gap*, and $\lambda \stackrel{\triangle}{=} \max\{|\lambda_2|, |\lambda_n|\}$ the (two-sided) *spectral expansion*. In the normalized setting, let D be the diagonal degree matrix and $W \stackrel{\triangle}{=} AD^{-1}$ the random walk matrix, with eigenvalues $1 = \omega_1 \geq \omega_2 \geq \cdots \geq \omega_n$. Here ω_2 is the *one-sided normalized spectral expansion*, $1-\omega_2$ the corresponding gap, and $\omega \stackrel{\triangle}{=} \max\{|\omega_2|, |\omega_n|\}$ the (two-sided) *normalized spectral expansion*.

A connected 2-regular graph is a cycle, whose spectral gap vanishes with its size. By contrast, 3-regular graphs can attain normalized spectral expansion $\frac{\sqrt{8}}{3}$, bounded away from 1. More generally, the optimal asymptotic value for d-regular graphs is $\frac{2\sqrt{d-1}}{d}$ [28], attained by Ramanujan graphs. Thus, greater degree buys better expansion.

1.1 Ultra-sparse expanders

Since the main utility of expanders is normalized spectral expansion bounded away from 1, we ask how sparse a graph can be while retaining this property, even beyond the regular-graph barrier $\frac{\sqrt{8}}{3} \approx 0.94$. Our goal is to characterize the sparsity–expansion tradeoff in this regime.

Any connected n-vertex graph has average degree at least $2 - \frac{2}{n}$, so we focus on average degree $2+\varepsilon$, where $\varepsilon > 0$ controls the sparsity. We seek the corresponding Ramanujan bound as a function of ε.

To keep degree variance small, we mainly study graphs with degrees in $\{2, 3\}$. High-degree vertices may impose disproportionate load, so we exclude hub-and-spoke examples such as the wheel graph, even though they can be more amortization-efficient. Our methods extend to broader degree distributions. In the normalized setting we obtain essentially optimal bounds, while the unnormalized setting remains more open.

For irregular graphs, normalized and unnormalized expansion capture different phenomena. The normalized spectrum governs random walks, while the unnormalized spectrum is better suited to edge expansion and expander-mixing-type bounds, with different treatments of degree heterogeneity; see [1]. Although less studied for irregular graphs, the unnormalized spectrum remains informative when the degree variance is small, as in the $\{2, 3\}$ regime.

There are two main frameworks for constructing Ramanujan graphs. The first uses highly symmetric Cayley graphs of carefully chosen non-abelian groups, beginning with Lubotzky, Phillips, and Sarnak [20] and Margulis [25]. The second, initiated by Marcus, Spielman, and Srivastava, is analytic and draws on free probability [22, 23, 24]; Cohen later made this approach explicit [11].

The group-theoretic framework appears poorly suited to ultra-sparse graphs because Cayley graphs are regular. Irregular group-based constructions, for example via Schreier graphs, remain an interesting direction.

The MSS framework studies unions of d suitably uncorrelated perfect matchings and targets one-sided expansion. Although it does not directly match our setting, it is our main point of departure.

1.2 Five models of ultra-sparse graphs

The MSS approach studies a graph distribution and proves that some graph in its support is Ramanujan. For d-regular graphs, the distribution is the union of d perfect matchings. We ask which analogous models are natural in the ultra-sparse regime, and consider five.

Two-and-a-fraction matchings

Our first model is the union of two perfect matchings and an ε-matching, denoted $\mathcal{M}+\mathcal{M}+\varepsilon\mathcal{M}$ or $(2+\varepsilon)\mathcal{M}$. The partial matching covers an ε-fraction of the vertices. At $\varepsilon = 0$ and $\varepsilon = 1$, this recovers the MSS models for 2- and 3-regular graphs.

Three equally sized partial matchings

Alternatively, take three β-matchings with $\beta = \frac{2+\varepsilon}{3}$, denoted $3\left(\frac{2+\varepsilon}{3}\mathcal{M}\right)$. This model has a basic connectivity drawback: for small ε, the expected fraction of isolated vertices is $\left(\frac{1-\varepsilon}{3}\right)^3 \approx \frac{1}{27}$. We nevertheless study it to compare the models rather than select a single "best" one.

Cycle plus partial matching

To guarantee connectivity, we also study the union of a spanning cycle and an ε-partial matching, denoted $\mathcal{C} + \varepsilon\mathcal{M}$. Unlike $(2+\varepsilon)\mathcal{M}$, this model is connected before the partial matching is added.

A related explicit 3-regular construction [19] joins each field element x to $x+1$, $x-1$, and x^{-1}, forming a cycle plus a matching. A similar model was recently studied from a property-testing perspective [14].

The configuration model

Here each vertex v contributes d_v half-edges, and a uniformly chosen perfect matching on all half-edges determines the graph. In our ultra-sparse setting, $d_v \in \{2, 3\}$.

The configuration model is standard in spectral random graph theory [6] and in the analysis of graph operators such as the zig-zag product [31, 9]. Unlike a union of perfect matchings, it naturally supports varying degrees. Our analysis also gives another proof of the MSS result in the regular case.

Subdividing 3-regular graphs

Finally, start from a 3-regular Ramanujan graph, or more generally a d-regular one, and replace every edge by a long path. This subdivision operation, classical since Kuratowski [18], inserts degree-2 vertices and drives the average degree toward 2. Choosing the path length appropriately yields average degree $2+\varepsilon$ while preserving the base graph's global structure.

This model is explicit whenever the base graph is explicit, and strongly explicit whenever the base graph is strongly explicit.

2 Our Results

In this section, we present our results on the five ultra-sparse graph models introduced above. In the normalized setting, we essentially settle the question of the optimal ultra-sparse expanders. In the unnormalized setting, we introduce a new framework for analyzing the problem, while many basic questions remain open.

As an additional application, the full version proves that suitable unions of Ramanujan graphs remain nearly Ramanujan, and that suitable unions of cycles attain the Ramanujan bound.

2.1 Ultra-sparse expanders in the normalized setting

We begin by presenting our results in the normalized setting. Our first result uses the configuration model (the fourth model) and applies to general irregular graphs – indeed, to any prescribed degree sequence.

▶ **Theorem 1** (Irregular graphs via the configuration model). *Let $(d_1, \ldots, d_n)$ be a sequence of degrees such that $\sum_{i=1}^{n} d_i$ is even. Then there exists a graph with this degree sequence whose one-sided normalized spectral expansion is bounded above by $\frac{2\sqrt{\bar{d}-1}}{\bar{d}}$, where $\bar{d}$ is the average degree.*

Our proof is based on the configuration model (rather than the perfect matchings model used in [23]) and is inspired by the notion of *free projections* from classical free probability theory, which we discuss in Section 5. As a direct corollary we obtain the following result for ultra-sparse graphs.

▶ **Corollary 2** (Ultra-sparse expanders via the configuration model). *For every $\varepsilon > 0$ and for infinitely many values of n, there exists a graph on n vertices with degrees 2 or 3, with average degree $2 + \varepsilon$, whose one-sided normalized spectral expansion is bounded by $\frac{2\sqrt{1+\varepsilon}}{2+\varepsilon} = 1 - \frac{\varepsilon^2}{8} + O(\varepsilon^3)$.*

At first glance, the bound in Theorem 1 resembles the Ramanujan bound for d-regular graphs. Moreover, empirical evidence suggests that the typical behavior of random configuration graphs is indeed captured by Theorem 1. However, optimality in the irregular setting is more delicate, and the bound is not generally tight. For example, consider the wheel graph, formed from a cycle plus one additional vertex connected to all cycle vertices (we elaborate on this example in the full version of this paper). The normalized spectral expansion of the wheel approaches $\frac{2}{3}$, since within two steps one reaches a uniformly random vertex with probability $\frac{1}{3}$. Yet its average degree approaches 4 as the number of vertices grows, so Theorem 1 guarantees only a graph G with $\omega(G) \leq \frac{\sqrt{3}}{2} \approx 0.866$, which is significantly worse.

This gap suggests that even for graphs with degrees 2 and 3 – where degree variance is kept to a minimum – Corollary 2 may not be tight. Indeed, our second result shows that the subdivision model (our fifth model) does yield better expansion. For a d-regular graph G and parameter $\varepsilon > 0$, let G_ε denote the graph obtained by subdividing each edge of G into paths of equal length, so that the resulting graph has average degree $2 + \varepsilon$.

▶ **Theorem 3** (Ultra-sparse expanders via subdivision). *Let G be a d-regular graph with normalized spectral expansion ω, and let $\varepsilon > 0$. Then the normalized spectral expansion of G_ε is $\cos\left(\frac{d}{2(d-2)} \arccos(\omega)\varepsilon\right)$.*

Specializing to $d = 3$ and taking G be a 3-regular Ramanujan graph, the guaranteed spectral expansion for the resulting ultra-sparse graph is the following.

▶ **Corollary 4.** *Let G to be a 3-regular Ramanujan graph. The normalized spectral expansion of G_ε is $\cos\left(\frac{3}{2}\arccos\left(\frac{\sqrt{8}}{3}\right)\varepsilon\right) \approx 1 - 0.1299\varepsilon^2$.*

This improves upon the bound obtained via the configuration model in Corollary 2. In particular, the syntactically Ramanujan-like bound in Theorem 1 is not optimal.

It is, perhaps, surprising that the configuration model yields weaker expanders. In the configuration model, the degree-2 vertices are incorporated *while* the expander is being constructed, whereas in the subdivision approach they are added only after the 3-regular Ramanujan base graph has been fixed – and in an indifferent, uniform manner: every edge is replaced by a path of the same length. However, the Ramanujan property only guarantees a large spectral gap; it conveys little about local edge densities, so some regions can still be denser than others. Thus, it can be advantageous to distribute the degree-2 vertices nonuniformly, taking into account these density variances.

On the other hand, the expected time spent "stuck" on a path – which weakens the spectral expansion – is quadratic in its length. Since the total length summed over all paths is fixed as a function of ε, it is therefore beneficial to make all paths the same length. Still, one might hope to exploit a 3-regular Ramanujan base graph with substantial variation in local edge density by distributing the subdivision lengths nonuniformly, potentially yielding an even larger spectral gap.

The gap is, however, bounded, in a concrete way that shows both Corollaries 2 and 4 are asymptotically optimal in the dependence on ε. The aforementioned quadratic time to escape a path is levaraged to obtain the following lower bound (proved in the full version), serving as an asymptotic "Alon-Boppana" bound for ultra-sparse graphs.

▶ **Theorem 5.** *Let G be a graph with all vertices of degrees 2 or 3 and average degree $2+\varepsilon$. Then the normalized spectral expansion of G is at least $1-O(\varepsilon^2)$.*

This leads to the following open problem.

▶ **Open Problem 6.** *What is the optimal normalized spectral gap for graphs with degrees 2 and 3 and average degree $2+\varepsilon$?*

Corollary 4, together with Theorem 5, prove that the true answer to Open Problem 6 is $C\varepsilon^2 + o\left(\varepsilon^2\right)$ for some constant $C \geq 0.1299$.

2.2 Ultra-sparse expanders in the unnormalized setting

In this section we present our results in the unnormalized setting. We begin with the subdivision model, presenting our result for ultra-sparse graphs in the unnormalized setting, and then turn to the other four models in the same setting. Although we are not yet able to prove the existence of ultra-sparse graphs for these other models in the unnormalized setting, we introduce the *Free Method*, which yields quantitative *predictions* for the attainable spectral expansion as a function of ε in each case. While nonrigorous, these predictions align with empirical observations. We view the Free Method, discussed in Section 6, as a main contribution alongside our formal results: it lets us "peek" at the expected behavior before an existence proof is in hand.

▶ **Theorem 7** (Ultra-sparse expanders via subdivision)**.** *Let G be a d-regular graph with spectral expansion λ, and let $\varepsilon > 0$. Then the spectral expansion of G_ε is obtained as follows: find the unique positive ξ solving*

$$\lambda = \frac{\sinh((k+1)\xi) - (d-1)\sinh((k-1)\xi)}{\sinh(\xi)}. \tag{1}$$

where $k = \left\lceil \frac{(d-2)(2+\varepsilon)}{d\varepsilon} \right\rceil$. Then the spectral expansion μ is given by $2\cosh\xi$.

Although Theorem 7 gives the exact one-sided spectral expansion, it is not straightforward to read off its dependence on ε (a numerical derivation for μ for the case where G is a 3-regular Ramanujan graph is shown in Figure 1). However, by expanding about $\varepsilon = 0^+$, we show that $\mu = \sqrt{d-1} + \frac{1}{\sqrt{d-1}} + (1+o_k(1))\frac{\lambda}{2}\cdot\frac{(d-2)^2}{\left(\sqrt{d-1}\right)^{k+3}}$. Observe the *exponential* decay of the error in $k \approx 1/\varepsilon$, in contrast to the normalized setting, where the decay in ε is only quadratic – even for the same model.

We now switch gears to the other four models and the free method we use to analyze them.

2.3 The free method

We view the free method as an analogue of the probabilistic method, and so we begin by discussing the latter. The probabilistic method is a powerful tool: it proves the *existence* of an object without revealing what it looks like. The probabilistic method offers no insight into the structure of the object or how to find it explicitly. The value associated with the guaranteed object often serves as a benchmark (a quantitative prediction) for researchers aiming to find explicit constructions – e.g., the dependence of k on n for Ramsey graphs, or the distance–rate tradeoff in coding theory.

However, in many graph-theoretic settings even proving existence is technically formidable. Consider, for example, the value $2\sqrt{d-1}$. Proving the existence of graphs that attain this spectral expansion is notoriously difficult. Nonetheless, the value itself – serving as a benchmark – is both informative and insightful.

The free method, in a sense, takes things one step further. It is designed for situations where even the *mere existence* of an object with the desired properties is too difficult to prove, and thus the optimal value cannot be established via the same route as in the probabilistic method (namely, by proving existence). We reiterate that the main takeaway from the probabilistic method is often the *value* that serves as a benchmark for explicit constructions. When it comes to devising such constructions, the existence proof is typically unused, as it generally ignores precisely the structure required for explicit constructions. The free method provides *only* this key information.

More concretely, the free method targets graph-theoretic problems by abstracting away everything except the spectrum. Given a problem on finite graphs, we first *model* it by an infinite-dimensional object that captures the essential spectral features of the original problem. We then apply tools from free probability (powerful yet simple to use) to solve the infinite-dimensional problem, and the resulting quantity serves as a prediction for the finite case. We denote such predicted values by $\mathsf{pred}(\cdot)$ throughout the paper.

This perspective generalizes the "universal cover" viewpoint, but without requiring identification of a specific cover or combinatorial structure – only the spectral data.

To summarize, the philosophy of the probabilistic method is to prove existence without providing an explicit construction, while also yielding a quantitative benchmark – often the most valuable piece of information when constructing explicit objects. In contrast, the free method aims to derive this benchmark while entirely sidestepping a proof of existence, let alone an explicit construction. Because it makes weaker guarantees, the free method applies in much more challenging settings – ubiquitous in spectral graph theory – where the probabilistic method often falls short due to intricate eigenvalue behavior and the problem's inherent noncommutativity.

To set the stage for a more formal discussion, we fix notation and recall the *Cauchy transform* of an undirected graph G on n vertices: $\mathcal{G}_G(x) = \frac{1}{n}\sum_{i=1}^{n}\frac{1}{x-\lambda_i}$.

Consider the $3\left(\frac{2+\varepsilon}{3}\mathcal{M}\right)$ model, the union of three ρ-partial matchings with $\rho = \frac{2+\varepsilon}{3}$. In settings where one unions t independent samples from the same distribution (here $t = 3$), the first procedure we present in the free method prescribes:

1. Find the unique solution $x_0 > \lambda_1$ to

$$(t-1)\,\mathcal{G}'_G(x) + t\,\mathcal{G}_G(x)^2 \;=\; 0. \tag{2}$$

2. The prediction is given by

$$t \cdot x_0 \;-\; \frac{t-1}{\mathcal{G}_G(x_0)}. \tag{3}$$

At this point we have not justified this procedure (let alone the existence and uniqueness of $x_0 > \lambda_1$). The point is that the resulting procedure is quite general and easy to apply. In Section 6 we explain the rationale and derivation; here we focus solely on applying the method.

Before applying the free method to ultra-sparse graphs, we warm up by rederiving the Ramanujan bound $2\sqrt{d-1}$ using the recipe above.

2.3.1 Predictions for the three partial matchings model via the free method

We now apply the free method to ultra-sparse expanders, in particular to the $3\left(\frac{2+\varepsilon}{3}\mathcal{M}\right)$ model. Concretely, we take $t = 3$ independent copies of a ρ-partial matching with $\rho = \frac{2+\varepsilon}{3}$. Such a matching has a $(1-\rho)$-fraction of its eigenvalues equal to 0, with the remaining eigenvalues split evenly between $+1$ and -1. The corresponding Cauchy transform, denoted $\mathcal{G}_\rho$, is therefore $\mathcal{G}_\rho(x) = \frac{x^2-1+\rho}{x(x^2-1)}$. Equation (2) now becomes $2\,\mathcal{G}'_\rho(x) + 3\,\mathcal{G}_\rho(x)^2 = 0$, whose unique solution for $x > 1$ is

$$x_0(\rho) = \sqrt{1 + \sqrt{\rho(4-3\rho)}}\,.$$

Plugging this to Equation (3) and expressing the result in terms of ε yields the prediction

$$\begin{aligned}\mathsf{pred}_{3\left(\frac{2+\varepsilon}{3}\mathcal{M}\right)}(\varepsilon) &= \sqrt{1 + \sqrt{\frac{4-\varepsilon^2}{3}} \cdot \frac{\sqrt{3(4-\varepsilon^2)} - 3\varepsilon}{2(1-\varepsilon)}} \\ &= \sqrt{3+\sqrt{12}} + \frac{\sqrt{3+\sqrt{12}}}{4+\sqrt{12}}\,\varepsilon + O(\varepsilon^2).\end{aligned} \tag{4}$$

On the other extreme, when $\varepsilon = 1$, we recover the $2\sqrt{2}$ bound for 3-regular Ramanujan graphs. In fact, the Taylor expansion to the left of $\varepsilon = 1$ is $2\sqrt{2} - \frac{1-\varepsilon}{3\sqrt{2}} + O\left((1-\varepsilon)^2\right)$. This ε–dependence is hard to infer purely from experiments or by combinatorial means alone, and it matches experimental results.

2.3.2 Predictions for the remaining models

In Section 6–where we also explain the rationale behind the method–we apply the free method to the remaining models using techniques analogous to the procedure introduced above. For the configuration model, we apply a procedure to bound the spectrum of the product of two matrices, one of which is PSD, which has common ground with the proof of Theorem 1. Its application gives

$$\mathsf{pred}_{\mathsf{conf}}(\varepsilon) = \frac{3}{\sqrt{2}} + \frac{3}{4}\,\varepsilon^{1/2} + \frac{9\sqrt{2}}{32}\,\varepsilon + O(\varepsilon^{3/2}). \tag{5}$$

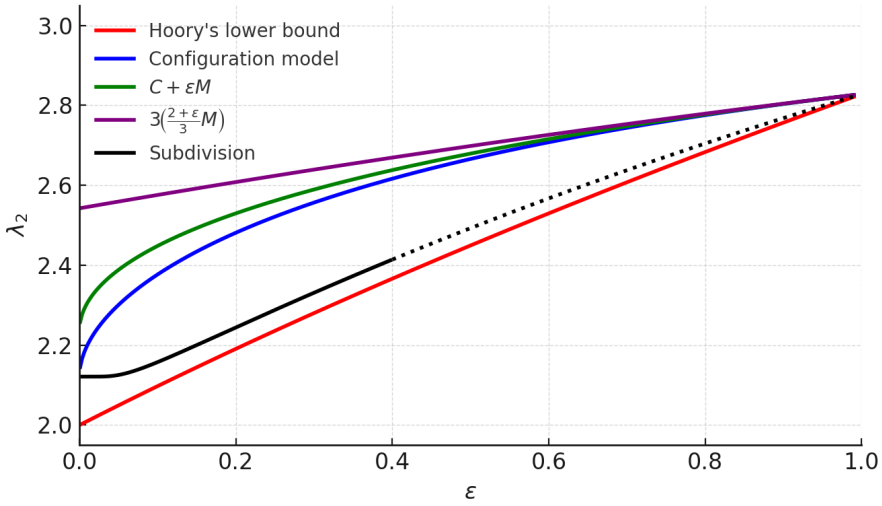

Figure 1 Comparison of the predictions for the bound on λ_2 for the conf, $\mathcal{C} + \varepsilon\mathcal{M}$ and $3\left(\frac{2+\varepsilon}{3}\mathcal{M}\right)$ models. Hoory's lower bound of $2\sqrt{\bar{d}-1}$ is displayed in red, and the subdivision model of a 3-regular Ramanujan graph ($\lambda = 2\sqrt{2}$) appears in black. Note that, as the number of subdivisions k is an integer, the largest possible value for ε in this model is 0.4. For clarity, however, we also plot the solution to Equation (1) for real $k < 2$ as a dotted line.

Interestingly, although $(2+\varepsilon)\mathcal{M}$ and $\mathcal{C} + \varepsilon\mathcal{M}$ are quite different as finite-graph models, their behavior coincides under the free-method analysis (based on classical free probability). Using an additive analog of the multiplicative procedure used for the configuration model yields the prediction

$$\mathsf{pred}_{\mathcal{C}+\varepsilon\mathcal{M}}(\varepsilon) = \mathsf{pred}_{(2+\varepsilon)\mathcal{M}}(\varepsilon) = \sqrt{5} + \sqrt{\frac{4}{5\phi}}\,\sqrt{\varepsilon}, \tag{6}$$

where $\phi = (1+\sqrt{5})/2$ is the golden ratio. The analysis uses a variant of the procedure used for $3\left(\frac{2+\varepsilon}{3}\mathcal{M}\right)$, applied to two distinct distributions.

For comparison, Hoory's lower bound [15] states that if a graph G has average degree at least $\bar{d}$ even after deleting any ball of radius r, then

$$\lambda_2(G) \;\geq\; 2\sqrt{\bar{d}-1}\left(1 - c\,\frac{\log r}{r}\right), \tag{7}$$

for a universal constant c. In our unbounded-size models the r-dependent error should be negligible, so we compare to $2\sqrt{\bar{d}-1} = 2\sqrt{1+\varepsilon}$. Together with our predictions, this yields the comparison shown in Figure 1. As the figure suggests, there is an ordering of the models, and the curves coincide only at $\varepsilon = 1$.

3 Ultra-Sparse Expanders via Subdivision

Let G be a d-regular graph and denote its adjacency matrix by $\mathbf{A}$ and random walk matrix by $\mathbf{W}$. Let G_k be the k-subdivision of G, which is defined by replacing every edge of G with a path of length k, effectively adding $k-1$ new vertices of degree 2. While we will focus on analyzing the spectrum of the corresponding matrices $\mathbf{A}_k$ and $\mathbf{W}_k$ of the resulting graph, we clarify already at this point that this process yields a graph of average degree $2+\varepsilon$ by

choosing $k \approx \frac{2(d-2)}{d\varepsilon}$, tying it to our motivation. Nevertheless, the result is more general. The analysis provided here is elementary (i.e., it does not rely on finite free probability), and is inspired by the proofs in [38].

▶ **Lemma 8** (Subdivision and the random walk spectrum). *Let $k \geq 2$, and let G_k be as defined above. Then for every eigenvalue ω of $\mathbf{W}$ and every $t = 0, 1, \ldots, k-1$, $r_t = \cos\left(\frac{\arccos(\omega)+2\pi t}{k}\right)$ is an eigenvalue of $\mathbf{W}_k$. The rest of the eigenvalues are of the form $r_j = \cos\left(\frac{\pi j}{k}\right)$ for $j = 1, \ldots, k-1$.*

The proof uses elementary means, and appears in the full version of this paper.

▶ **Corollary 9.** *Let G be a d-regular graph with normalized one-sided spectral expansion $\omega(G)$, and let S be its subdivision with average degree $2+\varepsilon$. Then*

$$\omega_d(\varepsilon) \;=\; \cos\left(\frac{d\,\varepsilon}{2(d-2)}\,\arccos\left(\omega(G)\right)\right). \tag{8}$$

In particular:

1. *If $d = 3$ and G is Ramanujan, then $\omega_3(\varepsilon) \;=\; \cos\left(\frac{3}{2}\arccos\left(\frac{\sqrt{8}}{3}\right)\varepsilon\right) \;\approx\; 1 - 0.12993\,\varepsilon^2$.*
2. *As $d \to \infty$ (with G Ramanujan), since $\arccos\left(\frac{2\sqrt{d-1}}{d}\right) \to \frac{\pi}{2}$, we obtain $\omega_d(\varepsilon) \longrightarrow \cos\left(\frac{\pi}{4}\,\varepsilon\right) \;=\; 1 - \frac{\pi^2}{32}\,\varepsilon^2 + O(\varepsilon^4)$.*

Proof. Let $k = \left\lceil \frac{(d-2)(2+\varepsilon)}{d\,\varepsilon} \right\rceil$ be the subdivision parameter so that the resulting graph has average degree $2+\varepsilon$. By Lemma 8, the normalized expansion after k-subdivision is $\cos\left(\frac{\arccos(\omega(G))}{k}\right)$. Using the relation between k and ε established in Theorem 3 yields Equation (8).

For (1), put $\omega(G) = \frac{2\sqrt{2}}{3}$ (Ramanujan) and set $\phi \triangleq \arccos(\omega(G)) \approx 0.33984$, giving $\omega_3(\varepsilon) \;=\; \cos\left(\frac{3}{2}\phi\,\varepsilon\right) \;=\; 1 - \frac{(3\phi)^2}{8}\,\varepsilon^2 + O(\varepsilon^3) \;\approx\; 1 - 0.12993\,\varepsilon^2$. For (2), observe that for Ramanujan d-regular graphs, $\omega(G) = \frac{2\sqrt{d-1}}{d}$ and hence $\arccos(\omega(G)) \to \frac{\pi}{2}$ as $d \to \infty$. Plugging into Equation (8) gives the stated limit and its Taylor expansion. ◀

For the unnormalized case, we have the following:

▶ **Lemma 10** (Subdivision and the adjacency matrix spectrum). *Let $k \geq 2$, and let G_k be as defined above. Then every eigenvalue μ of $\mathbf{A}_k$ satisfies one of the conditions below.*

1. *$\mu = 2\cos(\pi j/k)$ for $j = 1, \ldots, k-1$.*
2. *$\mu = 2\cos\theta$ for real θ, satisfying*

$$\lambda = \frac{\sin((k+1)\theta) - (d-1)\,\sin((k-1)\theta)}{\sin\theta}, \tag{9}$$

   where λ is an eigenvalue of $\mathbf{A}$.
3. *$\mu = \pm 2\cosh\xi$ for real $\xi > 0$, satisfying*

$$\lambda = \frac{\sinh((k+1)\xi) - (d-1)\sinh((k-1)\xi)}{\sinh(\xi)}, \tag{10}$$

   where λ is an eigenvalue of $\mathbf{A}$.

Explicit solutions are feasible for $k = 2, 3$, but this is not the case for general k. Nonetheless, We give a sharp estimate of the result for large k, which is the regime of interest in our paper (as $k \approx 1/\varepsilon$ in our desired model).

▶ **Corollary 11.** *All eigenvalues μ of $\mathbf{A}_k$ with $\mu > 2$ satisfy*

$$\mu \;=\; \sqrt{d-1} + \frac{1}{\sqrt{d-1}} \;+\; (1+o_k(1))\,\frac{\lambda}{2}\cdot\frac{(d-2)^2}{\left(\sqrt{d-1}\right)^{k+3}},$$

where λ is an eigenvalue of $\mathbf{A}$.

4 Interlacing Families and Free Convolutions

In this section we review definitions and known results in free probability and interlacing families of polynomials. We use the following standard notation: for a symmetric matrix $\mathbf{A}$, $\chi_x(\mathbf{A})$ is the characteristic polynomial of $\mathbf{A}$ with variable x. We denote by $\lambda_k(\mathbf{A})$ the k-th largest eigenvalue of $\mathbf{A}$ (as $\mathbf{A}$ is symmetric, all eigenvalues are real and hence can be ordered as above). For every symmetric matrix $\mathbf{B}$ for which the all-ones vector $\mathbf{1}$ is an eigenvector and $\mathbf{B1} = b\mathbf{1}$, we denote by $p_{\mathbf{B}}(x)$ the polynomial satisfying $(x-b)p_{\mathbf{B}}(x) = \chi_x(\mathbf{B})$.

For a real-rooted polynomial $p(x)$, we denote by $\alpha_k(p)$ the k-th largest root of $p(x)$. Given a distribution P over polynomials, we denote by $\mathbf{E}_{p\sim P}[p(x)]$ the *expected* polynomial over this distribution, where the expectation is taken in coefficient space, namely, for every k, the coefficient of x^k in $\mathbf{E}_{p\sim P}[p(x)]$ is the expectation over coefficients corresponding to x^k in $p(x)$ drawn according to P.

The following lemma is a simplified version of a more general statement from [23], where it appeared as the main tool enabling us to analyze the expected characteristic polynomial over a distribution, and deduce an existence result.

▶ **Lemma 12.** *Let $\mathbf{A}_1,\ldots,\mathbf{A}_t$ be symmetric $m\times m$ matrices and $(\mathbf{P}_i)_{i\in[t]}$ be uniformly random $m\times m$ permutation matrices. Let $\mathbf{A}_{\mathbf{P}} = \sum_{i=1}^t \mathbf{P}_i\mathbf{A}_i\mathbf{P}_i^{\mathsf{T}}$. Then, for every $k\le m$ there exist permutation matrices $(\mathbf{R}_i)_{i\in[t]}$ such that*

$$\lambda_k(\mathbf{A}_{\mathbf{R}}) \le \alpha_k\left(\mathop{\mathbf{E}}_{\mathbf{P}}\chi_x(\mathbf{A}_{\mathbf{P}})\right). \tag{11}$$

The multiplicative analog of Lemma 12 was proved in [10]. A simplified version, suitable for our needs, is stated below [1].

▶ **Lemma 13.** *Let $\mathbf{M},\mathbf{N}$ be symmetric $m\times m$ matrices such that $\mathbf{M}$ is positive semidefinite, and let $\mathbf{P}$ be a uniformly random $m\times m$ permutation matrix. Then, for every $k\le m$ there exists a permutation matrix $\mathbf{S}$ such that*

$$\lambda_k\left(\mathbf{MSNS}^{\mathsf{T}}\right) \le \alpha_k\left(\mathop{\mathbf{E}}_{\mathbf{P}}\chi_x\left(\mathbf{MPNP}^{\mathsf{T}}\right)\right). \tag{12}$$

▶ **Definition 14** (Additive and multiplicative convolutions)**.** *Let $\mathbf{A},\mathbf{B}$ be real symmetric matrices of dimension m, with characteristic polynomials $a(x) = \chi_x(\mathbf{A})$ and $b(x) = \chi_x(\mathbf{B})$. The* additive convolution *$a\boxplus_m b$ and the* multiplicative convolution *$a\boxtimes_m b$ are the polynomials defined by*

$$(a\boxplus_m b)(x) = \mathop{\mathbf{E}}_{\mathbf{Q}}\chi_x\left(\mathbf{A}+\mathbf{QBQ}^{\mathsf{T}}\right),$$

[1] Lemma 13 was proved in [10, Theorem 6.5 and Lemma 6.3] in more generality (for a sequence of permutation matrices, as in Lemma 12). It is phrased therein, however, only for the case $\mathbf{M} = \mathbf{A}^2$ and $\mathbf{N} = \mathbf{A}$ for a symmetric matrix $\mathbf{A}$.

and

$$(a \boxtimes_m b)(x) = \mathop{\mathbf{E}}_{\mathbf{Q}} \chi_x \left(\mathbf{A}\mathbf{Q}\mathbf{B}\mathbf{Q}^{\mathsf{T}}\right),$$

where $\mathbf{Q}$ *is a Haar random orthogonal matrix. We will use* $\boxplus$ *and* $\boxtimes$ *instead of* $\boxplus_m$ *and* $\boxtimes_m$ *for simplifying notation when the dimension is clear from the context.*

Working with graph matrices, an issue with the above definition is that the Haar measure does not have a meaningful combinatorial interpretation. Therefore, we need a way to relate *permutation* matrices - which do have such interpretation - to Haar random matrices. To this end we state the following lemma (which appeared first in [23] for the additive case, and later on in [10] for the multiplicative case, whose proof uses similar ideas) which is described as a *Quadrature* result, translating an infinite (continuous) measure space to a finite one.

▶ **Lemma 15** (*Quadrature*; Corollary 4.9 from [23] and Lemma 2.3 from [10])**.** *Let* $\mathbf{A}, \mathbf{B}$ *be real* $m \times m$ *symmetric matrices such that* $\mathbf{A}\mathbf{1} = a\mathbf{1}$ *and* $\mathbf{B}\mathbf{1} = b\mathbf{1}$*. Denote by* $p_{\mathbf{A}}, p_{\mathbf{B}}$ *the polynomials satisfying* $\chi_x(\mathbf{A}) = (x-a)p_{\mathbf{A}}(x)$*,* $\chi_x(\mathbf{B}) = (x-b)p_{\mathbf{B}}(x)$*. Let* $\mathbf{P}$ *be a uniformly random* $m \times m$ *permutation matrix. Then,*

$$\mathop{\mathbf{E}}_{\mathbf{P}} \chi_x \left(\mathbf{A} + \mathbf{P}\mathbf{B}\mathbf{P}^{\mathsf{T}}\right) = (x - (a+b)) \left(p_{\mathbf{A}} \boxplus p_{\mathbf{B}}\right)(x), \tag{13}$$

$$\mathop{\mathbf{E}}_{\mathbf{P}} \chi_x \left(\mathbf{A}\mathbf{P}\mathbf{B}\mathbf{P}^{\mathsf{T}}\right) = (x - ab) \left(p_{\mathbf{A}} \boxtimes p_{\mathbf{B}}\right)(x). \tag{14}$$

4.1 Transforms

Let μ be a compactly supported probability distribution over $\mathbb{R}$, and let $a = \sup(\mu)$. The *Cauchy transform* of μ is defined on the domain (a, ∞) as the function

$$\mathcal{G}_\mu(x) = \int_{\mathbb{R}} \frac{1}{x-t} \mu(t) dt.$$

We remark that in many settings it is instructive to study the Cauchy transform as a function whose domain is $\mathbb{C}^+$. However, we will consider the Cauchy transform as a function on $\mathbb{R}$. The Cauchy transform is also related to the moments of a distribution. If $m_r(\mu)$ is the r-th moment of μ, then for every $x > a$ we have (see [27, Remark 2.19]):

$$\mathcal{G}_\mu(x) = \sum_{r=0}^{\infty} \frac{m_r(\mu)}{x^{r+1}}. \tag{15}$$

Let $p(x)$ be a degree m real-rooted polynomial with roots $\alpha_1 \geq \alpha_2 \geq \cdots \geq \alpha_m$. To $p(x)$ we associate the uniform distribution over its roots, and therefore its Cauchy transform (defined for $x > \alpha_1$) is

$$\mathcal{G}_p(x) = \frac{1}{m} \sum_{i=1}^{m} \frac{1}{x - \alpha_i} = \frac{1}{m} \cdot \frac{p'(x)}{p(x)}.$$

Accompanying the Cauchy transform of μ is the *$\mathcal{M}$-transform* (or moment transform), which is defined by $\mathcal{M}_\mu(x) = x\mathcal{G}_\mu(x) - 1$. It is easy to see that $\mathcal{G}_\mu(x)$ is monotonically decreasing within its domain, and thus invertible. Denote the range of $\mathcal{G}_\mu(x)$ by $(0, L^+)$, that is, $L^+ = \lim_{x \to +a} \mathcal{G}_\mu(x)$ (for a polynomial $p(x)$, $L^+ = \infty$). With this in mind, we

define $\mathcal{K}_\mu : (0, L^+) \to (a, \infty)$ as the inverse of $\mathcal{G}_\mu$. In cases where $\mathcal{M}_\mu(x)$ is monotonically decreasing in the same domain, we can define $\mathcal{N}_\mu(y)$ as the inverse of $\mathcal{M}_\mu$ in a similar manner. By definition, for every $y \in (0, L^+)$, both $\mathcal{K}_\mu(y)$ and $\mathcal{N}_\mu(y)$ provide an upper bound on a, the supremum of the support of μ. In case of a polynomial $p(x)$, this bounds the largest root of $p(x)$, which we state for later reference in the following claim:

▷ Claim 16. Let $p(x)$ be a degree m real-rooted polynomial with roots $\alpha_1 \geq \alpha_2 \geq \cdots \geq \alpha_m$. Then for every $y \in (0, \infty)$, both $\alpha_1 \leq \mathcal{K}_p(y)$ and $\alpha_1 \leq \mathcal{N}_p(y)$.

For a symmetric matrix $\mathbf{A}$, we use the notation $\mathcal{G}_\mathbf{A}$ for $\mathcal{G}_{\chi_x(\mathbf{A})}$, and $\mathcal{G}_{p_\mathbf{A}}$ for the Cauchy transform of $p_\mathbf{A}$ as used in Lemma 15 if applicable, and similar notations for the other transforms.

The key feature of the $\mathcal{K}$ and the $\mathcal{N}$ transforms is that they behave very well under additive and multiplicative convolutions, respectively, as was shown in [24, Theorem 1.11] and [9, Claim 4.12], and stated below.

▶ **Lemma 17** (Convolution bounds). *For real-rooted polynomials $p(x)$ and $q(x)$ of degree m, and for any $y > 0$,*

$$\mathcal{K}_{p \boxplus_m q}(y) \leq \mathcal{K}_p(y) + \mathcal{K}_q(y) - \frac{1}{y}.$$

When one of the polynomials has only non-negative roots, then for every $y > 0$,

$$\mathcal{N}_{p \boxtimes_m q}(y) \leq \frac{y}{y+1} \cdot \mathcal{N}_p(y) \cdot \mathcal{N}_q(y).$$

Both inequalities are strict in case both polynomials have at least two distinct roots.

An immediate corollary of Lemma 17 and Claim 16 is the following.

▶ **Corollary 18.** *For every real-rooted polynomial $p(x)$, $t \in \mathbb{N}$ and $y > 0$,* $\mathsf{maxroot}\left(p^{\boxplus t}(x)\right) \leq t \cdot \mathcal{K}_p(y) - \frac{t-1}{y}$.

▷ Claim 19. [9, Claim 4.12] Let $\mathbf{B}$ be a symmetric matrix such that $\mathbf{B}\mathbf{1} = b\mathbf{1}$ and b is its largest eigenvalue. Then, for every $x > b$, $\mathcal{G}_{p_\mathbf{B}}(x) \leq \mathcal{G}_\mathbf{B}(x)$ and $\mathcal{M}_{p_\mathbf{B}}(x) \leq \mathcal{M}_\mathbf{B}(x)$, and for every $y > 0$, $\mathcal{K}_{p_\mathbf{B}}(y) \leq \mathcal{K}_\mathbf{B}(y)$ and $\mathcal{N}_{p_\mathbf{B}}(y) \leq \mathcal{N}_\mathbf{B}(y)$.
When $\mathbf{B} \neq b\mathbf{I}$, all inequalities are sharp.

5 Ultra-Sparse Expanders in the Configuration Model

In this section we prove Theorem 1, which immediately implies Corollary 2.

▶ **Definition 20** (Configuration model for regular graphs). *A random undirected d-regular graph on n vertices is said to be sampled by the* configuration model *if it is generated by choosing a uniformly random perfect matching on the nd* half-edges.

5.1 Alternate MSS proof via finite free projection

In this section, we present our alternative proof of the MSS result using the configuration model.

▶ **Theorem 21.** *For every $d \geq 2, n \in \mathbb{N}$ such that $N = nd$ is even, there exists an $N \times N$ permutation matrix $\mathbf{P}$ such that the d-regular n-vertex graph $G_\mathbf{P}$ satisfies*

$$\lambda_2(G_\mathbf{P}) < 2\sqrt{d-1}.$$

Proof. We begin with the useful observation that

$$\mathbf{V} \triangleq \mathbf{U}\mathbf{U}^\mathsf{T} = \mathbf{J}_d \otimes \mathbf{I}_n,$$

where $\mathbf{J}_d$ denotes the $d \times d$ matrix with all entries equal to 1. Note that $\mathbf{J}_d$ is the random walk matrix (i.e., the normalized adjacency matrix) of the complete graph on d vertices with self-loops. Observe that

$$\chi_x(\mathbf{M}) = (x-1)^{\frac{N}{2}}(x+1)^{\frac{N}{2}},$$
$$\chi_x(\mathbf{V}) = x^{n(d-1)}(x-d)^n,$$

yielding the $\mathcal{M}$-transforms

$$\mathcal{M}_{\mathbf{M}}(x) = \frac{1}{x^2-1}, \quad \mathcal{M}_{\mathbf{V}}(x) = \frac{1}{x-d}. \tag{16}$$

As both are decreasing in their respective domains $(1,\infty)$, (d,∞), we can calculate their $\mathcal{N}$-transforms (see Section 4.1) and get

$$\mathcal{N}_{\mathbf{M}}(y) = \sqrt{\frac{y+1}{y}}, \quad \mathcal{N}_{\mathbf{V}}(y) = \frac{dy+1}{y}. \tag{17}$$

Now, for any matrix $\mathbf{P}$,

$$x^{n(d-1)}\chi_x\left(\mathbf{U}^\mathsf{T}\mathbf{P}\mathbf{M}\mathbf{P}^\mathsf{T}\mathbf{U}\right) = \chi_x\left(\mathbf{U}\mathbf{U}^\mathsf{T}\mathbf{P}\mathbf{M}\mathbf{P}^\mathsf{T}\right),$$

since characteristic polynomials are invariant under cyclic rotations – up to a multiplicative factor of x, depending on the difference in dimensions. By Lemma 13, it is enough to prove that

$$\alpha_2 \triangleq \alpha_2\left(\mathop{\mathbf{E}}_{\mathbf{P}} \chi_x\left(\mathbf{U}\mathbf{U}^\mathsf{T}\mathbf{P}\mathbf{M}\mathbf{P}^\mathsf{T}\right)\right) < 2\sqrt{d-1}, \tag{18}$$

where recall that for a real-rooted polynomial $p(x)$, we let $\alpha_i(p(x))$ denote its i-th largest root. By Lemma 15,

$$\mathop{\mathbf{E}}_{\mathbf{P}} \chi_x\left(\mathbf{U}\mathbf{U}^\mathsf{T}\mathbf{P}\mathbf{M}\mathbf{P}^\mathsf{T}\right) = (x-d)\left(p_{\mathbf{V}} \boxtimes p_{\mathbf{M}}\right)(x), \tag{19}$$

where $p_{\mathbf{V}}(x)$ and $p_{\mathbf{M}}(x)$ are the polynomials defined by $\chi_x(\mathbf{V}) = (x-d)p_{\mathbf{V}}(x)$ and $\chi_x(\mathbf{M}) = (x-1)p_{\mathbf{M}}(x)$, respectively. Therefore,

$$\mathcal{N}_{p_{\mathbf{V}} \boxtimes p_{\mathbf{M}}}(y) \le \frac{y}{y+1}\mathcal{N}_{p_{\mathbf{M}}}(y)\mathcal{N}_{p_{\mathbf{V}}}(y) < \frac{dy+1}{\sqrt{(y(y+1))}}, \tag{20}$$

where the first inequality follows by Lemma 17, and the second, sharp, inequality follows by Claim 19 and the calculations of $\mathcal{N}_{\mathbf{M}}(y), \mathcal{N}_{\mathbf{V}}(y)$ above.

By Claim 16, $\alpha_2 \le \mathcal{N}_{p_{\mathbf{V}} \boxtimes p_{\mathbf{M}}}(y)$ for any $y > 0$. Choosing the point $y_0 = \frac{1}{d-2}$, we get by the above inequality that

$$\alpha_2 \le \mathcal{N}_{p_{\mathbf{V}} \boxtimes p_{\mathbf{M}}}(y_0) < \frac{dy_0+1}{\sqrt{y_0(y_0+1)}} = 2\sqrt{d-1}. \qquad \blacktriangleleft$$

5.2 Non-regular graphs in the configuration model

In this section, we extend our alternative proof of MSS's theorem, presented in the previous section, to the setting of irregular graphs. The configuration model is well-suited for handling vertices with varying degrees, and the required changes are minor, mostly involving appropriate normalizations.

Before proceeding, we recall the definition of the random walk matrix for irregular graphs. First, recall that the random walk matrix of a d-regular graph G, with adjacency matrix $\mathbf{A}$, is given by $\mathbf{W} = \frac{1}{d}\mathbf{A}$, and we denote its eigenvalues by $1 = \omega_1 \geq \omega_2 \geq \cdots \geq \omega_n \geq -1$. The *normalized spectral expansion* of G, denoted $\omega(G)$, is defined as $\max(|\omega_2|, |\omega_n|) \in [0,1]$. When G is *not* regular, the random walk matrix is defined as $\mathbf{W} = \mathbf{A}\mathbf{D}^{-1}$, where $\mathbf{D}$ is the diagonal matrix of vertex degrees (we assume no isolated vertices). This generalizes the above definition for regular graphs. The parameter $\omega(G)$ governs the convergence rate of random walks on G. It is easy to see that the eigenvalues of $\mathbf{W}$ are the same as those of the symmetric matrix $\mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2}$. Since we are primarily interested in the eigenvalues, we will treat this symmetric matrix as the random walk matrix in what follows.

To derive the analogue in the irregular case, we introduce the following notation. Let $d_1, \ldots, d_n$ be a degree sequence such that $N = \sum_{i=1}^{n} d_i$ is even. Define $j_k = \sum_{i=1}^{k} d_i$ as the sum of the first k degrees, and let $J_k \subset [N]$ be the set of indices

$$J_k = \{j_{k-1} + 1, j_{k-1} + 2, \ldots, j_{k-1} + d_k\}.$$

The analogue of the matrix $\mathbf{U}$ in the non-regular case is the $N \times n$ matrix $\mathbf{C}$ defined by $\mathbf{C}e_k = \frac{1}{\sqrt{d_k}}\mathbf{1}_{J_k}$ for every $k \in [n]$. Using this notation, we obtain

$$\mathbf{W}_{\mathbf{P}} = \mathbf{C}^{\mathsf{T}}\mathbf{P}\mathbf{M}\mathbf{P}^{\mathsf{T}}\mathbf{C}, \tag{21}$$

where $\mathbf{M}$ is the adjacency matrix of a perfect matching on the N half-edges, as in the regular configuration model. With this, we are ready to prove Theorem 1. The proof follows similar lines to that of Theorem 21, and so we refrain from repeating it in full, instead focusing on the differences.

Proof of Theorem 1. First, observe that $\mathbf{C}\mathbf{C}^{\mathsf{T}}$ is the block-diagonal matrix, which we denote by $\bar{\mathbf{V}}$, consisting of n blocks of the form $\frac{1}{d_i}\mathbf{J}_{d_i}$. Note that

$$\chi_x\left(\bar{\mathbf{V}}\right) = (x-1)^n x^{N-n}.$$

A straightforward calculation gives $\mathcal{N}_{\bar{\mathbf{V}}}(y) = \frac{\bar{d}y+1}{\bar{d}y}$. Following the same steps as in the proof of Theorem 21, we arrive at the analogue of Equation (20),

$$\mathcal{N}_{p_{\bar{\mathbf{V}}} \boxtimes p_{\mathbf{M}}}(y) \leq \frac{y}{y+1} \cdot \mathcal{N}_{p_{\mathbf{M}}}(y) \cdot \mathcal{N}_{p_{\bar{\mathbf{V}}}}(y) < \frac{\bar{d}y+1}{\bar{d}\sqrt{y(y+1)}}.$$

The proof follows as the right-hand side attains its minimum value $\frac{2\sqrt{\bar{d}-1}}{\bar{d}}$ (at $y_0 = \frac{1}{\bar{d}-2}$). ◀

6 The Free Method

The analysis in Section 5.2 deals with non-regular graphs directly for the normalized spectrum (of the matrix $\mathbf{W}$), which governs the convergence of random walks (among other characteristics). This raises the question of what can be said about the adjacency spectrum of $\mathbf{A}$, which is of importance when analyzing various generalizations of the expander mixing lemma (see [1] for an up to date survey of the latter).

There are several frameworks for using results from free probability to deduce analysis on graph distributions. One of these is the *finite free* approach using interlacing families of polynomials, pioneered in [23] (and later used in [26, 10] and others), and exemplified here in Section 5.2. Others are the strong convergence approaches of Bordenave and Collins [7] and Chen et al. [8]. All these approaches can be looked at as a two-step process:

1. A reduction from a combinatorial question to a setting of free random variables.
2. Solution in the free setting.

The reduction of Item 1 can yield either an existence proof (as in the MSS approach used here in Theorem 1), or a high probability result as in [7, 8], reduced to the solution of Item 2. The latter, however, is an elusive topic which did not get nearly enough attention in the literature, and we overview it next. We then analyze specific examples in the free regime and verify that the results well represent the behavior of random graphs.

6.1 Free method procedures

In this section, we present a couple of procedures within the framework of the free method. We begin with a brief overview of techniques used in free probability for computing distributions of sums and products of free random variables. In our context, we think of these as the eigenvalue distributions of matrices, for which the eigenspaces are maximally decoupled (for example, by rotating one matrix using a Haar unitary). However, in the free probability literature this context is not necessary, as there are clean self-contained definitions of free random variables expressed in terms of joint moments (for an excellent textbook on the topic, we refer the reader to [27]).

Let a and b be *free* random variables, and denote their distributions by μ_a and μ_b. We wish to find the distribution μ_c of the variable $c = a + b$, by which we define the free additive convolution of distributions $\mu_c = \mu_a \boxplus \mu_b$. This represents, in matrix terms, the eigenvalue distribution of $\mathbf{A} + \mathbf{Q}^\mathsf{T}\mathbf{B}\mathbf{Q}$ where $\mathbf{Q}$ is a Haar unitary and $\mathbf{A}, \mathbf{B}$ are square matrices with eigenvalue distributions μ_a, μ_b respectively. The recipe doing so is the following, provided here without proof[2]:

Algorithm 1. Free additive convolution.

1. Calculate the Cauchy transforms $\mathcal{G}_{\mu_a}(x)$ and $\mathcal{G}_{\mu_b}(x)$ as defined in Section 4.1.
2. Find the compositional inverses, denoted by $\mathcal{K}_{\mu_a}(y)$ and $\mathcal{K}_{\mu_b}(y)$ (as defined in Section 4.1).
3. Calculate $\mathcal{K}_{\mu_c}(y) = \mathcal{K}_{\mu_a}(y) + \mathcal{K}_{\mu_b}(y) - \frac{1}{y}$.
4. Invert $\mathcal{K}_{\mu_c}(y)$ to get $\mathcal{G}_{\mu_c}(x)$.
5. Calculate μ_c from $\mathcal{G}_{\mu_c}(x)$ using the Stieltjes inversion formula (details omitted).

Note that when at least one of the distributions is supported on non-negative reals only (in the context of matrices, at least one of them is PSD) there is a multiplicative analog of the above recipe – that is, the calculation of the distribution $\mu_c = \mu_a \boxtimes \mu_b$ for $c = ab$ – where the $\mathcal{G}$ and $\mathcal{K}$ transforms are replaced with $\mathcal{M}$, $\mathcal{N}$ respectively, and Item 3 is replaced with $\mathcal{N}_{\mu_c}(y) \leq \frac{y}{y+1} \cdot \mathcal{N}_{\mu_a}(y) \cdot \mathcal{N}_{\mu_b}(y)$.

The vast majority of the literature focuses on proofs of the above, and its generalizations. However, explicit applications of it as stated are not very common, due to a few clear caveats. The first is that for Item 1 we need to have explicit analytic formulas for μ_a, μ_b, which

[2] The proof is standard in the free probability literature, and can be found in [27, Chapter 12].

may not be available. The second is that inverting a function is a complicated, sometimes infeasible, task. Given a distribution μ supported on only 3 values, inverting $\mathcal{G}_\mu$ involves solving a cubic equation, which may be possible but leads to a function that is hard to analyze. For more complicated distributions, we know the task to be infeasible, making Items 2 and 4 mere theoretical ideas and not practical tools.

A solution to the inversion problem of Item 4 is implicit in the work of Marcus, Spielman and Srivastava. Once we relax our goal of having an explicit formula for μ_c and wish to only *bound* its support, the only necessary part is knowing $\mathcal{K}_{\mu_c}(y)$. This is due to the observation (discussed here in Section 4.1) that every value of this function is an upper bound on the support. Therefore Items 4 and 5 can be replaced with minimizing $\mathcal{K}_{\mu_c}(y)$ over $y > 0$, which is typically a simple analytic task, leading to the following simpler procedure:

Algorithm 2. Bounding the free additive convolution.

- Perform Items 1–3 of Procedure 1 to get $\mathcal{K}_{\mu_c}(y)$.
- Output $\min_{y>0} \mathcal{K}_{\mu_c}(y)$.

Although this procedure is simpler, we are still left with the case of Item 2 not being feasible, which is the issue we wish to solve next in Section 6.1.1. Note that other works have looked into relaxing the requirement to get a closed formula for μ_c, to rather learn characteristics of its support [3] or develop numerical techniques for this task (see [12, 29] and the subordination technique presented in [34]). To the best of our knowledge, although the technique presented here is elementary, this work is the first to formally define it.

6.1.1 Sums of identical spectra

The procedure given in the next lemma solves the inversion issue of Item 2 for the case that the random variables have an equal distribution μ. We use $\mu^{\boxplus t}$ to denote the additive convolution of μ with itself $t-1$ times.

▶ **Lemma 22.** *Let μ be a compactly supported distribution on $\mathbb{R}$, and $t \in \mathbb{N}$. Then the supremum of the support of $\mu^{\boxplus t}$ is achieved by minimizing*

$$\widetilde{\mathcal{K}_t}(x) \triangleq tx - \frac{t-1}{\mathcal{G}_\mu(x)}$$

over $\{x > \max(\mu)\}$, or equivalently applying the following procedure:

Algorithm 3. Bounding the support of $\mu^{\boxplus t}$.

1. Find the solution x_0 of the equation
$$\frac{t-1}{t}\mathcal{G}'_\mu(x) = -\mathcal{G}_\mu(x)^2. \tag{22}$$
2. Evaluate $y_0 \triangleq \mathcal{G}_\mu(x_0)$.
3. Output $t \cdot x_0 - \frac{t-1}{y_0}$.

Notice that at no point in Lemma 22 do we need to invert a function.

Proof. By definition of inverse under composition, $\mathcal{G}_\mu(\mathcal{K}_\mu(y)) = y$. Differentiating both sides and rearranging gives

$$\mathcal{K}'_\mu(y) = \frac{1}{\mathcal{G}'_\mu(\mathcal{K}_\mu(y))}. \tag{23}$$

As shown, we look for the minimal value of

$$\mathcal{K}_{\mu_t}(y) = t \cdot \mathcal{K}_\mu(y) - \frac{t-1}{y} \tag{24}$$

achieved at a point y_0 satisfying $\mathcal{K}'_{\mu_t}(y_0) = 0$. Note that such a minimum always exists, as $\mathcal{G}_\mu(x)$ decays like $\frac{1}{x}$. Therefore by Equation (24)

$$t \cdot \mathcal{K}'_\mu(y_0) = -\frac{t-1}{y_0^2}.$$

Plugging in Equation (23) one concludes

$$\frac{t}{\mathcal{G}'_\mu(\mathcal{K}_\mu(y_0))} = -\frac{t-1}{y_0^2}.$$

Let x_0 be the value such that $y_0 = \mathcal{G}_\mu(x_0)$. Then we get from the above that

$$\frac{t-1}{t}\mathcal{G}'_\mu(x_0) = -\mathcal{G}(x_0)^2,$$

as required in Equation (22). The minimal value of Equation (24) is thus

$$\mathcal{K}_{\mu_t}(y_0) = t \cdot \mathcal{K}_\mu(y_0) - \frac{t-1}{y_0} = t \cdot x_0 - \frac{t-1}{y_0}.$$ ◀

6.1.2 Sums and products of two distinct spectra

The procedure of Lemma 22 is very easy to use, but does not cover cases where we need to perform an additive convolution of different distributions μ_1 and μ_2. A straightforward variation of Lemma 22 shows that when one distribution has a simple Cauchy transform $\mathcal{G}_{\mu_1}(x)$ with an explicit inverse $\mathcal{K}_{\mu_1}(y)$, the supremum of the support of $\mu_1 \boxplus \mu_2$ can be found using the following lemma.

▶ **Lemma 23.** *Let μ_1, μ_2 be compactly supported distributions on $\mathbb{R}$. The supremum of the support of $\mu_1 \boxplus \mu_2$ is achieved by minimizing over $\{x > \max(\mu_2)\}$ the function*

$$\widetilde{\mathcal{K}}_{\mu_1 \boxplus \mu_2}(x) \triangleq \mathcal{K}_{\mu_1}(\mathcal{G}_{\mu_2}(x)) + x - \frac{1}{\mathcal{G}_{\mu_2}(x)}. \tag{25}$$

If either μ_1 or μ_2 is supported on $\mathbb{R}^+$ only, the supremum of the support of $\mu_1 \boxtimes \mu_2$ is achieved by minimizing over $\{x > \max(\mu_2)\}$ the function

$$\widetilde{\mathcal{N}}_{\mu_1 \boxtimes \mu_2}(x) \triangleq \frac{\mathcal{M}_{\mu_2}(x)}{\mathcal{M}_{\mu_2}(x)+1} \cdot \mathcal{N}_{\mu_1}(\mathcal{M}_{\mu_2}(x)) \cdot x. \tag{26}$$

Proof. We will prove the additive case, the multiplicative follows similar arguments. By Item 3 of Procedure 1, we need to minimize

$$\mathcal{K}_{\mu_1 \boxplus \mu_2}(y) = \mathcal{K}_{\mu_1}(y) + \mathcal{K}_{\mu_2}(y) - \frac{1}{y}.$$

Set $y = \mathcal{G}_{\mu_2}(x)$, and we get the equation

$$\widetilde{\mathcal{K}}_{\mu_1 \boxplus \mu_2}(x) = \mathcal{K}_{\mu_1}(\mathcal{G}_{\mu_2}(x)) + x - \frac{1}{\mathcal{G}_{\mu_2}(x)},$$

completing the proof. ◀

6.2 Application to ultra-sparse graphs

As previewed in Section 2.2, we predict spectral bounds for our graph models by analyzing the spectra of their constituent pieces and how they combine. Our prediction for the resulting graph is the free convolution of the component spectral measures – additive ($\boxplus$) or multiplicative ($\boxtimes$), depending on the model. For each model we apply the appropriate theorem from Section 6.1 and express the bound as a function of the sparsity ε, denoted $\mathsf{pred}_{\mathsf{model}}(\varepsilon)$, where we substitute the suitable model in the subscript.

Free method predictions for the configuration model

As mentioned above, in order to apply the techniques of Section 6.1 to random graph models, one needs to understand the distributions involved. For the configuration model, the convolution is of the eigenvalue distribution of the matrix $\mathbf{M}$, which we already know to be the uniform distribution on ± 1 and we denote by μ_1, and the one of $\mathbf{V} = \mathbf{U}\mathbf{U}^{\mathsf{T}}$ which we denote by μ_2. The latter's form is defined by the distribution of degrees. In the case of a graph with degrees 2 and 3 and average degree $2+\varepsilon$, a straightforward calculation shows its Cauchy transform to be

$$\mathcal{G}_{\mu_2}(x) = \frac{1}{2+\varepsilon}\left(\frac{1+\varepsilon}{x} + \frac{\varepsilon}{x-3} + \frac{1-\varepsilon}{x-2}\right).$$

By Equation (17) we have that $\mathcal{N}_{\mu_1}(y) = \sqrt{\frac{y+1}{y}}$. Thus, applying Lemma 23 gives us that $\sup(\mu_1 \boxtimes \mu_2)$ is found by minimizing over $x > 3$ the function

$$\widetilde{\mathcal{N}}_{\mu_1 \boxtimes \mu_2}(x) = x \cdot \sqrt{\frac{\mathcal{M}_{\mu_2}(x)}{\mathcal{M}_{\mu_2}(x)+1}} = x \cdot \sqrt{\frac{x\mathcal{G}_{\mu_2}(x)-1}{x\mathcal{G}_{\mu_2}(x)}}. \tag{27}$$

This leads us to the main result of this section.

▶ **Lemma 24** (Small–ε bound for $\mathsf{pred}_{\mathsf{conf}}(\varepsilon)$)**.**

$$\mathsf{pred}_{\mathsf{conf}}(\varepsilon) = \frac{3}{\sqrt{2}} + \frac{3}{4}\varepsilon^{1/2} + \frac{9\sqrt{2}}{32}\varepsilon - O(\varepsilon^{3/2}).$$

The proof uses elementary means and appears in the full version of this paper.

Free method predictions for the $\mathcal{C} + \varepsilon\mathcal{M}$, $(2+\varepsilon)\mathcal{M}$ and $3\left(\frac{2+\varepsilon}{3}\mathcal{M}\right)$ models appear in the full version of the paper.

Abstract

We introduce the problem of *entropy equivalence testing* for probability distributions, a relaxation of the well-studied closeness testing problem, where the distribution testing algorithm is now only required to distinguish, given samples from two unknown distributions p, q and a parameter $\varepsilon \in (0, 1/2]$, between $p = q$ and $|H(p) - H(q)| \geqslant \varepsilon$ (where H denotes the Shannon entropy). We provide a time- and sample-efficient algorithm for this task, showing that the optimal sample complexity for this task can be significantly lower than that of closeness testing. As an application, we leverage this result to provide the first non-trivial testing algorithm for (standard) closeness of low-degree *Bayesian networks*, which significantly improves on either the sample or time complexity of a baseline based on full learning.

1 Introduction

Distribution testing, a subfield of property testing [35, 30] concerned with efficient algorithms for deciding statistical properties of data, has witnessed a significant interest since its systematic introduction by Batu, Fortnow, Rubinfeld, Smith, and White [5], with a flurry of works over the past two decades addressing a range of hypothesis testing tasks, under various models of distribution testing (see, e.g., [34, 10, 11] and [29, Chapter 11] for surveys and expositions).

Two of the flagship and most fundamental tasks in distribution testing are *identity testing* (and its special case, *uniformity testing*), and *closeness testing* (also known as *equivalence* testing): in the first, an algorithm is given independent samples from an (unknown) discrete

© Clément L. Canonne, Yash Pote, Jonathan Scarlett, and Joy Qiping Yang;
licensed under Creative Commons License CC-BY 4.0

probability distribution, and must decide whether the distribution is equal to some known reference distribution, or significantly deviates from it in a meaningful notion of distance (typically total variation distance). In the second, the algorithm has access to samples from *two* unknown distributions, and similarly must decide whether they are equal, or significantly far from each other. Here, "significantly far" is quantified by an input parameter $\varepsilon > 0$, and the algorithm is required to be correct with high probability $1 - \delta$,[1] while minimizing the *sample complexity*, that is, the total number of samples taken from the distribution(s) in the worst case as a function of the domain size n, distance parameter ε, and error probability δ.

The sample complexity of these two flagship tasks is by now well understood, with several time-efficient algorithms known to achieve the optimal sample complexity, as a function of all parameters: namely,

$$\Theta\left(\frac{\sqrt{n\log(1/\delta)} + \log(1/\delta)}{\varepsilon^2}\right)$$

for identity testing [32, 1, 28, 27], and

$$\Theta\left(\frac{n^{2/3}\log^{1/3}(1/\delta) + \log(1/\delta)}{\varepsilon^{4/3}} + \frac{\sqrt{n\log(1/\delta)} + \log(1/\delta)}{\varepsilon^2}\right)$$

for closeness testing [5, 17, 28, 26]. However, in spite of these impressive advances, these sample complexities can remain prohibitively large for many combinations of (n, ε), notably for small ε corresponding to distributions that may be very close to one another. Given that their sample complexities are constant-factor *optimal*, there would seem to be little room for improvement, yet two possible avenues remain. The first is to *relax the guarantees*: total variation is known to be a very stringent measure of distance, and testing with respect to a more permissive distance measure may enable significant sample complexity savings, while still being "good enough" for the application at hand. This direction was partially explored in, for instance, [24]. The second avenue, particularly well suited to high-dimensional data, is to *make additional structural assumptions* on the distribution: high-dimensional data is seldom fully unstructured, and one can usually leverage domain knowledge to make modelling assumptions, for instance that the probability distributions exhibit a low-degree Bayesian network structure, or are consistent with an Ising model. This line of work, in the context of distribution testing, was initiated in [12, 23].

Our work makes progress on both of these fronts. We first define a relaxation of closeness testing, which we term *entropy equivalence testing*, where one is asked to detect if the two unknown distributions have significantly different (Shannon) entropy:[2]

> **Entropy Equivalence Testing (EET)**: Given sample access to distributions p, q over a known domain of size n and parameters $\varepsilon \in (0, 1/2]$ and $\delta \in (0, 1]$, distinguish, with probability at least $1 - \delta$, between the following two cases: (1) $p = q$, and (2) $|H(p) - H(q)| \geq \varepsilon$.

[1] One typically sets δ to be a small constant, e.g., $\delta = 1/10$: this is without much loss of generality, as one can amplify this by repetition to any target $1 - \delta$, at the cost of an $O(\log(1/\delta))$ factor in sample and time complexity.

[2] Recall that the (Shannon) entropy of a probability distribution p over a discrete domain $\mathcal{X}$ is defined as $H(p) = \sum_{x\in\mathcal{X}} p(x)\log\frac{1}{p(x)}$.

We note that the "single-distribution" version of this task, when q is fully known to the algorithm, was recently introduced [15], under the name Entropy Identity Testing (EIT). [15] then leveraged their algorithm for EIT to obtain an improved identity testing algorithm for "standard" identity testing (i.e., in total variation distance) of *bounded-in-degree Bayes nets*, establishing a connection between the two aforementioned avenues of research. We build upon and deepen this connection to obtain, from our algorithm for EET, the first non-trivial *closeness* testing algorithm for Bayes nets.

1.1 Our results

We now describe our results in more detail. Our first contribution is an efficient algorithm for the EET task defined above (where we implicitly set the probability of failure δ to be a small constant):

▶ **Theorem 1.** *There exists an algorithm for the Entropy Equivalence Testing problem with sample complexity*

$$\tilde{O}\left(\frac{n^{3/4}}{\varepsilon}\right) + O\left(\frac{\log^2(n/\varepsilon)}{\varepsilon^2}\right)$$

and running time near-linear in the number of samples.

Combining Theorem 1 and the "baseline tester" discussed below (see Section 1.2) which follows from a reduction from entropy difference to total variation distance and has sample complexity $\tilde{O}\left(\max\left(\frac{n^{2/3}}{\varepsilon^{4/3}}, \frac{\sqrt{n}}{\varepsilon^2}\right)\right)$, one gets, after simplifying the resulting sample complexity, our main result:

▶ **Corollary 2** (Main testing result)**.** *There exists an algorithm for the Entropy Equivalence Testing problem with sample complexity*

$$\tilde{O}\left(\min\left\{\frac{n^{3/4}}{\varepsilon}, \frac{n^{2/3}}{\varepsilon^{4/3}}\right\}\right) + O\left(\frac{\log^2(n/\varepsilon)}{\varepsilon^2}\right)$$

and running time near-linear in the number of samples.

We complement this positive result with an information-theoretic lower bound, showing that our algorithm has nearly optimal sample complexity:

▶ **Theorem 3** (Lower bound)**.** *Any algorithm for the Entropy Equivalence Testing problem must draw*

$$\widetilde{\Omega}\left(\min\left\{\frac{n^{3/4}}{\varepsilon}, \frac{n^{2/3}}{\varepsilon^{4/3}}\right\}\right) + \Omega\left(\frac{\log^2 n}{\varepsilon^2}\right)$$

total samples from p and q.

Finally, we show how to leverage our algorithm for EET to obtain a closeness testing algorithm for bounded in-degree Bayes nets: we emphasize that, to the best of our knowledge, this is the *first* testing algorithm for this problem, besides the "naïve" (and computationally inefficient) testing-by-learning approach that fully learns the two unknown distributions with $\tilde{O}(2^d n/\varepsilon^2)$ samples, in time $2^{\Omega(n)}$:

▶ **Theorem 4.** *There exists an algorithm for closeness testing (in total variation distance) of in-degree d Bayesian networks with sample complexity*

$$s = \tilde{O}\left(\min\left\{\frac{2^{3d/4}n}{\varepsilon^2}, \frac{2^{2d/3}n^{4/3}}{\varepsilon^{8/3}}\right\} + \frac{n^2}{\varepsilon^4}\right),$$

and running time $\tilde{O}(n^{d+1}s)$.

Interestingly, the techniques underlying Theorem 4 can also be easily adapted to obtain an algorithm for identity testing of Bayes nets, improving upon the work of [15]: see Corollary 18.

1.2 Technical overview

We now provide an overview of the techniques and main ideas underlying our results.

1.2.1 Upper bound for EET

A bound of $\tilde{O}\left(\max\left\{\frac{n^{2/3}}{\varepsilon^{4/3}}, \frac{\sqrt{n}}{\varepsilon^2}\right\}\right)$ readily follows from a standard inequality, allowing one to reduce the entropy difference problem to closeness testing in TV: namely, when $d_{\mathrm{TV}}(p,q) \leqslant \frac{1}{2}$, then $|H(p) - H(q)| \leqslant d_{\mathrm{TV}}(p,q) \log \frac{n}{d_{\mathrm{TV}}(p,q)}$ [21, Lemma 2.7]. Another straightforward upper bound is obtained by estimating the entropy, a harder task, which takes $\Theta\left(\frac{n}{\varepsilon \cdot \log n} + \frac{\log^2 n}{\varepsilon^2}\right)$ samples [42]. This hints at the possibility of getting a better bound of $O(n^c/\varepsilon + \log^2 n/\varepsilon^2)$ for some absolute constant $c < 1$. Surprisingly, the final upper bound of $\tilde{O}\left(\min\left\{\frac{n^{2/3}}{\varepsilon^{4/3}}, \frac{n^{3/4}}{\varepsilon}\right\} + \frac{1}{\varepsilon^2}\right)$ is related to the squared Hellinger distance (and not the total variation). This is a result of considering two testers that can solve EET independently, and choosing the one with lower sample complexity. The main contribution of our work is providing an alternative tester to the TV reduction tester above.

An $\tilde{O}(\frac{n^{3/4}}{\varepsilon} + \frac{1}{\varepsilon^2})$ tester. Our analysis starts with a reduction to testing both farness (vs. equality) in Hellinger distance and a cross-entropy difference term (with respect to the uniform mixture) via some algebraic manipulations (see Lemma 9). The problem thus becomes testing whether Hellinger distance is large (which we know costs $O(\min\{\frac{n^{3/4}}{\varepsilon}, \frac{n^{2/3}}{\varepsilon^{4/3}}\}) \leqslant O(\frac{n^{3/4}}{\varepsilon})$) and testing whether the cross-entropy term is large (since one of them will be large if the entropy difference is large). A natural idea is of course to employ a plug-in estimator for the cross entropy difference (see (1)). Unfortunately, this empirical estimator has an inherent[3] bias of the form $\sum_{i \in [n]} \frac{|p_i - q_i|}{m(p_i+q_i)}$, where m is the (equal) number of samples we take from p and q to compute the estimate. Our argument to deal with the bias is as follows: If the expectation of the plug-in estimator has *low bias* (at most $O(\varepsilon)$), then we can rely on its estimate alone. On the other hand, if it has *high bias* (at least $\Omega(\varepsilon)$), we hope to catch it and reject (i.e., declare that $|H(p) - H(q)| > \epsilon$) early.

Low mass regime: Reduction to TV. One main challenge to designing this test is that the bias is impossible to test without a lower bound on $p_i + q_i$ (the variance of estimating the bias could be huge). The key to passing this hurdle is an idea inspired by a different algorithm from [28], whose analysis implies that for the elements $i \in [n]$ where q_i (or p_i) is small, we can perform tests more efficiently (in TV) via access to its conditional distribution (as efficiently as $\tilde{O}(n^{3/4}/\varepsilon)$), with the intuition being: The TV distance between the conditional distributions is actually larger (inverse of its mass size $\tilde{\Omega}(\varepsilon/q(T))$, where T is the set of small-mass elements). Via a reduction to TV from cross-entropy difference, we can also test farness on these elements with $\tilde{O}(n^{3/4}/\varepsilon)$ samples.

[3] In the works of [42], their plug-in estimator also exhibits similar bias in the analysis, and they resort to machinery from polynomial approximation to reduce the bias (which will increase the variance the higher the degree of the polynomial).

Detecting bias in the high mass regime. Capitalizing on this, we will consider exclusively elements with large mass: $p_i \geqslant \tilde{\Omega}(\varepsilon/n^{3/4})$. With a bound on $m(p_i + q_i) \geqslant \Omega(1)$ (since we take $m = \tilde{O}(\frac{n^{3/4}}{\varepsilon})$), this reduces to testing farness in TV distance, which can be performed with $O(\sqrt{n}/\varepsilon^2)$ samples (to bound the bias term by $O(\varepsilon)$), rather than the $O(n^c/\varepsilon)$ for some $c < 1$ that we set out for. Luckily our problem can be easier (depending on relation between n and ε) than testing in TV (see Lemma 13). Intuitively, this is related to testing in the instance-optimal setting [40, 28] – one can test with sample complexity as a function of p, q (for our case p, q has exclusively large probability masses), rather than as a function of the domain size (the worst case over all possible p, q). Interestingly, to detect the bias, we are using the same test statistic (with different threshold) first used in [17] to test in TV distance and subsequently in [24] to test in Hellinger distance.

Had we not made a "reject" decision after the bias check in the high mass regime (nor rejected due to its low mass cross-entropy difference), it would suggest that the bias on the high mass regime is at most $O(\varepsilon)$ and therefore, the estimator for $\sum_i (p_i - q_i) \log((p_i + q_i)/2)$ is reliable: A standard analysis of expectation and variance followed by an application of Chebyshev's inequality then yields Theorem 1.

1.2.2 Lower bound for EET

The lower bound is a combination of $\tilde{\Omega}(\min\{\frac{n^{2/3}}{\varepsilon^{4/3}}, \frac{n^{3/4}}{\varepsilon}\})$ and $\Omega(\frac{\log^2 n}{\varepsilon^2})$. The former is derived via a reduction from testing mutual information to entropy difference. The task of testing mutual information (MI) is as follows: if $I(X : Y) = 0$, then accept with probability 0.99; If $I(X : Y) \geqslant \varepsilon$, then reject with probability 0.99. Given the close relation between mutual information and entropy: $I(X : Y) = H(X) + H(Y) - H(X, Y)$, one can reduce the problem of MI testing to EET by treating p as the joint distribution of X, Y and q as the product of X and Y (we can simulate sample access to the product of X and Y with two samples from the joint distribution). Therefore, the existing lower bound from [37, Corollary 6.2] holds for our problem. The latter lower bound of $\Omega(\frac{\log^2 n}{\varepsilon^2})$ comes from [15, Lemma 2.7], given the reduction from identity testing to equivalence testing.

1.2.3 Application to equivalence testing of Bayes nets

As laid out by [15], one can utilize testing entropy difference as a subroutine to testing Bayes nets. The key of the analysis is derived via the celebrated Chow-Liu decomposition [20]: If two Bayes nets p and q have similar local entropies, then they must share approximately similar structures (their corresponding DAGs are close in some sense; see [15, Lemma 3.4]). Once we confirm that they share a similar structure, the problem boils down to checking local (every subset of random variables of size at most $d + 1$) KL-divergences. While KL-divergences are known to be untestable [24, Theorem 7] in the extreme cases when $q(x) = 0$, there is hope if one can obtain a lower bound on $q(x)$. In fact, we can reduce testing in KL to testing in Hellinger distance with an $O\left(\max_x \log \frac{p(x)}{q(x)}\right)$ factor overhead using [37, Lemma 3.1]. To get a lower bound on $q(x)$, we use a standard technique of testing the mixture of q and the uniform distribution.

1.3 Related works

Estimating entropy. Entropy estimation is a well-studied problem in both the information theory [41, 42, 31] and property testing [39, 3] communities, with the near-optimal sample complexity $\Theta(\frac{n}{\varepsilon \log n} + \frac{\log^2 n}{\varepsilon^2})$ being eventually established by [42, 31] (for discrete distributions).

As we are considering the testing problem, our upper bound is less costly compared to its learning (estimation) variant. Moreover, other variants of entropy have been studied, such as Rényi entropy [2]. The more general problem of estimating functionals of distributions was also considered by [31].

Identity testing and closeness testing. The standard formulation of identity testing asks the following problem: Given a full description of a hypothesis q, how many i.i.d. samples are needed from p to distinguish between $p = q$ and $d_{\mathrm{TV}}(p, q) \geqslant \varepsilon$, where p and q are both distributions over support of size $[n]$? This problem is well-known to have a sample complexity of $\Theta\left(\sqrt{n}/\varepsilon^2\right)$, a much lower cost compared to fully learning every parameter of p, which takes $\Theta(n/\varepsilon^2)$ samples. A similar problem can be asked if one is instead only provided sample access to p and q, both unknown. This is the closeness testing problem (in TV) and it is known that a $\Theta\left(\max\{\frac{\sqrt{n}}{\varepsilon^2}, \frac{n^{2/3}}{\varepsilon^{4/3}}\}\right)$ sample complexity is necessary and sufficient, making this a slightly harder problem than identity testing while still saving on samples compared to fully learning p and q. Our problem differs from the standard formulation by testing in the entropy difference rather than in TV distance. Most relevant to our work is the work of [15], which solves the problem of entropy identity testing (up to polylogarithmic factors) with a sample complexity of $\tilde{\Theta}(\frac{\sqrt{n}}{\varepsilon} + \frac{1}{\varepsilon^2})$. Another relevant work is that of [24], which asks the question of testing in different distances, e.g., distinguishing between $d_{\mathrm{KL}}(p\|q) \leqslant \varepsilon^2/100$ and $d_{\mathrm{H}}(p, q) \geqslant \varepsilon$ for identity testing (sample access to p and the full description of q). Interestingly, as shown in the same work, equivalence testing in squared Hellinger distance, i.e., distinguishing between $p = q$ and $d_H^2(p, q) \geqslant \varepsilon$ has a similar cost of $\Theta\left(\min\{\frac{n^{2/3}}{\varepsilon^{4/3}}, \frac{n^{3/4}}{\varepsilon}\}\right)$ (though perhaps not so surprising, as we are reducing to testing in squared Hellinger square in one of the cases we handle). Our work adds to their results for equivalence testing in entropy difference.

Testing mutual information. Testing mutual information (MI) asks the following question: Given sample access to a (discrete) distribution p over two random variables X, Y with a domain of size $|\Sigma_X|$ and $|\Sigma_Y|$ respectively, how many samples do we need from p to distinguish between $I(X : Y) = 0$ and $I(X : Y) \geqslant \varepsilon$? The study of this problem was initiated by [9] to solve the problem of learning a special variant of Bayes net (trees). While their MI tester is sufficient for learning trees-structured distributions near-optimally, their upper bound is loose in terms of dependence on $|\Sigma_X|$ and $|\Sigma_Y|$: $O(\frac{|\Sigma_X|\cdot|\Sigma_Y|}{\varepsilon})$. More recently, [37] gave a near-optimal bound of $\tilde{\Theta}(\min\{\frac{|\Sigma_X|^{3/4}|\Sigma_Y|^{1/4}}{\varepsilon}, \frac{|\Sigma_X|^{2/3}|\Sigma_Y|^{1/3}}{\varepsilon^{4/3}}\})$ (assuming $|\Sigma_X| \geqslant |\Sigma_Y|$). We note that this bound bears similarity (e.g., setting $|\Sigma_Y| = O(1)$) to ours due to the close relation between MI and entropy: $I(X : Y) = H(X) + H(Y) - H(X, Y)$. Indeed, MI testing can be reduced to EET naturally (as outlined above). Before these works, [4, 13] studied the problem of (conditional) independence testing in the TV distance.

Testing Bayesian networks. A Bayesian network (Bayes net) is a high-dimensional distribution over n random variables that factorizes into n conditional probabilities: $p(X_1, \ldots, X_n) = \prod_{i=1}^{n} p(X_i \mid \Pi_i)$, where $\Pi_i \in [n]$ is called the parent set of X_i. This factorization is associated with a directed acyclic graph (DAG) $G = (V, E)$ ($V = \{X_1, \ldots, X_n\}$), and if $X_j \in \Pi_i$, then the edge $(X_j, X_i) \in E$ (with X_j being one of X_i's parents). A distribution p is called a Bayes net if its joint probability density function factorizes according to G and p is called Markov with respect to G. Learning Bayesian networks from samples is a fundamental problem in learning theory, and there is a plethora of evidence that this problem is hard computationally [18, 22, 7]. On the other hand, time-efficient algorithms (polynomial in n, the number of random variables) do exist in some special cases [19, 8, 9].

Identity testing and closeness testing of Bayes nets were systematically studied by [12], though their stronger upper bounds only consider relaxed version of Bayes nets where both p and q are required be *balanced* and *non-degenerate*. While they also provide a more general upper bound (without assuming balancedness and non-degeneracy for Bayes nets), they still require that the node ordering be the same between p and q, a non-trivial assumption. Our upper bound does not make any assumption other than the bounded in-degree d, which is a natural and necessary parameter to consider, since testing unbounded degree Bayes nets is exponentially hard: $\Omega(\frac{2^{n/2}}{\varepsilon^2})$ (e.g., see [6, Theorem B.1]). The strongest upper bound that we are aware of is by [25], which can solve the identity testing[4] problem in $\tilde{O}(\frac{2^{d/2}n}{\varepsilon^2})$ samples,[5] under the assumption that p and q have the same structure (Markov with respect to the same DAG). For equivalence testing, under the same assumption, they give a bound of $\tilde{O}(\min\{\frac{2^{3d/4}n}{\varepsilon^2}, \frac{2^{2d/3}n^{4/3}}{\varepsilon^{8/3}}\})$.[6] Our results match their bounds if $d \gg \log(n/\varepsilon)$, and our algorithm will work without the extra assumption that p and q share the same structure. A lower bound of $\Omega(\frac{2^{d/2}n}{\varepsilon^2})$ when $d \leqslant \log n$ [6, Theorem 4.1] holds for identity testing of Bayes nets and thus also for its closeness testing variant (our setting).

1.4 Preliminaries

Define the factorial moment by $(x)_m := \frac{x!}{(x-m)!}$, which gives an unbiased estimator for the monomials of the Poisson mean: namely, if $X \sim \mathrm{Poi}(\lambda)$, then $\mathbb{E}[(X)_m] = \lambda^m$ for all $m \geqslant 0$. More generally, we have the following fact, whose proof we provide in Appendix A for completeness:

▶ **Fact 5.** *Let X be a Poisson random variable with parameter λ, and $f\colon \mathbb{R} \to \mathbb{R}$ be any function, then, we have that $\mathbb{E}[(X)_m \cdot f(X)] = \lambda^m \cdot \mathbb{E}[f(X+m)]$. In particular, choosing $f \equiv 1$, we have that $\mathbb{E}[(X)_m] = \lambda^m$ for all $m \geqslant 0$.*

▶ **Fact 6** (Folklore). *For any $0 < \alpha \leqslant 1/2$ and $\varepsilon \in (0,1]$, testing whether the bias of a coin is at most α or at least $\alpha(1+\varepsilon)$, with probability at least $1-\delta$, can be done with $n = O\left(\frac{1}{\alpha\varepsilon^2}\log\frac{1}{\delta}\right)$ samples.*

Distances and norms. We will use a number of standard distance measures for two distributions p, q over $[n]$, and various known inequalities between them, e.g., see [36]. The *squared Hellinger distance* is

$$d_H^2(p,q) := \frac{1}{2}\sum_{i\in[n]}\left(\sqrt{p_i}-\sqrt{q_i}\right)^2$$

The *total variation distance* is $d_{\mathrm{TV}}(p,q) := \frac{1}{2}\|p-q\|_1 = \frac{1}{2}\sum_{i\in[n]}|p_i - q_i|$. The *$\ell_2$ distance* is $\|p-q\|_2 := \left(\sum_{i\in[n]}(p_i-q_i)^2\right)^{1/2}$, and the *$\chi^2$-divergence* of p from q is $d_{\chi^2}(p,q) := \sum_{i\in[n]}(p_i-q_i)^2/q_i$. These satisfy the chain of inequalities

$$d_{\mathrm{TV}}(p,q) \leqslant \sqrt{2}\, d_H(p,q) \qquad \text{and} \qquad d_H^2(p,q) \leqslant d_{\mathrm{TV}}(p,q) \leqslant \sqrt{d_{\chi^2}(p,q)},$$

and the equivalence $\frac{1}{2}\sum_i (p_i-q_i)^2/(p_i+q_i) = \Theta(d_H^2(p,q))$. The *Kullback–Leibler (KL) divergence* is $d_{\mathrm{KL}}(p\|q) := \sum_i p_i \log(p_i/q_i)$, which satisfies $d_{\mathrm{KL}}(p\|q) \leqslant d_{\chi^2}(p,q)$ and Pinsker's inequality $d_{\mathrm{TV}}(p,q) \leqslant \sqrt{d_{\mathrm{KL}}(p\|q)/2}$.

[4] Note that their setting of identity testing actually corresponds to equivalence testing in our setting.
[5] Implicitly, using the Hellinger testing result of [24, Theorem 1].
[6] Implicitly, using the optimal Hellinger equivalence test [24].

Notation. In what follows, for a given integer $n \geqslant 1$, we denote by $[n]$ the set $[n] = \{1, 2, \ldots, n\}$, and by U_n the uniform distribution on $[n]$. When clear from context, we will omit the subscript, and write U instead of U_n. Given a probability distribution p over $[n]$ and a set $S \subseteq [n]$ such that $p(S) > 0$ we write $p(\cdot \mid S)$ for the conditional distribution of p on S. For the high dimensional (Bayes net) section, we use p_T to denote the marginalization of p over T, where T is a subset of $\{X_1, \ldots, X_n\}$, e.g., p_{X_1,X_2} denotes the marginal distribution of (X_1, X_2). We also use Π_i to denote the parent set of the random variable X_i in a Bayes net.

Throughout the paper, we use log for the natural logarithm, and adopt the standard asymptotic notation $O(\cdot), \Omega(\cdot), \Theta(\cdot)$, as well as the closely related $\tilde{O}(\cdot), \tilde{\Omega}(\cdot), \tilde{\Theta}(\cdot)$, which hide polylogarithmic factors in their argument.

2 An $\tilde{O}(\frac{n^{3/4}}{\varepsilon} + \frac{\log^2(n/\varepsilon)}{\varepsilon^2})$ Upper Bound for EET

In this section, we establish our main theorem, Theorem 1. We begin with a simple algorithmic "trick" that allows us to reduce the task to one where both p, q put at least some minimum probability $\eta > 0$ on every element of the domain:

▶ **Lemma 7.** *Let p, q be distributions over $[n]$, and set $\eta := \varepsilon/(4\log(n/\varepsilon))$. Let $\tilde{p} := (1-\eta)p + \eta U$ and likewise for $\tilde{q}$. Then $\tilde{p}_i, \tilde{q}_i \geqslant \varepsilon/(4n\log(n/\varepsilon))$ for every $i \in [n]$, and*

$$||H(\tilde{p}) - H(\tilde{q})| - |H(p) - H(q)|| \leqslant \varepsilon/2.$$

Moreover, one sample from $\tilde{p}$ (resp. $\tilde{q}$) can be simulated from one sample from p (resp. q).

Proof. Since $d_{\mathrm{TV}}(p, \tilde{p}) \leqslant \frac{\eta}{2} = \frac{\varepsilon}{8\log(n/\varepsilon)}$, by invoking the bound on entropy difference with respect to TV distance in [21, Lemma 2.7], we get

$$|H(p) - H(\tilde{p})| \leqslant \frac{\varepsilon}{8\log(n/\varepsilon)} \log\left(\frac{n \cdot 8\log(n/\varepsilon)}{\varepsilon}\right) = \varepsilon \cdot \frac{\log(n/\varepsilon) + \log(8\log(n/\varepsilon))}{8\log(n/\varepsilon)} \leqslant \varepsilon/4.$$

Similarly, we have $|H(q) - H(\tilde{q})| \leqslant \varepsilon/4$. By the triangle inequality, we then have

$$|H(\tilde{p}) - H(\tilde{q})| \leqslant |H(p) - H(\tilde{p})| + |H(q) - H(\tilde{q})| + |H(p) - H(q)| \leqslant \varepsilon/2 + |H(p) - H(q)|,$$

and

$$|H(p) - H(q)| \leqslant |H(\tilde{p}) - H(\tilde{q})| + |H(p) - H(\tilde{p})| + |H(q) - H(\tilde{q})| \leqslant \varepsilon/2 + |H(\tilde{p}) - H(\tilde{q})|,$$

establishing the lemma. ◀

Of course, if $p = q$, then $\tilde{p} = \tilde{q}$; Lemma 7 guarantees that if $|H(p) - H(q)| \geqslant \varepsilon$, then $|H(\tilde{p}) - H(\tilde{q})| \geqslant \Omega(\varepsilon)$. That is, $\tilde{p}, \tilde{q}$ satisfy the promise with the same ε (up to constants) whenever p, q do, so we can henceforth assume that $\min_{i\in[n]} p_i, \min_{i\in[n]} q_i \geqslant \frac{\varepsilon}{4n\log(n/\varepsilon)}$. With this in hand, we are ready to establish our main theorem, restated, as follows:

▶ **Theorem 8** (Theorem 1, restated)**.** *There exists an algorithm (Algorithm 1) which, given sample access to two unknown probability distributions p, q over a known domain $[n]$, as well as parameter $\varepsilon \in (0, 1/2]$, takes*

$$O\left(\frac{n^{3/4}\log(n/\varepsilon)\cdot\log n}{\varepsilon} + \frac{\log^2(n/\varepsilon)}{\varepsilon^2}\right)$$

samples from both p and q, and has the following guarantees:

Algorithm 1 Entropy equivalence testing (EET).

Require: Sample access to p and q, both over $[n]$; accuracy parameter $\varepsilon \in (0,1]$.

Run a Hellinger closeness tester on p, q with $O\left(\frac{n^{3/4}}{\varepsilon}\right)$ samples.
if $d_H^2(p,q) \geqslant \Omega(\varepsilon)$ **then return** reject
Set $m_1 := \tilde{O}(n^{3/4}/\varepsilon)$. Take m_1 samples each from p, q; let X_i, Y_i be the empirical counts.
$S \leftarrow \left\{ i \in [n] : X_i + Y_i \geqslant \Omega(m_1 \cdot \varepsilon/(n^{3/4}\log(n/\varepsilon))) \right\}$ ▷ heavy elements
Set $m_2 := \tilde{O}(1/\varepsilon)$. Using m_2 samples, test whether $p(\bar{S}) \geqslant \tilde{\Omega}(\varepsilon)$ and $q(\bar{S}) \geqslant \tilde{\Omega}(\varepsilon)$.
if only one of the preceding inequalities hold **then** ▷ p and q differ on $\bar{S}$.
    return reject
if both preceding inequalities hold **then** ▷ low-mass regime on $\bar{S}$
    Set $m_3 := O(\log^2(n/\varepsilon)/\varepsilon^2)$. Using m_3 samples, estimate $|p(\bar{S}) - q(\bar{S})|$.
    if $|p(\bar{S}) - q(\bar{S})| \geqslant \tilde{\Omega}(\varepsilon)$ **then return** reject
    Via rejection sampling on $\bar{S}$, run a TV closeness tester on $p_{\bar{S}}, q_{\bar{S}}$ at threshold $\tilde{\Omega}(\varepsilon/q(\bar{S}))$ using $\tilde{O}(n^{3/4}/\varepsilon)$ samples.
    if the conditional tester rejects **then**
        return reject
Set $m_4 := \tilde{O}\left(n^{3/4}/\varepsilon + \log^2(n/\varepsilon)/\varepsilon^2\right)$ and $s := \Omega(n^{3/4}\log(n/\varepsilon)/\varepsilon)$.
Using s samples, compute $T \leftarrow \sum_{i \in S} \frac{(X_i - Y_i)^2 - (X_i + Y_i)}{X_i + Y_i}$. ▷ bias check
if $T \geqslant \Omega(\sqrt{n})$ **then**
    return reject
Using $O(\log^2(n/\varepsilon)/\varepsilon^2)$ samples, test both $|p(S) - q(S)| \geqslant \Omega\left(\frac{\varepsilon}{\log(n/\varepsilon)}\right)$ and $\|p - q\|_2^2 \geqslant \Omega\left(\frac{\varepsilon^2}{\log^2(n/\varepsilon)}\right)$.
if either preceding inequality holds **then**
    return reject
Take m_4 samples; let X_i, Y_i be the empirical counts on S. Compute

$$Z \leftarrow \sum_{i \in S} \frac{X_i - Y_i}{m_4} \log \frac{1}{X_i + Y_i}.$$

if $|Z| \geqslant \Omega(\varepsilon)$ **then return** reject
else return accept

- *If $p = q$, then the algorithm outputs* accept *with probability at least $9/10$;*
- *If $|H(p) - H(q)| \geqslant \varepsilon$, then the algorithm outputs* reject *with probability at least $9/10$.*

Further, the algorithm runs in time $O(N \log N)$, where N is the total number of samples.

The remainder of this section is dedicated to proving this theorem, which we do via a series of lemmas.

The first lemma relates a difference in entropy to a difference in (squared) Hellinger distance and a cross entropy term with respect to a mixture:

▶ **Lemma 9.** *For any two distributions p, q over $[n]$, we have*

$$|H(p) - H(q)| \leqslant \Theta(d_H^2(p,q)) + \left| \sum_{i=1}^{n} (p_i - q_i) \log \frac{1}{(p_i + q_i)/2} \right|.$$

Proof. Letting $r \coloneqq \frac{p+q}{2}$, we can write

$$\begin{aligned}
&H(p) - H(q) \\
&= \sum_i \left(p_i \log \frac{1}{p_i} - q_i \log \frac{1}{q_i} \right) \\
&= \sum_i \left(-p_i \log \frac{p_i}{(p_i+q_i)/2} + p_i \log \frac{1}{(p_i+q_i)/2} + q_i \log \frac{q_i}{(p_i+q_i)/2} - q_i \log \frac{1}{(p_i+q_i)/2} \right) \\
&= d_{\mathrm{KL}}\left(q \,\|\, r\right) - d_{\mathrm{KL}}\left(p \| r\right) + \sum_i \left(p_i \log \frac{1}{(p_i+q_i)/2} - q_i \log \frac{1}{(p_i+q_i)/2} \right) \\
&= d_{\mathrm{KL}}\left(q \,\|\, r\right) - d_{\mathrm{KL}}\left(p \| r\right) + \sum_i (p_i - q_i) \log \frac{1}{(p_i+q_i)/2}.
\end{aligned}$$

We then observe that

$$d_{\mathrm{KL}}\left(q \,\|\, r\right) \leqslant d_{\chi^2}\left(q, r\right) = \sum_i \frac{\left(q_i - \frac{p_i+q_i}{2}\right)^2}{\frac{p_i+q_i}{2}} = \sum_i \frac{1}{2} \frac{(p_i - q_i)^2}{p_i + q_i} = \Theta(d_H^2(p,q)),$$

where the last equality comes from the equivalence of between Hellinger distance and Triangle distance (e.g., see [24, Proposition 3]).[7] Similarly, we have that $d_{\mathrm{KL}}\left(p \,\|\, r\right) \leqslant d_{\chi^2}\left(p, r\right) = \Theta(d_H^2(p,q))$, and we conclude that

$$\begin{aligned}
|H(p) - H(q)| &\leqslant |d_{\mathrm{KL}}\left(q \,\|\, r\right)| + |d_{\mathrm{KL}}\left(p \,\|\, r\right)| + \left| \sum_i (p_i - q_i) \log \frac{1}{(p_i+q_i)/2} \right| \\
&\leqslant \Theta(d_H^2(p,q)) + \left| \sum_i (p_i - q_i) \log \frac{1}{(p_i+q_i)/2} \right|,
\end{aligned}$$

as claimed. ◀

Lemma 9 allows us to split the entropy difference $|H(p) - H(q)|$ into a Hellinger part and a term $|\sum_i (p_i - q_i) \log(1/((p_i+q_i)/2))|$, so that an entropy difference ε implies at least one of these two terms must be $\varepsilon/2$: thus, it suffices to test both, and reject if, and only if, at least one of them is detected to be $\Omega(\varepsilon)$. (Clearly, if $p = q$, both the Hellinger and KL-like terms are zero.)

The Hellinger term can be tested with $\widetilde{O}(n^{3/4}/\varepsilon)$ samples using a Hellinger closeness tester (e.g., [28, Proposition 2.15]): if $d_H^2(p,q) \geqslant \Omega(\varepsilon)$, this tester will allow us to reject with high probability. For the rest of the subsection we therefore can assume $d_H^2(p,q) \leqslant O(\varepsilon)$, and the task reduces to testing the second, "KL-like" term,

$$\Lambda(p,q) \coloneqq \left| \sum_i (p_i - q_i) \log \frac{1}{(p_i+q_i)/2} \right|, \tag{1}$$

and specifically to distinguish $\Lambda(p,q) = 0$ from $\Lambda(p,q) \geqslant \frac{\varepsilon}{2}$.

To do so, the idea is to handle separately the set S^* of "heavy" elements, on which either p or q puts relatively high probability (specifically, at least some threshold $\tau \coloneqq \tilde{\Omega}(\varepsilon/n^{3/4})$), and the remaining set $\bar{S^*} = [n] \setminus S^*$ of "light" elements (which have low probability under

[7] Note that the induced KL terms have been studied in information theory (called Jensen-Shannon divergence; see e.g., [33, Chapter 7] and more systematically in [38], where they actually show that the Jensen-Shannon divergence and the Triangle distance are equivalent up to constant factors).

both p and q). Of course, we do not know this set S^*, as both p, q are unknown; however, by taking $\tilde{O}(1/\tau) = \tilde{O}(n^{3/4}/\varepsilon)$ samples (which is inconsequential, as we will pay this sample complexity for the Hellinger test anyway), we can obtain a set S which is a good proxy for S^*. To make this formal, define the following two sets:

$$S_1 := \left\{ i \in [n] \mid p_i + q_i \geqslant C_1 \cdot \frac{\varepsilon}{n^{3/4}\log(n/\varepsilon)} \right\}.$$
$$S_2 := \left\{ i \in [n] \mid p_i + q_i \geqslant C_2 \cdot \frac{\varepsilon}{n^{3/4}\log(n/\varepsilon)} \right\},$$

where $C_2 \geqslant C_1 > 0$ are two absolute constants. Our focus is to identify a set $S \subseteq [n]$ such that $S_2 \subseteq S \subseteq S_1$.

▶ **Lemma 10.** *Using $O\left(\frac{n^{3/4}\log(n/\varepsilon)\log n}{\varepsilon}\right)$ samples from p and q, one can efficiently return a set S satisfying $S_2 \subseteq S \subseteq S_1$ with probability at least $\frac{99}{100}$.*

Proof. By Fact 6, choosing $2C_1 \leqslant C_2$, as we have sample access to the uniform mixture $\frac{p+q}{2}$, we can distinguish $\frac{p_i+q_i}{2} \geqslant C_2 \cdot \frac{\varepsilon}{2n^{3/4}\log(n/\varepsilon)}$ and $\frac{p_i+q_i}{2} \leqslant C_1 \cdot \frac{\varepsilon}{2n^{3/4}\log(n/\varepsilon)}$ with probability $1 - \frac{1}{100n}$ costing $O\left(\frac{n^{3/4}\log(n/\varepsilon)\cdot\log n}{\varepsilon}\right)$ samples from p and q. Therefore, running the test over the support $[n]$ (using the same set of samples to run this test for all i's) and adding each $i \in [n]$ to the set S if we detect $p_i + q_i \geqslant C_2 \cdot \frac{\varepsilon}{n^{3/4}\log(n/\varepsilon)}$, by a union bound, the algorithm will be simultaneously correct on all $i \in [n]$ with probability at least $\frac{99}{100}$. ◀

To summarize, once we have identified such a set S, given that

$$\underbrace{\Lambda(p,q)}_{0 \text{ or } \geqslant \frac{\varepsilon}{2}} \leqslant \underbrace{\left|\sum_{i\in\overline{S}}(p_i - q_i)\cdot\log\frac{1}{p_i+q_i}\right|}_{=:\Lambda_{\overline{S}}(p,q)} + \underbrace{\left|\sum_{i\in S}(p_i - q_i)\cdot\log\frac{1}{p_i+q_i}\right|}_{=:\Lambda_S(p,q)}$$

it suffices to separately test (1) $\Lambda_{\overline{S}}(p,q) = 0$ vs. $\Lambda_{\overline{S}}(p,q) \geqslant \varepsilon/4$, and (2) $\Lambda_S(p,q) = 0$ vs. $\Lambda_S(p,q) \geqslant \varepsilon/4$; we do so below, assuming that our set S satisfies $S_2 \subseteq S$.[8]

Test 1: $\Lambda_{\overline{S}}(p,q) = 0$ vs. $\Lambda_{\overline{S}}(p,q) \geqslant \varepsilon$

Inspired by the ideas of [28], we can then check if the distributions are far *in TV distance* in the low-probability regime (i.e., elements in $\overline{S}$), which will suffice by a simple reduction from entropy difference to TV (using the lower bound $\min_i p_i, \min_i q_i \geqslant \tilde{\Omega}(\varepsilon/n)$). In more detail, we have

$$\left|\sum_{i\in\overline{S}}(p_i - q_i)\cdot\log\frac{1}{p_i+q_i}\right| \leqslant \sum_{i\in\overline{S}}|p_i - q_i|\cdot\log\frac{1}{p_i+q_i} \leqslant O(\log(n/\varepsilon))\cdot\sum_{i\in\overline{S}}|p_i - q_i|.$$

While this is a task that would in general require a large number of samples, here we can leverage the additional fact that $\overline{S}$ does not contain any heavy elements.

▶ **Lemma 11.** *Let $T \subseteq [n]$ be a set such that $\max_{i\in T}(p_i + q_i) \leqslant C_2 \cdot \frac{\varepsilon}{n^{3/4}\log(n/\varepsilon)}$. Then, testing $p_T = q_T$ versus $\sum_{i\in T}|p_i - q_i| \geqslant \frac{\varepsilon}{\log(n/\varepsilon)}$ (with probability of success $9/10$) can be done with $O\big(n^{3/4}\cdot\log(n/\varepsilon)/\varepsilon\big)$ samples from p, q.*

[8] For simplicity of exposition, we henceforth ignore the factor 4, and consider ε instead of $\varepsilon/4$; a simple rescaling argument gives the original guarantees.

Proof. By [28], we know that $\tilde{O}\left(\frac{n^{3/4}}{\varepsilon}\right)$ samples suffice to distinguish $p_T = q_T$ from $d_{\mathrm{TV}}(p_T, q_T) \geqslant \varepsilon$ with high constant probability. For the sake of completeness, we briefly explain how to adapt their argument to our setting. First, it takes $O(\frac{\log(n/\varepsilon)}{\varepsilon})$ samples to check whether the mass of p on T is larger than $\Omega(\varepsilon/\log(n/\varepsilon))$, and similarly for q: if both have mass smaller that this, we accept, as $\sum_{i\in\overline{S}} |p_i - q_i| \leqslant p(T) + q(T) < \frac{\varepsilon}{\log(n/\varepsilon)}$. If only one of the two puts large enough mass on T, we reject, as this shows that $\sum_{i\in T} |p_i - q_i| \neq 0$. Otherwise, both p, q put enough mass on T, and we continue.

With $O\left(\frac{\log^2(n/\varepsilon)}{\varepsilon^2}\right)$ samples, we then confirm that their probability masses on T approximately match, i.e., that $|p(T) - q(T)| \leqslant O\left(\frac{\varepsilon}{\log(n/\varepsilon)}\right)$. If they do not, we can output reject. Otherwise, we have

$$\begin{aligned}\sum_{i\in T} |p_i - q_i| &= \sum_{i\in T} |p(i|i\in T)p(T) - q(i|i\in T)q(T)| \\ &\leqslant \sum_{i\in T} (|p(i|i\in T)p(T) - p(i|i\in T)q(T)| + |p(i|i\in T)q(T) - q(i|i\in T)q(T)|) \\ &= |p(T) - q(T)| + q(T)\cdot\|p(\cdot|T) - q(\cdot|T)\|_1.\end{aligned}$$

Thus, if $\|p_T - q_T\| \geqslant \Omega\left(\frac{\varepsilon}{\log(n/\varepsilon)}\right)$ and $|p(T) - q(T)| \leqslant O\left(\frac{\varepsilon}{\log(n/\varepsilon)}\right)$ (for suitable choice of constants in the $O(\cdot)$, $\Omega(\cdot)$), then we have that

$$d_{\mathrm{TV}}(p_T, q_T) = \frac{1}{2}\|p(\cdot|T) - q(\cdot|T)\|_1 \geqslant \Omega\left(\frac{\varepsilon}{q(T)\cdot\log(n/\varepsilon)}\right).$$

Recalling that $q(T), p(T) \geqslant \frac{\varepsilon}{\log(n/\varepsilon)}$ and $q(T) = \Theta(p(T))$, we can sample from p_T, q_T via rejection sampling at the cost of an expected $O(1/q(T))$, $O(1/p(T))$ factor in the sample complexity. Thus, we can use an off-the-shelf TV equivalence tester (e.g., from [17, Theorem 1]) to test $d_{\mathrm{TV}}(p(\cdot|T), q(\cdot|T)) \geqslant \Omega\left(\frac{\varepsilon}{q(T)\cdot\log(n/\varepsilon)}\right)$ vs. $p(\cdot|T) = q(\cdot|T)$ at the cost of

$$\max\left\{\frac{n^{2/3}q^{4/3}(T)\log^{4/3}(n/\varepsilon)}{\varepsilon^{4/3}}, \frac{n^{1/2}q^2(T)\log^2(n/\varepsilon)}{\varepsilon^2}\right\}$$

samples from $p(\cdot|T), q(\cdot|T)$; which, by the above discussion, requires an expected

$$\max\left\{\frac{n^{2/3}q^{1/3}(T)\log^{4/3}(n/\varepsilon)}{\varepsilon^{4/3}}, \frac{n^{1/2}q(T)\log^2(n/\varepsilon)}{\varepsilon^2}\right\}$$

samples from p, q (which can be made high-probability via Markov's inequality, paying a constant factor in the sample complexity and a small additional probability of failure). Since $q(T) \leqslant \frac{\varepsilon}{n^{3/4}\log(n/\varepsilon)}\cdot n = \frac{\varepsilon\cdot n^{1/4}}{\log(n/\varepsilon)}$, we finally conclude that taking $O\left(\frac{n^{3/4}\cdot\log(n/\varepsilon)}{\varepsilon}\right)$ samples suffices. ◀

Test 2: $\Lambda_S(p,q) = 0$ vs. $\Lambda_S(p,q) \geqslant \varepsilon$

We now look at the second – and more involved – case, namely, detecting when the entropy difference is far in the high mass regime. That is, we are testing $\Lambda_S(p,q) = 0$ vs. $\Lambda_S(p,q) \geqslant \varepsilon$.

We will define a suitable test statistic, Z, and analyze its expectation (with the goal of bounding its bias and relate it to $\Lambda_S(p,q)$), before bounding its variance to conclude with an application of Chebyshev's inequality. At a high level, our strategy is as follows: either the

empirical entropy difference Z has *low bias*, which means we can simply rely on its output for the test, or it has *high bias*, in which case this can be detected by performing additional checks to detect this bias.

Let $m = \tilde{O}\left(\frac{n^{3/4}}{\varepsilon} + \frac{\log(n/\varepsilon)}{\varepsilon^2}\right)$ be the number of samples taken from p, q, and assume the Poissonized setting: that is, instead of exactly m samples, we take a random $\mathrm{Poi}(m)$ number of samples.[9] Recall that by construction of the set $S \subseteq S_1$, we can assume $p_i + q_i \geqslant \tilde{\Omega}\left(\frac{\varepsilon}{n^{3/4}}\right)$ for all $i \in S$. Focusing on S, we run two further checks, each at cost $O(\log^2 m/\varepsilon^2)$:

1. $|p(S) - q(S)| \leqslant O(\varepsilon/\log m)$, which implies $|\sum_{i\in S}(p_i - q_i)| \log m \leqslant O(\varepsilon)$.
2. $\|p - q\|_2^2 \leqslant O(\varepsilon^2/\log^2 m)$, which is checked via testing at distance $\varepsilon/\log m$ using an ℓ_2-closeness tester (e.g., via learning p, q in ℓ_2 distance, see for instance [16]).

If either check rejects, we reject; otherwise we proceed assuming both guarantees hold.

Letting X_i (resp. Y_i) be the number of occurrences of element $i \in S$ among the samples from p (resp. from q), we define our entropy difference estimator to be

$$Z := \sum_{i\in S} \frac{X_i - Y_i}{m} \log \frac{1}{X_i + Y_i},$$

and we write $Z_i := \frac{X_i - Y_i}{m} \log \frac{1}{X_i+Y_i}$ for the i-th summand and let $Z_i = 0$ when $X_i + Y_i = 0$. By the above Poissonization procedure, we have $X_i \sim \mathrm{Poi}(m \cdot p_i)$ and $Y_i \sim \mathrm{Poi}(m \cdot q_i)$ for all i, and the $(X_i)_i$ (resp. $(Y_i)_i$) are independent. We first bound the bias of this estimator Z:

▶ **Lemma 12.** *For any set $S \subseteq [n]$,*

$$\left|\sum_{i\in S}(p_i - q_i)\log\tfrac{1}{m(p_i+q_i)} - \mathbb{E}[Z]\right| \leqslant \sum_{i\in S}\frac{|p_i - q_i|}{m(p_i + q_i)}.$$

Proof. Let $J_i := X_i + Y_i \sim \mathrm{Poi}(\lambda_i)$ with $\lambda_i := m(p_i + q_i)$. Conditional on $J_i = j$, the count X_i is $\mathrm{Bin}(j, p_i/(p_i + q_i))$-distributed, so $\mathbb{E}[X_i - Y_i \mid J_i] = J_i \cdot (p_i - q_i)/(p_i + q_i)$. By the law of total expectation, pulling the factor $\log(1/J_i)$ outside the inner expectation,

$$\mathbb{E}[Z_i] = \tfrac{1}{m}\,\mathbb{E}\left[(X_i - Y_i)\log\tfrac{1}{J_i}\right] = \tfrac{1}{m}\,\mathbb{E}\left[\log\tfrac{1}{J_i}\cdot\mathbb{E}[X_i - Y_i \mid J_i]\right] = \tfrac{p_i - q_i}{m(p_i+q_i)}\,\mathbb{E}[J_i\log(1/J_i)].$$

We then apply the Poisson identity (Fact 5) $\mathbb{E}[J_i f(J_i)] = \lambda_i\,\mathbb{E}[f(J_i + 1)]$, taking $f(j) = \log(1/j)$:

$$\mathbb{E}[Z_i] = \tfrac{p_i - q_i}{m(p_i+q_i)} \cdot \lambda_i\,\mathbb{E}[\log(1/(J_i + 1))] = -(p_i - q_i)\,\mathbb{E}[\log(J_i + 1)].$$

Subtracting the target $(p_i - q_i)\log(1/\lambda_i)$,

$$(p_i - q_i)\log\tfrac{1}{\lambda_i} - \mathbb{E}[Z_i] = (p_i - q_i)\,\mathbb{E}\left[\log\tfrac{J_i+1}{\lambda_i}\right].$$

We proceed to bound $\mathbb{E}[\log((J_i + 1)/\lambda_i)]$ from above and below. By Jensen's inequality applied to the concave function log,

$$\mathbb{E}\left[\log\tfrac{J_i+1}{\lambda_i}\right] \leqslant \log\left(1 + \tfrac{1}{\lambda_i}\right) \leqslant \tfrac{1}{\lambda_i}.$$

[9] This standard technique is valid as it only affects the sample complexity by constant terms and an arbitrarily small error probability adjustment, since a Poisson random variable tightly concentrates around its mean. Its advantage is to provide additional independence between the empirical counts of each element, which is useful in the analysis.

For the lower bound, the inequality $\log x \geqslant 1 - 1/x$ applied to $x = (J_i + 1)/\lambda_i$, together with $\mathbb{E}[1/(J_i + 1)] = (1 - e^{-\lambda_i})/\lambda_i$ for $J_i \sim \mathrm{Poi}(\lambda_i)$, gives

$$\mathbb{E}\Big[\log \tfrac{J_i+1}{\lambda_i}\Big] \geqslant 1 - \lambda_i \,\mathbb{E}\Big[\tfrac{1}{J_i+1}\Big] = e^{-\lambda_i} \geqslant 0.$$

Combining these findings gives $|\mathbb{E}[\log((J_i+1)/\lambda_i)]| \leqslant 1/\lambda_i$ (using $e^{-\lambda_i} \leqslant 1/\lambda_i$ for all $\lambda_i > 0$), so

$$\big|(p_i - q_i)\log \tfrac{1}{\lambda_i} - \mathbb{E}[Z_i]\big| \leqslant \tfrac{|p_i - q_i|}{\lambda_i}.$$

Summing over $i \in S$ yields the claim. ◀

The bias of our estimator is determined by the RHS of Lemma 12; note that if $p = q$, the RHS simplifies to 0. As a result, a natural idea would be to use this RHS as a proxy, and to check if the RHS is noticeably large using another test: if it is larger than $\geqslant \Omega(\varepsilon)$, we can immediately reject, as this is clear evidence that $p \neq q$. We do so in the following lemma:

▶ **Lemma 13.** *Suppose that $d_H^2(p, q) \leqslant O(\varepsilon)$. Then, with $s = O(n^{3/4}\log(n/\varepsilon)/\varepsilon)$ samples from p, q, one can distinguish between the following two cases with high constant probability:*

1. *$p = q$ (which implies $\sum_{i\in S} \frac{|p_i - q_i|}{m(p_i+q_i)} = 0$).*
2. *$\sum_{i\in S} \frac{|p_i - q_i|}{(p_i+q_i)} \geqslant \Omega(m\varepsilon)$.*

Proof. We use the test statistic

$$T := \sum_{i\in S} \frac{(X_i - Y_i)^2 - (X_i + Y_i)}{X_i + Y_i},$$

where $X_i \sim \mathrm{Poi}(s \cdot p_i)$ and $Y_i \sim \mathrm{Poi}(s \cdot q_i)$. We show:

- In the first case, $\mathbb{E}[T] = 0$, while in the second case $\mathbb{E}[T] \geqslant \Omega(\sqrt{n})$.
- $\mathrm{Var}[T] \leqslant O(n)$ in both cases.

Chebyshev's inequality then will enable us to separate the two cases by thresholding T at a value scaling as $\Theta(\sqrt{n})$.

Analyzing $\mathbb{E}[T]$. The first part is similar to the analysis from [17, Lemma 4], which relies on the same statistic T (for a different purpose): write $\delta_i := (p_i - q_i)/(p_i + q_i)$ and $J_i := X_i + Y_i$. Conditional on $J_i = j$, we have $Y_i = j - X_i$ so $X_i - Y_i = 2X_i - j$, and $X_i \sim \mathrm{Bin}(j, p_i/(p_i+q_i))$. Hence,

$$\mathbb{E}[X_i - Y_i \mid J_i = j] = j\delta_i,$$

and the binomial variance $\mathrm{Var}[X_i \mid J_i = j] = j \cdot \frac{p_i q_i}{(p_i+q_i)^2}$ gives

$$\mathrm{Var}[X_i - Y_i \mid J_i = j] = 4j \cdot \tfrac{p_i q_i}{(p_i+q_i)^2} = j(1 - \delta_i^2).$$

Combining, $\mathbb{E}[(X_i - Y_i)^2 \mid J_i = j] = \mathrm{Var}[X_i - Y_i \mid J_i = j] + \mathbb{E}[X_i - Y_i \mid J_i = j]^2 = j(1 - \delta_i^2) + j^2\delta_i^2$. The i-th summand of T is $\frac{(X_i - Y_i)^2 - J_i}{J_i}$, which we set to 0 when $J_i = 0$ (the 0/0 case). For $J_i = j \geqslant 1$,

$$\mathbb{E}\left[\frac{(X_i - Y_i)^2 - J_i}{J_i} \,\middle|\, J_i = j\right] = \frac{(j^2 - j)\delta_i^2}{j} = (j-1)\delta_i^2.$$

Taking the outer expectation, with the indicator $\mathbf{1}\{J_i \geqslant 1\}$ enforcing the 0/0 convention,

$$\mathbb{E}[T] = \sum_{i\in S} \delta_i^2 \cdot \mathbb{E}[(J_i - 1)\mathbf{1}\{J_i \geqslant 1\}] = \sum_{i\in S} \delta_i^2 \big(\lambda_i - 1 + e^{-\lambda_i}\big),$$

where $\mathbb{E}[(J_i - 1)\mathbf{1}\{J_i \geqslant 1\}] = \mathbb{E}[J_i] - \Pr[J_i \geqslant 1] = \lambda_i - (1 - e^{-\lambda_i})$.

In particular, in the first case (when $p = q$), $\delta_i = 0$ for every $i \in S$, and so $\mathbb{E}[T] = 0$. We therefore now focus on the second case, for which we depart from [17]. By the construction of S (Lemma 10), $p_i + q_i \geqslant \Omega(\frac{\varepsilon}{n^{3/4}\log(n/\varepsilon)})$ for every $i \in S$, so choosing $s = \Omega(n^{3/4} \cdot \log(n/\varepsilon)/\varepsilon)$ with a sufficiently large constant gives $\lambda_i = s(p_i + q_i) \geqslant 2$ for all $i \in S$. The bound $\lambda - 1 + e^{-\lambda} \geqslant \lambda - 1 \geqslant \lambda/2$ for $\lambda \geqslant 2$ then yields

$$\mathbb{E}[T] \geqslant \tfrac{1}{2} \sum_{i\in S} \lambda_i \delta_i^2 = \tfrac{s}{2} \sum_{i\in S} \frac{(p_i - q_i)^2}{p_i + q_i}.$$

By Cauchy–Schwarz,

$$\sum_{i\in S} \frac{(p_i - q_i)^2}{p_i + q_i} \geqslant \frac{1}{n} \left(\sum_{i\in S} \frac{|p_i - q_i|}{\sqrt{p_i + q_i}} \right)^2.$$

Since $m(p_i + q_i) \geqslant 1$ (in view of $i \in S$ and $m = \tilde{\Omega}(\frac{n^{3/4}}{\varepsilon})$), we have $\frac{1}{\sqrt{p_i+q_i}} \geqslant \frac{1}{\sqrt{m}(p_i+q_i)}$. Applying this termwise and using the definition of the second case,

$$\sum_{i\in S} \frac{|p_i - q_i|}{\sqrt{p_i + q_i}} \geqslant \frac{1}{\sqrt{m}} \sum_{i\in S} \frac{|p_i - q_i|}{p_i + q_i} \geqslant \Omega(\sqrt{m}\varepsilon).$$

Combining,

$$\mathbb{E}[T] \geqslant \frac{s}{2n} \cdot \Omega(m\varepsilon^2) = \Omega\left(\frac{sm\varepsilon^2}{n}\right),$$

which is $\Omega(\sqrt{n} + \frac{\log^2(n/\varepsilon)}{n^{1/4}\varepsilon}) \geqslant \Omega(\sqrt{n})$ given the settings of $s = \tilde{\Theta}(n^{3/4}/\varepsilon)$ and $m = \tilde{\Theta}(n^{3/4}/\varepsilon + \frac{\log^2(n/\varepsilon)}{\varepsilon^2})$.

Upper bound on $\mathbf{Var}[T]$. The variance bound from [17, Lemma 5] gives

$$\mathrm{Var}[T] \leqslant 2\min\{n, s\} + 5s \sum_{i\in S} \frac{(p_i - q_i)^2}{p_i + q_i}.$$

Under the lemma's assumption on the Hellinger distance, $\sum_{i\in S}(p_i - q_i)^2/(p_i + q_i) = \Theta(d_H^2(p, q)) \leqslant O(\varepsilon)$, so the second term is $\widetilde{O}(s \cdot \varepsilon)$, and $\mathrm{Var}[T] \leqslant O(n + s \cdot \varepsilon)$, where $s = \tilde{O}\left(n^{3/4}/\varepsilon\right)$. This scaling of s leads to the simplified bound $\mathrm{Var}[T] \leqslant O(n)$.

Concluding via Chebyshev. In the first case, $\mathbb{E}[T] = 0$ and $\mathrm{Var}[T] \leqslant O(n)$, so $|T| \leqslant O(\sqrt{n})$ with probability $\geqslant 9/10$. In the second case, $\mathbb{E}[T] \geqslant C\sqrt{n}$ and $\mathrm{Var}[T] \leqslant O(n) \leqslant \mathbb{E}[T]^2/C'$, so $T \geqslant C''\sqrt{n}$ with probability $\geqslant 9/10$. Thresholding at $\Theta(\sqrt{n})$ thus distinguishes the two cases. ◀

Having used the RHS of Lemma 12 as a proxy for the bias, and checked that it is small (and rejected otherwise), we are not yet done: we could still have both small bias for Z (so that $\mathbb{E}[Z] \approx \sum_{i\in S}(p_i - q_i)\log\frac{1}{m(p_i+q_i)}$) *and* large $\Lambda_S(p, q) = \left|\sum_{i\in S}(p_i - q_i)\log\frac{1}{m(p_i+q_i)}\right|$. However, now, since we know that $|\mathbb{E}[Z]| \approx \Lambda_S(p, q)$, to conclude it suffices to run one last check: namely, that Z is small enough.

Indeed, we know now that Z has small bias: if we can also show, via a variance argument, that Z concentrates around its expectation, then we will have $|Z| \approx_{\text{w.h.p.}} |\mathbb{E}[Z]| \approx \Lambda_S(p,q)$, and checking that $|Z|$ is small will ensure (with high probability) that we can guarantee that $\Lambda_S(p,q)$ is small. Thus, our last missing piece is an upper bound on $\mathrm{Var}[Z]$, which will let us show that Z concentrates around its expectation.

▶ **Lemma 14.** *The variance of the entropy difference estimator Z satisfies*

$$\mathrm{Var}[Z] \leqslant O(\log^2 m)\|p-q\|_2^2 + \frac{\log^2 m}{m} \leqslant O(\varepsilon^2).$$

Proof. Under Poissonization, the counts $\{X_i\}_{i\in S}$ and $\{Y_i\}_{i\in S}$ are mutually independent across coordinates. As a result, the Z_i's are also independent, and

$$\mathrm{Var}[Z] = \sum_{i\in S} \mathrm{Var}[Z_i] \leqslant \sum_{i\in S} \mathbb{E}[Z_i^2].$$

Fix any $i \in S$, letting $J_i := X_i + Y_i \sim \mathrm{Poi}(m(p_i+q_i))$, and defining the event $\mathcal{E}_i := \{J_i \leqslant 3m\}$. Since $m(p_i+q_i) \leqslant m$, the Chernoff bound for Poisson random variables gives $\Pr[\mathcal{E}_i^c] \leqslant e^{-\Omega(m)}$. Then:

- On $\mathcal{E}_i$: $|\log(1/J_i)| \leqslant \log(3m)$ for $J_i \neq 0$, and noting from before that $Z_i = 0$ when $J_i = 0$, we have $|Z_i|\,\mathbf{1}_{\mathcal{E}_i} \leqslant \frac{\log(3m)}{m}|X_i - Y_i|$. Squaring and taking expectations,

  $$\mathbb{E}[Z_i^2\,\mathbf{1}_{\mathcal{E}_i}] \leqslant \tfrac{\log^2(3m)}{m^2}\,\mathbb{E}[(X_i-Y_i)^2] = \tfrac{\log^2(3m)}{m^2}\big(m(p_i+q_i) + m^2(p_i-q_i)^2\big),$$

  using $\mathrm{Var}[X_i - Y_i] = m(p_i+q_i)$ and $\mathbb{E}[X_i - Y_i] = m(p_i - q_i)$ (moments of Poisson r.v.'s).
- On $\mathcal{E}_i^c$: from $|X_i - Y_i| \leqslant J_i$ and $|\log(1/J_i)| = \log J_i \leqslant J_i$ (valid since $J_i > 3m \geqslant 1$), we get $|Z_i|\,\mathbf{1}_{\mathcal{E}_i^c} \leqslant J_i^2/m$. Combining Cauchy–Schwarz with the moment bound $\mathbb{E}[J_i^8] = O(m^8)$ (since Poisson moments are polynomials in the mean, by Fact 5) and the tail bound $\Pr[\mathcal{E}_i^c] \leqslant e^{-\Omega(m)}$,

  $$\mathbb{E}[Z_i^2\,\mathbf{1}_{\mathcal{E}_i^c}] \leqslant \tfrac{1}{m^2}\,\mathbb{E}[J_i^4\,\mathbf{1}_{\mathcal{E}_i^c}] \leqslant \tfrac{1}{m^2}\sqrt{\mathbb{E}[J_i^8]\,\Pr[\mathcal{E}_i^c]} \leqslant e^{-\Omega(m)}.$$

  Summing over $i \in S$, using $\log^2(3m) \leqslant 4\log^2 m$ (for $m \geqslant 3$) and $\sum_i (p_i+q_i) \leqslant 2$,

  $$\mathrm{Var}[Z] \leqslant O(\log^2 m)\,\|p-q\|_2^2 + \tfrac{O(\log^2 m)}{m} + n\cdot e^{-\Omega(m)}.$$

The last term is absorbed into $O(\frac{\log^2 m}{m})$ since $m \geqslant \log n$ makes $n\cdot e^{-\Omega(m)} \leqslant 1/m$. ◀

Combining Lemma 12 and Lemma 13, and conditioning on all tests passing, the expectation of Z has small bias:

$$\left|\mathbb{E}[Z] - \sum_i (p_i - q_i)\log\tfrac{1}{(p_i+q_i)}\right| \leqslant O(\varepsilon).$$

By Lemma 14, $\mathrm{Var}[Z] \leqslant O(\varepsilon^2)$, so Chebyshev gives $|Z - \mathbb{E}[Z]| \leqslant O(\varepsilon)$ with probability at least $9/10$. Combining via the triangle inequality,

$$\Pr\left[\left|Z - \sum_i (p_i-q_i)\log\tfrac{1}{(p_i+q_i)}\right| \leqslant O(\varepsilon)\right] \geqslant \tfrac{9}{10}.$$

To conclude this subcase. We choose a threshold for $|Z|$ at a suitable constant multiple of ε that distinguishes the two cases. If $\Lambda(p,q) = \left|\sum_{i\in S}(p_i - q_i)\log\frac{1}{(p_i+q_i)}\right| = 0$, then with probability at least 9/10 the test on T from Lemma 13 will not reject and $|Z| \leqslant O(\varepsilon)$, and so this overall test accepts. If $d_H^2(p,q) \leqslant O(\varepsilon)$ and $\left|\sum_{i\in S}(p_i - q_i)\log\frac{1}{(p_i+q_i)}\right| \geqslant \Omega(\varepsilon)$, then with probability at least 9/10 either the test on T from Lemma 13 rejects, or it does not and then $|Z| \geqslant \Omega(\varepsilon)$, and this overall test rejects.

Wrapping up

Putting the above ingredients together:

- If $p = q$, then with high constant probability, (1) the Hellinger test on $d_H(p,q)$ accepts, and (2) (a) the set S is correctly identified, (b) the test on $\Lambda_{\overline{S}}(p,q)$ accepts, (c) (i) the test on T (checking for low bias for Z) accepts, and (ii) the test on Z (test on $\Lambda_S(p,q)$ assuming low bias for Z) accepts. Overall, the algorithm accepts with probability at least 9/10 by a union bound.
- If $|H(p) - H(q)| \geqslant \varepsilon$, then with high constant probability (1) either the Hellinger test on $d_H(p,q)$ rejects; or it accepts because $d_H(p,q)$ is small, in which case $\Lambda(p,q)$ must be large; then, with high constant probability (2) (a) the set S is correctly identified, (b) the test on $\Lambda_{\overline{S}}(p,q)$ rejects, or it accepts because $\Lambda_{\overline{S}}(p,q)$ is small, which means $\Lambda_S(p,q)$ must be large: in which case (c) (i) the test on T (checking for low bias for Z assuming $d_H(p,q)$ is small) rejects, or it accepts because the bias is small, in which case (ii) the test on Z (test on $\Lambda_S(p,q)$ assuming low bias for Z) rejects. Overall, the algorithm rejects with probability at least 9/10 by a union bound.

Overall, each subtest in Algorithm 1 uses no more than $O\left(\frac{n^{3/4}\log(n/\varepsilon)\log n}{\varepsilon}\right)$ or $O\left(\frac{\log^2(n/\varepsilon)}{\varepsilon^2}\right)$ samples, and hence the total sample complexity of our algorithm is

$$O\left(\frac{n^{3/4}\log(n/\varepsilon)\log n}{\varepsilon} + \frac{\log^2(n/\varepsilon)}{\varepsilon^2}\right).$$

All our test statistics can be computed in $O(n)$ time once all X_i, Y_i are collected.[10] To compute X_i, Y_i, one can first sort over all samples which takes $O(s\log s)$ time, where s is the number of samples in one of the subtests, and then sum them up. Thus, the time complexity of our algorithm is $O(N\log N)$, where N is the total number of samples. This concludes the proof of Theorem 8.

3 Bayesian Network Equivalence Testing

In this section, we show how to leverage our Entropy Equivalence Testing (EET) algorithm (Algorithm 2) to obtain an *equivalence testing* (closeness testing) algorithm for bounded-degree Bayesian networks (Bayes nets). Specifically, the problem we consider is the following:

[10] The statistics for testing Hellinger square is the same as T (albeit with different threshold; see [24, Theorem 5]). T can be computed in $O(n)$ time once all X_i, Y_i are known. Computing $S \leftarrow \left\{ i \in [n] : X_i + Y_i \geqslant \Omega(m_1 \cdot \varepsilon/(n^{3/4}\log(n/\varepsilon))) \right\}$ can be done in $O(n)$ time and calculating the empirical of S can be implemented in $O(m_2)$ time. As for the conditional TV tester, the rejection sampling will cost as many samples as we take in total, and for TV closeness testing we use the same statistic T (see, e.g., [24, Theorem 4]). For ℓ_2 tester, the statistic is also computable in $O(n)$ time [17, Section 3]. Assuming that we can compute $\log(x)$ in constant time, one can compute the statistic Z in $O(n)$ time.

Bayes-Net Equivalence Testing: Given sample access to distributions p, q over $\{0,1\}^n$, each Markov with respect to a DAG of in-degree at most d (the DAG is unknown, and possibly distinct between p and q), and parameters $\varepsilon \in (0, 1/2]$ and $\delta \in (0, 1]$, distinguish, with probability at least $1 - \delta$, between the following two cases: (1) $p = q$, and (2) $d_{\mathrm{TV}}(p, q) \geq \varepsilon$.

▶ **Definition 15.** *A* projection of a Bayes net p *on* $\{0,1\}^n$ *onto a DAG* G *is denoted by* p_G*, and is defined by its probability mass function (PMF) as follows:*

$$p_G(X_1, \ldots, X_n) = \prod_{i=1}^{n} p(X_i \mid \Pi_i^G),$$

where Π_i^G *is the set of parents of* X_i *in* G*. Moreover, with a slight abuse of notation, we write* p_{X_i,Π_i} *or* $p_{X_i,\Pi_i}(x_i, \pi_i)$ *for the marginal distribution of* p *on the subset* $\{X_i, \Pi_i\}$*.*

The baseline here is the testing-by-learning approach, whereby one learns the two unknown in-degree d Bayes nets to TV distance $\frac{\varepsilon}{3}$ and checks the distance between the two learned hypotheses. It is known that learning an in-degree d Bayes net in total variation distance can be done in $\tilde{O}(2^d n/\varepsilon^2)$ samples (see [12, Appendix A]): to the best of our knowledge, the time complexity of any learning algorithm achieving this bound is exponential, namely, $2^{\tilde{\Omega}(n)}$. In contrast, we obtain a testing algorithm with drastically better running time (for all $d = o(n)$), and significantly better sample complexity whenever $d \gg \log(n/\varepsilon^2)$.

▶ **Theorem 16** (Theorem 4, restated)**.** *There exists an algorithm (Algorithm 2) that, given sample access to two Bayesian networks* p *and* q *over* $\{0,1\}^n$ *with in-degree at most* d*, as well as a parameter* $\varepsilon \in (0, 1]$*, takes*

$$s = \tilde{O}\left(\min\left\{\frac{2^{3d/4}n}{\varepsilon^2}, \frac{2^{2d/3}n^{4/3}}{\varepsilon^{8/3}}\right\} + \frac{n^2}{\varepsilon^4}\right),$$

samples from p, q*, and distinguishes with probability at least* $2/3$ *between (1)* $p = q$ *and (2)* $d_{\mathrm{TV}}(p, q) \geqslant \varepsilon$*. Moreover, the algorithm runs in time* $\tilde{O}(n^{d+1}s)$*.*

Proof. The pseudocode is provided in Algorithm 2. Due to space constraints, we defer the proof of correctness to the full version [14]. ◀

▶ Remark 17. We have an interesting dichotomy: our algorithm is efficient (polynomial in n) only if d is constant. However, it is worse than its learning counterpart when d is constant: n^2 (our test) vs. n (learning). On the other hand, if $d = \Omega(\log n)$, then our tester will be more efficient than learning sample-wise, but its runtime becomes $n^{\Omega(\log n)}$, and is thus quasi-polynomial.

As identity testing is a special case of closeness testing, our above analysis can straightforwardly be ported to yield an identity testing algorithm (using an algorithm for identity testing in Hellinger instead of a closeness one as the first building block). An immediate consequence of this is to yield an improved identity tester for Bayes net with sample complexity $\tilde{O}(\frac{2^{d/2}n}{\varepsilon^2} + \frac{n^2}{\varepsilon^4})$, thus improving on the prior bound $\tilde{O}(\frac{2^{d/2}n^{3/2}}{\varepsilon^2} + \frac{n^2}{\varepsilon^4})$ [15, Theorem 1.2].

Algorithm 2 Closeness testing for Bayesian networks.

Require: Sample access to p and q, both in-degree d Bayesian networks over $\{0,1\}^n$; accuracy parameter $\varepsilon \in (0,1]$.

1: Set $\varepsilon_1 \leftarrow \Theta\left(\frac{\varepsilon^2}{n}\right)$, $\varepsilon_2 \leftarrow \Theta\left(\frac{\varepsilon^2}{d\cdot n\cdot\log(dn/\varepsilon)}\right)$, $\delta \leftarrow \frac{1}{20\binom{n}{d+1}}$

2: Set

$$m \leftarrow \tilde{O}\left(\min\left\{\frac{2^{3d/4}\cdot n}{\varepsilon^2}, \frac{2^{2d/3}\cdot n^{4/3}}{\varepsilon^{8/3}}\right\}\right) + O\left(\frac{d^3n^2\cdot\log^2(n/\varepsilon)}{\varepsilon^4}\right)$$

3: Take a multiset set S_p (resp. S_q) of m samples from $\tilde{p}$ (resp. $\tilde{q}$), defined by

$$\tilde{p} := \left(1 - \frac{C_3\cdot\varepsilon^2}{dn\log(n/\varepsilon)}\right)p + \frac{C_3\cdot\varepsilon^2}{dn\log(n/\varepsilon)}\cdot U \quad \text{and} \quad \tilde{q} := \left(1 - \frac{C_3\cdot\varepsilon^2}{dn\log(n/\varepsilon)}\right)q + \frac{C_3\cdot\varepsilon^2}{dn\log(n/\varepsilon)}\cdot U$$

4: **for all** subset $T \subseteq [n]$ with $|T| = d+1$ **do** ▷ $\binom{n}{d+1}$ possible subsets

5: Let $\mathcal{T} \leftarrow \{0,1\}^T$

6: Test $\tilde{p}_{\mathcal{T}} = \tilde{q}_{\mathcal{T}}$ vs. $|H(\tilde{p}_{\mathcal{T}}) - H(\tilde{q}_{\mathcal{T}})| \geqslant \varepsilon_1$ with failure probability δ, using S_p, S_q

7: ▷ By Corollary 2

8: Test $\tilde{p}_{\mathcal{T}} = \tilde{q}_{\mathcal{T}}$ vs. $d_H^2(\tilde{p}_{\mathcal{T}}, \tilde{q}_{\mathcal{T}}) \geqslant \varepsilon_2$ with failure probability δ, using S_p, S_q ▷ By [28]

9: **if** either test rejects **then return** reject

10: **return** accept

▶ **Corollary 18.** *Given sample access to a Bayesian networks p and a full description of Bayesian network q over $\{0,1\}^n$ with in-degree at most d, as well as a parameter $\varepsilon \in (0,1]$, there is an algorithm that takes*

$$s = \tilde{O}\left(\frac{2^{d/2}n}{\varepsilon^2} + \frac{n^2}{\varepsilon^4}\right),$$

samples from p, and distinguishes with probability at least $2/3$ between (1) $p = q$ and (2) $d_{\mathrm{TV}}(p,q) \geqslant \varepsilon$. Moreover, the algorithm runs in time $\tilde{O}(n^{d+1}s)$.

4 Lower Bound

In this section, we establish our sample complexity lower bound for EET (Theorem 3). The $\widetilde{\Omega}(\min\{n^{3/4}/\varepsilon, n^{2/3}/\varepsilon^{4/3}\})$ term follows from a reduction to mutual information (MI) testing combined with [37, Corollary 6.2], and the $\Omega(\log^2 n/\varepsilon^2)$ term follows directly from [15, Lemma 2.7], whose two-point construction is also a hard instance for EET.

For a joint distribution P_{AC} over $[k_A]\times[k_C]$ with marginals P_A, P_C, the *mutual information* between coordinates is

$$I(A:C) := H(A) + H(C) - H(A,C),$$

and equals zero if and only if $P_{AC} = P_A \otimes P_C$. The MI testing problem asks, given sample access to P_{AC}, to distinguish $I(A:C) = 0$ from $I(A:C) \geqslant \varepsilon$ with probability at least $2/3$. [37, Corollary 6.2] established the lower bound

$$\widetilde{\Omega}\left(\min\left\{\frac{k_A^{3/4}k_C^{1/4}}{\varepsilon}, \frac{k_A^{2/3}k_C^{1/3}}{\varepsilon^{4/3}}\right\}\right)$$

for this task.

Reduction from MI testing to EET

▶ **Lemma 19.** *Let $k_A, k_C \geqslant 2$ and $n = k_A k_C$. Any* EET *algorithm $\mathcal{A}$ over $[n]$ with sample complexity T yields an* MI *testing algorithm over $[k_A] \times [k_C]$ with sample complexity $3T$ and the same success probability.*

Proof. Map $[k_A] \times [k_C]$ with $[n]$ via some fixed bijection. Using $\mathcal{A}$, we construct a MI tester for P_{AC} over $[k_A] \times [k_C]$ as follows:

1. Draw $3T$ i.i.d. samples $(a_1, c_1), \ldots, (a_{3T}, c_{3T})$ from P_{AC}.
2. Form T samples of $P := P_{AC}$, denoted by (a_i, c_i) for $i = 1, \ldots, T$.
3. Form T samples of $Q := P_A \otimes P_C$, denoted by (a_{T+2i-1}, c_{T+2i}) for $i = 1, \ldots, T$. Since the samples are i.i.d., the a- and c-coordinates of each pair are independent draws from P_A and P_C respectively.
4. Run $\mathcal{A}$ on the T samples of P and the T samples of Q.

Observe that $|H(P) - H(Q)| = |H(A, C) - H(A) - H(C)| = I(A : C)$. Then:

- If $I(A : C) = 0$, then $P_{AC} = P_A \otimes P_C$, so $P = Q$ and $\mathcal{A}$ returns accept.
- If $I(A : C) \geqslant \varepsilon$, then $|H(P) - H(Q)| \geqslant \varepsilon$ and $\mathcal{A}$ returns reject. ◀

▶ **Theorem 20** (EET lower bound: Theorem 3, restated)**.** *Any algorithm that, given sample access to two unknown distributions p, q over $[n]$ and parameter $\varepsilon \in (0, 1]$, distinguishes $p = q$ from $|H(p) - H(q)| \geqslant \varepsilon$ with probability at least $2/3$ requires*

$$\widetilde{\Omega}\left(\min\left\{\frac{n^{3/4}}{\varepsilon}, \frac{n^{2/3}}{\varepsilon^{4/3}}\right\}\right) + \Omega\left(\frac{\log^2 n}{\varepsilon^2}\right)$$

samples from each of p and q.

Proof. Apply Lemma 19 with $k_A = n/2$ and $k_C = 2$. Combining with [37, Corollary 6.2] gives the first term:

$$\widetilde{\Omega}\left(\min\left\{\frac{(n/2)^{3/4} \cdot 2^{1/4}}{\varepsilon}, \frac{(n/2)^{2/3} \cdot 2^{1/3}}{\varepsilon^{4/3}}\right\}\right) = \widetilde{\Omega}\left(\min\left\{\frac{n^{3/4}}{\varepsilon}, \frac{n^{2/3}}{\varepsilon^{4/3}}\right\}\right).$$

For the second term, [15, Lemma 2.7] exhibits distributions p, q over $[n]$ with $|H(p) - H(q)| \geqslant \varepsilon$ that no algorithm can distinguish from $p = q$ using fewer than $\Omega(\log^2 n/\varepsilon^2)$ samples from p when q is given. Any EET algorithm using T samples from each of p, q yields such a tester by simulating T samples from the known q, so EET also requires $\Omega(\log^2 n/\varepsilon^2)$ samples. ◀

A Deferred Proofs

▶ **Fact 5.** *Let X be a Poisson random variable with parameter λ, and $f\colon \mathbb{R} \to \mathbb{R}$ be any function, then, we have that $\mathbb{E}[(X)_m \cdot f(X)] = \lambda^m \cdot \mathbb{E}[f(X+m)]$. In particular, choosing $f \equiv 1$, we have that $\mathbb{E}[(X)_m] = \lambda^m$ for all $m \geqslant 0$.*

Proof. We first show that $\mathbb{E}[X \cdot f(X)] = \lambda \cdot \mathbb{E}[f(X+1)]$ by standard Poisson calculations:

$$\mathbb{E}[X \cdot f(X)] = \sum_{k=0} \frac{\lambda^k e^{-\lambda}}{k!} \cdot k \cdot f(k) = \lambda \cdot \sum_{k=1} \frac{\lambda^{k-1} e^{-\lambda}}{(k-1)!} \cdot f(k) = \lambda \cdot \sum_{k=0} \frac{\lambda^k e^{-\lambda}}{k!} f(k+1)$$
$$= \lambda \cdot \mathbb{E}[f(X+1)]$$

The proof is then completed by induction, by noting that

$$\begin{aligned}\mathbb{E}[(X)_m \cdot f(X)] &= \mathbb{E}[X \cdot (X-1)_{m-1} \cdot f(X)] \\ &= \lambda \cdot \mathbb{E}[(X-1+1)_{m-1} \cdot f(X+1)] \\ &= \lambda^2 \cdot \mathbb{E}[(X)_{m-2} \cdot f(X+2)] \\ &= \dots \\ &= \lambda^m \cdot \mathbb{E}[f(X+m)].\end{aligned}$$

Abstract

We study the problem of approximating the total variation distance between two mixtures of product distributions over an n-dimensional discrete domain. Given two mixtures $\mathbb{P}$ and $\mathbb{Q}$ with k_1 and k_2 product distributions over $[q]^n$, respectively, we give a randomized algorithm that approximates $d_{\mathrm{TV}}(\mathbb{P},\mathbb{Q})$ within a multiplicative error of $(1\pm\varepsilon)$ in time $\mathrm{poly}((nq)^{k_1+k_2},1/\varepsilon)$. We also study the special case of mixtures of Boolean subcubes over $\{0,1\}^n$. For this class, we give a deterministic algorithm that exactly computes the total variation distance in time $\mathrm{poly}(n,2^{O(k_1+k_2)})$, and show that exact computation is #P-hard when $k_1+k_2=\Theta(n)$.

1 Introduction

Let $\mathbb{P}$ and $\mathbb{Q}$ be two discrete distributions over a sample space Ω. The *total variation distance (TV-distance)* between $\mathbb{P}$ and $\mathbb{Q}$ is defined as

$$d_{\mathrm{TV}}(\mathbb{P},\mathbb{Q})=\frac{1}{2}\sum_{\omega\in\Omega}|\mathbb{P}(\omega)-\mathbb{Q}(\omega)|=\sum_{\omega\in\Omega}\max\{0,\mathbb{P}(\omega)-\mathbb{Q}(\omega)\}.$$

The TV-distance is one of the most fundamental metrics for measuring the difference between distributions, as it characterizes the optimal distinguishability between $\mathbb{P}$ and $\mathbb{Q}$. Computing the TV-distance is therefore a basic problem arising in learning and testing.

A line of research has investigated the problem of *approximating* the TV-distance between two high-dimensional distributions, which is particularly interesting when the two distributions admit *succinct representations*. Early works [22, 8, 10, 19, 5] studied the algorithms and complexity of approximating the TV-distance with additive error. More recently, [2] established that even for two product distributions, the *exact computation* of the

© Weiming Feng, Yucheng Fu, Minji Yang, and Anqi Zhang;

TV-distance is #P-hard. In the same paper, the authors initiated the study of approximating the TV-distance with *relative error*, a more challenging task than the classical additive-error approximation. Subsequently, polynomial-time approximation algorithms have been developed for product distributions [2, 12, 14], as well as for many high-dimensional distributions defined by *local interactions*, including Markov chains [14], Bayesian networks [3], and undirected graphical models [13].

Beyond local interactions, it is natural to consider more general high-dimensional distributions with inherently *non-local structure*. A fundamental and extensively studied example is given by *mixtures of product distributions*. Let $[q] = \{1, 2, \ldots, q\}$ and let $\Omega = [q]^n$ denote the n-dimensional sample space. Fix two integers $k_1, k_2 \geq 1$. For each $s \in [k_1]$, let $\mathbb{P}^{(s)} = \bigotimes_{i=1}^n \mathbb{P}_i^{(s)}$ be a product distribution over Ω, where $\mathbb{P}_i^{(s)}$ denotes the marginal on the i-th coordinate, so that the coordinates are mutually independent under $\mathbb{P}^{(s)}$. Let $\alpha^{(1)}, \alpha^{(2)}, \ldots, \alpha^{(k_1)}$ be mixing weights satisfying $\sum_{s=1}^{k_1} \alpha^{(s)} = 1$. The resulting mixture distribution is written as

$$\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}.$$

More explicitly, $\mathbb{P}$ is the distribution over $\Omega = [q]^n$ given by

$$\forall \omega \in \Omega, \quad \mathbb{P}(\omega) = \sum_{s=1}^{k_1} \alpha^{(s)} \mathbb{P}^{(s)}(\omega) = \sum_{s=1}^{k_1} \alpha^{(s)} \prod_{i=1}^{n} \mathbb{P}_i^{(s)}(\omega_i), \tag{1}$$

Mixtures of product distributions form a fundamental class of *latent-variable models* and have been extensively studied in learning theory [11, 17, 9, 15, 16]. To draw a random sample $X \sim \mathbb{P}$, one first samples a *hidden* component index $S \in [k_1]$ according to $\mathbf{Pr}[S = s] = \alpha^{(s)}$, and then samples $X \sim \mathbb{P}^{(S)} = \bigotimes_{i=1}^n \mathbb{P}_i^{(S)}$ from the product distribution $\mathbb{P}^{(S)}$. Although each component $\mathbb{P}^{(s)}$ is itself a product distribution, the hidden index S induces a highly *non-local dependency* that simultaneously couples all coordinates of the sample $X = (X_1, X_2, \ldots, X_n)$, which cannot be captured by any sparse local structure.

In this paper, we study the problem of *approximating* the TV-distance between two mixtures of product distributions to within an arbitrarily small relative error, formally stated as follows.

▶ **Problem 1.** *Approximate the TV-distance between two mixtures of product distributions.*

- ***Input****: An error bound $\varepsilon > 0$ and two mixtures of product distributions over $\Omega = [q]^n$:*

$$\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)} \text{ and } \mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}_i^{(t)}.$$

  The distribution $\mathbb{P}$ is specified by the k_1 mixing weights $\alpha^{(1)}, \alpha^{(2)}, \ldots, \alpha^{(k_1)}$ together with the k_1 product distributions $\mathbb{P}^{(1)}, \mathbb{P}^{(2)}, \ldots, \mathbb{P}^{(k_1)}$, where each $\mathbb{P}^{(s)}$ is described by its n marginals $\mathbb{P}_1^{(s)}, \mathbb{P}_2^{(s)}, \ldots, \mathbb{P}_n^{(s)}$ over $[q]$. The distribution $\mathbb{Q}$ is given analogously. The total input size of the two mixtures is $O((k_1 + k_2)nq)$.
- ***Output****: A number $\hat{d}$ such that*

$$(1 - \varepsilon) d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}) \leq \hat{d} \leq (1 + \varepsilon) d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}).$$

Due to the non-local nature of these dependencies among all coordinates, existing techniques for TV-distance approximation cannot be directly applied to mixtures of product distributions. The only prior progress is a polynomial-time algorithm for *deciding* whether

$d_{\mathrm{TV}}(\mathbb{P},\mathbb{Q}) = 0$ or $d_{\mathrm{TV}}(\mathbb{P},\mathbb{Q}) > 0$ [4], leaving the approximation problem open. We partially resolve this open question by giving an FPRAS for the TV-distance between two mixtures of product distributions, provided that the numbers of components k_1 and k_2 are constants.

▶ **Theorem 2.** *Let $k_1, k_2 \geq 1$ be constants. There exists an FPRAS for Problem 1: given any $\varepsilon > 0$ and any pair of mixtures of product distributions $\mathbb{P},\mathbb{Q}$ over $[q]^n$, where $\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}$ has k_1 components and $\mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}_i^{(t)}$ has k_2 components, it solves the problem in time $O(\frac{q^2(nq)^{2(k_1+k_2-1)}}{\varepsilon^2})$ with success probability at least 99%.*

Our algorithm is a Monte Carlo algorithm based on a carefully designed estimator, and we provide an overview of it in Section 2. Since the number of components $k_1 + k_2$ appears as an exponent in the running time, we require $k_1 + k_2$ to be a constant. A similar dependence on the number of components also arises in the running time of certain learning tasks for mixtures of product distributions [11, 9, 15]. We leave it as an open question to understand the computational complexity when the number of components grows with n.

Our second result concerns mixtures of Boolean subcubes, a special case of mixtures of product distributions. A distribution $\mathbb{P} = \sum_{s=1}^{k} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}$ over $\{0,1\}^n$ is called a mixture of Boolean subcubes if $\mathbb{P}_i^{(s)}(1) \in \{0, \frac{1}{2}, 1\}$ for every $s \in [k]$ and $i \in [n]$, where $\mathbb{P}_i^{(s)}$ denotes the marginal distribution of the i-th coordinate in the s-th component. Equivalently, for each component s, the product distribution $\mathbb{P}^{(s)}$ fixes every coordinate i with $\mathbb{P}_i^{(s)}(1) = 1$ to 1, fixes every coordinate i with $\mathbb{P}_i^{(s)}(1) = 0$ to 0, and is uniform on the remaining coordinates. Mixtures of Boolean subcubes have been extensively studied in learning theory [9, 6, 7] and capture many natural distributions; for instance, the uniform distribution over the satisfying assignments of a decision tree is a mixture of Boolean subcubes [11].

In contrast to the general case, where we only obtain an FPRAS when $k_1 + k_2 = O(1)$, we show that the TV-distance between two mixtures of Boolean subcubes $\mathbb{P}$ and $\mathbb{Q}$ can be computed *exactly* in time polynomial in the dimension n, provided that $k_1 + k_2 = O(\log n)$.

▶ **Problem 3.** *Compute exactly the total variation distance between two mixtures of Boolean subcubes $\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}$ and $\mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}_i^{(t)}$.*

- ***Input**: two mixtures of Boolean subcubes, given in the same format as in Problem 1.*
- ***Output**: the* exact *value of $d_{\mathrm{TV}}(\mathbb{P},\mathbb{Q})$*

▶ **Theorem 4.** *There exists a deterministic algorithm for Problem 3: given any pair of mixtures of Boolean subcubes $\mathbb{P},\mathbb{Q}$ over $\{0,1\}^n$, where $\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}$ has k_1 components and $\mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}_i^{(t)}$ has k_2 components, it solves the problem in $O((k_1+k_2)3^{k_1+k_2} \cdot n)$ time.*

The running time in Theorem 4 is polynomial in n whenever $k_1 + k_2 = O(\log n)$, yielding a deterministic polynomial-time algorithm in this regime. This does not contradict the #P-hardness of exact TV-distance computation established in [2]: their hardness already holds for two product distributions with arbitrary marginals, whereas our algorithm crucially exploits the restriction that each marginal of a Boolean subcube takes value in $\{0, \frac{1}{2}, 1\}$.

The idea of the algorithm is as follows. For each component $\mathbb{P}^{(s)}$ (and similarly for each $\mathbb{Q}^{(t)}$), the value of $\mathbb{P}^{(s)}(\omega)$ is either 0 or 2^{-r}, where r is the number of coordinates $i \in [n]$ with $\mathbb{P}_i^{(s)}(1) = \frac{1}{2}$. Indeed, if some coordinate is fixed to be 1 (or 0) but $\omega_i = 0$ (or 1), then $\mathbb{P}^{(s)}(\omega) = 0$; otherwise, each free coordinate contributes a factor of 1/2, so $\mathbb{P}^{(s)}(\omega) = 2^{-r}$. Thus, although there are 2^n configurations $\omega \in \{0,1\}^n$, the possible values of $|\mathbb{P}(\omega) - \mathbb{Q}(\omega)|$ are at most $2^{k_1+k_2}$. Our algorithm enumerates these possible values of $|\mathbb{P}(\omega) - \mathbb{Q}(\omega)|$ and counts the number of configurations $\omega \in \{0,1\}^n$ that achieve each one. The details are given in Section 5.

Finally, we complement this positive result by showing that the dependence on the number of components cannot be removed entirely: when the number of components grows linearly with n, exact computation becomes #P-hard.

▶ **Theorem 5.** *If the number of mixture components is $k_1 + k_2 = \Theta(n)$, then the exact computation of the total variation distance in Problem 3 is #P-hard.*

The theorem is proved by a reduction showing that if we can exactly compute the TV-distance between two mixtures of Boolean subcubes with $k_1 + k_2 = \Theta(n)$ in polynomial time, then we can also exactly compute #3SAT in polynomial time. The detailed proof is in Section 6.

Open problems. As discussed after Theorem 2, the dependence on the number of components in the running time is not yet well understood. [4] gave an algorithm that decides whether $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}) = 0$ in time $\mathrm{poly}(n, k_1 + k_2)$, whereas the running time of our approximation algorithm depends exponentially on $k_1 + k_2$. The analogous regime $k_1 + k_2 = \omega(1)$ is also not well understood for learning tasks on mixtures of product distributions, where obtaining algorithms with polynomial dependence on the number of components remains a central challenge [11, 9, 15]. A natural question is whether one can approximate $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q})$ in time polynomial in $k_1 + k_2$, or prove a hardness result ruling this out when the number of components grows with n. As a first step toward the latter, Theorem 5 already shows that exact computation is #P-hard when $k_1 + k_2 = \Theta(n)$, and one direction is to extend its proof to rule out approximation as well.

One can ask analogous TV-distance approximation questions for other structured mixture models. Natural candidates include mixtures of Gaussians [1, 21], mixtures of Markov chains and MDPs [18]. These models also give succinct descriptions of high-dimensional distributions and are widely studied in machine learning, but their dependence structures are more complex than that of mixtures of product distributions. More generally, it would be interesting to understand the complexity of computing or approximating the TV-distance between trajectory distributions induced by reward-mixing Markov decision processes (RMMDPs). RMMDPs use latent mixture structure to model the reward context, and TV-distance bounds between trajectory distributions have been used to learn near-optimal policies [20]. The problem of computing the TV-distance between RMMDPs appears to require new ideas.

At last, our algorithm for mixtures of product distributions is randomized. It remains open to design a deterministic algorithm for approximating the TV-distance between mixtures of product distributions. Currently, deterministic algorithms are only known for approximating the TV-distance between product distributions [14, 2].

2 Technical Overview

We present the main ideas behind the algorithm in Theorem 2. An obstacle for approximating the TV-distance is that the TV-distance itself can be very small. To see the reason, for two distributions $\mathbb{P}$ and $\mathbb{Q}$ over the sample space Ω, where $\mathbb{Q}$ is absolutely continuous w.r.t. $\mathbb{P}$, one can write

$$d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}) = \sum_{\omega \in \Omega} \mathbb{P}(\omega) \max\left\{0, 1 - \frac{\mathbb{Q}(\omega)}{\mathbb{P}(\omega)}\right\} = \mathbf{E}_{\omega \sim \mathbb{P}}\left[g(\omega)\right],$$

where $g(\omega) := \max\left\{0, 1 - \frac{\mathbb{Q}(\omega)}{\mathbb{P}(\omega)}\right\}$. We can efficiently sample ω and compute $g(\omega)$, so that a direct Monte Carlo estimate of $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}) = \mathbf{E}_{\omega \sim \mathbb{P}}\left[g(\omega)\right]$ can only achieve *additive* error in polynomial time. However, since the expectation $\mathbf{E}_{\omega \sim \mathbb{P}}\left[g(\omega)\right]$ itself can be exponentially small, this simple approach is not sufficient to achieve a *relative* error approximation required by Problem 1.

2.1 Approximating the TV-distance via a coarse coupling

A framework for approximating the TV-distance was proposed in [12] for two product distributions (i.e., $k_1 = k_2 = 1$ in our setting). It can be generalized to any two distributions $\mathbb{P}$ and $\mathbb{Q}$. Instead of approximating $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q})$ directly, they estimated the normalized quantity $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}) / \tilde{d}$, where $\tilde{d}$ is a polynomial-time computable *coarse* estimator. Moreover, if the ratio $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}) / \tilde{d}$ is lower bounded by $1/\mathrm{poly}(n)$, one can try to achieve a relative-error approximation to the ratio in polynomial time. Hence, we can recover $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q})$ by multiplying $\tilde{d}$ by the estimate of the ratio.

The coarse estimator $\tilde{d}$ can be constructed via a *coupling*. For two distributions $\mathbb{P}$ and $\mathbb{Q}$ over Ω, a coupling is a pair of joint random variables (X, Y) such that $X \sim \mathbb{P}$ and $Y \sim \mathbb{Q}$. It is well known that $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}) = \mathbf{Pr}_{\mathcal{O}}[X' \neq Y']$, where $\mathcal{O} = (X', Y')$ is the *optimal* coupling between $\mathbb{P}$ and $\mathbb{Q}$. Suppose we can construct a coupling $\mathcal{C} = (X, Y)$ that is not far from the optimal coupling $\mathcal{O}$. Formally, $\mathbf{Pr}_{\mathcal{O}}[X' \neq Y'] = \gamma \cdot \mathbf{Pr}_{\mathcal{C}}[X \neq Y]$ for some $\gamma = 1/\mathrm{poly}(n)$. Then $\tilde{d} = \mathbf{Pr}_{\mathcal{C}}[X \neq Y]$ is a coarse estimator of $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q})$. To estimate the ratio $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}) / \tilde{d}$, define a distribution π:

$$\omega \in \Omega, \quad \pi(\omega) = \mathbf{Pr}_{\mathcal{C}}[X = \omega \mid X \neq Y] \tag{2}$$

and define function f such that

$$\omega \in \Omega, \quad f(\omega) = \frac{\max\{0, \mathbb{P}(\omega) - \mathbb{Q}(\omega)\}}{\mathbf{Pr}_{\mathcal{C}}[X = \omega \wedge X \neq Y]}.$$

We can verify that $\mathbf{E}_{\pi}[f] = \frac{d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q})}{\mathbf{Pr}_{\mathcal{C}}[X \neq Y]} = \frac{d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q})}{\tilde{d}} = \gamma \geq \frac{1}{\mathrm{poly}(n)}$. Using the approach described above, if we can perform the following operations in polynomial time

(a) sample $\omega \sim \pi$;
(b) compute $f(\omega)$ for any ω;
(c) compute $\mathbf{Pr}_{\mathcal{C}}[X \neq Y]$;

then we can get a relative-error approximation of $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q})$. Specifically, we draw $T = \mathrm{poly}(\frac{1}{\gamma}) = \mathrm{poly}(n)$ independent samples $\omega_1, \ldots, \omega_T \sim \pi$ and compute $\bar{f} = \frac{1}{T} \sum_{i=1}^{T} f(\omega_i)$. By Chebyshev's inequality, with high probability, $\bar{f} \cdot \mathbf{Pr}_{\mathcal{C}}[X \neq Y]$ is an estimate of $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q})$ within relative error.

2.2 Recursive coupling for mixtures of product distributions

It remains to construct a coupling that supports the three operations above. For product distributions, [12] used a coordinate-wise greedy coupling $\mathcal{C} = (X, Y)$, which couples each coordinate optimally and independently, and showed that $1/n \leq \mathbf{E}_{\pi}[f] \leq 1$. This approach does not directly extend to mixtures of product distributions, where all the coordinates are *correlated*, so one cannot optimally couple all coordinates simultaneously.

Our main technical contribution in this part is a new *explicit recursive coupling* for mixtures of product distributions, together with an algorithmic implementation of the three operations above. At a high level, the recursive structure draws inspiration from [20], who introduced a recursive argument to bound the TV-distance between two mixtures of product distributions. Their analysis, however, is non-constructive: it yields a *fixed-error* bound on the TV-distance, but does not by itself provide the algorithmic interface required here. To obtain a relative-error approximation with *arbitrary* ε, we need a coupling whose failure probability can be computed, and whose failure-conditioned distribution can be sampled and evaluated. We design such a coupling tailored to mixtures of product distributions, adapt the recursive analysis of [20] to this explicit construction, and show that the three operations in Item a, Item b, and Item c can all be implemented in polynomial time.

We construct a coupling between two mixtures of product distributions $\mathbb{P}$ and $\mathbb{Q}$, where

$$\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)} \quad \text{and} \quad \mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}_i^{(t)}.$$

Although coupling the first coordinate would bias the marginal distribution of the remaining coordinates, we can still extract the common parts of $\mathbb{P}_1^{(s)}$ and $\mathbb{Q}_1^{(t)}$, and reduce the problem to coupling *another* mixture of product distributions on the remaining coordinates. For each $c \in [q]$, we first compute a lower bound for each active mixture component:

$$\ell(c) \triangleq \min \left\{ \min_{s \in [k_1]: \alpha^{(s)} > 0} \mathbb{P}_1^{(s)}(c), \min_{t \in [k_2]: \beta^{(t)} > 0} \mathbb{Q}_1^{(t)}(c) \right\}, \tag{3}$$

where $\mathbb{P}_1^{(s)}$ (resp. $\mathbb{Q}_1^{(t)}$) is the marginal distribution of the first coordinate of the s-th component of $\mathbb{P}^{(s)}$ (resp. $\mathbb{Q}^{(t)}$). For $\omega \in [q]^n$ with $\omega_1 = c$, we can write the probability of ω as

$$\begin{aligned}
\mathbb{P}(\omega) &= \ell(c) \sum_{s=1}^{k_1} \alpha^{(s)} \prod_{i=2}^{n} \mathbb{P}_i^{(s)}(\omega_i) + \sum_{s=1}^{k_1} \alpha^{(s)} \left(\mathbb{P}_1^{(s)}(c) - \ell(c) \right) \prod_{i=2}^{n} \mathbb{P}_i^{(s)}(\omega_i) \\
&= \ell(c) \underbrace{\sum_{s=1}^{k_1} \alpha^{(s)} \prod_{i=2}^{n} \mathbb{P}_i^{(s)}(\omega_i)}_{A_{\mathbb{P}}} + (\mathbb{P}_1(c) - \ell(c)) \underbrace{\sum_{s=1}^{k_1} \alpha_c^{(s)} \prod_{i=2}^{n} \mathbb{P}_i^{(s)}(\omega_i)}_{B_{\mathbb{P},c}},
\end{aligned}$$

where $\alpha_c^{(s)} \triangleq \frac{\alpha^{(s)} \left(\mathbb{P}_1^{(s)}(c) - \ell(c) \right)}{(\mathbb{P}_1(c) - \ell(c))}$ is a valid distribution over $s \in [k_1]$. Note that $\mathbb{P}_1$ in the denominator is the marginal distribution of the mixture $\mathbb{P}$ over the first coordinate. Similarly, let $\beta_c^{(t)} \triangleq \frac{\beta^{(t)} \left(\mathbb{Q}_1^{(t)}(c) - \ell(c) \right)}{(\mathbb{Q}_1(c) - \ell(c))}$ and

$$\mathbb{Q}(\omega) = \ell(c) \underbrace{\sum_{t=1}^{k_2} \beta^{(t)} \prod_{i=2}^{n} \mathbb{Q}_i^{(t)}(\omega_i)}_{A_{\mathbb{Q}}} + (\mathbb{Q}_1(c) - \ell(c)) \underbrace{\sum_{t=1}^{k_2} \beta_c^{(t)} \prod_{i=2}^{n} \mathbb{Q}_i^{(t)}(\omega_i)}_{B_{\mathbb{Q},c}}.$$

Each of $A_{\mathbb{P}}, A_{\mathbb{Q}}, B_{\mathbb{P},c}$, and $B_{\mathbb{Q},c}$ is a mixture of product distributions over the remaining coordinates. The component distributions in $A_{\mathbb{P}}$ and $B_{\mathbb{P},c}$ are obtained from the components of $\mathbb{P}$ by removing the first coordinate; the same relation holds between $A_{\mathbb{Q}}, B_{\mathbb{Q},c}$ and $\mathbb{Q}$. However, the mixing weights may be different from those in $\mathbb{P}$ and $\mathbb{Q}$.

We use the above decomposition to construct a coupling (X, Y) between $\mathbb{P}$ and $\mathbb{Q}$. We first couple the first coordinate of X and Y. For each $c \in [q]$, with probability $\ell(c)$, we set $X_1 = Y_1 = c$ and then couple $A_{\mathbb{P}}$ and $A_{\mathbb{Q}}$ *recursively* for the remaining coordinates. For each $c \in [q]$, with probability $\min\{\mathbb{P}_1(c) - \ell(c), \mathbb{Q}_1(c) - \ell(c)\}$, we set $X_1 = Y_1 = c$ and couple $B_{\mathbb{P},c}$ and $B_{\mathbb{Q},c}$ *recursively* for the remaining coordinates. For the remaining probability mass[1] of the first coordinate, there is no common part with $X_1 = Y_1 = c$ for any $c \in [q]$. We arbitrarily couple this remaining mass; it must hold that $X_1 \neq Y_1$, and hence $X \neq Y$. We call this case the *coupling failure* case. Suppose that after coupling the first coordinate, we have $X_1 = c \neq c' = Y_1$ for some $c, c' \in [q]$. We then independently sample the remaining coordinates according to $B_{\mathbb{P},c}$ and $B_{\mathbb{Q},c'}$, respectively.

[1] Specifically, the remaining probability for $X_1 = c$ is $\max\{0, \mathbb{P}_1(c) - \mathbb{Q}_1(c)\}$ and the remaining probability for $Y_1 = c$ is $\max\{0, \mathbb{Q}_1(c) - \mathbb{P}_1(c)\}$.

The above recursive process terminates either when coupling fails at some coordinate or when it reaches the last coordinate. Denote the resulting recursive coupling by $\mathcal{C}_{\mathrm{RC}}$. Adapting the recursive TV-distance analysis of [20] to this explicit coupling, we show that $\mathcal{C}_{\mathrm{RC}}$ is not far from the optimal coupling:

$$\mathbf{Pr}_{\mathcal{C}_{\mathrm{RC}}}[X \neq Y] \leq (4nq)^{k_1+k_2-1} \cdot d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}).$$

Therefore, we set $\gamma = (4nq)^{-k_1-k_2+1}$, which is inverse-polynomial in n and q when k_1 and k_2 are constants.

2.3 Implementation of three operations

We now give polynomial-time algorithms for the three operations in Item a, Item b, and Item c. We create a state space $\mathcal{S}$ to keep track of the recursive coupling process. A state $S \in \mathcal{S}$ is a tuple $S = (i, \bar{\alpha}, \bar{\beta})$, where $i \in [n]$ means we need to couple the remaining coordinates $i, i+1, \ldots, n$, and $\bar{\alpha} = (\bar{\alpha}^{(s)})_{s\in[k_1]}$ and $\bar{\beta} = (\bar{\beta}^{(t)})_{t\in[k_2]}$ are the *current* mixing weights for each mixture component. Section 2.2 describes the recursive coupling starting from the root state $(1, \alpha, \beta)$, and hence defines the quantities $A_{\mathbb{P}}, A_{\mathbb{Q}}, B_{\mathbb{P},c}, B_{\mathbb{Q},c}$ and $\ell(c)$ in that setting. For the implementation, we use the same decomposition at an arbitrary state $S = (i, \bar{\alpha}, \bar{\beta})$, replacing the first coordinate by the current coordinate i and the original mixing weights by the current weights $\bar{\alpha}, \bar{\beta}$. Thus,

$$\ell(c) = \min\left\{ \min_{s\in[k_1]:\bar{\alpha}^{(s)}>0} \mathbb{P}_i^{(s)}(c), \min_{t\in[k_2]:\bar{\beta}^{(t)}>0} \mathbb{Q}_i^{(t)}(c) \right\}.$$

Similarly, the updated weights $\bar{\alpha}_c = (\bar{\alpha}_c^{(s)})_{s\in[k_1]}$ in the $B_{\mathbb{P},c}$ branch are defined by

$$\forall s \in [k_1], \bar{\alpha}_c^{(s)} = \bar{\alpha}^{(s)} \cdot \frac{\mathbb{P}_i^{(s)}(c) - \ell(c)}{\bar{\mathbb{P}}_i(c) - \ell(c)} \text{ where } \bar{\mathbb{P}}_i(c) = \sum_{s\in[k_1]} \bar{\alpha}^{(s)} \mathbb{P}_i^{(s)}(c).$$

The $\bar{\beta}_c$ for the $B_{\mathbb{Q},c}$ is analogous. There is also a failure state $\perp$. If we couple $X_i \neq Y_i$ (coupling failure case), the state S transitions to the failure state $\perp$. If we couple $X_i = Y_i$ and then recursively couple $A_{\mathbb{P}}$ and $A_{\mathbb{Q}}$ for the remaining coordinates (we call it the good case A), the state S transitions to $S' = (i+1, \bar{\alpha}, \bar{\beta})$. If we couple $X_i = Y_i$ and then recursively couple $B_{\mathbb{P},c}$ and $B_{\mathbb{Q},c}$ for the remaining coordinates (we call it the good case B), the state S transitions to $S'_c = (i+1, \bar{\alpha}_c, \bar{\beta}_c)$.

The whole recursive coupling process is a random walk on the state space $\mathcal{S}$ starting from the root state $S_{\mathrm{root}} = (1, \alpha, \beta)$. Every non-failure state $S = (i, \bar{\alpha}, \bar{\beta}) \neq \perp$ can transition to a state in $\{\perp\} \cup \{S'\} \cup \{S'_c\}_{c\in[q]}$, and it transitions to some S'_c if and only if the good case B occurs. The key observation is that case B can occur at most $k_1 + k_2 - 2$ times in the whole recursive coupling process. By the definition of $\ell(c)$, $\ell(c)$ is equal to some $\mathbb{P}_i^{(s)}(c)$ or $\mathbb{Q}_i^{(t)}(c)$. Suppose $\ell(c) = \mathbb{P}_i^{(s)}(c)$. Then, the new mixing weights in S'_c satisfy $\bar{\alpha}_c^{(s)} = \bar{\alpha}^{(s)} \cdot \frac{\mathbb{P}_i^{(s)}(c) - \ell(c)}{\bar{\mathbb{P}}_i(c) - \ell(c)} = 0$. Thus, whenever case B occurs, the total number of positive mixing weights decreases by at least one. Since the root state has $k_1 + k_2$ positive mixing weights, case B can occur at most $k_1 + k_2 - 2$ times. Using this property, we can show that the total number of states is $|\mathcal{S}| = (nq)^{O(k_1+k_2)}$, which is polynomial in n and q.

Given a state S, it is easy to compute the transition probabilities to the next states. The whole transition graph forms a DAG with polynomial size. To sample $\omega \sim \pi$ in (2), it suffices to sample a trajectory starting from the root state, conditioned on the random walk reaching the failure state $\perp$. We first run a dynamic programming algorithm to compute the

probability of reaching $\perp$ from each state in $\mathcal{S}$. Then, we use these probabilities to sample the desired conditional trajectory. Similarly, using dynamic programming, we can compute $f(\omega)$ and $\mathbf{Pr}_{\mathcal{C}_{\mathrm{RC}}}[X \neq Y]$ in polynomial time.

▶ Remark 6 (Comparison with the coupling in [3]). Finally, it is worth comparing our coupling with the coupling used in [3]. They proposed a simpler coupling and applied it to approximating the TV-distance between two Bayesian networks. Given two n-dimensional distributions $\mathbb{P}$ and $\mathbb{Q}$ over $[q]^n$, they couple the coordinates one by one using the optimal coupling of the conditional marginals. Suppose the first $i-1$ coordinates of X and Y have been generated and coupled consistently such that $X_{1:i-1} = Y_{1:i-1} = \sigma \in [q]^{i-1}$. For the i-th coordinates X_i and Y_i, they use the optimal coupling of the conditional marginals $\mathbb{P}_i$ and $\mathbb{Q}_i$ given σ. The coupling terminates if $X_i \neq Y_i$ at some coordinate or when it reaches the last coordinate.

Their coupling is *different* from ours. Unlike Bayesian networks, for general mixtures of product distributions, the conditional marginals at the i-th coordinate require the *full information* of the prefix condition $\sigma \in [q]^{i-1}$. Since there are $O(q^n)$ possible prefix conditions σ, this coupling needs to consider exponentially many possible distributions for our problem. In our coupling, even when the good event $X_i = Y_i$ occurs, we further split it into two sub-cases, A and B. This splitting allows us to exploit the structure of mixtures of product distributions, so the total number of possible distributions appearing in our coupling is bounded by a polynomial.

3 A General Approach for Approximating the TV-Distance

When $k_1 = k_2 = 1$, the problem reduces to approximating the TV-distance between two product distributions P and Q over $\Omega = [q]^n$. This special case was studied in [12]. Although the algorithm there is tailored to product distributions, its underlying idea extends to a more general framework for approximating TV-distances for general discrete distributions.

Let $\mathbb{P}$ and $\mathbb{Q}$ be arbitrary discrete distributions over Ω. A *coupling* of $\mathbb{P}$ and $\mathbb{Q}$ is a pair of jointly distributed random variables (X, Y) such that $X \sim \mathbb{P}$ and $Y \sim \mathbb{Q}$. For every coupling $\mathcal{C}$ of $\mathbb{P}$ and $\mathbb{Q}$, the coupling inequality states that

$$d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}) \leq \mathbf{Pr}_{\mathcal{C}}[X \neq Y].$$

A coupling $\mathcal{C}$ is called *optimal* if equality holds, namely if $\mathbf{Pr}_{\mathcal{C}}[X \neq Y] = d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q})$. An optimal coupling exists for every pair of distributions $\mathbb{P}$ and $\mathbb{Q}$.

The following fact holds for every coupling $\mathcal{C}$ of $\mathbb{P}$ and $\mathbb{Q}$.

▶ **Fact 7.** *For any coupling $\mathcal{C}$ of $\mathbb{P}$ and $\mathbb{Q}$, it holds that*

$$\forall \omega \in \Omega, \quad \mathbf{Pr}_{\mathcal{C}}[X = \omega \wedge X \neq Y] \geq \max\{0, \mathbb{P}(\omega) - \mathbb{Q}(\omega)\}.$$

If $\mathcal{C}$ is an optimal coupling, then for all $\omega \in \Omega$,

$$\mathbf{Pr}_{\mathcal{C}}[X = \omega \wedge X \neq Y] = \max\{0, \mathbb{P}(\omega) - \mathbb{Q}(\omega)\}.$$

The proof can be found in the full version.

We now state an abstract version of the algorithm from [12], formulated for two arbitrary discrete distributions $\mathbb{P}$ and $\mathbb{Q}$. Let $\gamma, T_0, T_1, T_2, T_3 > 0$ be parameters.

▶ **Assumption 8.** *There exists a probability mass oracle that, for any $\omega \in \Omega$, returns $\mathbb{P}(\omega)$ and $\mathbb{Q}(\omega)$ in time T_0.*

▶ **Assumption 9.** *There exists a coupling $\mathcal{C}$ between $\mathbb{P}$ and $\mathbb{Q}$ such that $\frac{d_{\mathrm{TV}}(\mathbb{P},\mathbb{Q})}{\mathbf{Pr}_{\mathcal{C}}[X\neq Y]} \geq \gamma$, together with an oracle that can be preprocessed in time T_1 and supports the following query:*

- *Discrepancy query: return the value of $\mathbf{Pr}_{\mathcal{C}}[X \neq Y]$ in time $O(1)$.*

Furthermore, if $\mathbf{Pr}_{\mathcal{C}}[X \neq Y] > 0$, then the oracle also supports the following two queries:

- *Sampling query: draw an independent sample of X from the conditional distribution of X given $X \neq Y$ under $\mathcal{C}$ in time T_2. Equivalently, it returns $\omega \in \Omega$ with probability $\mathbf{Pr}_{\mathcal{C}}[X = \omega \mid X \neq Y]$.*
- *Evaluation query: given any $\omega \in \Omega$, return the value of $\mathbf{Pr}_{\mathcal{C}}[X = \omega \wedge X \neq Y]$ in time T_3.*

Under Assumption 8 and Assumption 9, the following theorem gives an algorithm for approximating the TV-distance between two *arbitrary* discrete distributions $\mathbb{P}$ and $\mathbb{Q}$.

▶ **Theorem 10** ([12]). *Suppose Assumption 8 and Assumption 9 hold for distributions $\mathbb{P}$ and $\mathbb{Q}$ with parameters $\gamma, T_0, T_1, T_2, T_3$. Then there exists a randomized algorithm such that, given any $\varepsilon > 0$, the parameters γ, and access to the two oracles above, it outputs a random number $\hat{d}$ in time $O(T_1 + \frac{T_0+T_2+T_3}{\gamma\varepsilon^2})$ satisfying $\mathbf{Pr}\left[(1-\varepsilon)d_{\mathrm{TV}}(\mathbb{P},\mathbb{Q}) \leq \hat{d} \leq (1+\varepsilon)d_{\mathrm{TV}}(\mathbb{P},\mathbb{Q})\right] \geq 99\%$.*

The proof can be found in the full version.

4 Algorithm for Mixtures of Product Distributions

To apply Theorem 10 to the problem of approximating the TV-distance between two mixtures of product distributions, we need to verify Assumption 8 and Assumption 9. By the definition of mixture of product distributions in (1), the first assumption holds with $T_0 = O(n(k_1+k_2))$. Our main task is to construct a coupling to verify the second assumption.

▶ **Lemma 11.** *Let $k_1, k_2 \geq 1$ be two constants. For any two mixtures of product distributions $\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}$ and $\mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}_i^{(t)}$, there exists a coupling $\mathcal{C}$ between $\mathbb{P}$ and $\mathbb{Q}$ such that Assumption 9 holds with parameters $\gamma = (4nq)^{-k_1-k_2+1}$, $T_1, T_2, T_3 = O(q^2(nq)^{k_1+k_2-1})$.*

Theorem 2 is a simple corollary of Theorem 10 and Lemma 11. The rest of this section is devoted to the proof of the lemma.

4.1 The recursive coupling for mixtures of product distributions

In this subsection, we construct a recursive coupling between two mixtures of product distributions $\mathbb{P}$ and $\mathbb{Q}$ in two steps. In Section 4.1.1, we first introduce a recursive procedure for drawing a sample from a single mixture $\mathbb{P}$. Building on this procedure, in Section 4.1.2 we then construct a recursive coupling between $\mathbb{P}$ and $\mathbb{Q}$. Our construction is inspired by the technique of [20], who develop a recursive analysis that bounds the total variation distance between two mixtures of product distributions up to a *fixed* error. Our main contribution is a new recursive coupling process, which is crucial for approximating the TV-distance with *arbitrary* relative error. In Section 4.2, we use this process to implement an oracle that answers the queries in Assumption 9 within polynomial time.

4.1.1 The recursive sampling process

We now describe a recursive sampling procedure that generates a sample X from the mixture of product distributions

$$\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}.$$

This sampling procedure will later serve as the basis for our coupling construction. Throughout the recursion, the component product distributions $\mathbb{P}^{(s)}$ remain fixed, while the mixing weights are updated from one recursive step to the next. We use $(\bar{\alpha}^{(s)})_{s=1}^{k_1}$ to denote the mixing weights at the current recursive step, to distinguish them from the original mixing weights $(\alpha^{(s)})_{s=1}^{k_1}$. At recursion depth j, let

$$\bar{\mathbb{P}} = \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \bigotimes_{i=j}^{n} \mathbb{P}_i^{(s)}$$

be the current mixture over $[q]^{n-j+1}$. We consider the recursive coordinate-wise procedure

$$\text{RecursiveSample}\,(j, \bar{\alpha})\,,$$

where $j \in [n]$ is the current coordinate. At this point, the coordinates $X_1, \ldots, X_{j-1}$ have already been fixed, and the task is to generate X_j from the current mixture $\bar{\mathbb{P}}$ and then update the mixing weights for the next recursive step. To describe the procedure, we define a lower-bound selector.

▶ **Definition 12** (lower-bound selector). *A lower-bound selector $\ell^{\mathbb{P}}$ is a function $\ell^{\mathbb{P}}(j, \bar{\alpha}, c)$ defined for any coordinate $j \in [n]$, any mixing-weight vector $\bar{\alpha} = (\bar{\alpha}^{(s)})_{s=1}^{k_1}$, and any $c \in [q]$, satisfying:*

$$\min_{s \in [k_1] : \bar{\alpha}^{(s)} > 0} \mathbb{P}_j^{(s)}(c) \geq \ell^{\mathbb{P}}(j, \bar{\alpha}, c) \geq 0. \tag{4}$$

Here the minimum ranges over all components $s \in [k_1]$ with $\bar{\alpha}^{(s)} > 0$, namely over the components that are still active at the current recursive step. Thus $\ell^{\mathbb{P}}(j, \bar{\alpha}, c)$ is required to be a nonnegative lower bound on the marginal probability of seeing value c in coordinate j across all active components. The above definition does *not* specify a unique lower-bound selector $\ell^{\mathbb{P}}$. Any function satisfying (4) is valid. Let us fix an arbitrary lower-bound selector $\ell^{\mathbb{P}}$ satisfying (4). Our recursive sampling process in Section 4.1.1 works for any lower-bound selector $\ell^{\mathbb{P}}$. In Section 4.1.2, when constructing the coupling, we will specify a particular choice of $\ell^{\mathbb{P}}$.

For the current recursive state $(j, (\bar{\alpha}^{(s)})_{s=1}^{k_1})$, we first compute the lower bounds $\ell^{\mathbb{P}}(j, \bar{\alpha}, c)$ for all $c \in [q]$. Fix a value $c \in [q]$ and an assignment $\omega \in [q]^{n-j+1}$ satisfying $\omega_j = c$. The probability of ω under the current mixture $\bar{\mathbb{P}}$ can be written as

$$\bar{\mathbb{P}}(\omega) = \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \prod_{i=j}^{n} \mathbb{P}_i^{(s)}(\omega_i) = \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \mathbb{P}_j^{(s)}(c) \prod_{i=j+1}^{n} \mathbb{P}_i^{(s)}(\omega_i),$$

where the second equality uses the assumption $\omega_j = c$. By (4), it holds that $\mathbb{P}_j^{(s)}(c) \geq \ell^{\mathbb{P}}(j, \bar{\alpha}, c)$ for all $s \in [k_1]$ with $\bar{\alpha}^{(s)} > 0$. Hence, for each s with $\bar{\alpha}^{(s)} > 0$, we can decompose $\mathbb{P}_j^{(s)}(c)$ as two non-negative terms: $\ell^{\mathbb{P}}(j, \bar{\alpha}, c)$ and $\mathbb{P}_j^{(s)}(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c)$. We have the following decomposition:

$$\bar{\mathbb{P}}(\omega) = \ell^{\mathbb{P}}(j, \bar{\alpha}, c) \underbrace{\sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \prod_{i=j+1}^{n} \mathbb{P}_i^{(s)}(\omega_i)}_{A} + \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \left(\mathbb{P}_j^{(s)}(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c) \right) \prod_{i=j+1}^{n} \mathbb{P}_i^{(s)}(\omega_i). \tag{5}$$

The above summation enumerates all $s \in [k_1]$, which may contain inactive components s with $\bar{\alpha}^{(s)} = 0$. However, those inactive components only contribute 0 to the whole sum. In (5), the first term is the product of $\ell^{\mathbb{P}}(j, \bar{\alpha}, c)$ and A, where A is exactly the probability of the suffix $(\omega_i)_{i=j+1}^{n}$ under the current mixture $\sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \bigotimes_{i=j+1}^{n} \mathbb{P}_i^{(s)}$. To write the second term in a similar form, we introduce a modified mixing weight $\bar{\alpha}_{j,c}^{(s)}$ for all $s \in [k_1]$ as follows:

$$\bar{\alpha}_{j,c}^{(s)} \triangleq \begin{cases} \bar{\alpha}^{(s)}, & \bar{\mathbb{P}}_j(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c) = 0; \\ \bar{\alpha}^{(s)} \frac{\mathbb{P}_j^{(s)}(c) - \ell^{\mathbb{P}}(j,\bar{\alpha},c)}{\bar{\mathbb{P}}_j(c) - \ell^{\mathbb{P}}(j,\bar{\alpha},c)}, & \text{otherwise,} \end{cases} \quad \text{where } \bar{\mathbb{P}}_j(c) = \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \mathbb{P}_j^{(s)}(c).$$

We next verify that $\bar{\alpha}_{j,c}$ defines a valid mixing-weight vector. By Definition 12, $\mathbb{P}_j^{(s)}(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c) \geq 0$, and $\bar{\mathbb{P}}_j(c) = \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \mathbb{P}_j^{(s)}(c)$ is an average of the active values $\mathbb{P}_j^{(s)}(c)$, therefore $\bar{\mathbb{P}}_j(c) \geq \ell^{\mathbb{P}}(j, \bar{\alpha}, c)$. If $\bar{\mathbb{P}}_j(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c) = 0$, $\bar{\alpha}_{j,c} = \bar{\alpha}$ is a valid mixing-weight vector as long as $\bar{\alpha}$ is valid. Otherwise, when $\bar{\mathbb{P}}_j(c) > \ell^{\mathbb{P}}(j, \bar{\alpha}, c)$,

$$\sum_{s=1}^{k_1} \bar{\alpha}_{j,c}^{(s)} = \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \frac{\mathbb{P}_j^{(s)}(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c)}{\bar{\mathbb{P}}_j(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c)} = \frac{\sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \mathbb{P}_j^{(s)}(c)}{\bar{\mathbb{P}}_j(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c)} - \frac{\ell^{\mathbb{P}}(j, \bar{\alpha}, c)}{\bar{\mathbb{P}}_j(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c)} = 1.$$

Hence, for $\omega \in [q]^{n-j+1}$ with $\omega_j = c$, we can rewrite $\bar{\mathbb{P}}(\omega)$ as

$$\bar{\mathbb{P}}(\omega) = \ell^{\mathbb{P}}(j, \bar{\alpha}, c) \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \prod_{i=j+1}^{n} \mathbb{P}_i^{(s)}(\omega_i) + \left(\bar{\mathbb{P}}_j(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c)\right) \sum_{s=1}^{k_1} \bar{\alpha}_{j,c}^{(s)} \prod_{i=j+1}^{n} \mathbb{P}_i^{(s)}(\omega_i). \quad (6)$$

Equation (6) naturally suggests a recursive sampling rule. Given the state $(j, (\bar{\alpha}^{(s)})_{s=1}^{k_1})$, we first sample the current coordinate X_j, and then reduce the task of sampling the suffix $X_{j+1:n}$ to sampling from one of two smaller mixtures. Concretely, once the current coordinate is set to c, the suffix distribution is either $\sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \bigotimes_{i=j+1}^{n} \mathbb{P}_i^{(s)}$ or $\sum_{s=1}^{k_1} \bar{\alpha}_{j,c}^{(s)} \bigotimes_{i=j+1}^{n} \mathbb{P}_i^{(s)}$. The component distributions remain the same (except that their dimension is reduced by one), while the mixing weights may change from $\bar{\alpha}$ to $\bar{\alpha}_{j,c}$. Applying this rule recursively yields the sampling procedure shown in Algorithm 1.

In Algorithm 1, the lower-bound selector function $\ell^{\mathbb{P}}$ is treated as part of the input. The following lemma shows that the algorithm outputs a correct sample from $\mathbb{P}$ as long as $\ell^{\mathbb{P}}$ satisfies (4).

▶ **Lemma 13.** *Given a mixture of product distributions $\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}$ and an arbitrary lower-bound selector function $\ell^{\mathbb{P}}$ satisfying (4), the procedure RecursiveSample$(1, \alpha)$ in Algorithm 1 outputs a sample $X \sim \mathbb{P}$.*

Lemma 13 follows by induction on the recursion depth using (6). The proof can be found in the full version.

The same recursive procedure applies to any mixture of product distributions. In particular, we may use it to sample from $\bar{\mathbb{Q}} = \sum_{t=1}^{k_2} \bar{\beta}^{(t)} \bigotimes_{i=j}^{n} \mathbb{Q}_i^{(t)}$ by replacing k_1 with k_2, replacing $(\bar{\alpha}^{(s)})_{s=1}^{k_1}$ with $(\bar{\beta}^{(t)})_{t=1}^{k_2}$, replacing $\mathbb{P}^{(s)}$ with $\mathbb{Q}^{(t)}$, and using an arbitrary lower-bound selector $\ell^{\mathbb{Q}}(j, \bar{\beta}, c)$ satisfying

$$\min_{t \in [k_2]: \bar{\beta}^{(t)} > 0} \mathbb{Q}_j^{(t)}(c) \geq \ell^{\mathbb{Q}}(j, \bar{\beta}, c) \geq 0. \quad (7)$$

Lemma 13 also shows that by substituting P with Q and α with β, the procedure RecursiveSample$(1, \beta)$ outputs a sample $Y \sim \mathbb{Q}$.

Algorithm 1 Recursive sampling process for mixtures of product distributions.

1 RecursiveSample $(j, \bar{\alpha})$;
Parameter : an index $j \in [n+1]$ and mixing weights $\bar{\alpha}^{(1)}, \bar{\alpha}^{(2)}, \ldots, \bar{\alpha}^{(k_1)}$
Static Input : product distributions $\mathbb{P}^{(1)}, \mathbb{P}^{(2)}, \ldots, \mathbb{P}^{(k_1)}$ over $[q]^n$; an arbitrary lower-bound selector function $\ell^{\mathbb{P}}$ satisfying (4)
Output : a random sample $X = (X_j, X_{j+1}, \ldots, X_n) \sim \bar{\mathbb{P}} = \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \bigotimes_{i=j}^{n} \mathbb{P}_i^{(s)}$
2 **if** $j > n$ **then return** $\emptyset$;
3 Compute the probability lower bound $\ell^{\mathbb{P}}(j, \bar{\alpha}, c)$ for all $c \in [q]$;
4 Sample a random pair $(c, e) \in [q] \times \{0, 1\}$ such that for each $c \in [q]$, the probability of $(c, 0)$ is $\ell^{\mathbb{P}}(j, \bar{\alpha}, c)$ and the probability of $(c, 1)$ is $\bar{\mathbb{P}}_j(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c)$, where $\bar{\mathbb{P}}_j(c) = \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \mathbb{P}_j^{(s)}(c)$ is the marginal probability of coordinate j under $\bar{\mathbb{P}}$;
5 **if** $e = 0$ **then**
6 Sample $(X_{j+1}, X_{j+2}, \ldots, X_n) \leftarrow$ RecursiveSample$(j+1, \bar{\alpha})$;
7 **else**
8 Compute mixing weights $\bar{\alpha}_{j,c}^{(s)} = \bar{\alpha}^{(s)} \frac{\mathbb{P}_j^{(s)}(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c)}{\bar{\mathbb{P}}_j(c) - \ell^{\mathbb{P}}(j, \bar{\alpha}, c)}$ for all $s \in [k_1]$;
9 Sample $(X_{j+1}, X_{j+2}, \ldots, X_n) \leftarrow$ RecursiveSample$(j+1, \bar{\alpha}_{j,c})$;
10 **return** $(X_j = c, X_{j+1}, X_{j+2}, \ldots, X_n)$;

4.1.2 The recursive coupling process

We now define a coupling between two mixtures of product distributions

$$\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)} \qquad \text{and} \qquad \mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}_i^{(t)}.$$

At a high level, the coupling runs Algorithm 1 on both $\mathbb{P}$ and $\mathbb{Q}$ to generate samples $X \sim \mathbb{P}$ and $Y \sim \mathbb{Q}$, while sharing randomness between the two executions so that the resulting pair (X, Y) is a coupling of $\mathbb{P}$ and $\mathbb{Q}$.

We use RecursiveSample$(1, \alpha)$ to generate a sample $X \sim \mathbb{P}$ and RecursiveSample$(1, \beta)$ to generate a sample $Y \sim \mathbb{Q}$, and couple the two recursive procedures at the same time. Suppose that at some point the execution for $\mathbb{P}$ is at recursion state RecursiveSample$(j, \bar{\alpha})$ and the execution for $\mathbb{Q}$ is at recursion state RecursiveSample$(j, \bar{\beta})$, where $\bar{\alpha} = (\bar{\alpha}^{(s)})_{s=1}^{k_1}$ and $\bar{\beta} = (\bar{\beta}^{(t)})_{t=1}^{k_2}$ denote the current mixing weights and may differ from the original vectors α and β. We define a shared lower-bound selector $\ell(j, \bar{\alpha}, \bar{\beta}, c)$ as follows.

▶ **Definition 14.** *For any $j \in [n]$, $c \in [q]$, and valid mixing-weight vectors $\bar{\alpha} = (\bar{\alpha}^{(s)})_{s=1}^{k_1}$ and $\bar{\beta} = (\bar{\beta}^{(t)})_{t=1}^{k_2}$, define*

$$\ell\left(j, \bar{\alpha}, \bar{\beta}, c\right) \triangleq \min\left\{ \min_{s \in [k_1] : \bar{\alpha}^{(s)} > 0} \mathbb{P}_j^{(s)}(c), \min_{t \in [k_2] : \bar{\beta}^{(t)} > 0} \mathbb{Q}_j^{(t)}(c) \right\}.$$

The one-sided lower-bound selectors used by the two recursive sampling procedures are then defined by

$$\ell^{\mathbb{P}}(j, \bar{\alpha}, c) = \ell^{\mathbb{Q}}(j, \bar{\beta}, c) = \ell(j, \bar{\alpha}, \bar{\beta}, c).$$

By construction, $\ell^{\mathbb{P}}(j, \bar{\alpha}, c)$ satisfies (4) for $\mathbb{P}$, and $\ell^{\mathbb{Q}}(j, \bar{\beta}, c)$ satisfies (7) for $\mathbb{Q}$. In Line 4 of Algorithm 1, each process draws a random pair $(c, e) \in [q] \times \{0, 1\}$. Let $(c_{\bar{\mathbb{P}}}, e_{\bar{\mathbb{P}}})$ and $(c_{\bar{\mathbb{Q}}}, e_{\bar{\mathbb{Q}}})$ denote the pairs drawn by RecursiveSample$(j, \bar{\alpha})$ and RecursiveSample$(j, \bar{\beta})$, respectively. Since both procedures use the same lower bounds $\ell(j, \bar{\alpha}, \bar{\beta}, c)$, we define a coupling $\bar{\mathcal{C}}$ between these two pairs as follows:

- For each $c \in [q]$, $\mathbf{Pr}_{\bar{\mathcal{C}}}\left[c_{\bar{\mathbb{P}}} = c_{\bar{\mathbb{Q}}} = c \wedge e_{\bar{\mathbb{P}}} = e_{\bar{\mathbb{Q}}} = 0\right] = \ell(j, \bar{\alpha}, \bar{\beta}, c)$.
- For each $c \in [q]$, $\mathbf{Pr}_{\bar{\mathcal{C}}}\left[c_{\bar{\mathbb{P}}} = c_{\bar{\mathbb{Q}}} = c \wedge e_{\bar{\mathbb{P}}} = e_{\bar{\mathbb{Q}}} = 1\right] = \min\{\bar{\mathbb{P}}_j(c), \bar{\mathbb{Q}}_j(c)\} - \ell(j, \bar{\alpha}, \bar{\beta}, c)$, where $\bar{\mathbb{P}} = \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \bigotimes_{i=j}^{n} \mathbb{P}_i^{(s)}$ and $\bar{\mathbb{Q}} = \sum_{t=1}^{k_2} \bar{\beta}^{(t)} \bigotimes_{i=j}^{n} \mathbb{Q}_i^{(t)}$ are the mixtures of product distributions at the current recursive step.
- Given the above two points, for each $c \in A = \{x \in [q] \mid \bar{\mathbb{P}}_j(x) > \bar{\mathbb{Q}}_j(x)\}$, the random variable $(c_{\bar{\mathbb{P}}}, e_{\bar{\mathbb{P}}})$ has a remaining probability $\bar{\mathbb{P}}_j(c) - \bar{\mathbb{Q}}_j(c)$ of taking value $(c, 1)$; and for each $c \in B = \{x \in [q] \mid \bar{\mathbb{P}}_j(x) < \bar{\mathbb{Q}}_j(x)\}$, the random variable $(c_{\bar{\mathbb{Q}}}, e_{\bar{\mathbb{Q}}})$ has remaining probability $\bar{\mathbb{Q}}_j(c) - \bar{\mathbb{P}}_j(c)$ of taking value $(c, 1)$. The total remaining probabilities on the two sides are equal: $\sum_{c \in A}(\bar{\mathbb{P}}_j(c) - \bar{\mathbb{Q}}_j(c)) = \sum_{c \in B}(\bar{\mathbb{Q}}_j(c) - \bar{\mathbb{P}}_j(c))$. We therefore couple the remaining mass arbitrarily. Since A and B are disjoint, in this case we necessarily have

$$c_{\bar{\mathbb{P}}} \neq c_{\bar{\mathbb{Q}}} \quad \text{and} \quad e_{\bar{\mathbb{P}}} = e_{\bar{\mathbb{Q}}} = 1.$$

Using the coupling $\bar{\mathcal{C}}$ between $(c_{\bar{\mathbb{P}}}, e_{\bar{\mathbb{P}}})$ and $(c_{\bar{\mathbb{Q}}}, e_{\bar{\mathbb{Q}}})$, we now couple two sampling processes RecursiveSample$(j, \bar{\alpha})$ and RecursiveSample$(j, \bar{\beta})$ as follows:

- Sample $(c_{\bar{\mathbb{P}}}, e_{\bar{\mathbb{P}}})$ and $(c_{\bar{\mathbb{Q}}}, e_{\bar{\mathbb{Q}}})$ according to $\bar{\mathcal{C}}$.
- If $c_{\bar{\mathbb{P}}} = c_{\bar{\mathbb{Q}}} = c$ for some $c \in [q]$ and $e_{\bar{\mathbb{P}}} = e_{\bar{\mathbb{Q}}} = 0$, then we set $X_j = Y_j = c$ and recursively couple the suffixes via RecursiveCouple$(j+1, \bar{\alpha}, \bar{\beta})$.
- If $c_{\bar{\mathbb{P}}} = c_{\bar{\mathbb{Q}}} = c$ for some $c \in [q]$ and $e_{\bar{\mathbb{P}}} = e_{\bar{\mathbb{Q}}} = 1$, then we set $X_j = Y_j = c$ and recursively couple the suffixes via RecursiveCouple$(j+1, \bar{\alpha}_{j,c}, \bar{\beta}_{j,c})$.
- In the remaining case, we have $X_j = c_{\bar{\mathbb{P}}} \neq c_{\bar{\mathbb{Q}}} = Y_j$ and $e_{\bar{\mathbb{P}}} = e_{\bar{\mathbb{Q}}} = 1$. Hence the coupling already fails at coordinate j, and we simply sample the suffixes independently using RecursiveSample$(j+1, \bar{\alpha}_{j,c_{\bar{\mathbb{P}}}})$ and RecursiveSample$(j+1, \bar{\beta}_{j,c_{\bar{\mathbb{Q}}}})$.

The pseudocode of the coupling process is given in Algorithm 2.

▶ **Lemma 15** (Validity of recursive coupling). *Given two mixtures of product distributions $\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}$ and $\mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}_i^{(t)}$, fix a shared lower-bound selector ℓ as in Definition 14. Then RecursiveCouple$(1, \alpha, \beta)$ in Algorithm 2 outputs joint random variables (X, Y) such that $X \sim \mathbb{P}$ and $Y \sim \mathbb{Q}$.*

Lemma 15 follows by a straightforward induction. The proof can be found in the full version.

4.1.3 Discrepancy of recursive coupling

We now analyze the discrepancy of the recursive coupling process. Let $\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}$ and $\mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}_i^{(t)}$ be two mixtures of product distributions. Define

$$(X, Y) \leftarrow \text{RecursiveCouple}(1, \alpha, \beta).$$

Let $\mathcal{C}_{\mathrm{RC}}$ denote the joint distribution of (X, Y). By the coupling inequality, the discrepancy $\mathbf{Pr}_{\mathcal{C}_{\mathrm{RC}}}[X \neq Y]$ is always at least $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q})$. The following lemma provides an upper bound on the discrepancy of our recursive coupling.

▶ **Lemma 16** (Discrepancy of recursive coupling). *Let $[q]$ be a finite domain. For two mixtures of product distributions $\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}$ and $\mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}_i^{(t)}$ over $[q]^n$, the recursive coupling satisfies*

$$\mathbf{Pr}_{\mathcal{C}_{\mathrm{RC}}}[X \neq Y] \leq (4nq)^{k_1+k_2-1} \cdot d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q}).$$

The proof of Lemma 16 follows the known techniques of [20] and can be found in the full version.

Algorithm 2 Recursive coupling process for mixtures of product distributions.

RecursiveCouple $(j, \bar{\alpha}, \bar{\beta})$;
Parameter : an index $j \in [n+1]$ and mixing weights $\bar{\alpha} = (\bar{\alpha}^{(s)})_{s=1}^{k_1}$, $\bar{\beta} = (\bar{\beta}^{(t)})_{t=1}^{k_2}$
Static Input : product distributions $\mathbb{P}^{(1)}, \mathbb{P}^{(2)}, \ldots, \mathbb{P}^{(k_1)}$ and $\mathbb{Q}^{(1)}, \mathbb{Q}^{(2)}, \ldots, \mathbb{Q}^{(k_2)}$ over $[q]^n$; a fixed shared probability lower-bound selector ℓ as in Definition 14
Output : joint random variables (X, Y) such that $X = (X_j, X_{j+1}, \ldots, X_n) \sim \bar{\mathbb{P}} = \sum_{s=1}^{k_1} \bar{\alpha}^{(s)} \bigotimes_{i=j}^{n} \mathbb{P}_i^{(s)}$ and $Y = (Y_j, Y_{j+1}, \ldots, Y_n) \sim \bar{\mathbb{Q}} = \sum_{t=1}^{k_2} \bar{\beta}^{(t)} \bigotimes_{i=j}^{n} \mathbb{Q}_i^{(t)}$
if $j > n$ **then return** $(\emptyset, \emptyset)$;
Compute $\ell(j, \bar{\alpha}, \bar{\beta}, c)$ for all $c \in [q]$, and then use the coupling $\bar{\mathcal{C}}$ to jointly sample $(c_{\bar{\mathbb{P}}}, e_{\bar{\mathbb{P}}})$ and $(c_{\bar{\mathbb{Q}}}, e_{\bar{\mathbb{Q}}})$;
if $e_{\bar{\mathbb{P}}} = e_{\bar{\mathbb{Q}}} = 0$ **then**
    Sample $(X_{j+1:n}, Y_{j+1:n}) \leftarrow$ RecursiveCouple$(j+1, \bar{\alpha}, \bar{\beta})$;
else
    Let $\bar{\alpha}_{j,c_{\bar{\mathbb{P}}}}^{(s)} = \bar{\alpha}^{(s)} \frac{\mathbb{P}_j^{(s)}(c_{\bar{\mathbb{P}}}) - \ell(j, \bar{\alpha}, \bar{\beta}, c_{\bar{\mathbb{P}}})}{\bar{\mathbb{P}}_j(c_{\bar{\mathbb{P}}}) - \ell(j, \bar{\alpha}, \bar{\beta}, c_{\bar{\mathbb{P}}})}$ for $s \in [k_1]$ and $\bar{\beta}_{j,c_{\bar{\mathbb{Q}}}}^{(t)} = \bar{\beta}^{(t)} \frac{\mathbb{Q}_j^{(t)}(c_{\bar{\mathbb{Q}}}) - \ell(j, \bar{\alpha}, \bar{\beta}, c_{\bar{\mathbb{Q}}})}{\bar{\mathbb{Q}}_j(c_{\bar{\mathbb{Q}}}) - \ell(j, \bar{\alpha}, \bar{\beta}, c_{\bar{\mathbb{Q}}})}$ for $t \in [k_2]$;
    if $c_{\bar{\mathbb{P}}} = c_{\bar{\mathbb{Q}}}$ **then**
        Sample $(X_{j+1:n}, Y_{j+1:n}) \leftarrow$ RecursiveCouple$(j+1, \bar{\alpha}_{j,c}, \bar{\beta}_{j,c})$, where $c = c_{\bar{\mathbb{P}}} = c_{\bar{\mathbb{Q}}}$;
    else
        Sample $X_{j+1:n} \leftarrow$ RecursiveSample$(j+1, \bar{\alpha}_{j,c_{\bar{\mathbb{P}}}})$ with $\ell^{\mathbb{P}} = 0$;
        Sample $Y_{j+1:n} \leftarrow$ RecursiveSample$(j+1, \bar{\beta}_{j,c_{\bar{\mathbb{Q}}}})$ with $\ell^{\mathbb{Q}} = 0$;
Let $X = (X_j = c_{\bar{\mathbb{P}}}, X_{j+1:n})$ and $Y = (Y_j = c_{\bar{\mathbb{Q}}}, Y_{j+1:n})$ and return (X, Y);

4.2 Implementation of oracles

In this section, we implement the oracle queries in Assumption 9 based on Algorithm 2. Consider the execution of Algorithm 2 on two mixtures of product distributions $\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}_i^{(s)}$ and $\mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}_i^{(t)}$. Define the following set of states and transitions between them.

For each recursion instance RecursiveCouple$(j, \bar{\alpha}, \bar{\beta})$, we create a state S with label $(j, \bar{\alpha}, \bar{\beta})$, where $1 \le j \le n+1$. A state S is said to be in layer j if j is the first coordinate of the label. We add a special failure state $S = \perp$ to denote that the coupling fails. Let $\mathcal{S}$ denote the set of all possible states that can be reached by the coupling process with a *positive* probability, including the failure state $\perp$.

For each state $S \in \mathcal{S}$ with label $(j, \bar{\alpha}, \bar{\beta})$ for $j \in [n]$, we define the following transitions according to the coupling process. The coupling process samples $(c_{\bar{\mathbb{P}}}, e_{\bar{\mathbb{P}}})$ and $(c_{\bar{\mathbb{Q}}}, e_{\bar{\mathbb{Q}}})$ for $\bar{\mathbb{P}}$ and $\bar{\mathbb{Q}}$, respectively, and then makes the transition.

- **Type-I**: For any $c \in [q]$ with $\ell(j, \bar{\alpha}, \bar{\beta}, c) > 0$, with probability $\ell(j, \bar{\alpha}, \bar{\beta}, c)$, S moves to a new state S' with label $(j+1, \bar{\alpha}, \bar{\beta})$. Define a transition t from S to S' with weight $w(t) = \ell(j, \bar{\alpha}, \bar{\beta}, c)$ and label $L(t) = (c, c)$. This means that S moves to S' through t with probability $\ell(j, \bar{\alpha}, \bar{\beta}, c)$ and sets $X_j = Y_j = c$.
- **Type-II**: For any $c \in [q]$ with $p_c \triangleq \min\{\bar{\mathbb{P}}_j(c), \bar{\mathbb{Q}}_j(c)\} - \ell(j, \bar{\alpha}, \bar{\beta}, c) > 0$, with probability p_c, S moves to a new state S' with label $(j+1, \bar{\alpha}_{j,c}, \bar{\beta}_{j,c})$. Define a transition t from S to S' with weight $w(t) = p_c$ and label $L(t) = (c, c)$. This means that S moves to S' through t with probability p_c and sets $X_j = Y_j = c$.

- **Type-III**: With the remaining probability, the coupling fails ($X_j \neq Y_j$). For any $c, c' \in [q]$ with $c \neq c'$ and $p_{c,c'} \triangleq \mathbf{Pr}\left[c_{\bar{\mathbb{P}}} = c \wedge c_{\bar{\mathbb{Q}}} = c'\right] > 0$, define a transition t from S to the failure state $\perp$ with weight $w(t) = p_{c,c'}$ and label $L(t) = (X_{j:n}, Y_{j:n})$, where $X_j = c$, $Y_j = c'$, and $X_{j+1:n}, Y_{j+1:n}$ are sampled independently in Lines 11 and 12 of Algorithm 2. Hence, the label contains a pair of random configurations, both of length $n - j + 1$. The label $L(t)$ is random because we further sample the pair $(X_{j+1:n}, Y_{j+1:n})$. We remark that there are multiple transitions from S to the failure state $\perp$ with different weights and labels.

▶ **Lemma 17.** *The total number of states is bounded by* $|\mathcal{S}| \leq (nq+1)^{k_1+k_2-1} + 1$.

The proof can be found in the full version.

The oracle queries in Assumption 9 can be implemented by the following algorithm. One execution of the coupling process can be represented as a random walk on the state space $\mathcal{S}$. The random walk starts from the root state $S = S_{\text{root}} = (1, \alpha, \beta)$. At each step, the random walk samples a transition $t = (S \to S')$ from S with probability $w(t)$ and moves to the next state S'. The random walk ends either at a state in layer $n+1$ (coupling succeeds) or at the failure state $\perp$ (coupling fails). The coupling process outputs a pair $(X_{1:n}, Y_{1:n})$, which is determined by the labels of all transitions along the random walk.

Preprocessing step. We build the DAG with all states in $\mathcal{S}$ and all transitions between them. Using Lemma 17, the total number of states and transitions in the DAG is at most $O(q^2(nq+1)^{k_1+k_2-1})$. For each state $S \in \mathcal{S}$, compute $p_{\text{fail}}(S)$, the probability that a random walk starting from S reaches the failure state $\perp$. By definition,

$$p_{\text{fail}}(\perp) = 1 \text{ and } p_{\text{fail}}(S) = 0 \text{ for all } S \text{ in layer } n+1.$$

For each non-failed state $S \in \mathcal{S}$ in layer $j \in [n]$, we have the following recursive relation:

$$p_{\text{fail}}(S) = \sum_{t=(S\to S') \in \text{transitions from } S} w(t) p_{\text{fail}}(S').$$

Using dynamic programming, we can compute $p_{\text{fail}}(S)$ for all $S \in \mathcal{S}$ in time $O(q^2(nq+1)^{k_1+k_2-1})$. By the definition of $p_{\text{fail}}(S)$, the failure probability of the recursive coupling is

$$\mathbf{Pr}_{\mathcal{C}_{\text{RC}}}[X \neq Y] = p_{\text{fail}}(S_{\text{root}}).$$

Sampling query. Next, we give an algorithm that generates a random sample of X conditional on $X \neq Y$ in the recursive coupling. Equivalently, we can sample a random walk on the DAG starting from the root state S_{root}, conditional on the random walk reaching the failure state $\perp$. If $p_{\text{fail}}(S_{\text{root}}) = 0$, then $d_{\text{TV}}(\mathbb{P}, \mathbb{Q}) = 0$ by the coupling inequality, and this sampling query is not needed. Otherwise, the query can be implemented by the following algorithm.

- Initialize $S = S_{\text{root}}$.
- Sample a random transition $t = (S \to S')$ from S with probability $\frac{w(t)p_{\text{fail}}(S')}{p_{\text{fail}}(S)}$ and then update the current state S to S'.
- The process terminates when S reaches the failure state $\perp$.

The above process gives a random sequence of transitions on the DAG. By concatenating the labels in the sequence, we obtain a random pair $(X, Y) \in [q]^n \times [q]^n$, and we output the sample $X \in [q]^n$.

The correctness of the conditional sample X follows directly from the definition of $p_{\text{fail}}(\cdot)$. The running time to generate a random sample X is $O(q^2(nq+1)^{k_1+k_2-1})$.

Evaluation query. Given a fixed configuration $\sigma \in [q]^n$, we want to evaluate the probability

$$\mathbf{Pr}_{\mathcal{C}_{\mathrm{RC}}}[X = \sigma \wedge X \neq Y].$$

For each non-failed state $S \in \mathcal{S}$ in layer $j \in [n]$, let $p^{\sigma}_{\mathrm{fail}}(S)$ be the probability that a random walk starting from S reaches the failure state $\perp$ and that the label $X_{j:n}$ of the random walk is exactly $\sigma_{j:n}$. By definition, since S_{root} is the layer-1 state, it holds that

$$p^{\sigma}_{\mathrm{fail}}(S_{\mathrm{root}}) = \mathbf{Pr}_{\mathcal{C}_{\mathrm{RC}}}[X = \sigma \wedge X \neq Y].$$

For each $S \in \mathcal{S}$ in layer $j = n+1$, by definition, we have $p^{\sigma}_{\mathrm{fail}}(S) = 0$.
Fix any non-failed state $S \in \mathcal{S}$ in layer $j \in [n]$ with $S = (j, \bar{\alpha}, \bar{\beta})$. Define

$$\mathcal{T} = \{t \mid t \text{ is a transition from } S \text{ to } S' \neq \perp \text{ and } L(t) = (\sigma_j, \sigma_j)\}.$$

The above definition considers all transitions from S to non-failed states S'. We still need to consider the type-III transitions from S to the failure state $\perp$. By definition, there are at most $q(q-1)$ such transitions. Let $\mathcal{T}_{\perp}(S)$ denote the set of all type-III transitions from S to the failure state $\perp$. Every such transition can be specified by a pair (c, c') with $c \neq c'$. We use $t_{c,c'}$ to denote the corresponding type-III transition. Note that the weight $w(t_{c,c'})$ is $\mathbf{Pr}\left[c_{\bar{\mathbb{P}}} = c \wedge c_{\bar{\mathbb{Q}}} = c'\right]$ in the coupling at Line 3 of Algorithm 2. The label of $t_{c,c'}$ is a random pair $(X_{j:n}, Y_{j:n})$, where $X_j = c$, $Y_j = c'$, and $X_{j+1:n}$ and $Y_{j+1:n}$ are sampled independently in Lines 11 and 12 of Algorithm 2. We define

$$\tau(t_{c,c'}, \sigma) \triangleq \mathbf{Pr}[X_{j+1:n} = \sigma_{j+1:n}] = \sum_{s=1}^{k_1} \bar{\alpha}^{(s)}_{j,c} \prod_{i=j+1}^{n} \mathbb{P}^{(s)}_i(\sigma_i).$$

Now, we have the following recursive relation:

$$p^{\sigma}_{\mathrm{fail}}(S) = \sum_{t=(S \to S') \in \mathcal{T}} w(t) p^{\sigma}_{\mathrm{fail}}(S') + \sum_{t_{c,c'} \in \mathcal{T}_{\perp}(S): c = \sigma_j} w(t_{c,c'}) \tau(t_{c,c'}, \sigma).$$

Again, we can use dynamic programming on the DAG from layer $n+1$ to layer 1 to compute all values $p^{\sigma}_{\mathrm{fail}}(S)$ for all $S \in \mathcal{S}$ in time $O(q^2(nq+1)^{k_1+k_2-1})$. The final result is $p^{\sigma}_{\mathrm{fail}}(S_{\mathrm{root}})$.

5 Algorithm for Mixtures of Boolean Subcubes

5.1 Reduction to a counting problem

Consider two mixtures of Boolean subcubes $\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^{n} \mathbb{P}^{(s)}_i$ and $\mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^{n} \mathbb{Q}^{(t)}_i$. A component $\mathbb{P}^{(s)}$ over $\{0,1\}^n$ is a Boolean subcube if, for any $i \in [n]$, $\mathbb{P}^{(s)}_i(1) \in \{0, \frac{1}{2}, 1\}$. Thus, for any $\omega \in \{0,1\}^n$, $\mathbb{P}^{(s)}(\omega) = \prod_{i=1}^{n} \mathbb{P}^{(s)}_i(\omega_i)$ is a product of values in $\{0, \frac{1}{2}, 1\}$. We define the following partition $\Lambda^{\mathrm{one}}_{\mathbb{P}^{(s)}}$, $\Lambda^{\mathrm{zero}}_{\mathbb{P}^{(s)}}$, and $\Lambda^{\mathrm{half}}_{\mathbb{P}^{(s)}}$ of $[n]$:

$$\Lambda^{\mathrm{one}}_{\mathbb{P}^{(s)}} = \{i \in [n] \mid \mathbb{P}^{(s)}_i(1) = 1\},\ \Lambda^{\mathrm{zero}}_{\mathbb{P}^{(s)}} = \{i \in [n] \mid \mathbb{P}^{(s)}_i(1) = 0\},$$
$$\Lambda^{\mathrm{half}}_{\mathbb{P}^{(s)}} = \left\{i \in [n] \mid \mathbb{P}^{(s)}_i(1) = \frac{1}{2}\right\}.$$

In words, for the product distribution $\mathbb{P}^{(s)}$, the set $\Lambda^{\mathrm{one}}_{\mathbb{P}^{(s)}}$ contains all dimensions whose value is fixed to 1, the set $\Lambda^{\mathrm{zero}}_{\mathbb{P}^{(s)}}$ contains all dimensions whose value is fixed to 0, and the set $\Lambda^{\mathrm{half}}_{\mathbb{P}^{(s)}}$ contains all dimensions whose value is sampled uniformly at random. Similarly, for a component $\mathbb{Q}^{(t)}$, we define the sets $\Lambda^{\mathrm{one}}_{\mathbb{Q}^{(t)}}$, $\Lambda^{\mathrm{zero}}_{\mathbb{Q}^{(t)}}$, and $\Lambda^{\mathrm{half}}_{\mathbb{Q}^{(t)}}$ in the same way.

The probability of each $\omega \in \{0,1\}^n$ can be written as follows:

$$\mathbb{P}^{(s)}(\omega) = \left(\frac{1}{2}\right)^{\left|\Lambda^{\text{half}}_{\mathbb{P}^{(s)}}\right|} \cdot \mathbb{1}\left[\forall i \in \Lambda^{\text{one}}_{\mathbb{P}^{(s)}}, \omega_i = 1\right] \cdot \mathbb{1}\left[\forall i \in \Lambda^{\text{zero}}_{\mathbb{P}^{(s)}}, \omega_i = 0\right],$$

$$\mathbb{Q}^{(t)}(\omega) = \left(\frac{1}{2}\right)^{\left|\Lambda^{\text{half}}_{\mathbb{Q}^{(t)}}\right|} \cdot \mathbb{1}\left[\forall i \in \Lambda^{\text{one}}_{\mathbb{Q}^{(t)}}, \omega_i = 1\right] \cdot \mathbb{1}\left[\forall i \in \Lambda^{\text{zero}}_{\mathbb{Q}^{(t)}}, \omega_i = 0\right],$$

where the indicator function $\mathbb{1}[*]$ returns 1 if statement $*$ holds and 0 otherwise. For the distribution $\mathbb{P}^{(s)}$, we say $\omega \in \{0,1\}^n$ is *feasible* if for all $i \in \Lambda^{\text{one}}_{\mathbb{P}^{(s)}}$, $\omega_i = 1$ and for all $i \in \Lambda^{\text{zero}}_{\mathbb{P}^{(s)}}$, $\omega_i = 0$. Each feasible $\omega \in \{0,1\}^n$ has probability $(1/2)^{|\Lambda^{\text{half}}_{\mathbb{P}^{(s)}}|}$ under the distribution $\mathbb{P}^{(s)}$, while each infeasible $\omega \in \{0,1\}^n$ has probability 0. A similar structural property holds for the distribution $\mathbb{Q}^{(t)}$.

The feasibility of a configuration $\omega \in \{0,1\}^n$ under the distribution $\mathbb{P}^{(s)}$ can be expressed by a Boolean formula $F_{\mathbb{P}^{(s)}} : \{0,1\}^n \to \{0,1\}$ as follows:

$$F_{\mathbb{P}^{(s)}}(\omega) = \bigwedge_{i \in \Lambda^{\text{one}}_{\mathbb{P}^{(s)}}} \omega_i \wedge \bigwedge_{i \in \Lambda^{\text{zero}}_{\mathbb{P}^{(s)}}} \neg\omega_i. \tag{8}$$

Similarly, for the distribution $\mathbb{Q}^{(t)}$, define the Boolean formula $F_{\mathbb{Q}^{(t)}} : \{0,1\}^n \to \{0,1\}$ as follows:

$$F_{\mathbb{Q}^{(t)}}(\omega) = \bigwedge_{i \in \Lambda^{\text{one}}_{\mathbb{Q}^{(t)}}} \omega_i \wedge \bigwedge_{i \in \Lambda^{\text{zero}}_{\mathbb{Q}^{(t)}}} \neg\omega_i. \tag{9}$$

By definition, $\mathbb{P}^{(s)}(\omega) = (1/2)^{|\Lambda^{\text{half}}_{\mathbb{P}^{(s)}}|} \cdot F_{\mathbb{P}^{(s)}}(\omega)$ and $\mathbb{Q}^{(t)}(\omega) = (1/2)^{|\Lambda^{\text{half}}_{\mathbb{Q}^{(t)}}|} \cdot F_{\mathbb{Q}^{(t)}}(\omega)$. The total variation distance between mixtures of Boolean subcubes $\mathbb{P} = \sum_{s=1}^{k_1} \alpha^{(s)} \bigotimes_{i=1}^n \mathbb{P}_i^{(s)}$ and $\mathbb{Q} = \sum_{t=1}^{k_2} \beta^{(t)} \bigotimes_{i=1}^n \mathbb{Q}_i^{(t)}$ can be expressed as follows:

$$\begin{aligned}
d_{\text{TV}}(\mathbb{P}, \mathbb{Q}) &= \frac{1}{2} \sum_{\omega \in \{0,1\}^n} |\mathbb{P}(\omega) - \mathbb{Q}(\omega)| \\
&= \frac{1}{2} \sum_{\omega \in \{0,1\}^n} \left| \sum_{s=1}^{k_1} \alpha^{(s)} \prod_{i=1}^n \mathbb{P}_i^{(s)}(\omega_i) - \sum_{t=1}^{k_2} \beta^{(t)} \prod_{i=1}^n \mathbb{Q}_i^{(t)}(\omega_i) \right| \\
&= \frac{1}{2} \sum_{\omega \in \{0,1\}^n} \left| \sum_{s=1}^{k_1} \alpha^{(s)} \cdot \left(\frac{1}{2}\right)^{\left|\Lambda^{\text{half}}_{\mathbb{P}^{(s)}}\right|} \cdot F_{\mathbb{P}^{(s)}}(\omega) - \sum_{t=1}^{k_2} \beta^{(t)} \cdot \left(\frac{1}{2}\right)^{\left|\Lambda^{\text{half}}_{\mathbb{Q}^{(t)}}\right|} \cdot F_{\mathbb{Q}^{(t)}}(\omega) \right|.
\end{aligned}$$

Define the *characteristic function* $F : \{0,1\}^n \to \{0,1\}^{k_1+k_2}$ as follows:

$$F(\omega) = \left(F_{\mathbb{P}^{(1)}}(\omega), F_{\mathbb{P}^{(2)}}(\omega), \ldots, F_{\mathbb{P}^{(k_1)}}(\omega), F_{\mathbb{Q}^{(1)}}(\omega), F_{\mathbb{Q}^{(2)}}(\omega), \ldots, F_{\mathbb{Q}^{(k_2)}}(\omega)\right).$$

By the above calculation, the value of $|\mathbb{P}(\omega) - \mathbb{Q}(\omega)|$ is fully determined by $F(\omega)$. The key observation is that the image space of F has constant size $2^{k_1+k_2}$, so we can reorganize all $\omega \in \{0,1\}^n$ according to the value of the characteristic function $F(\omega)$. Formally,

$$d_{\text{TV}}(\mathbb{P}, \mathbb{Q}) = \frac{1}{2} \sum_{\chi \in \{0,1\}^{k_1+k_2}} N_\chi \cdot \left| \sum_{s=1}^{k_1} \alpha^{(s)} \cdot \left(\frac{1}{2}\right)^{\left|\Lambda^{\text{half}}_{\mathbb{P}^{(s)}}\right|} \cdot \chi_s - \sum_{t=1}^{k_2} \beta^{(t)} \cdot \left(\frac{1}{2}\right)^{\left|\Lambda^{\text{half}}_{\mathbb{Q}^{(t)}}\right|} \cdot \chi_{t+k_1} \right| \tag{10}$$

where N_χ counts the number of $\omega \in \{0,1\}^n$ such that $F(\omega) = \chi$, i.e.,

$$N_\chi = |\{\omega \in \{0,1\}^n \mid F(\omega) = \chi\}|.$$

By (10), computing the total variation distance between two mixtures of Boolean subcubes $\mathbb{P}$ and $\mathbb{Q}$ reduces to counting N_χ for all $\chi \in \{0,1\}^{k_1+k_2}$.

5.2 The counting algorithm

▶ **Lemma 18.** *Given any $\chi \in \{0,1\}^{k_1+k_2}$, the value of N_χ can be computed in time $O(2^{|S_0|} \cdot n(k_1+k_2))$, where $S_0 = \{\, j \in [k_1+k_2] \mid \chi_j = 0 \,\}$ is the set of indices j with $\chi_j = 0$.*

Fix $\chi \in \{0,1\}^{k_1+k_2}$, and consider the set of $\omega \in \{0,1\}^n$ such that $F(\omega) = \chi$. We need to count the number of such $\omega \in \{0,1\}^n$. To simplify the notation, define a sequence of Boolean functions $F_1, F_2, \ldots, F_{k_1+k_2} : \{0,1\}^n \to \{0,1\}$ as follows:

$$\forall j \in [k_1+k_2], \quad F_j(\omega) = \begin{cases} F_{\mathbb{P}^{(j)}}(\omega) & \text{if } j \in [k_1], \\ F_{\mathbb{Q}^{(j-k_1)}}(\omega) & \text{if } j \in [k_1+1, k_1+k_2], \end{cases}$$

where $F_{\mathbb{P}^{(s)}}$ and $F_{\mathbb{Q}^{(t)}}$ are defined in (8) and (9), respectively. For a configuration $\omega \in \{0,1\}^n$ with $F(\omega) = \chi$, we have $F_j(\omega) = \chi_j$ for all $j \in [k_1+k_2]$.

For a subset $S \subseteq [k_1+k_2]$ of indices, define the following set of configurations:

$$\Phi(S) = \{\omega \in \{0,1\}^n \mid F_j(\omega) = 1 \text{ for all } j \in S\}.$$

Let $S_1 = \{j \in [k_1+k_2] \mid \chi_j = 1\}$ and $S_0 = \{j \in [k_1+k_2] \mid \chi_j = 0\}$. By the definition of N_χ and the inclusion-exclusion principle, we have

$$N_\chi = |\Phi(S_1)| - |\{\omega \in \Phi(S_1) \mid \exists\, j \in S_0, F_j(\omega) = 1\}| = \sum_{S \subseteq S_0} (-1)^{|S|} \cdot |\Phi(S_1 \cup S)|. \tag{11}$$

▶ **Observation 19.** *Given any $S \subseteq [k_1+k_2]$, the size $|\Phi(S)|$ can be computed in time $O(n \cdot |S|)$.*

Proof. By the definition of $F_{\mathbb{P}^{(s)}}$ and $F_{\mathbb{Q}^{(t)}}$, we have $F_{\mathbb{P}^{(s)}}(\omega) = 1$ iff $\omega_i = 1$ for all $i \in \Lambda^{\text{one}}_{\mathbb{P}^{(s)}}$ and $\omega_i = 0$ for all $i \in \Lambda^{\text{zero}}_{\mathbb{P}^{(s)}}$. Similarly, $F_{\mathbb{Q}^{(t)}}(\omega) = 1$ iff $\omega_i = 1$ for all $i \in \Lambda^{\text{one}}_{\mathbb{Q}^{(t)}}$ and $\omega_i = 0$ for all $i \in \Lambda^{\text{zero}}_{\mathbb{Q}^{(t)}}$. We can go through all $j \in S$ and fix the values of the corresponding dimensions $i \in [n]$. If there is a contradiction, then $|\Phi(S)| = 0$. Otherwise, $|\Phi(S)| = 2^r$, where r is the number of dimensions whose values are not fixed. The running time is $O(n \cdot |S|)$. ◀

We now prove Lemma 18. Combining (11) and Observation 19, we can exactly compute the value of N_χ in time

$$\sum_{S \subseteq S_0} O(n|S_1 \cup S|) \le \sum_{0 \le k \le |S_0|} \binom{|S_0|}{k} \cdot O(n(k_1+k_2)) = O(2^{|S_0|} \cdot n(k_1+k_2)).$$

5.3 The total variation distance algorithm

The algorithm for computing the total variation distance between two mixtures of Boolean subcubes $\mathbb{P}$ and $\mathbb{Q}$ is obtained by combining (10) and Lemma 18. Let $K = k_1 + k_2$. The overall running time is

$$\sum_{0 \le m \le K} \binom{K}{m} \cdot O(2^m \cdot nK) = O(3^K K \cdot n) = O(3^{k_1+k_2}(k_1+k_2) \cdot n).$$

Here m enumerates the number of indices j with $\chi_j = 0$. This proves the main result in Theorem 4.

6 Proof of the hardness result

Proof of Theorem 5. We show that if there is a polynomial-time algorithm for computing the TV-distance between two mixtures of Boolean subcubes with $k_1 + k_2 = \Theta(n)$, then there is a polynomial-time algorithm for #3SAT, restricted to 3-CNF formulas. Let

$$\varphi(x_1, x_2, \ldots, x_r) = C_1 \wedge C_2 \wedge \ldots \wedge C_m$$

be a 3-CNF formula over the used variables $x_1, x_2, \ldots, x_r$, and $m \geq 1$. Set $N = \max\{r, m\}$. If $N > r$, we add $N - r$ dummy variables $x_{r+1}, \ldots, x_N$. Let S denote the number of satisfying assignments of φ over $x_1, \ldots, x_N$. As the dummy variables do not appear in any clause, the number of satisfying assignments for φ is given by

$$\#\mathsf{SAT}(\varphi) = \frac{S}{2^{N-r}}.$$

We establish the proof by showing the relation between S and the TV-distance between certain mixtures of Boolean subcubes. Let $n = N + 1$. We construct two mixtures of subcubes $\mathbb{P}$ and $\mathbb{Q}$ over $\{0,1\}^n$. A point in this space can be represented as $(b, \omega_1, \ldots, \omega_N)$, where $b \in \{0,1\}$ is an additional bit, and $(\omega_1, \ldots, \omega_N)$ is an assignment to $(x_1, \ldots, x_N)$. For each $j \in [m]$, let $x_{j,a}, x_{j,b}, x_{j,c}$ be the three variables appearing in the clause C_j. Define $(\omega_{j,a}, \omega_{j,b}, \omega_{j,c}) \in \{0,1\}^3$ to be the unique assignment to $x_{j,a}, x_{j,b}, x_{j,c}$ that falsifies C_j. Let U_j be a subcube such that

$$\mathbf{Pr}_{U_j}\left[(b, x_{j,a}, x_{j,b}, x_{j,c}) = (0, \omega_{j,a}, \omega_{j,b}, \omega_{j,c})\right] = 1,$$

and the other $N - 3$ coordinates are uniform over $\{0,1\}$. Define

$$\mathbb{P} = \frac{1}{m}\sum_{j=1}^{m} U_j,$$

is a mixture of $k_1 = m$ subcubes. Next we define $\mathbb{Q}$. Let V_0 and V_1 be two subcubes such that

$$\mathbf{Pr}_{V_0}[b = 0] = \mathbf{Pr}_{V_1}[b = 1] = 1,$$

and that are uniform over $(x_1, \ldots, x_N)$. Let $\lambda = \frac{1}{2m}$, and define

$$\mathbb{Q} = \lambda V_0 + (1 - \lambda) V_1,$$

which is a mixture of $k_2 = 2$ subcubes.

We now compute $d_{\mathrm{TV}}(\mathbb{P}, \mathbb{Q})$. For any assignment $\omega = (\omega_1, \ldots, \omega_N)$, let

$$F(\omega) = |\{j \in [m] \mid \omega \text{ falsifies } C_j\}|$$

denote the number of clauses falsified by ω. For every $\omega \in \{0,1\}^N$, we have

$$\mathbb{P}(0,\omega) = \frac{1}{m}\sum_{j=1}^{m} U_j(0,\omega) = \frac{1}{m}\sum_{j=1}^{m} \mathbf{1}[\omega \text{ falsifies } C_j]\cdot 2^{-(N-3)} = \frac{F(\omega)}{m}\cdot 2^{-(N-3)} = \frac{8F(\omega)}{m}\cdot 2^{-N},$$

and $\mathbb{P}(1,\omega) = 0$ by definition of U_j. Remark that

$$\mathbb{Q}(0,\omega) = \lambda \cdot 2^{-N} = \frac{1}{2m}\cdot 2^{-N} < \frac{8F(\omega)}{m}\cdot 2^{-N} = \mathbb{P}(0,\omega) \quad \text{iff } F(\omega) \geq 1;$$

$$\mathbb{Q}(1,\omega) = (1-\lambda)\cdot 2^{-N} > 0 = \mathbb{P}(1,\omega).$$

Therefore

$$\begin{aligned} d_{\mathrm{TV}}(\mathbb{P},\mathbb{Q}) &= \sum_{(b,\omega)\in\{0,1\}^{N+1}} \max\{0, \mathbb{P}(b,\omega) - \mathbb{Q}(b,\omega)\} = \sum_{\omega\in\{0,1\}^N : F(\omega)\geq 1} \mathbb{P}(0,\omega) - \mathbb{Q}(0,\omega) \\ &= \sum_{\omega\in\{0,1\}^N : F(\omega)\geq 1} \frac{8F(\omega)}{m}\cdot 2^{-N} - \sum_{\omega\in\{0,1\}^N : F(\omega)\geq 1} \frac{1}{2m}\cdot 2^{-N}. \end{aligned} \tag{12}$$

For the first term, we consider counting all pairs (ω, C_j) such that ω falsifies C_j. On the one hand, for each ω, it falsifies $F(\omega)$ clauses; on the other hand, for each C_j, it is falsified by 2^{N-3} assignments. Thus

$$\sum_{\omega\in\{0,1\}^N : F(\omega)\geq 1} F(\omega) = \sum_{\omega\in\{0,1\}^N} F(\omega) = m\cdot 2^{N-3}.$$

For the second term, there are S assignments ω satisfying all clauses, that is, $F(\omega) = 0$. So there are $2^N - S$ assignments satisfying $F(\omega) \geq 1$. Substituting back to (12), we have

$$\begin{aligned} d_{\mathrm{TV}}(\mathbb{P},\mathbb{Q}) &= \sum_{\omega\in\{0,1\}^N : F(\omega)\geq 1} \frac{8F(\omega)}{m}\cdot 2^{-N} - \sum_{\omega\in\{0,1\}^N : F(\omega)\geq 1} \frac{1}{2m}\cdot 2^{-N} \\ &= \frac{2^{-N+3}}{m}\cdot(m\cdot 2^{N-3}) - \frac{2^{-N}}{2m}\cdot(2^N - S) = 1 - \frac{1}{2m} + \frac{2^{-N}}{2m}S. \end{aligned}$$

Thus the number of satisfying assignments is given by

$$\#\mathsf{SAT}(\varphi) = \frac{S}{2^{N-r}} = 2^r(2m\cdot d_{\mathrm{TV}}(\mathbb{P},\mathbb{Q}) - 2m + 1).$$

The constructed distributions live on the $n = N+1$ dimensional subcube, with $k_1 + k_2 = m + 2$ total components. Since $N = \max\{r, m\}$ and $r \leq 3m$, we have $m \leq N \leq 3m$, hence

$$k_1 + k_2 = m + 2 = \Theta(N+1) = \Theta(n).$$

Therefore, an algorithm for Problem 3 with $k_1 + k_2 = \Theta(n)$ yields an exact algorithm for #3SAT. ◀

Abstract

We initiate the study of property testing for k–submodular functions, a higher-dimensional analogue of submodular functions defined on partial partitions of a ground set. While k–submodularity retains the diminishing-returns flavor of ordinary submodularity, it also introduces a pairwise monotonicity constraint comparing competing assignments of the same element. This additional local structure makes the testing problem qualitatively different from the classical case.

Our results show a sharp contrast between distance regimes. In the ℓ_p regime for $p \geq 1$, we prove that every bounded k–submodular function is close to a junta on the hypergrid. Combined with an implicit-learning tester for hypergrid domains, this yields a constant-query tester for k–submodularity. In the Hamming distance regime, k–submodularity admits two qualitatively different local witnesses – violated *squares* for diminishing marginal gains, and violated *triangles* for pairwise-monotonicity failures – and the latter has no counterpart at $k = 1$. We prove density theorems for both witness types via repair on filters and ideals of partial partitions, yielding non-adaptive, one-sided sub-exponential-query testers for the two component properties of k–submodularity. We then exhibit a configuration in which the two repair directions are forced into opposition on a shared vertex, identifying a structural barrier to combining these into a tester for the full property.

Finally, for bounded-range functions, we give an adaptive tester for monotone k–submodularity via a pseudo-DNF representation and learning on the hypergrid. Several of the structural and learning tools developed here may be useful for testing other properties over product domains.

We thank Fabian Spaeh for inspiring us to investigate this question through his work on k-submodular optimization.

1 Introduction

Submodularity is one of the canonical examples of a global property with a simple local interpretation. A set function is submodular when it satisfies the principle of *diminishing marginal returns*: the incremental value of adding an element can only decrease as the set to which it is added grows. Formally, a set function $f : 2^{[n]} \to \mathbb{R}$ is said to be *submodular* if, for all subsets $X, Y \subseteq [n]$, it satisfies the inequality:

$$f(X) + f(Y) \geq f(X \cap Y) + f(X \cup Y).$$

© Themistoklis Haris and Diptaksho Palit;

This local-to-global nature makes submodularity a natural target for property testing [8], where one is given oracle access to an unknown function and must distinguish functions satisfying a property from those that are far from satisfying it. Yet even for ordinary submodularity, the query complexity of testing remains poorly understood. Seshadhri and Vondrák [16] gave a tester using roughly $(1/\varepsilon)^{\sqrt{n}}$ queries and proved a linear lower bound; the latter was later improved to a nearly quadratic lower bound by Hatami and Vondrák [10]. The resulting exponential gap has remained open, and has motivated the study of more structured regimes, such as bounded-range submodular functions [15] and testing under ℓ_p distance rather than Hamming distance [1].

In this work we ask what happens to this picture for a higher-dimensional analogue of submodularity. For a fixed integer $k \geq 1$, a point in $[k+1]^n$ can be viewed as a *partial partition* of the ground set $[n]$: each element is either assigned to one of k parts, or left unassigned. A function on these partial partitions is k–*submodular* if marginal gains diminish no matter which part an element is assigned to. The case $k = 1$ is ordinary submodularity, while already for $k = 2$ the domain has multiple incompatible directions in which a single element may be added. This function class has been studied extensively in optimization [12, 4], with applications including tensor placement [12] and online ad allocation [5].

From a testing perspective, k–submodularity is not merely submodularity on a larger domain. A useful characterization, due to Ward and Živný [17], decomposes k–submodularity into two conditions. The first is *diminishing marginal gains*, which generalizes the familiar submodular inequality inside each direction of the hypergrid. The second is *pairwise monotonicity*, a constraint comparing the marginal gains of assigning the same element to two different parts. One way to understand this decomposition is to separate two kinds of local interactions. When two partial partitions make compatible choices, k–submodularity behaves like ordinary diminishing returns along the corresponding direction. When they make incompatible choices for the same element, the join operation discards that element from both parts; the resulting inequality says that assigning the element to two different parts cannot have two strongly negative marginal gains at the same time. This second condition has no analogue when $k = 1$, and it is the source of much of the new combinatorial structure in the testing problem.

We initiate the study of testing k–submodularity. Our results show a sharp contrast between two distance regimes. In the ℓ_p regime, analytic structure survives the passage from the Boolean hypercube to the hypergrid: we prove a junta-approximation theorem for k–submodular functions and combine it with an implicit-learning tester on hypergrids. In the Hamming distance regime, the local structure fragments: we obtain testers for the two local constraints by developing square and triangle witness structures, and show that their repair procedures expose a genuine obstruction to the standard local-repair paradigm for full k–submodularity. Along the way, we develop testing and learning tools for hypergrid domains that may be useful beyond this problem.

1.1 Our Results

We organize our contributions around three questions. First, does the analytic structure that makes submodularity testable in ℓ_p distance survive on the richer domain of partial partitions? Second, in the Hamming distance regime, can the local-violation framework for submodularity be adapted to the two distinct constraints that characterize k–submodularity? Third, can bounded range assumptions recover efficient testability for a meaningful subclass of k–submodular functions?

ℓ_p testing from hypergrid junta structure

Our first result is a constant-query tester for k–submodularity in ℓ_p distance. Here and throughout this section, constant means independent of the ambient dimension n.

▶ **Theorem 1.** *For all $p \geq 1$, there exists an adaptive, one-sided error ℓ_p-tester for k-submodularity making $q = \left(\frac{p}{\varepsilon}\right)^2 \cdot 2^{\left(\frac{p}{\varepsilon}\right)^2 \log\left(\frac{p}{\varepsilon}\right)}$ queries.*

The main structural input is not a black-box reduction to the submodular case. We prove that every bounded k–submodular function is close to a function depending on only a small number of coordinates, even though each coordinate can move in k competing directions. This requires choosing influential coordinates in a way that respects all parts of a partial partition, and uses the fact that k–submodular functions satisfy a self-bounding variance inequality.

▶ **Theorem 2.** *Let $f : [k+1]^J \to [0,1]$ be a k–submodular function and $\varepsilon > 0$ be a small enough constant. Then there exists a k–submodular function $h : [k+1]^J \to [0,1]$ that depends only on $J' \subseteq J$ dimensions, where*

$$|J'| = O\left(\frac{1}{\varepsilon^2} \cdot \log \frac{1}{\varepsilon}\right),$$

and the function h satisfies

$$\|f - h\|_2 \leq \varepsilon.$$

We then develop the testing component needed to turn this structure into an algorithm. The implicit-learning framework of Blais and Bommireddi [1] relies on identifying influential coordinates and checking consistency with a small junta. We formulate and analyze this framework on hypergrid domains using Fourier analysis over generalized product spaces, and simplify parts of the original argument by separating the learning and final testing samples.

▶ **Theorem 3.** *Let $p \geq 1$. Suppose $\mathcal{P} \subseteq \{f : [k+1]^n \to [0,1]\}$ is a property of functions such that for any $f \in \mathcal{P}$ there exists a κ-junta $h : [k+1]^n \to [0,1]$ satisfying $||f - h||_2 \leq \varepsilon$. Then, there exists a tester that, given query access to an unknown function f, will make $\varepsilon^{-9} \cdot 2^{O(\kappa \log \kappa)}$ queries to f and with probability at least $2/3$ accept if $f \in \mathcal{P}$ and reject if f is ε-far from $\mathcal{P}$ in the ℓ_2 norm.*

Local testing in Hamming distance

Our second set of results addresses the Hamming-distance regime, where the Seshadhri–Vondrák local-repair paradigm for ordinary submodularity does not extend directly. Pairwise monotonicity is vacuous when $k = 1$, but on the hypergrid its violations form a new witness shape – *triangles* – incomparable with the *squares* that witness diminishing-marginal-gain failures. Repair likewise shifts from Boolean subcubes to filters and ideals of partial partitions, and the density arguments must be re-proved in this setting. We obtain non-adaptive, one-sided testers for the two component properties of k–submodularity:

▶ **Theorem 4.** *Let $f : [k+1]^n \to \mathbb{R}$ be given via oracle access. There exist non-adaptive, one-sided error testers for the diminishing marginal gains and pairwise monotonicity properties with the following guarantees:*

- *If f satisfies the property, the tester accepts with probability 1.*
- *If f is ε-far from the property (i.e., at least $\varepsilon \cdot [k+1]^n$ values must be modified to satisfy it), the tester rejects with probability at least $2/3$.*

The tester for diminishing marginal gains makes $q = 4n^2 \cdot (1/\varepsilon)^{\Theta(\sqrt{n \log n})}$ *queries; the tester for pairwise monotonicity makes* $q = 3kn \cdot (1/\varepsilon)^{\Theta(\sqrt{n \log n})}$ *queries.*

Notably, only the pairwise-monotonicity tester has query complexity depending on k, despite k governing the structure of the domain.

Combined, these results expose a structural difference between k–submodularity and ordinary submodularity that the analytic (ℓ_p) regime does not see. In Section 4.3 we exhibit an explicit configuration (Figure 1) on a high item-weight filter in which repairing a triangle violation forces value changes in the *opposite* direction from those needed to repair an overlapping square violation, on a shared vertex. The two repair directions are not merely incompatible at one point – they are jointly inconsistent across an entire region. We record this as Observation 32: it rules out the natural component-wise extension of local repair to full k–submodularity, and isolates a concrete barrier that any sub-exponential local-witness tester must overcome by enlarging the witness vocabulary beyond squares and triangles.

Bounded range and monotone k–submodularity

Finally, we show that efficient Hamming-distance testing can be recovered for monotone k–submodular functions with bounded range. The result is again obtained through learning, but the relevant representation is no longer a junta. Instead, we utilize pseudo-DNF representations for functions on the hypergrid and prove that bounded-range monotone k–submodular functions have bounded-width pseudo-DNFs.

▶ **Theorem 5.** *Let* $\varepsilon, \delta \in (0,1)$ *be constants. There exists a tester* $\mathcal{T}$ *which, given query access to a function* $f : [k+1]^n \to \{0, 1, \cdots, r\}$ *satisfies the following.*

1. *If* f *is monotone* k*–submodular, then* $\mathcal{T}$ **accepts** *with probability* $\geq 1 - \delta$.
2. *If* f *is* ε*-far from monotone* k*–submodularity, then* $\mathcal{T}$ **rejects** *with probability* $\geq 1 - \delta$.
3. $\mathcal{T}$ *makes at most* $\mathsf{poly}(n, 1/\varepsilon, 1/\delta, (kr)^{O(rk^2 \log(r/\varepsilon))})$ *queries.*

The learning result for bounded-width pseudo-DNFs uses a hypergrid version of the switching-lemma/Fourier-sparsity route and yields a tester via the Kushilevitz-Mansour algorithm. We expect this learner to be useful beyond k–submodularity.

1.2 Prior Work

Testing whether a given function is submodular was first examined by Parnas, Ron and Rubinfeld [13], who studied the limited setting of testing for a class of matrices called *Monge matrices*. In its full generality, the problem was considered by Seshadhri and Vondrák [16]. They developed the local-witness and repair framework for Hamming-distance testing on the Boolean hypercube, proving an upper bound of $(1/\varepsilon)^{O(\sqrt{n \log n})}$ and a linear lower bound. The latter was later improved to $\Omega(n^2/\log n)$ by Hatami and Vondrák [10]. Blais and Bommireddi [1] subsequently studied the problem in the ℓ_p norm, and using an approximation result from [6], designed an implicit-learning tester with constant query complexity in the input length. Raskhodnikova and Yaroslavtsev [15] studied bounded-range submodular functions through a learning-based approach and proved a polynomial-time upper bound in this regime. Chakrabarty and Huang [3] studied the problem of testing for coverage functions, which are a special type of submodular function.

Our work is informed most directly by the three submodularity-testing frameworks of Seshadhri and Vondrák [16], Blais and Bommireddi [1], and Raskhodnikova and Yaroslavtsev [15]. These works provide the conceptual starting points for the three regimes we study.

The passage to k–submodularity introduces new difficulties in each case: local witnesses split into squares and triangles in the Hamming regime, influential coordinates must account for competing assignments in the ℓ_p regime, and bounded-range learning requires representations over the hypergrid rather than the Boolean cube.

To our knowledge, there is no prior work on testing k-submodularity, though the property has been studied extensively from the optimization perspective [12, 4]. We also use the structural characterization of Ward and Živný [17], which identifies k–submodularity with the conjunction of diminishing marginal gains and pairwise monotonicity.

1.3 Technical Overview

The main technical theme is that the hypergrid introduces several inequivalent notions of locality. In the ℓ_p regime, locality is analytic and is captured by influential coordinates. In the Hamming regime, locality is combinatorial and is captured by small violated configurations. For bounded-range functions, locality appears through compact symbolic representations. In each part of the paper we develop the corresponding notion of locality for partial partitions.

The analytic regime: finding the right influential coordinates

The ℓ_p tester has two ingredients: a junta-approximation theorem for k–submodular functions, and a tester for properties that are close to juntas on the hypergrid. The obstacle in the first ingredient is that a coordinate has k possible nonzero directions. Several natural ways of declaring a coordinate influential in one part at a time almost work, but fail to interact correctly with the boosting lemma for down-monotone families (Lemma 12).

Our solution is to define the relevant influence threshold by looking across all partitions of the remaining coordinates. This lets the selection rule remain compatible with the combinatorial boosting argument while still respecting the multi-directional nature of the domain. The second key input is a variance bound: we prove that k–submodular functions are 2-self bounding (Lemma 14). Together, these ingredients yield a junta depending on only $O(\varepsilon^{-2}\log(1/\varepsilon))$ coordinates.

Once the junta structure is established, the testing step is conceptually separate. We analyze implicit learning directly on $[k+1]^n$ using Fourier analysis over product domains. The tester identifies a candidate set of influential coordinates and then checks whether the observed behavior is consistent with a junta from the target property. Using an independent sample in the final testing stage also simplifies the decorrelation issues that arise in the original Boolean-domain analysis of [1].

The Hamming regime: local witnesses and repair

In Hamming distance, a tester needs many local witnesses whenever the function is far from the property. For ordinary submodularity, the relevant witness is a violated square in the Boolean hypercube, and the analysis of Seshadhri and Vondrák [16] shows that few violated squares imply a global repair.

For k–submodularity, a single witness shape is no longer sufficient. Using the characterization of Ward and Živný [17], we separate the property into diminishing marginal gains and pairwise monotonicity. Diminishing marginal gains is witnessed by generalized violated squares, while pairwise monotonicity is witnessed by violated triangles. We prove density statements for both witnesses by designing repair procedures on large inclusion-closed regions of the hypergrid: ideals $\{Y \preceq X\}$ and filters $\{Y \succeq X\}$. This gives sub-exponential testers for the two component properties.

The same repair viewpoint also yields a structural observation about the full Hamming-distance problem (Observation 32, illustrated in Figure 1). On high item-weight filters, the repair direction needed for a violated square is forced into conflict with the repair direction needed for an overlapping violated triangle on a shared vertex. This is not a limitation of our proof – it is a structural property of the problem: any tester built on the squares-and-triangles vocabulary, no matter how the repair is organized, must encounter a configuration of this kind. A sub-exponential tester for full k–submodularity in Hamming distance therefore requires an enriched witness vocabulary, not merely a more clever combination of square and triangle repairs.

The bounded-range regime: representation before testing

For bounded-range monotone k–submodular functions, we take a representation-theoretic route. We first show that such functions admit bounded-width pseudo-DNF representations over the hypergrid. This representation captures the monotone threshold-like structure imposed jointly by bounded range and diminishing marginal gains.

We then prove a hypergrid switching lemma for pseudo-DNFs, using low-depth k-ary decision trees in place of binary trees. Combined with Fourier analysis on the hypergrid, this implies sparse Fourier approximation for bounded-width pseudo-DNFs. The resulting learner, together with the Kushilevitz-Mansour algorithm [11], yields the bounded-range tester.

1.4 Discussion and Open Problems

Our results leave several natural questions open. The most immediate is whether full k–submodularity can be tested in Hamming distance with sub-exponential query complexity. Our component testers for diminishing marginal gains and pairwise monotonicity show that each constraint has many local witnesses when violated, but the repair procedures for the two constraints can be forced to conflict. Resolving this – either by exhibiting a richer witness family with a compatible repair procedure, or by proving a sub-exponential lower bound that confirms the barrier is fundamental – is, in our view, the right next step in this regime.

A second direction is to understand the bounded-range setting without monotonicity. Our tester in this regime relies on a pseudo-DNF representation for monotone k–submodular functions, and it is unclear whether a comparable representation exists for non-monotone functions.

Finally, it would be interesting to prove lower bounds for testing k–submodularity. The known lower bounds for submodularity do not transfer directly, since natural embeddings can destroy pairwise monotonicity. Thus even formulating the right hard instances appears to require using the genuinely multi-part structure of the domain.

1.5 Organization

The paper is organized as follows. In Section 2, we formally define the problem and related structures on the hypergrid. In Section 3, we prove the junta approximability theorem for k–submodular functions. In Section 4, we develop Hamming-distance testers for *diminishing marginal gains* and *pairwise monotonicity*, and analyze the obstruction to combining their repairs into a local-repair tester for full k–submodularity. We refer to the full version of the paper [9] for the analysis of the hypergrid implicit-learning theorem and construction of our ℓ_0 tester for monotone k–submodularity in the bounded range regime.

2 Preliminaries

▶ **Definition 6** (Partial partition). *A* partial partition *of* $[n]$ *into* k *subsets is defined* $X = (X_1, ..., X_k)$*, where each* $X_i \subseteq [n]$ *and* $X_i \cap X_j = \emptyset$ *for all* $i \neq j \in [k]$*. We let* $X_{k+1} = [n] \setminus \cup_{i=1}^{k} X_i$*, and this allows us to associate* partial partitions *of* $[n]$ *into* k *subsets with the hypergrid* $[k+1]^n$ *(each element of* $[n]$ *is associated to a bucket in* $[k+1]$*, yielding a vector in* $[k+1]^n$*). If* $e \notin X_{k+1}$*, we say that* $e \in X$*. We impose a* partial order *on* partial partitions *by defining* $X \preceq Y$ *if and only if* $X_i \subseteq Y_i$ *for all* $i \in [k]$*. We let* $|X|$ *denote the* item-weight *of a partial partition, which is the total number of items picked. Numerically, this is equal to* $\sum_{i=1}^{k} |X_i|$*.*

▶ **Definition 7** (Marginal gains). *Define the* marginal gains *of a function* f *on a partial partition* X *with respect to an index* $i \in [k]$ *and an element* $e \in X_{k+1}$ *as*

$$\Delta_f(X, i, e) := f(X_1, ..., X_i \cup \{e\}, ..., X_k) - f(X).$$

Letting $X_e^i := (X_1, ..., X_i \cup \{e\}, ..., X_k)$*, we can rewrite this as* $\Delta_f(X, i, e) = f(X_e^i) - f(X)$*.*

▶ **Definition 8** (k–submodularity). *A function* $f : [k+1]^n \to \mathbb{R}$ *is* k–submodular *if, for all partial partitions* X, Y*, the following holds.*

$$f(X) + f(Y) \geq f(X \sqcup Y) + f(X \sqcap Y),$$

where $X \sqcap Y := (X_1 \cap Y_1, \cdots, X_k \cap Y_k)$ *and*

$$X \sqcup Y = \left((X_1 \cup Y_1) \setminus \bigcup_{i \neq 1} (X_i \cup Y_i), \cdots, (X_k \cup Y_k) \setminus \bigcup_{i \neq k} (X_i \cup Y_i) \right).$$

The following theorem of Ward and Živnỳ [17] gives us an equivalent definition of k–submodularity, one that is described by two more intuitive properties. The intuition is that every local comparison between two partial partitions can be decomposed into compatible and conflicting moves. Compatible moves are governed by the usual diminishing-returns principle: adding an unassigned element to part i becomes less valuable as the current partial partition grows. Conflicting moves arise only when the same element could be assigned to two different parts. For example, comparing X_e^i and X_e^j gives $X_e^i \sqcap X_e^j = X$ and $X_e^i \sqcup X_e^j = X$, so the k–submodular inequality becomes

$$\Delta_f(X, i, e) + \Delta_f(X, j, e) \geq 0.$$

Thus pairwise monotonicity is the local condition that prevents two competing assignments of the same element from both being too costly.

▶ **Theorem 9** ([17]). *A function* $f : [k+1]^n \to \mathbb{R}$ *is* k–submodular *if and only if the following two conditions hold.*

- ***Diminishing marginal gains.*** *For all partial partitions* X, Y *such that* $X \preceq Y$*,* $e \notin Y$*, and* $i \in [k]$*, the following holds.*

$$\Delta_f(X, i, e) \geq \Delta_f(Y, i, e).$$

- ***Pairwise monotonicity.*** *For all partial partitions* X*,* $e \notin X$*, and* $i \neq j \in [k]$*, the following holds.*

$$\Delta_f(X, i, e) + \Delta_f(X, j, e) \geq 0.$$

3 Junta approximation of k–submodular functions

In the following two sections, we prove the structural and algorithmic ingredients behind our ℓ_p tester for k–submodularity. The structural ingredient is a junta approximation theorem for k–submodular functions on the hypergrid. The main difficulty is choosing influential coordinates in a way that accounts for all k directions of a coordinate while still giving a dimension-independent approximation.

This approximation theorem, combined with an implicit learning tester for properties on hypergrids with a good junta approximation, yields the desired tester.

We prove the following approximation theorem.

▶ **Theorem 10** (Reminder of Theorem 2). *Let $f : [k+1]^J \to [0,1]$ be a k–submodular function and $\varepsilon > 0$ be a small enough constant. Then there exists a k–submodular function $h : [k+1]^J \to [0,1]$ that depends only on $J' \subseteq J$ dimensions, where*

$$|J'| = O\left(\frac{1}{\varepsilon^2} \cdot \log \frac{1}{\varepsilon}\right),$$

and the functions h satisfies

$$\|f - h\|_2 \leq \varepsilon.$$

Before we get to the proof of Theorem 2, we first set up some necessary machinery.

3.1 Setup

There are three main parts to the setup.

Boosting lemma. We cite the following boosting lemma due Goemans and Vondrák [7].

▶ **Definition 11** (Down-monotone family). *Let X be a finite set and $\mathcal{F} \subseteq 2^X$ be a collection of subsets of X. The family $\mathcal{F}$ is called down-monotone if the following condition holds.*

$$A \in \mathcal{F} \wedge B \subseteq A \implies B \in \mathcal{F}.$$

▶ **Lemma 12** ([7] Boosting lemma). *Let X be a finite set and $\mathcal{F} \subseteq 2^X$ be a down-monotone family. For $p \in (0,1)$, define*

$$\sigma_p := \Pr[X(p) \in \mathcal{F}],$$

where $X(p)$ is a random subset of X such that each element is picked independently with probability p. Then

$$\sigma_p = (1-p)^{\phi(p)},$$

where $\phi(p)$ is a non-decreasing function for $p \in (0,1)$.

Self–bounding functions and concentration. A very useful tool in bounding the variance of submodular functions comes from the literature of concentration for *self–bounding* functions.

▶ **Definition 13** (Self–bounding function). *A function $f : \mathcal{X}^n \to [0,1]$ is **α-self–bounding** if there exist functions $f_i : \mathcal{X}^{n-1} \to [0,1]$ such that for all $x_1, \cdots, x_n \in \mathcal{X}$ and all $i \in [n]$, the following conditions hold.*

1. $0 \leq f(x_1, \cdots, x_n) - f_i(x_1, \cdots, x_{i-1}, x_{i+1}, \cdots, x_n) \leq 1$; *and*
2. $\sum_{i=1}^{n} (f(x_1, ..., x_n) - f_i(x_1, x_2, ..., x_{i-1}, x_{i+1}, ..., x_n)) \leq \alpha f(x_1, ..., x_n)$.

▶ **Lemma 14** ([2] Bounded variance lemma). *If a function $f : \mathcal{X}^n \to [0,1]$ is α-self–bounding then*

$$\mathrm{Var}[f(X)] \leq \alpha \cdot \mathbb{E}[f(X)].$$

Bounded variance of k–submodular functions. Submodular functions that are Lipschitz are self–bounding, which allows us to bound their variance. We show that a similar property holds for k–submodular functions.

▶ **Definition 15** (Lipschitz function). *A function $f : [k+1]^n \to [0,1]$ is α-Lipschitz if $|\Delta_f(X,j,i)| \leq \alpha$ for all $i \in [n]$ and $j \in [k]$.*

▶ **Lemma 16.** *Let $f : [k+1]^n \to [0,1]$ be 1–Lipschitz and k–submodular. Then:*

$$\mathrm{Var}[f] \leq 2 \cdot \mathbb{E}[f].$$

Proof. We prove this by showing that f is 2-self–bounding, and invoking Lemma 14. For $i \in [n]$, define the function f_i as

$$f_i(x_1, \cdots, x_{i-1}, x_{i+1}, \cdots x_n) := \min_{j \in [k+1]} \{f(x_1, \cdots, x_{i-1}, j, x_{i+1}, x_n)\}.$$

Then the first condition

$$0 \leq f(x_1, ..., x_n) - f_i(x_1, ..., x_{i-1}, x_{i+1}, ..., x_n) \leq 1$$

holds trivially (by choice of minimum value and the range of f being $[0,1]$). By pairwise monotonicity of f, the following holds.

$$\begin{aligned} &f(x_1, ..., x_n) - f_i(x_1, ..., x_{i-1}, x_{i+1}, ..., x_n) \\ &\qquad \leq 2 \cdot \left(f(x_1, ..., x_n) - f(x_1, ..., x_{i-1}, k+1, x_{i+1}, ..., x_n)\right). \end{aligned}$$

Here, $x_i = k+1$ corresponds to item i not being put into any bucket. Finally, the following holds for all $i \in [n]$ due to the marginal gains property.

$$\begin{aligned} &f(x_1, ..., x_n) - f(x_1, ..., x_{i-1}, k+1, x_{i+1}, ..., x_n) \\ &\leq f(x_1, \cdots, x_i, k+1, \cdots, k+1) - f(x_1, \cdots, x_{i-1}, k+1, \cdots, k+1). \end{aligned}$$

This yields the desired condition.

$$\begin{aligned} &\sum_{i=1}^{n} (f(x_1, \cdots, x_n) - f_i(x_1, \cdots, x_{i-1}, x_{i+1}, \cdots, x_n)) \\ &\qquad \leq \sum_{i=1}^{n} 2 \cdot ((f(x_1, \cdots, x_n) - f(x_1, \cdots, x_{i-1}, k+1, x_{i+1}, \cdots, x_n)) \\ &\qquad \leq \sum_{i=1}^{n} 2 \cdot (f(x_1, \cdots, x_i, k+1, \cdots) - f(x_1, \cdots, x_{i-1}, k+1, \cdots)) \\ &\qquad \leq 2 \cdot f(x_1, \cdots, x_n). \end{aligned}$$

We have thus shown that f is 2-self–bounding, and by Lemma 16, $\mathrm{Var}[f] \leq 2 \cdot \mathbb{E}[f]$. ◀

3.2 Weak junta approximation

We first prove the following "weak" junta approximation for k–submodular functions.

▶ **Theorem 17** (Weak junta approximation). *Let $f : [k+1]^J \to [0,1]$ be a k–submodular function and $\varepsilon \in (0,1)$ be a constant. Then there exists a k–submodular function $h : [k+1]^J \to [0,1]$ that depends only on $J' \subseteq J$ dimensions, where*

$$|J'| \leq \frac{32}{\varepsilon^2} \cdot \log \frac{8|J|}{\varepsilon^2},$$

and the function h satisfies

$$\|f - h\|_2 := \left(\mathbb{E}_{x \in [k+1]^J} \left[(f(x) - h(x))^2\right]\right)^{\frac{1}{2}} \leq \frac{1}{2} \cdot \varepsilon.$$

We prove Theorem 17 by first describing a procedure to construct the set J' and then showing that there exists a J'-junta satisfying the desired properties.

Let $S \subseteq J$ and $P : J \to [k+1]^n$ be some partition function over J. We denote by S_P the point on the hypergrid obtained by placing each $i \in S$ into bucket $P(i)$. We denote by $S(\delta)_P$ a random set generated by sampling each element in S independently with probability δ.

Algorithm 1 Identifying the junta set J'.

Input: Oracle access to k–submodular function $f : [k+1]^J \to [0,1]$; parameters $\alpha, \delta > 0$

$S \leftarrow \emptyset$.

while there exists $i \notin S$ such that for all partitions P of J we have $\Pr\left[\Delta_f(S(\delta)_P, P(i), i) > \alpha\right] > \frac{1}{2}$ **do**

    $S \leftarrow S \cup \{i\}$

return $J' = S$.

First we show that the number of indices picked by Algorithm 1 is small.

▷ Claim 18. The set J' output by Algorithm 1 satisfies $|J'| \leq \frac{2}{\alpha\delta}$.

Proof. Let P be an arbitrary partition of J, and X be an arbitrary subset of J. For any $i \in X$, let $X_{<i}$ denote the set of items in X that were added to S before i in Algorithm 1. Define

$$X_P^+ := \{i \in X \mid \Delta_f(X_{<i,P}, P(i), i) > \alpha\}.$$

Then by *diminishing marginal gains*, at the end of the execution of Algorithm 1, we have

$$\begin{aligned}\mathbb{E}[f(S(\delta)_P^+)] &= f(\emptyset) + \sum_{i \in S(\delta)_P^+} \Delta_f(S(\delta)_{<i,P}^+, P(i), i) \\ &> \mathbb{E}[|S(\delta)_P^+|] \cdot \alpha. && \text{[Assuming } f(\emptyset) = 0 \text{ WLOG]}\end{aligned}$$

Next, we show that $\mathbb{E}[|S(\delta)_P^+|] \geq \frac{\delta \cdot |S|}{2}$. If that is true, then

$$1 \geq \mathbb{E}[f(S(\delta)_P^+)] > \frac{\delta \cdot |S| \cdot \alpha}{2} \implies |S| \leq \frac{2}{\delta\alpha}.$$

To prove our claim, we observe that by construction, for all $u \in S$,

$$\Pr[u \in S(\delta)_P^+] = \Pr[u \in S(\delta)] \cdot \Pr[\Delta_f(S(\delta)_{<u,P}, P(u), u) > \alpha] > \frac{\delta}{2}.$$

Writing $|S(\delta)_P^+| = \sum_{u \in S} X_u$, where X_u is the indicator for whether $u \in S(\delta)_P^+$, we get

$$\mathbb{E}[|S(\delta)_P^+|] = \sum_{u \in S} \Pr[X_u] \geq \frac{\delta \cdot |S|}{2}.$$ ◁

Next, we show that for all partitions P and any "unimportant" coordinate $i \in J \setminus J'$, the probability of the marginal gains on top of J' being large with respect to P when adding i to $P(i)$ is very small if we sample elements from J' with probability $\frac{k}{k+1}$ rather than δ.

▷ Claim 19. For all $i \in J \setminus J'$, all $j \in [k]$, and all partitions $P : J' \to [k]$, the following holds.

$$\Pr_{J'(\frac{k}{k+1})}\left[\Delta_f\left(J'\left(\frac{k}{k+1}\right)_P, j, i\right) > \alpha\right] \leq \left(\frac{1}{k+1}\right)^{\frac{1}{2\delta}}.$$

Proof. Consider the following family of points

$$\mathcal{F} = \{X \in [k+1]^n \mid X \preceq J'_P \text{ and } \Delta_f(X, j, i) > \alpha\}$$

This is a down-monotone set – if $Y \preceq X \in \mathcal{F}$ then $Y \in \mathcal{F}$. This is due to *diminishing marginal gains* – $\Delta_f(Y, j, i) \geq \Delta(X, j, i)$. If we let $\sigma_p := \Pr[J'(p)_P \in \mathcal{F}]$ for $p \in (0, 1)$, then by Lemma 12,

$$\sigma_p = (1-p)^{\phi(p)},$$

for some non-decreasing function ϕ. The termination condition of Algorithm 1 guarantees that

$$\sigma_\delta := \Pr[J'(\delta)_P \in \mathcal{F}] = (1-\delta)^{\phi(\delta)} \leq \frac{1}{2},$$

which implies $\phi(\delta) \geq \frac{1}{2\delta}$ for $\delta \leq \frac{1}{2}$. Since ϕ is non-decreasing, we have

$$\phi\left(\frac{k}{k+1}\right) \geq \phi(\delta) \geq \frac{1}{2\delta} \implies$$
$$\sigma_{\frac{k}{k+1}} = \left(1 - \frac{k}{k+1}\right)^{\phi\left(\frac{k}{k+1}\right)} \leq \left(\frac{1}{k+1}\right)^{1/2\delta}. \qquad \triangleleft$$

We now define our junta function. Let $\bar{J} := J \setminus J'$. Define $h : [k+1]^n \to [0, 1]$ as

$$h(X) := \mathop{\mathbb{E}}_{Y \in [k+1]^{\bar{J}}}[f(X_{J'}, Y)], \tag{1}$$

where $x_{J'}$ is the point in the hypergrid where the coordinates in J' are assigned as they were in J and the coordinates in $\bar{J}$ are non-assigned.

First, we show that h is k–submodular.

▷ Claim 20. The function h defined in Equation (1) is k–submodular.

Proof. We have to show that h satisfies the two following conditions.

1. *Diminishing marginal gains.* Let $X, Z \in [k+1]^n$ with $Z \preceq X$ and $e \notin X$. Let $j \in [k]$. Then, we have

$$\Delta_h(Z, j, e) = h(Z^i_e) - h(Z) = \begin{cases} 0, & \text{if } j \notin J' \\ \mathop{\mathbb{E}}_{Y \in [k+1]^{\bar{J}}}[f((Z^i_e)_{J'}, Y) - f(Z_{J'}, Y)], & \text{otherwise} \end{cases}.$$

If $j \notin J'$, then $\Delta_h(X, j, e) = 0$ as well, so the diminishing marginal gains condition holds. Otherwise, by the k–submodularity of f, we know that for all $y \in [k+1]^{\bar{J}}$,

$$f((Z^i_e)_{J'}, Y) - f(Z_{J'}, Y) \geq f((X^i_e)_{J'}, Y) - f(X_{J'}, Y)$$

which allows us to conclude that $\Delta_h(Z, j, e) \geq \Delta_h(X, j, e)$, and thus that h satisfies diminishing marginal gains.

2. *Pairwise Monotonicity.* Let $X \in [k+1]^n$, $i \neq j \in [k]$ and $e \in X_{k+1}$. If $e \notin J$, then $\frac{1}{2}\left(h(X^i_e) + h(X^j_e)\right) = h(X)$. Otherwise, by the pairwise monotonicity of f,

$$\frac{1}{2}\left(h(X^i_e) + h(X^j_e)\right) = \mathop{\mathbb{E}}_{Y\in[k+1]^{\bar{J}}} \frac{1}{2}[f((X^i_e)_{J'}, Y) - f((X^j_e)_{J'}, Y)] \geq \mathop{\mathbb{E}}_{Y\in[k+1]^{\bar{J}}} [f(X_{J'}, Y)] = h(X).$$

We can thus conclude by Theorem 9 that h is k–submodular. ◁

Our final step is to show that h is a good approximation to f in the ℓ_2-norm.

▶ **Definition 21** (Bad points). *A point $X_{J'}$ in the restricted hypergrid is called* bad *if there exists $i \in \bar{J}$ and $j \in [k]$ such that*

$$\Delta_f(X_{J'}, j, i) > \alpha,$$

or there exists $i \in X_{J'}$

$$\Delta_f(X_{J'} \setminus i, X_{J'}(i), i) < -\alpha.$$

The ℓ_2 distance can be bounded as below.

$$\begin{aligned}
\|h - f\|_2^2 &= \mathop{\mathbb{E}}_{X\in[k+1]^J}[(f(X) - h(X))^2] \\
&= \mathop{\mathbb{E}}_{X_{J'}\in[k+1]^{J'}}\left[\mathop{\mathbb{E}}_{Y\in[k+1]^{\bar{J}}}\left[(f(X_{J'}, Y) - \mathop{\mathbb{E}}_{Y'\in[k+1]^{\bar{J}}}[f(X_{J'}, Y')])^2\right]\right] \\
&= \mathop{\mathbb{E}}_{X_{J'}\in[k+1]^{J'}}\left[\mathop{\mathrm{Var}}_{Y\in[k+1]^{\bar{J}}}[f(X_{J'}, Y)]\right] \\
&\leq \Pr[X_{J'} \text{ is } \textit{bad}] + \mathop{\mathbb{E}}_{X_{J'}\in[k+1]^{J'} \text{ good}}\left[\mathop{\mathrm{Var}}_{Y\in[k+1]^{\bar{J}}}[f(X_{J'}, Y)]\right]. \qquad \text{[Because } f(X) \leq 1\text{]}
\end{aligned}$$

We first show that for appropriate parameters to Algorithm 1, the probability that a point is bad is small.

▷ Claim 22. If we set $\delta = \dfrac{\log(k+1)}{2\log(8 \cdot k \cdot |J| \cdot \varepsilon^{-2})}$ in Algorithm 1, then

$$\Pr_{X_{J'}\in[k+1]^{J'}}[X_{J'} \text{ is } \textit{bad}] \leq \frac{\varepsilon^2}{8}.$$

Proof. Recall that we consider a uniform distribution over $X_{J'} \in [k+1]^{J'}$. This distribution is the same as sampling a partition $P : J' \to [k]$ uniformly at random and returning $J'\left(\frac{k}{k+1}\right)_P$. To see this, fix an arbitrary point $X \in [k+1]^{J'}$. Let $A := \{i \in J' : x_i = k+1\}$ and $B = J' \setminus A$. The probability of generating this particular X with the latter sampling procedure is

$$\Pr[X] = \left(\frac{1}{k+1}\right)^{|A|} \cdot \left(\frac{k}{k+1}\right)^{|B|} \cdot \left(\frac{1}{k}\right)^{|B|} = \frac{1}{(k+1)^{|J'|}}$$

So, via a union bound, Claim 19 and by plugging in $\delta = \frac{\log(k+1)}{2\log(8\cdot k\cdot |J|\cdot \varepsilon^{-2})}$, we get that

$$\begin{aligned}\Pr[X_{J'} \text{ is } bad] &= \Pr_{J'\left(\frac{k}{k+1}\right),P:J'\to[k]}\left[\bigcup_{j\in[k]}\bigcup_{i\in\bar{J}}\left(\Delta_f\left(J'\left(\frac{k}{k+1}\right)_P, j, i\right) > \alpha\right)\right] \\ &\leq |\bar{J}|\cdot k\cdot\left(\frac{1}{k+1}\right)^{1/2\delta} \\ &\leq \frac{\varepsilon^2}{8}.\end{aligned}$$

◁

Finally, we show that for appropriate parameters to Algorithm 1, the variance of $f(X_{J'},\cdot)$ when $X_{J'}$ is good is small.

▷ Claim 23. If we set $\alpha = \frac{\varepsilon^2}{16}$ in Algorithm 1, then

$$\mathop{\mathbb{E}}_{X_{J'}\in[k+1]^{J'}\text{ good}} \mathrm{Var}\left[f(X_{J'},\cdot)\right] \leq \frac{\varepsilon^2}{8}.$$

Proof. When $X_{J'}$ is good, we have that the marginal gain $\Delta_f(X_{J'}, j, i)$ of adding any $i \in \bar{J}$ to any bucket $j \in [k]$ is at most α. Because of *diminishing marginal gains*, this bounds the marginal gains of $f(X_{J'},\cdot)$ over its entire domain by α. Also, the marginal gains of $f(X_{J'},\cdot)$ are at least $-\alpha$, because if there existed some $Y \geq X_{J'}$, $i \in \bar{J}$ and $j \in [k]$ with $\Delta_f(Y, j, i) < -\alpha$, then by *pairwise monotonicity* we must have for all $j' \neq j$ that $\Delta_f(Y, j', i) \geq \alpha$ as

$$\Delta_f(Y, j, i) + \Delta_f(Y, j', i) \geq 0.$$

But this contradicts the upper bound of α to the marginal gains. Thus, $f(X_{J'},\cdot)$ is α–Lipschitz and we can appeal to Lemma 14 to get

$$\mathrm{Var}[f(x_{J'},\cdot)] \leq 2\alpha\cdot\mathbb{E}[f(x_{J'},\cdot)] \leq \frac{\varepsilon^2}{8}.$$

◁

We are now ready to finish the proof of Theorem 17.

Proof of Theorem 17. We let J' by the output of Algorithm 1 with input f and parameters

$$\delta = \frac{\log(k+1)}{2\log(8\cdot k\cdot |J|\cdot\varepsilon^{-2})}, \qquad \alpha = \frac{\varepsilon^2}{16}.$$

Then the function h defined by Equation (1) is the desired junta function. Indeed, combining (22) and (23), we get

$$\|h - f\|_2^2 \leq \frac{\varepsilon^2}{8} + \frac{\varepsilon^2}{8} = \frac{\varepsilon^2}{4}.$$

To bound the size of J', we use Claim 18 to get

$$|J'| \leq \frac{2}{\alpha\delta} = 32\cdot\frac{1}{\log(1+k)}\cdot\frac{1}{\varepsilon^2}\cdot\log\frac{8\cdot k\cdot|J|}{\varepsilon^2} \leq \frac{32}{\varepsilon^2}\cdot\log\frac{8|J|}{\varepsilon^2}.$$

◀

Using the weak junta approximation, we are able arrive at our final junta approximation.

3.3 Proof of Theorem 2

Let $f : [k+1]^n \to [0,1]$ be a k–submodular function. We will prove a bound of $|J| \leq \frac{4000}{\varepsilon^2} \log \frac{1}{\varepsilon^2}$ for the size of the approximating junta.

Observe that this bound holds trivially for $\varepsilon < n^{-1/2}$, because then we are allowed to choose $J = [n]$. For contradiction, suppose that there is $\varepsilon \in (n^{-1/2}, 1/2)$ for which the statement of Theorem 2 does not hold. Let $\mathcal{E} \subset (n^{-1/2}, 1/2)$ be the set of all ε for which the statement does not hold, and pick an $\varepsilon \in \mathcal{E}$ such that $\varepsilon < 2 \inf \mathcal{E}$. Then, the statement still holds for $\varepsilon_2 = \varepsilon^2 < \frac{1}{2}\varepsilon$.

By the statement of Theorem 2 for ε_2, there is a subset of variables J' of size $|J'| \leq \frac{4000}{\varepsilon^2} \log \frac{1}{\varepsilon} \leq \frac{2^{13}}{\varepsilon^2}$ and a k–submodular function g depending only on J, such that $\|f - g\|_2 \leq \varepsilon_2 \leq \frac{1}{2}\varepsilon$.

Now we apply Theorem 17 to g with parameter ε. Thus, there exists a k–submodular function h such that $\|g - h\|_2 \leq \frac{1}{2}\varepsilon$, and h depends only on a subset of variables $J'' \subseteq J'$, $|J''| \leq \frac{32}{\varepsilon^2} \log \frac{8|J'|}{\varepsilon}$. We have $|J'| \leq \frac{2^{13}}{\varepsilon^2}$, and therefore $|J''| \leq \frac{32}{\varepsilon^2} \log \frac{2^{16}}{\varepsilon^3} \leq \frac{32}{\varepsilon^2} \log \frac{1}{\varepsilon^3}$ (using $\varepsilon \leq \frac{1}{2}$). We conclude that $|J''| \leq \frac{32}{\varepsilon^2} \log \frac{1}{\varepsilon^3} \leq \frac{4000}{\varepsilon^2} \log \frac{1}{\varepsilon}$ as required in Theorem 2. By the triangle inequality, we have $\|f - h\|_2 \leq \|f - g\|_2 + \|g - h\|_2 \leq \frac{1}{2}\varepsilon + \frac{1}{2}\varepsilon = \varepsilon$.

However, this would mean that the statement of Theorem 2 holds for ε as well, which is a contradiction. ◀

4 Towards testing k–submodularity in the ℓ_0-norm

In this section, we develop the local-witness theory for the two constraints that characterize k–submodularity in Hamming distance. For diminishing marginal gains, the witnesses are generalized violated squares. For pairwise monotonicity, the witnesses are violated triangles. We prove that if either constraint is far from being satisfied, then the corresponding witnesses are dense enough to be found by a non-adaptive one-sided tester. The key step in both cases is a repair argument over ideals and filters in the hypergrid.

4.1 Setup

An inductive argument shows that absence of violating squares is equivalent to the diminishing marginal gains property:

▶ **Proposition 24.** *A function $f : [k+1]^n \to \mathbb{R}$ satisfies the diminishing marginal gains property if and only if it has no violating squares.*

Proof. If a function satisfies the diminishing marginal gains property, then it is easy to see that it has no violating squares: take $Y = X_g^j$. We show the converse by considering $X \preceq Y$, $e \notin Y$ and $i \in [k]$. Suppose $e_1, ..., e_\ell$ are the elements of Y not in $X \sqcap Y$ that have $Y(e) \neq k+1$. Then we have that:

$$f(X_e^i) - f(X) \geq f(X_{e,e_1}^{i,Y(e_1)}) - f(X_{e_1}^{Y(e_1)})$$

By induction we can telescopically build the partial partition Y on the right hand side and recover the diminishing marginal gains property. ◀

▶ **Definition 25** (Violating triangle). *Let $X \in [k+1]^n$, $i \neq j \in [k]$, and $e \in X_{k+1}$. We call $\{x, X_e^i, X_e^j\}$ a* triangle. *For a function $f : [k+1]^n \to \mathbb{R}$, this is called an f–*violating triangle *if*

$$\frac{f(X_e^i) + f(X_e^j)}{2} < f(X),$$

that is, it violates the pairwise monotonicity condition.

4.2 Testing diminishing marginal gains

Algorithm 2 A tester for diminishing marginal gains.

Input: Parameters k, n, a query oracle for function $f : [k+1]^n \to \mathbb{R}$, and an error parameter $\varepsilon > 0$.
for $n^2 \cdot (1/\varepsilon)^{\Theta(\sqrt{n \log n})}$ iterations **do**
  sample the following uniformly at random.
    A point $X \in [k+1]^n$ from the hypercube,
    two (possibly same) indices $i, j \in [k]$, and
    two elements $e \neq g \in X_{k+1}$.
  if $\{X, X^i_e, X^j_g, X^{(i,j)}_{(e,g)}\}$ is an f–violating square **then**
    reject.
accept.

We prove the following theorem.

▶ **Theorem 26.** *Algorithm 2 has the following properties.*

1. *If f has* diminishing marginal gains*, then Algorithm 2* **accepts** *with probability* 1.
2. *If f is ε-far from* diminishing marginal gains*, then Algorithm 2* **rejects** *with probability at least* 2/3.
3. *Algorithm 2 makes $q = 4n^2 \cdot (1/\varepsilon)^{\Theta(\sqrt{n \log n})}$ queries.*

Items 1 and 3 are easy to verify – they are direct consequences of Theorem 9 and the description of Algorithm 2, respectively. The rest of this section will be dedicated to proving Item 2.

Intuitively, our proof proceeds as follows. We first show that if a function f has a "low density" of violating squares, then it can be made to have the *diminishing marginal gains* property by changing the values of only a "few" points. By contrapositive, this means that a function that is "far" from *diminishing marginal gains* must have a "high density" of witnesses, which implies the correctness of our tester. To "repair" a function f towards *diminishing marginal gains*, we modify its values over a union of *ideals* and *filters*, defined as follows.

▶ **Definition 27** (Ideal). *Let $X \in [k+1]^n$. The* Ideal *of X is defined as*

$$I(X) := \{Y \mid Y \preceq X\}.$$

▶ **Definition 28** (Filter). *Let $X \in [k+1]^n$. The* Filter *of X is defined as*

$$F(X) := \{Y \mid X \preceq Y\}.$$

We start with the following "repair" lemma for violating squares.

▶ **Lemma 29** (Square repair lemma). *Let $f : [k+1]^n \to \mathbb{R}$ be a function in which $\{X, X^i_e, X^j_g, X^{(i,j)}_{(e,g)}\}$ is an f–violating square. There is a way to change only the values of the ideal $I(X)$ or the filter $F(X^{(i,j)}_{(e,g)})$ to obtain a function f' in which $\{X, X^i_e, X^j_g, X^{(i,j)}_{(e,g)}\}$ is no longer an f'–violating square, and no additional f'–violating squares have been introduced.*

Proof. Because $\{X, X_e^i, X_g^j, X_{(e,g)}^{(i,j)}\}$ is an f–violating square, we have

$$\Delta_X := f(X) + f(X_{(e,g)}^{(i,j)}) - f(X_e^i) - f(X_g^j) > 0.$$

Fix any constant $\Delta \geq \Delta_X$. We obtain f' by subtracting Δ from $f(Y)$ for all $Y \in I(X)$. Clearly, this repairs the f–violating square itself, but we must also argue that it does not introduce any new f'–violating squares.

Let $\{Y, Y_{e'}^{i'}, Y_{g'}^{j'}, Y_{(e',g')}^{(i',j')}\}$ be an f'–violating square that is not f–violating. If $Y \not\preceq X$, then none of the values in the square were modified. So we can assume $Y \preceq X$. We consider the following cases.

1. Neither $Y_{e'}^{i'} \not\preceq X$ nor $Y_{g'}^{j'} \not\preceq X$. Then the points $Y_{e'}^{i'}, Y_{g'}^{j'}, Y_{(e',g')}^{(i',j')}$ are not modified. Thus, the value of this square is

$$(f(Y)-\Delta)+f(Y_{(e',g')}^{(i',j')})-f(Y_{g'}^{j'})-f(Y_{e'}^{i'}) = f(Y)+f(Y_{(e',g')}^{(i',j')})-f(Y_{g'}^{j'})-f(Y_{e'}^{i'})-\Delta \leq -\Delta.$$

2. Only $Y_{e'}^{i'} \not\preceq X$ and $Y_{g'}^{j'} \preceq X$. Then the points $Y_{e'}^{i'}, Y_{(e',g')}^{(i',j')}$ are not modified. Thus, the value of this square is

$$(f(Y)-\Delta)+f(Y_{(e',g')}^{(i',j')})-(f(Y_{g'}^{j'})-\Delta)-f(Y_{e'}^{i'}) = f(Y)+f(Y_{(e',g')}^{(i',j')})-f(Y_{g'}^{j'})-f(Y_{e'}^{i'}) \leq 0.$$

   The case of $Y_{e'}^{i'} \preceq X$ and $Y_{g'}^{j'} \not\preceq X$ is symmetric and identical.

3. Both $Y_{e'}^{i'} \preceq X$ and $Y_{g'}^{j'} \preceq X$. Then $Y_{(e',g')}^{(i',j')} \preceq X$, and all the points are modified. Thus, the value of this square is

$$\begin{aligned}(f(Y) - \Delta) + (f(Y_{(e',g')}^{(i',j')}) - \Delta) - (f(Y_{g'}^{j'}) - \Delta) - (f(Y_{e'}^{i'}) - \Delta)& \\ = f(Y) + f(Y_{(e',g')}^{(i',j')}) - f(Y_{g'}^{j'}) - f(Y_{e'}^{i'}) \leq 0.&\end{aligned}$$

As a result, we have shown that no new violating squares are introduced after changing all the values in $I(X)$, and the original violating square rooted in X is repaired. An identical argument suffices to prove that subtracting Δ from the filter $F(X_{(e,g)}^{(i,j)})$ has the same consequence. ◀

The proof of this lemma also implies the following corollary.

▶ **Corollary 30.** *Let $f : [k+1]^n \to \mathbb{R}$ be a function and $X \in [k+1]^n$ be a domain point. For any constant $\Delta > 0$, the function f' obtained by subtracting Δ from $f(Y)$ for all $Y \in I(X)$ or all $Y \in F(X)$ does not introduce any new f'–violating squares.*

Next, we prove the following density lemma.

▶ **Lemma 31.** *Let $f : [k+1]^n \to \mathbb{R}$ be a function with m violating squares. If $m \leq \varepsilon^{\sqrt{n}\log n} \cdot (k+1)^n$ for $\varepsilon \in (0, e^{-5})$, then f can be made to have* diminishing marginal gains *by changing at most $\varepsilon \cdot (k+1)^n$ values.*

Proof. The proof is a counting argument on the number of points we will need to change by the square repair procedure above. We enumerate all m violating squares and arrange them in order of item-weight (equal to $\sum_{i=1}^{k} |X_i|$) of the bottom point. We split the hypercube evenly based on item-weight. It can be verified that this split occurs at weight $\frac{nk}{k+1}$.

1. For violating squares where the bottom vertex has item-weight $\leq \frac{nk}{k+1}$, we repair them by modifying values in the ideal. Let I denote the bottom vertex in these violating squares. Then the total number of modified points is $|\cup_{X \in I} I(X)|$.

2. For violating squares where the bottom vertex has item-weight $> \frac{nk}{k+1}$, we repair them by modifying values in the filter. Let F denote the top vertex in these violating squares. Then the total number of modified points is $|\cup_{X\in F} F(X)|$.

We first prove the counting argument for Item 1. We estimate this cardinality by combining two different bounds across levels of the hypergrid. Let $L_j := \{X \in [k+1]^n : |X| \le j\}$. Then we can write

$$\left|\bigcup_{X\in I} I(X)\right| = \sum_{j=0}^{\frac{nk}{k+1}} \left|\bigcup_{X\in I} (I(X)\cap L_j)\right|.$$

We can bound these terms in two ways. First, we have

$$\left|\bigcup_{X\in I} (I(X)\cap L_j)\right| \le \sum_{X\in I} |I(X)\cap L_j| = \sum_{X\in I} \binom{|X|}{j} \le |I|\cdot\binom{\frac{nk}{k+1}}{j}.$$

Second, there is the more trivial bound of

$$\left|\bigcup_{X\in I} (I(X)\cap L_j)\right| \le |L_j| = \binom{n}{j}\cdot k^j.$$

This second bound is reminiscent of the binomial distribution $\mathrm{Bin}\left(n, \frac{k}{k+1}\right)$. Combining this with a Chernoff bound, we can get an upper bound on the number of points with item-weight far from the mean. Now we just have to use the correct bound depending on j.

1. If $j \le \frac{nk}{k+1} - \alpha\sqrt{\frac{nk}{k+1}}$ for some constant α, then

$$\begin{aligned}
\sum_{j=0}^{\frac{nk}{k+1}-\alpha\sqrt{\frac{nk}{k+1}}} \binom{n}{j}\cdot k^j &= (k+1)^n \sum_{j=0}^{\frac{nk}{k+1}-\alpha\sqrt{\frac{nk}{k+1}}} \binom{n}{j}\cdot\left(\frac{k}{k+1}\right)^j\left(\frac{1}{k+1}\right)^{n-j} \\
&= (k+1)^n\cdot \Pr\left[Z \le \frac{nk}{k+1} - \alpha\sqrt{\frac{nk}{k+1}}\right] && \left[Z\sim \mathrm{Bin}\left(n,\frac{k}{k+1}\right)\right] \\
&= (k+1)^n\cdot \Pr\left[Z \le (1-\delta)\frac{nk}{k+1}\right] && \left[\text{Letting } \delta = \frac{\alpha}{\sqrt{\frac{nk}{k+1}}}\right] \\
&\le (k+1)^n\cdot e^{-\delta^2 nk/2(k+1)} && \text{[Chernoff bound]} \\
&= (k+1)^n\cdot e^{-\alpha^2/2}.
\end{aligned}$$

2. If $j > \frac{nk}{k+1} - \alpha\sqrt{\frac{nk}{k+1}}$, then

$$\begin{aligned}
\sum_{j=\frac{nk}{k+1}-\alpha\sqrt{\frac{nk}{k+1}}}^{\frac{nk}{k+1}} |I|\cdot\binom{\frac{nk}{k+1}}{j} &= |I|\cdot \sum_{j=0}^{\alpha\sqrt{\frac{nk}{k+1}}} \binom{\frac{nk}{k+1}}{j} \\
&\le |I|\cdot\left(\frac{nk}{k+1}\right)^{\alpha\sqrt{\frac{nk}{k+1}}} \\
&\le |I|\cdot n^{\alpha\sqrt{n}} \\
&= |I|\cdot e^{\alpha\sqrt{n}\ln n}.
\end{aligned}$$

Finally, setting $\alpha = \frac{1}{2}\ln\varepsilon^{-1}$ yields

$$\begin{aligned}
\left|\bigcup_{X\in I} I(X)\right| &= \sum_{j=0}^{\frac{nk}{k+1}} \left|\bigcup_{X\in I}(I(X)\cap L_j)\right| && \text{[Splitting by item-weight]}\\
&= \sum_{j=0}^{\frac{nk}{k+1}-\alpha\sqrt{\frac{nk}{k+1}}} \left|\bigcup_{X\in I}(I(X)\cap L_j)\right| + \sum_{j=\frac{nk}{k+1}-\alpha\sqrt{\frac{nk}{k+1}}}^{\frac{nk}{k+1}} \left|\bigcup_{X\in I}(I(X)\cap L_j)\right| && \text{[Splitting the sum]}\\
&\le \sum_{j=0}^{\frac{nk}{k+1}-\alpha\sqrt{\frac{nk}{k+1}}} \binom{n}{j}\cdot k^j + \sum_{j=\frac{nk}{k+1}-\alpha\sqrt{\frac{nk}{k+1}}}^{\frac{nk}{k+1}} |I|\cdot\binom{\frac{nk}{k+1}}{j} && \text{[Discussed bounds]}\\
&\le (k+1)^n\cdot e^{-\alpha^2/2} + |I|\cdot e^{\alpha\sqrt{n}\ln n} && \text{[From case analysis]}\\
&\le (k+1)^n\cdot e^{-\alpha^2/2} + m\cdot e^{\alpha\sqrt{n}\ln n} && [|I|\le m]\\
&\le (k+1)^n\cdot e^{-\alpha^2/2} + (k+1)^n\cdot\varepsilon^{\sqrt{n}\ln n}\cdot e^{\alpha\sqrt{n}\ln n} && [m\le(k+1)^n\cdot\varepsilon^{\sqrt{n}\ln n}]\\
&= (k+1)^n\cdot\varepsilon^{\frac{1}{8}\ln\varepsilon^{-1}} + (k+1)^n\cdot\varepsilon^{\sqrt{n}\ln n}\cdot\varepsilon^{-\frac{1}{2}\sqrt{n}\ln n} && [\alpha = 1/2\cdot\ln\varepsilon^{-1}]\\
&\le (k+1)^n\cdot\left(\varepsilon^{\frac{1}{8}\ln\varepsilon^{-1}} + \varepsilon^{\frac{1}{2}\sqrt{n}\ln n}\right) && \text{[Simplifying]}\\
&\le \frac{\varepsilon}{2}\cdot(k+1)^n. && [\varepsilon\in(0,e^{-5})]
\end{aligned}$$

This concludes the counting argument for Item 1.

The counting argument for Item 2 is almost identical. We split the filters by level, and for $j \ge \frac{nk}{k+1} + \alpha\sqrt{\frac{nk}{k+1}}$, the Chernoff-inequality based upper bound still holds. For $j < \frac{nk}{k+1} + \alpha\sqrt{\frac{nk}{k+1}}$, we get the following bound.

$$\begin{aligned}
\sum_{j=\frac{nk}{k+1}}^{\frac{nk}{k+1}+\alpha\sqrt{\frac{nk}{k+1}}} \left|\bigcup_{X\in F}(F(X)\cap L_j)\right| &\le \sum_{X\in F}|F(X)\cap L_j|\\
&= \sum_{j=\frac{nk}{k+1}}^{\frac{nk}{k+1}+\alpha\sqrt{\frac{nk}{k+1}}} \sum_{X\in F}\binom{n-|X|}{j-|X|}k^{j-|X|}\\
&\le \sum_{j=\frac{nk}{k+1}}^{\frac{nk}{k+1}+\alpha\sqrt{\frac{nk}{k+1}}} \sum_{X\in F}\binom{\frac{n}{k+1}}{j-|X|}k^{j-|X|}\\
&\le \sum_{j=\frac{nk}{k+1}}^{\frac{nk}{k+1}+\alpha\sqrt{\frac{nk}{k+1}}} \sum_{X\in F}\left(\frac{n}{k+1}\right)^{j-|X|}k^{j-|X|}\\
&\le \sum_{j=\frac{nk}{k+1}}^{\frac{nk}{k+1}+\alpha\sqrt{\frac{nk}{k+1}}} \sum_{X\in F} n^{j-|X|}\\
&\le \sum_{j=\frac{nk}{k+1}}^{\frac{nk}{k+1}+\alpha\sqrt{\frac{nk}{k+1}}} |F|\cdot n^{j-\frac{nk}{k+1}}\\
&\le |F|\cdot n^{\alpha\sqrt{\frac{nk}{k+1}}}\\
&\le |F|\cdot n^{\alpha\sqrt{n}}\\
&= |F|\cdot e^{\alpha\sqrt{n}\ln n}.
\end{aligned}$$

The rest of the counting argument is exactly the same and thus omitted.

In conclusion, we need to modify $\leq \varepsilon \cdot (k+1)^n$ values to make f have *diminishing marginal gains*. ◀

We are now ready to finish the analysis of our tester.

Proof of Theorem 26. We prove each part separately.

1. By Theorem 9, a function with *diminishing marginal gains* does not have any f–violating squares. As a result, the tester will always **accept**.
2. By the contrapositive of Lemma 31, a function that is ε-far from *diminishing marginal gains* has at least $(k+1)^n \cdot \varepsilon^{\sqrt{n}\ln n}$ violating squares. The total number of squares is $\binom{n}{2} \cdot k^2 \cdot (k+1)^{n-2} = \Theta(n^2(k+1)^n)$. Thus, by the witness lemma, $n^2 \cdot (1/\varepsilon)^{\Theta(\sqrt{n \log n})}$ queries suffice to catch an f–violating square with high probability.
3. This follows trivially from the design of the algorithm.

This completes the analysis of Algorithm 2. ◀

4.3 An obstruction to component-wise local repair

The component testers of the previous two sections each rest on a dense witness theorem and a local repair argument. A natural attempt at a tester for full k–submodularity is to apply both component testers in parallel and union-bound the failure probability over the two repair arguments. We now show that this attempt cannot succeed: there exist configurations on which the repair direction prescribed by a triangle witness is forced to oppose the repair direction prescribed by an overlapping square witness on a shared vertex.

For ideals rooted at item-weight $\leq \frac{nk}{k+1}$, the repairs for both witness types proceed downward and can be aligned. The obstruction lives in the upward direction. On filters rooted at item-weight $> \frac{nk}{k+1}$, repairing a violated square requires subtracting $\Delta > 0$ from a vertex, whereas repairing a violated triangle in the same filter requires *adding* $\Delta > 0$ to that vertex. The configuration in Figure 1 realizes both demands simultaneously on the vertices x_2 and x_3.

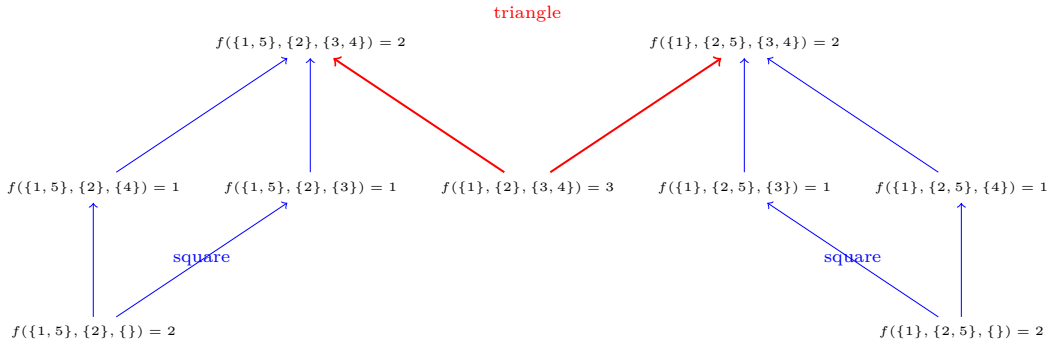

Figure 1 A configuration on a high item-weight filter realizing two incompatible local violations. The red edges form a violating *triangle* on item 5 above x_1: assigning item 5 to part 1 (giving x_2) or to part 2 (giving x_3) both yield marginal -1, summing to $-2 < 0$. The blue edges form two violating *squares* for diminishing marginal gains on items 3 and 4 in part 3, above x_8 (left) and x_9 (right). Repairing the triangle requires raising $f(x_2)$ or $f(x_3)$; repairing the squares requires lowering the same values.

The configuration is not isolated to a small region of the hypergrid. Embedding the same value pattern into any high-item-weight filter on a larger domain produces an instance of the same conflict, so an ideal-only repair strategy that avoids upward filters cannot route around it without losing the balance argument that makes the component testers work.

▶ **Observation 32** (Component-wise repair is insufficient). *For every $k \geq 2$ there exist functions $f : [k+1]^n \to \mathbb{R}$ and high item-weight filters on which a violated triangle witness and an overlapping violated square witness prescribe local repairs of opposite sign on a common vertex. In particular, the standard component-wise repair argument – repair triangles and squares independently and combine via union bound – does not yield a tester for k-submodularity.*

Observation 32 does not rule out a Hamming-distance tester for k-submodularity; it shows only that obtaining one will require either a richer witness vocabulary that simultaneously certifies both component constraints, or a non-local repair scheme that mediates between square and triangle repairs across the hypergrid.

Symmetric Distributions from Shallow Circuits

Abstract

We characterize the symmetric distributions that can be (approximately) generated by shallow Boolean circuits. More precisely, let $f\colon \{0,1\}^m \to \{0,1\}^n$ be a Boolean function where each output bit depends on at most d input bits. Suppose the output distribution of f evaluated on uniformly random input bits is close in total variation distance to a symmetric distribution $\mathcal{D}$ over $\{0,1\}^n$. Then $\mathcal{D}$ must be close to a mixture of the uniform distribution over n-bit strings of even Hamming weight, the uniform distribution over n-bit strings of odd Hamming weight, and γ-biased product distributions for γ an integer multiple of 2^{-d}. Moreover, the mixing weights are determined by low-degree, sparse $\mathbb{F}_2$-polynomials. This extends the previous classification for generating symmetric distributions that are also uniform over their support.

1 Introduction

One of the most celebrated results in complexity theory is that AC^0 circuits[1] require an exponential number of gates to compute the parity function [22, 1, 45, 26, 27]. Surprisingly, the weaker circuit class NC^0 suffices to perform a very similar task. In particular, mapping uniformly random bits $(x_1, x_2, \ldots, x_n)$ to $(x_1 \oplus x_2, x_2 \oplus x_3, \ldots, x_{n-1} \oplus x_n, x_n \oplus x_1)$ produces the uniform distribution over n-bit strings of even parity, or equivalently, over input-output pairs $(x, \mathrm{PARITY}(x))$ [5, 10]. This observation begs the question: what computational resources are required to (approximately) *generate* specific distributions, as opposed to the traditional task of *computing* specific functions?

A fundamental question in its own right, the complexity of sampling from distributions also has numerous applications. For example, results on the hardness of sampling can be translated to data structure lower bounds [40, 35, 6, 43, 11, 44, 47, 30, 2], provide input-independent quantum-classical separations [7, 44, 30, 24], and are key components

[1] Recall that these are (families of) Boolean circuits of constant depth and unbounded fan-in gates. They may be contrasted with NC^0 circuits, which are also of constant depth, but have bounded fan-in gates.

to the construction of explicit codes [37]. Moreover, techniques and intuition developed in this setting have successfully been applied to pseudorandom generators [40, 35, 6] and extractors [41, 17, 42, 13, 14].

While the general problem was considered in early work (see, e.g., [29]), a focus on generating distributions via shallow circuits was advocated for more recently by Viola [40]. Since then, the field has seen a number of exciting developments (see, e.g., the recent works [21, 44, 30, 37, 31, 2] and references therein). One notable takeaway from prior works is that NC^0 circuits can sample very few uniform symmetric distributions (i.e., uniform distributions over a symmetric support), even allowing for small errors. In particular, the line of work [40, 21, 44, 30, 31] recently culminated in the following classification result, which confirmed a conjecture of Filmus, Leigh, Riazanov, and Sokolov [21]. For a function $f\colon \{0,1\}^m \to \{0,1\}^n$, let $f(\mathcal{U}^m)$ be the distribution resulting from applying f to $x \sim \mathcal{U}^m$, the uniform distribution over $\{0,1\}^m$.

▶ **Theorem 1** ([31]). *Let $\varepsilon \in [0,1]$ be arbitrary. Assume $f\colon \{0,1\}^m \to \{0,1\}^n$ is computable by an NC^0 circuit of constant depth and $f(\mathcal{U}^m)$ is ε-close in total variation distance to a uniform symmetric distribution where n is sufficiently large. Then $f(\mathcal{U}^m)$ is $O(\varepsilon)$-close to one of the following six special uniform symmetric distributions:*

- *Point distribution on 0^n,*
- *Point distribution on 1^n,*
- *Uniform distribution over $\{0^n, 1^n\}$,*
- *Uniform distribution over n-bit strings with even Hamming weights,*
- *Uniform distribution over n-bit strings with odd Hamming weights,*
- *Uniform distribution over all n-bit strings.*

We emphasize that Theorem 1 works with *uniform* symmetric distributions, which does not capture, for example, the $(1/4)$-biased product distribution that is symmetric and easily sampleable by NC^0 circuits.

1.1 Our Result

In this paper, we take another step toward understanding the sampleability of distributions by extending Theorem 1 to handle *arbitrary* symmetric distributions. Let the *locality* of a Boolean function be the largest number of input bits that any output bit depends on. Note that NC^0 is precisely the class of sequences of functions with bounded locality.

▶ **Theorem 2** (Informal version of [32, Theorem 4.1]). *Let $d \geq 0$ be an integer. For any $\varepsilon \in (0,1]$, there exists some δ such that $\delta \to 0$ as $\varepsilon \to 0$ and the following holds.*

Suppose $f\colon \{0,1\}^m \to \{0,1\}^n$ is a d-local function and $f(\mathcal{U}^m)$ is ε-close in total variation distance to a symmetric distribution where n is sufficiently large in terms of d and ε. Then $f(\mathcal{U}^m)$ is δ-close to some mixture of

1. *The uniform distribution over n-bit strings of even Hamming weight,*
2. *The uniform distribution over n-bit strings of odd Hamming weight, and*
3. *γ-biased product distributions on n bits for γ an integer multiple of 2^{-d}.*

Moreover, the mixing weights are determined by degree-$O_d(1)$ $\mathbb{F}_2$-polynomials with $O_d(n)$ monomials.

The "moreover" conclusion implies this mixture can be exactly produced by $O_d(1)$-local functions (see [32, Remark 4.2]).

Learning Structured Distributions

As mentioned above, the study of sampling is rife with applications to other areas of theoretical computer science. Continuing this trend, we highlight one consequence of Theorem 2 to learning theory.

The reconstruction of an unknown probability density function based on observed data is a fundamental problem in both statistics and computer science. The typical setting is the PAC-learning model [38, 9, 33]: given access to independent samples of an unknown distribution $\mathcal{D}$, the goal is to output a hypothesis distribution $\mathcal{D}'$ close to $\mathcal{D}$. Much research has been carried out for Gaussian mixtures [16], log-concave distributions [20], monotone distributions [8], sums of independent integer random variables [15], junta distributions [3], mixtures of structured distributions [34], and more. The interested reader may wish to consult the survey [18] by Diakonikolas for additional background and references.

A black-box use of Theorem 2 in this setting is to learn symmetric distributions that are locally sampleable. Let $\mathcal{D}$ be a symmetric distribution over $\{0,1\}^n$. Assume $\mathcal{D}$ is produced by a d-local function, i.e., $\mathcal{D} = f(\mathcal{U}^m)$ for some d-local function $f\colon \{0,1\}^m \to \{0,1\}^n$. Then for any $\varepsilon > 0$ with n sufficiently large in terms of d and ε, Theorem 2 and the standard cover method [46] (see also [18, Theorem 1.5.1]) imply that we can efficiently learn $\mathcal{D}$ up to ε-error in total variation distance with $O_d(1/\varepsilon^2)$ samples with high probability. We believe this should hold for all $\varepsilon > 0$. Indeed, in Section 1.2 we propose Conjecture 4 for an exact classification of locally sampleable symmetric distributions, which, if true, would imply the desired learning theoretic result.

1.2 Open Problems

Recall that Theorem 2 does not work for the case of $\varepsilon = 0$, i.e., *exact* sampling. Indeed, we cannot conclude mixtures of the form given by Theorem 2 are the only distributions that can be exactly sampled by NC^0 circuits. We identify the following example, which illustrates that this is not simply a weakness in our analysis, but rather there are other symmetric distributions that can be sampled exactly.

▶ **Example 3.** Let $\mathcal{U}^n_{1/4}$ be the $(1/4)$-biased product distribution over $\{0,1\}^n$. Additionally, let $\texttt{evens}$ and $\texttt{odds}$ denote the uniform distribution over n-bit strings of even Hamming weight and odd Hamming weight, respectively. The distribution[2]

$$\mathcal{P} = \mathcal{U}^n_{1/4} + 2^{-n-1}\texttt{evens} - 2^{-n-1}\texttt{odds}$$

is not of the form given by Theorem 2, yet it can be sampled exactly by a bitwise AND of $\texttt{evens}$ and the uniform distribution over $\{0,1\}^n$, which is 3-local. The full details can be found in [32, Appendix A].

Additionally, we suspect that, similarly to the uniform symmetric case [31], one can take the upper bound in Theorem 2 to be linear in $\|f(\mathcal{U}^m) - \mathcal{D}\|_{\mathsf{TV}}$ without any dependency on d. Combining with the previous discussion, we conjecture the following strengthening of Theorem 2 holds. Observe that Conjecture 4 captures Example 3.

▶ **Conjecture 4.** *For every $d \in \mathbb{N}$, $\varepsilon \in (0,1)$, and n large enough in terms of d, if $f\colon \{0,1\}^m \to \{0,1\}^n$ is a d-local function and $f(\mathcal{U}^m)$ is ε-close in total variation distance to a symmetric distribution, then $f(\mathcal{U}^m)$ is $O(\varepsilon)$-close to some mixture*

$$\mathcal{M} = \sum_i \alpha_i \cdot g_i(\mathcal{D}^{(i)}_1, \ldots, \mathcal{D}^{(i)}_d),$$

[2] More formally, $\mathcal{P}$ is the distribution that assigns x probability $\mathcal{U}^n_{1/4}(x) + 2^{-n-1}\texttt{evens}(x) - 2^{-n-1}\texttt{odds}(x)$.

where each g_i is a bitwise function and each $\mathcal{D}_j^{(i)}$ is either the uniform distribution over n-bit strings of even Hamming weight or over n-bit strings of odd Hamming weight. Moreover, the mixing weights are determined by degree-$O_d(1)$ $\mathbb{F}_2$-polynomials with $O_d(n)$ monomials, as in Theorem 2.

Note the bitwise condition on the above g_i's guarantees the output distribution is symmetric.

Paper Organization

We provide an overview of the proof of Theorem 2 in Section 2, as well as a brief comparison of our techniques to those of prior literature. Our full results and proofs can be found in the arXiv version of the paper [32].

2 Proof Overview

In this section, we sketch the proof of Theorem 2 before discussing how the details compare to prior work.

2.1 Proof Overview of Theorem 2

We begin with a useful observation from [31]: the total variation distance between the distribution $f(\mathcal{U}^m)$ and any symmetric distribution $\mathcal{P}$ over $\{0,1\}^n$ is, up to constant factors, equal to the distance between the corresponding Hamming weight distributions of $f(\mathcal{U}^m)$ and $\mathcal{P}$ plus the distance between $f(\mathcal{U}^m)$ and its symmetrization (i.e., the distribution resulting from randomly permuting the coordinates of a string $x \sim f(\mathcal{U}^m)$). Expressed symbolically, we have

$$\|f(\mathcal{U}^m) - \mathcal{P}\|_{\mathsf{TV}} = \Theta(\||f(\mathcal{U}^m)| - |\mathcal{P}|\|_{\mathsf{TV}} + \|f(\mathcal{U}^m) - f(\mathcal{U}^m)_{\mathrm{sym}}\|_{\mathsf{TV}}). \tag{1}$$

The proof is straightforward, and it essentially follows from several applications of the triangle inequality which show that the two ways $f(\mathcal{U}^m)$ can be far from $\mathcal{P}$ are a weight mismatch or $f(\mathcal{U}^m)$ being far from symmetric itself (see [32, Lemma 3.5]).

By assumption, we know $f(\mathcal{U}^m)$ is ε-close to a symmetric distribution $\mathcal{D}$. Thus, Equation (1) implies $\|f(\mathcal{U}^m) - f(\mathcal{U}^m)_{\mathrm{sym}}\|_{\mathsf{TV}} = O(\varepsilon)$. Hence, it suffices to prove a weaker version of Theorem 2 that only compares the weight distributions ([32, Lemma 4.26]). More precisely, we want to show that for some δ tending to 0 with ε, the Hamming weight distribution of $f(\mathcal{U}^m)$, denoted $|f(\mathcal{U}^m)|$, is δ-close to a mixture $\mathcal{M}$ of

1. The binomial distribution $\mathsf{Bin}(n, \gamma)$ with n trials and success probability γ for γ an integer multiple of 2^{-d},
2. The binomial distribution $\mathsf{Bin}(n, 1/2)$ conditioned on the outcome being even, and
3. The binomial distribution $\mathsf{Bin}(n, 1/2)$ conditioned on the outcome being odd.

Moreover, we want the mixing weights to be determined by low-degree $\mathbb{F}_2$-polynomials with few monomials. (It will later become clear what "determined" means in this context.) We first prove a weaker version of this result that does not include mixing weight information ([32, Lemma 4.24]). Afterwards, we will discuss how to obtain the desired control over the weights. Before proceeding to the details, we first give a brief, high-level overview of the four main steps of the proof and how they fit together.

In the first step, we show that any fixing of the values of input bits which affect many output bits results in the bias of the output weight distribution of $f(\mathcal{U}^m)$ concentrating around a fixed dyadic rational[3] γ multiple of n. This allows us to represent the weight distribution $|f(\mathcal{U}^m)|$ as a mixture of distributions produced by the restricted functions. We then argue in step two that after grouping the parts of the mixture which concentrate around the same γ, each group assigns roughly the same amount of mass to any contiguous interval as the binomial distribution with success probability γ. The third step is to prove a continuity result for each grouped part of the mixture; namely, that the mass assigned to some weight w and to $w + \Delta$ for a small integer Δ are roughly equal. (There is a slight subtlety here in the case of $\gamma = 1/2$, but we will defer its discussion to later in the proof overview.) This allows us to conclude in the fourth and final step that most output weights are assigned comparable mass by the part of the mixture of $|f(\mathcal{U}^m)|$ concentrated around γ and the corresponding binomial distribution. In particular, our weight distribution is close in total variation distance to a mixture of binomial distributions, which is what we wanted to show.

2.1.1 Step 1: Removing Large Influences

In an extremely ideal setting, we might wish that all of f's output bits are roughly independent with bias around $\gamma = a/2^d$ for some integer $0 \le a \le 2^d$; in this case the output weight would resemble the binomial distribution $\mathsf{Bin}(n, \gamma)$. Of course, this is far too much to assume. In actuality, it may be that one specific input bit affects the value of *every* output bit, so none of them are independent.

To progress toward this dream scenario, we follow in the footsteps of many prior works (e.g., [40, 35, 6, 43, 44, 21, 30, 31, 24]) by strategically conditioning on certain input bits to express the distribution as a mixture of more structured sub-distributions. For example, suppose some input bit b affects many output bits. Since b takes value 0 and 1 with equal probability, we may express the distribution $f(\mathcal{U}^m)$ as the mixture

$$f(\mathcal{U}^m) = \frac{1}{2} \cdot f\left(\mathcal{U}^m \mid b = 0\right) + \frac{1}{2} \cdot f\left(\mathcal{U}^m \mid b = 1\right).$$

Observe that the large influence of b is no longer a problem in either of the restricted distributions, as its value is fixed.

In particular, we will condition on all "high degree" input bits that affect more than n/A output bits for some A to be chosen later. The goal is now to argue that the function resulting from each conditioning produces a distribution which is roughly of the form we originally sought. Note that this will not depend on the actual values that the input bits are set to in the conditioning.

We start with a result from [30]: let $\mathcal{D}_q$ be the uniform distribution over n-bit strings of Hamming weight q. If q/n is far from every integer multiple of 2^{-d}, then any d-local function must produce a distribution far (in total variation distance) from $\mathcal{D}_q$. This essentially follows from the fact that the input bits determining any fixed output bit can only be set in 2^d equally likely ways. Observe that symmetric distributions are simply mixtures of $\mathcal{D}_q$ for different q's. Thus we can show ([32, Lemma 4.8]) that if $f(\mathcal{U}^m)$ is close to a symmetric distribution $\mathcal{D}$, then for a typical $x \sim \mathcal{U}^m$, the normalized output weight $|f(x)|/n$ has distance at most $n^{-1/(800d)}$ from an integer multiple of 2^{-d}. Note that the closest multiple may be different for different inputs; however, after each conditioning $\rho \in \{0,1\}^S$ on the set of high degree input

[3] Recall a *dyadic rational* is a number that can be expressed as a fraction whose denominator is a power of two.

bits $S \subseteq [m] := \{1, 2, \ldots, m\}$, we can strengthen this result ([32, Lemma 4.9]) to say that for a typical $x \sim \mathcal{U}^{[m]\setminus S}$, the normalized output weight $|f(x, \rho)|/n$ is close to the *same* integer multiple of 2^{-d}. Here, we will only need "high degree" to correspond to affecting more than $n/O_d(1)$ many output bits (i.e., can take $A = O_d(1)$), although later we will obtain other constraints on how we must set A. Henceforth, we will shorthand $f(x, \rho)$ by $f_\rho(x)$ for clarity.

At a high level, the proof uses the second-moment method. By conditioning on the high degree input bits, we ensure that the variance of the resulting distribution is small, and thus we have concentration around a particular weight. Moreover, this weight must be close to an integer multiple of $n/2^d$, or else our previous insights imply $f(\mathcal{U}^m)$ cannot be close to $\mathcal{D}$. To be slightly more precise, a direct second-moment argument by itself is insufficient to rule out the case that some non-negligible fraction of the time the output weight is close to some other multiple of $n/2^d$. However, one can show ([32, Claim 4.14]) that if this occurs, $f_\rho(\mathcal{U}^{[m]\setminus S})$ would also have to assign decent probability mass to weights between these integer multiples, which would again imply $f(\mathcal{U}^m)$ cannot be close to $\mathcal{D}$.

Finally, we combine these deductions to prove that for each conditioning $\rho \in \{0, 1\}^S$ of the bits in S, there exists a set $T := T_\rho \subseteq [n]$ of size $|T| \leq O_{d,k}(1)$ such that every k-tuple of output bits in $[n] \setminus T$ has marginal distribution $\mathcal{U}^k_{\gamma_\rho}$, the γ_ρ-biased product distribution over $\{0, 1\}^k$, for γ_ρ an integer multiple of 2^{-d} (see [32, Proposition 4.5]). Here, k is some parameter at most $O_d(\log(1/\varepsilon))$. The proof operates by constructing a degree-k multilinear polynomial $P_i \colon \{0, 1\}^n \to \{0, 1\}$ for each k-tuple with the "wrong" distribution, where the expectation of P_i over $f_\rho(\mathcal{U}^{[m]\setminus S})$ is larger than over the γ-biased product distribution $\mathcal{U}^n_\gamma$ by at least an additive 2^{-kd} term. Note this follows from using our locality bound to view $P_i(f_\rho(\mathcal{U}^{[m]\setminus S}))$ as a polynomial of degree kd in the input bits. Summing the polynomials together into $P = \sum_i P_i$ magnifies the difference in expectations, and if the number of terms (i.e., number of bad k-tuples) is too large, we end up contradicting the assumption that $f(\mathcal{U}^m)$ is close to a symmetric distribution.

2.1.2 Step 2: Kolmogorov Distance

We now group the restricted functions according to their biases, defining $F_\gamma(\mathcal{U}^{[m]\setminus S}) = \mathbb{E}_{\rho:\gamma_\rho=\gamma}[f_\rho(\mathcal{U}^{[m]\setminus S})]$ for each γ. In this second step, we aim to show that every contiguous interval of output weights is assigned roughly the same amount of mass by $|F_\gamma(\mathcal{U}^{[m]\setminus S})|$ and $\mathsf{Bin}(n, \gamma)$. Since this difference in probability mass is convex over mixtures, it suffices to consider the individual distributions $|f_\rho(\mathcal{U}^{[m]\setminus S})|$. Moreover, it is enough to provide a bound on the *Kolmogorov distance*

$$\max_t \left| \Pr\left[|f_\rho(\mathcal{U}^{[m]\setminus S})| \geq t\right] - \Pr\left[\mathsf{Bin}(n, \gamma) \geq t\right] \right|.$$

In a sentence, the bound follows from combining the k-wise independence of most output coordinates with the fact that T is too small to have much of an effect. In the case of $\gamma = 1/2$ and $|T| = 0$, Diakonikolas, Gopalan, Jaiswal, Servedio, and Viola [19] gave an upper bound of roughly $1/\sqrt{k}$ using techniques from approximation theory. (In fact, their result holds for arbitrary threshold functions.) This was generalized by Gopalan, O'Donnell, Wu, and Zuckerman [23] to include the case of arbitrary $\gamma \in (0, 1)$. In our case, $|T|$ will likely not be 0, but it is small enough that a similar result ([32, Proposition 4.16]) still holds. In the edge cases of $\gamma \in \{0, 1\}$, we can no longer use [19, 23], nor would the size of T be negligible even if we could, but these special cases can be addressed later via simple arguments (see, e.g., the proof of [32, Lemma 4.23]).

For reasons that will become apparent in the subsequent step, we will also need a comparable bound in the case of $\gamma = 1/2$, even accounting for the parity of the output weight. That is, we wish to show

$$\Pr\left[|f_\rho(\mathcal{U}^{[m]\setminus S})| \geq t \text{ and } |f_\rho(\mathcal{U}^{[m]\setminus S})| \text{ is even}\right] \approx \Pr\left[\mathsf{Bin}(n,1/2) \geq t\right] \cdot \Pr\left[|f_\rho(\mathcal{U}^{[m]\setminus S})| \text{ is even}\right].$$

Our analysis here is similar to the previous case, but we now crucially rely on [12, Theorem 3.1]. In our context, it implies that there is a small set of input bits $R \subseteq [m] \setminus S$ such that re-randomizing over R typically re-randomizes the parity of f_ρ's output weight. Moreover, since R is small and we have already conditioned on input bits of large degree, the vast majority of output bits are unaffected by R. Thus, we can compare $\Pr\left[|f_\rho(\mathcal{U}^{[m]\setminus S})| \geq t\right]$ to $\Pr\left[\mathsf{Bin}(n,1/2) \geq t\right]$ using these unaffected output bits as a proxy for the entirety of the output bits. We briefly note that for the error bounds on the "parity Kolmogorov distance" to be meaningful given our choice of k, we need to take A (defined in our earlier high degree threshold) to be $O_{d,\varepsilon}(1)$ – larger than is necessary for Step 1.

2.1.3 Step 3: Approximate Continuity

Our third step is to argue that for each bias γ, the distribution $F_\gamma(\mathcal{U}^{[m]\setminus S})$ can be expressed as a mixture $\lambda \cdot E_\gamma + (1-\lambda) \cdot W_\gamma$, where λ is small and W_γ assigns similar probability mass to similar weights. Once again, it suffices to analyze the distributions produced by the individual restricted functions $f_\rho(\mathcal{U}^{[m]\setminus S})$. Here, we show that $f_\rho(\mathcal{U}^{[m]\setminus S})$ can be written as a mixture of distributions E and W, where E is extremely far from every symmetric distribution supported on strings of Hamming weight $\gamma n \pm n^{2/3}$, and the weight distribution of W satisfies a certain continuity property (see [32, Proposition 4.21]). More specifically, for positive integers w and Δ, the probability that W's output weight is w differs by no more than $O_d(\Delta/n)$ from the probability that W's output weight is $w + \Delta$. Since $f(\mathcal{U}^m)$ is close to $\mathcal{D}$, one can show that $F_\gamma(\mathcal{U}^{[m]\setminus S})$ is close to $\mathcal{D}$ conditioned on the output weight being $\gamma n \pm n^{2/3}$ (see [32, Claim 4.25]). Thus, proving the above result for $f_\rho(\mathcal{U}^{[m]\setminus S})$ implies minimal mass will typically be assigned to the E part of the mixtures, and so λ (in the mixture defining $F_\gamma(\mathcal{U}^{[m]\setminus S})$) will be small, as desired.

In our analysis, we will require a structural result about hypergraphs from [30]. Observe that we can associate any function $g\colon \{0,1\}^m \to \{0,1\}^n$ to a hypergraph on the vertex set $[n]$ with an edge for each input bit b containing all of the output bits that depend on b. In the case that g is d-local, this hypergraph has maximum degree at most d. We follow standard hypergraph terminology in defining the *neighborhood* of a vertex v to be the set of vertices sharing an edge with v. We additionally call two neighborhoods N_1, N_2 *connected* if there exist two adjacent (i.e., contained in the same edge) vertices $v_1 \in N_1, v_2 \in N_2$.

By [30, Corollary 4.11], we can find a collection of $r = \Omega_d(n)$ non-connected neighborhoods in $\mathcal{H}$ of size $O_d(1)$ by only removing $O_d(n)$ (with a small implicit constant) edges. Translating the result to f_ρ, we find that there exists a not-too-large set $B \subseteq [m]\setminus S$ of input bits such that any conditioning $\sigma \in \{0,1\}^B$ yields a sub-function $f_{\rho,\sigma}\colon \{0,1\}^{[m]\setminus(S\cup B)} \to \{0,1\}^n$ with many small, pairwise independent collections of output bits. We will define E and W according to the behavior of these neighborhoods, similarly to the arguments in [30, 31, 24].

Suppose for at least $r/2$ of the r non-connected neighborhoods $N_1, \ldots, N_r$, we have that $f_{\rho,\sigma}(\mathcal{U}^{[m]\setminus(S\cup B)})$ restricted to the neighborhood N_i has a marginal distribution which differs from the γ-biased product distribution over N_i, denoted $\mathcal{U}_\gamma^{N_i}$. Since $\mathcal{U}_\gamma^{N_i}$ is pointwise

close to the uniform distribution over strings of Hamming weight around γn, the marginal distributions of these neighborhoods (in $f_{\rho,\sigma}$) must also differ from the marginal distributions of the symmetric distribution $\mathcal{D}$. We can then accumulate these errors via concentration bounds to show that $f_{\rho,\sigma}(\mathcal{U}^{[m]\setminus(S\cup B)})$ is far from $\mathcal{D}$ (see [32, Lemma 3.3]).

We now set E to be the mixture over all conditions of the bits in B where most resulting neighborhoods differ from the corresponding γ-biased product distribution, and set W to be the mixture over the remaining conditionings. Since each sub-distribution in the mixture E is far from $\mathcal{D}$ by the previous paragraph, a union bound argument implies E, itself, must also be far from $\mathcal{D}$ (see [32, Lemma 3.4]). It remains to show the continuity property for W.

Suppose the r non-connected neighborhoods are generated by $v_1, v_2, \ldots, v_r \in [n]$ in the sense that all bits in the i-th neighborhood N_i are either v_i or in an edge that also contains v_i. We further condition on all input bits that do not affect any of $v_1, \ldots, v_r$, so that the value of every output bit outside of $N_1 \cup \cdots \cup N_r$ is fixed. In this way, the output weight of $f_{\rho,\sigma}(\mathcal{U}^{[m]\setminus(S\cup B)})$ becomes a fixed integer (corresponding to the fixed bits outside of the neighborhoods) plus the sum of the neighborhoods' output weights. Since we are in the case where most neighborhoods are extremely structured, we can show that for each $2 \leq \ell \leq t$, the output weight distribution modulo ℓ of N_i is not constant for a constant fraction of the N_i's with high probability (see [32, Claim 4.22]). Finally, we can obtain our desired continuity result through known density comparison theorems for sums of independent, non-constant integer random variables, such as [31, Theorem A.1], which relies on classical anticoncentration tools.

There is one important exception to the above analysis: the case of $\ell = 2$ and $\gamma = 1/2$. Here, we are not guaranteed to typically get many non-connected neighborhoods with variable output weight modulo 2 (even if most of them have the "correct" marginal distribution). To better understand where our reasoning breaks down, consider one of the most surprising examples in this area of work. Define $h\colon \{0,1\}^n \to \{0,1\}^n$ to be

$$h(x_1, \ldots, x_n) = (x_1 \oplus x_2, x_2 \oplus x_3, \ldots, x_{n-1} \oplus x_n, x_n \oplus x_1),$$

so that $h(\mathcal{U}^n)$ is the uniform distribution over n-bit strings of even Hamming weight. Observe that h is extremely simple, only requiring two bits of locality. Additionally, the marginal distribution onto any $k \leq n-1$ coordinates is exactly the product distribution $\mathcal{U}_{1/2}^k$.

Let us focus on a particular output bit $y_i = x_i \oplus x_{i+1}$. (For simplicity, assume i is not too close to 1 or n.) Its neighborhood is $y_{i-1} = x_{i-1} \oplus x_i$, y_i, and $y_{i+1} = x_{i+1} \oplus x_{i+2}$, so its Hamming weight modulo 2 is

$$(x_{i-1} \oplus x_i) \oplus (x_i \oplus x_{i+1}) \oplus (x_{i+1} \oplus x_{i+2}) = x_{i-1} \oplus x_{i+2}.$$

If we follow our earlier analysis and fix the value of the input bits that do not affect y_i (i.e., x_{i-1} and x_{i+2}), the neighborhood's Hamming weight modulo two is fixed, regardless of the values of x_i and x_{i+1}.

At a high level, the reason for this exceptional case is that it is the only setting of ℓ and γ for which the binomial distribution $\mathsf{Bin}(t,\gamma)$ mod ℓ can equal $\mathsf{Bin}(t-1,\gamma)$ mod ℓ. In other words, the weight distribution modulo ℓ of $\mathcal{U}_\gamma^k$ conditioned on the first bit being 0 is different than that distribution conditioned on the first bit being 1, unless $\ell = 2$ and $\gamma = 1/2$. This difference means that in the case of $\ell = 2$ and $\gamma = 1/2$, we can only derive a continuity result for weights that are an even distance apart. Hence, we must be cognizant of the output weight's parity throughout much of our analysis, which explains the required parity version of our Kolmogorov distance result mentioned earlier in the proof overview.

2.1.4 Step 4: Putting It Together

At this point, all that remains is to combine the pieces. Recall we have already conditioned on high degree (i.e., larger than $n/O_{d,\varepsilon}(1)$) input bits to find sub-functions $\{f_\rho\}_\rho$, each producing a distribution with some approximate bias γ_ρ. Additionally, the mixtures $F_\gamma(\mathcal{U}^{[m]\setminus S})$ obtained by grouping the sub-functions around their biases each satisfy a Kolmogorov distance bound and approximate continuity.

We partition $\{0, 1, \ldots, n\}$ into consecutive intervals of length $c\sqrt{n}$ for some small $c > 0$, and restrict our attention to the $O(\log(1/\alpha))$ of them that contain all but $O(\alpha)$ of the mass. By our Kolmogorov distance result ([32, Lemma 4.15]), we have that $|F_\gamma(\mathcal{U}^{[m]\setminus S})|$ and the binomial distribution $\mathsf{Bin}(n, \gamma)$ assign similar mass to each of these intervals. Moreover, our continuity result ([32, Proposition 4.21]) implies the mass in a fixed interval is almost uniformly distributed. Thus for most weights w, $|F_\gamma(\mathcal{U}^{[m]\setminus S})|$ assigns roughly the same mass to w as $\mathsf{Bin}(n, \gamma)$ does. Summing over all weights provides an upper bound on the total variation distance between the two weight distributions. We remark that there is a slight complication in the case of $\gamma = 1/2$, as there [32, Proposition 4.21] only lets us compare weights that are an even distance apart. However, by further subdividing each interval we consider into its even and odd parts, we are able to carry out a similar argument as before.

Finally, we recall that $f(\mathcal{U}^m)$ is a mixture of the distributions $F_\gamma(\mathcal{U}^{[m]\setminus S})$. Since the weight distribution of each $F_\gamma(\mathcal{U}^{[m]\setminus S})$ is close to the weight distribution corresponding to one from Theorem 2, their mixture $|f(\mathcal{U}^m)|$ naturally is close to a mixture of those weight distributions (see [32, Lemma 4.24]). We conclude by recalling that Equation (1) implies it was sufficient to classify the output weight distribution.

2.1.5 Mixing Weights

The above argument shows that $f(\mathcal{U}^m)$ is close to a mixture $\mathcal{M}$ of the form specified in Theorem 2, but without the additional control on the mixing weights. The reason for this shortcoming is that the threshold A at which we consider an input bit "high degree" depends not just on d, but also on ε, and so the mixing weights in the obtained mixture also depend on ε. If we instead chose a threshold that only depended on d, we would not have been able to obtain an effective error bound in the Kolmogorov distance step (i.e., [32, Proposition 4.16]) when $\gamma = 1/2$.

The key observation is that the arguments of Step 1 only require conditioning on input bits of degree larger than $n/O_d(1)$. In other words, if we perform some different conditioning κ on the set of input bits $S' \subseteq [m]$ above the weaker threshold $n/O_d(1)$, the distributions generated by the restricted functions will still have output weights which strongly concentrate around some integer multiple of $n/2^d$. Moreover, the mixing weights in this setting *are* integer multiples of $2^{-O_d(1)}$.

It remains to argue that the mixing weights on $\mathcal{M}$, the mixture we proved $f(\mathcal{U}^m)$ is close to by the stronger conditioning ρ, correspond to the mixing weights derived from the weaker conditioning κ (see [32, Lemma 4.26]). Since both conditionings produce mixtures of the same distribution, we have

$$\sum_\gamma \Pr_\rho[\gamma_\rho = \gamma] \cdot \mathop{\mathbb{E}}_{\rho:\gamma_\rho=\gamma} f_\rho(\mathcal{U}^{[m]\setminus S}) = f(\mathcal{U}^m) = \sum_\gamma \Pr_\kappa[\gamma_\kappa = \gamma] \cdot \mathop{\mathbb{E}}_{\kappa:\gamma_\kappa=\gamma} f_\kappa(\mathcal{U}^{[m]\setminus S'}).$$

By standard concentration bounds, the probability that $x \sim f(\mathcal{U}^m)$ has Hamming weight close to γn is almost entirely determined by the mass assigned to the distributions whose output weight concentrates around γ. In other words, we know $\Pr_\rho[\gamma_\rho = \gamma] \approx \Pr_\kappa[\gamma_\kappa = \gamma]$

for each γ. By our earlier analysis and the assumption that $f(\mathcal{U}^m)$ is close to $\mathcal{D}$, it must be that the mixing weight on $\mathsf{Bin}(n,\gamma)$ in $\mathcal{M}$ is roughly $\Pr_\rho[\gamma_\rho = \gamma]$, so it must also be close to $\Pr_\kappa[\gamma_\kappa = \gamma]$, which has the form we sought.

The analysis in the case of $\gamma = 1/2$ is similar, but as always, we need to keep track of the output weight's parity. Here, the analogous equivalence is

$$\Pr_\rho[\gamma_\rho = 1/2 \wedge |f(\mathcal{U}^m)| \text{ is even}] \approx \frac{1}{2^{|S'|}} \sum_{\kappa:\gamma_\kappa = 1/2} \Pr_{x \sim \mathcal{U}^{[m]\setminus S'}}[|f_\kappa(x)| \text{ is even}]. \tag{2}$$

Since f is d-local with n output bits, the parity of $|f_\kappa(x)|$ can be represented as a degree-d $\mathbb{F}_2$-polynomial with $O_d(n)$ monomials. Thus, the mixing weight for the uniform distribution over n-bit strings of even Hamming weight in $\mathcal{M}$ must be close to the right-hand side of Equation (2), which is the precise sense in which the mixing weights are "determined by low-degree $\mathbb{F}_2$-polynomials". The odd parity case is essentially identical. This concludes the proof overview of Theorem 2.

2.2 Technical Comparison to Prior Works

We now briefly survey the approaches of related prior works. To avoid an overly verbose digression, we attempt to focus only on the most relevant papers and do not hope to be exhaustive. Similarly, we restrict our attention within the mentioned works to the results and techniques most pertinent to our own; most, if not all, of the papers discussed contain a number of other interesting results.

The study of the complexity of sampling goes back to at least the 1980s in the influential work of Jerrum, Valiant, and Vazirani [29]. In the context of shallow circuits, several clever sampling constructions (including the one in the introduction) were devised in [5, 10, 28], while the first serious treatment of the complexity of sampling (with shallow circuits) appeared in [40]. There, Viola proved an assortment of sampling-related results, but we will confine our attention to two on the hardness of approximately generating $\mathcal{D}_{n/2}$, the uniform distribution over n-bit strings of Hamming weight $n/2$. (This specific choice is purely for simplicity, and both results also apply to the setting of $\mathcal{D}_{\alpha n}$ for $\alpha \in (0,1)$.)

The first result we will mention [40, Theorem 1.6] is an unconditional lower bound of $2^{-O(d)} - O(1/n)$ on the distance between $f(\mathcal{U}^m)$, where $f\colon \{0,1\}^m \to \{0,1\}^n$ is a d-local[4] function, and $\mathcal{D}_{n/2}$. The proof, much like our own (see Step 2), relies on a Kolmogorov distance bound obtained from a k-wise independence assumption [19, 23]. If the output distribution $f(\mathcal{U}^m)$ is k-wise independent for some large integer k, then [23, Theorem I.5] implies it has the wrong Hamming weight with constant probability, and we are done. Otherwise, there exists a k-tuple $T \subseteq [n]$ of output bits that are not uniformly distributed over $\{0,1\}^k$. In this case, one observes that the probability assigned to any element of $\{0,1\}^k$ is an integer multiple of 2^{-kd}, so the marginal distribution over T must be at least 2^{-kd}-far from uniform. The proof concludes by noting that the marginal distribution of $\mathcal{D}_{n/2}$ onto T is very close to uniform. Note that we use similar granularity ideas in the proof of [32, Proposition 4.5] (in Step 1).

The second result [40, Theorem 1.3] provides a much stronger lower bound of $1 - 1/\mathsf{poly}(n)$ for the distance between $f(\mathcal{U}^m)$ and $\mathcal{D}_{n/2}$ for any $O(\log n)$-local function f, but is *conditional* on the input size m not substantially exceeding the information-theoretic minimum required to generate the target distribution. The proof begins by partitioning the input bits u of f as $u = (x, y)$ and expressing

[4] In fact, the result is proven for an adaptive version of locality.

$$f(u) = f(x, y) = h(y) \circ g_1(x_1, y) \circ \cdots \circ g_s(x_s, y),$$

where each g_i may depend arbitrarily on y but only on the single bit x_i of x. Additionally, each $g_i(x_i, y) \in \{0,1\}^{O(d)}$. By a greedy approach, this can be accomplished with $s \geq \Omega(n/d^2) = n/\mathsf{polylog}(n)$. The argument proceeds by conditioning on certain input bits (in this case y) and splitting into two scenarios depending on the amount of concentration; this strategy has been employed by several later works, including this one.

In the "concentrated" case where at least $\sqrt{n}$ many g_i's become fixed, the output distribution of $f(x, y)$ has small support. Even taking the union over all choices of such y, one finds that many elements in the support of $\mathcal{D}_{n/2}$ cannot be obtained. Note that this is where the input length restriction originates. Alternatively, at least $s - \sqrt{n} = n/\mathsf{polylog}(n)$ of the g_i's take multiple values. One would like to apply standard anticoncentration results to argue the output weight is too spread out, but as noted earlier in the proof overview (see Step 3), it may be that the Hamming weight of a g_i is fixed, even if the output is not. Viola circumvents this issue by adding an additional "test" to determine whether at most $2\sqrt{n}$ many g_i's can output the all zeros string; in this case, taking two or more values implies the weight cannot be fixed, and thus anticoncentration inequalities can be applied.

We now turn to the recent work of Filmus, Leigh, Riazanov, and Sokolov [21], who addressed the case of $\mathcal{D}_k$ for $k = o(n)$. They proved [21, Theorem 1.2] that $\widetilde{\Omega}(\log(n/k))$ bits of locality (even adaptively chosen) are required to generate $\mathcal{D}_k$ to constant error. Moreover, the same result holds for the uniform distribution over strings whose Hamming weight lies in a set S, where $\max_{s \in S} s = k$. Their proof first reduces to the case of considering $\mathcal{D}_1$, and then proceeds via a hitting set vs independent set dichotomy. This can again be viewed as fitting into the concentration vs anticoncentration paradigm. If there are $O(d2^d)$ input bits that together affect every output bit, then one can afford to condition on them and induct on the remaining $(d-1)$-local sub-distributions. Bounds from these distributions can eventually be recombined to deduce bounds on the full distribution using some version of a union bound, such as [32, Lemma 3.4]. Otherwise, there are $\Omega(2^d)$ independent output bits, and one can argue it is very likely that two of these bits evaluate to 1, since each (nonzero) output bit is 1 with probability at least 2^{-d}. Interestingly, the authors are able to use the *robust sunflower lemma* [36, 4] from extremal combinatorics to improve their quantitative bounds; we refer the reader to their original paper for details.

Also recently, strong unconditional locality lower bounds for sampling $\mathcal{D}_{\alpha n}$ where α is a non-dyadic rational were proven independently in [44, 30]. At a very high level, both proofs follow from the observation (recorded in [39]) that the marginal distribution on any output bit of a d-local function f must have probabilities that are integer multiples of 2^{-d}, which cannot accurately approximate (say) $1/3$, corresponding to the marginal distribution for $\mathcal{D}_{n/3}$. We begin by describing the approach of Viola [44, Theorem 25], continuing to focus on the case of $\alpha = 1/3$ for simplicity. First assume by contradiction $\left\| f(\mathcal{U}^m) - \mathcal{D}_{n/3} \right\|_{\mathsf{TV}} \leq 1 - \varepsilon$ for some ε to be determined. The proof proceeds by arguing that there must exist a large subset $R \subseteq \{0,1\}^m$ of the inputs, such that $f(\mathcal{U}(R))$, f evaluated on inputs drawn uniformly at random from R, lands entirely in the support of $\mathcal{D}_{n/3}$ and has almost full min-entropy.[5] The so-called *fixed-set lemma* of Grinberg, Shaltiel, and Viola [25] then implies that R can be further restricted to a large subset $R' \subseteq R$ whose uniform distribution is nearly indistinguishable by d-local functions from a product distribution where each bit is either

[5] Recall the *min-entropy* of a random variable X is $\log(1/\max_{x \in \mathsf{supp}(X)} \Pr[X = x])$.

fixed or uniform. Then the large min-entropy of $f(\mathcal{U}(R))$ (and thus $f(\mathcal{U}(R'))$) combined with the fact that the distribution is contained in the support of $\mathcal{D}_{n/3}$ implies there must be at least one output bit whose marginal distribution is extremely close to 1/3. This, however, contradicts the fact that 1/3 cannot accurately be approximated by an integer multiple of 2^{-d}.

The proof in [30] instead operates very similarly to the details of Step 3. Through a graph-theoretic lemma [30, Corollary 4.8], they show that there must be a set of at most $r/2^d$ many input bits upon whose conditioning results in r many independent output bits for $r \approx n/2^{d^2}$. As previously noted, each of these output bits inevitably incurs some error from mismatched marginal distributions, and these errors can be aggregated via standard concentration inequalities (as in [32, Lemma 3.3]). Bounds from the individual sub-distributions can once again be recombined via a union bound result like [32, Lemma 3.4].

The work [30] also contains locality bounds for $\mathcal{D}_{\alpha n}$ when α is a dyadic rational. The proof has strong similarities to the non-dyadic case, except that now the marginal distributions on output bits of f do not necessarily disagree with those of the target distribution. The authors overcome this issue by turning to the familiar concentration vs. anticoncentration paradigm. The details have almost entirely been spelled out already in Step 3, as our analysis is nearly identical at that part. We briefly note that the quantitative dependencies here are much worse than in the non-dyadic case, essentially for the reason that one needs to obtain a much richer structure than simply independent output bits, and so the analogous graph-theoretic lemma in this case has poor bounds.[6]

Finally, let us mention the predecessor of this work [31], which classifies what uniform symmetric distributions can be sampled by functions of bounded locality, confirming a conjecture of [21]. In broad strokes, it follows similarly to the proof overview, so we will be brief. Through a strategic conditioning of input bits, one may reduce to the case where no input bits have large degree and almost all the output bits are k-wise independent. Then one can show the resulting Hamming weight distribution is close in Kolmogorov distance to the binomial distribution, and it satisfies a continuity-type property. Combining these steps together, one classifies the Hamming weight distribution, which is enough to classify the actual distribution, since we assume $f(\mathcal{U}^m)$ is close to a uniform symmetric distribution. Much of the present work is an extension of the ideas in [31] to the general symmetric case, although there are several parts (e.g., much of the analysis in Step 1 and the finer control on the mixing weights) that require substantially new ideas.

We conclude by noting that several works [35, 6, 42, 43, 11] prove hardness results against the more powerful classes of AC^0 circuits or read-once branching programs. There is a reasonable overlap in the techniques used with those discussed above, but the proofs of all these results rely on the special properties of certain pseudorandom objects like good codes [35, 6, 11] or extractors [41, 43].

Abstract

We analyze a balls-and-bins game against an adaptive adversary that sequentially deletes bins. Starting with n balls distributed across n bins, the adversary deletes a bin in each step, forcing the algorithm to redistribute its balls to surviving bins. We prove that after $n/2$ rounds, uniform random redistribution yields optimal $O(n)$ recourse and $O(\frac{\log n}{\log \log n})$ maximum load. Furthermore, we show that applying the "power of two choices" reduces the maximum load to $O(\log \log n)$ while maintaining linear recourse.

We also consider a variation of this game where the balls from the deleted bin are partitioned evenly among $d \ll n$ random bins rather than being redistributed independently. We demonstrate that keeping the balls together ($d = 1$), which gives small maximum load and recourse against an oblivious adversary, fails against an adaptive adversary. Nevertheless, we show that splitting the balls into just two groups ($d = 2$) is sufficient to recover linear recourse and efficient load balancing in the adaptive setting.

1 Introduction

Balls-and-bins processes serve as a fundamental abstraction for studying load balancing problems, with diverse applications across numerous domains [2, 22, 27, 25, 32, 17, 31]. In the simplest version of the problem, n balls are assigned to n bins. Here it is well established that distributing every ball independently and uniformly over the bins yields a maximum load of $O(\frac{\log n}{\log \log n})$ [19]. Furthermore, utilizing the "power of two choices", where balls are placed sequentially in the least loaded of two randomly chosen bins, dramatically reduces the maximum load to $O(\log \log n)$ [3].

Beyond these classical settings, the landscape of balls-and-bins problems is vast. Variations include settings with weighted balls [13, 26], heterogeneous bin capacities [10, 32], and graph-based constraints where balls can probe only specific subsets of bins [23, 18]. Berenbrink et al. [11, 12] extended the power of two choices from the *lightly-loaded* case studied by [3],

© Haim Kaplan, Shay Sapir, and Uri Stemmer;
licensed under Creative Commons License CC-BY 4.0

where the number of balls m is equal to the number of bins n, to the *heavily-loaded* case, where $m \gg n$. Remarkably, they showed that the additive gap between the maximum load and the average load remains the same as in the lightly-loaded case. Los and Sauerwald [24] analyzed the power of two choices in an "incomplete information" setting, investigating scenarios where algorithms must rely on load estimates rather than exact values. Vöcking [30] considered multiple-choice settings (rather than just two choices), where balls are placed in the least loaded of d selected bins, demonstrating that a nonuniform selection of the d locations leads to better load balancing.

Of particular relevance to our work are *dynamic* variations of balls-and-bins, where the goal is to maintain a balanced allocation over time as balls or bins arrive and depart. This line of work was initiated by [3], who considered a model where balls are added and deleted *at random*. They showed that their "power of two choices" extends to this dynamic setting, maintaining a maximum load of $O(\log \log n)$ in the lightly-loaded case. Subsequent works [15, 30, 4] generalized this to the heavily-loaded case. Furthermore, these works allowed the sequence of operations to be determined by an *oblivious adversary*, that is, an adversary that fixes the full sequence of ball insertions and deletions before the process begins. Note that the random case studied by [3] is a special instance of an oblivious adversary.

Adaptive adversary

Unlike an oblivious adversary, who commits to the sequence of operations before the game begins, an adaptive adversary chooses its actions sequentially, potentially basing its decisions on the entire history of the execution. Designing algorithms and data structures that cope with adaptive adversaries has been the focus of much recent work across various sub-fields of theoretical computer science, including streaming algorithms, dynamic graph algorithms, and learning theory [8, 7, 21, 29, 6, 14, 1, 20]. However, in the context of dynamic balls-and-bins, to our knowledge, only two works have addressed general adaptive adversaries: Bender et al. [9] and Fine et al. [16].

Another work by Becchetti et al. [5], considered a repeated balls-and-bins game, which can be viewed as *specific adaptive strategy*. In this game, n balls are arbitrarily assigned to n bins, and in each round, one ball is extracted from each non-empty bin, and re-assigned to a uniformly random bin. Becchetti et al. [5] proved that this game admits a self-stabilizing property: after $O(n)$ rounds, the maximum load is $O(\log n)$, and remains $O(\log n)$ for $\text{poly}(n)$ rounds, with high probability.[1] However, the focus of Becchetti et al. [5] is on that specific adaptive strategy, hence it does not bound general adaptive adversaries.

Bender et al. [9] considered an adaptive *ball-recycling* game where m balls are initially distributed across n bins. At each time step, an adversary adaptively selects a bin, removes all its balls, and re-throws them at random. The goal of the adversary is to maximize the expected number of balls re-thrown per step in the stationary distribution (when it exists), a metric we refer to as the *long-run average recourse*. Bender et al. [9] established nearly tight bounds for this setting: there exists an adversary that achieves a long-run average recourse of $2m/(n+1)$, while no adversary can achieve long-run average recourse greater than $2m/n + 1$. However, since the work of [9] focuses on the stationary distribution, it does not yield strong bounds on the achievable recourse in finite-horizon games.

This gap was addressed by Fine et al. [16], who considered a variant of this game in which bins are *deleted* rather than *recycled*. This implies that the game can last at most n steps. This is formulated as a two-player game between an (adaptive) adversary and a randomized algorithm, defined as follows.

[1] High probability means with probability at least $1/\text{poly}(n)$.

▶ **Definition 1.1** (The Bin-Deletion Game). *Initially, the algorithm distributes n balls into n bins according to its initialization strategy (in our setting, this will either be the uniform distribution or using the power of two choices). Then the game proceeds for $T \leq n$ rounds, where in each round:*

1. *The adversary inspects the current assignment and selects a bin to delete.*
2. *The algorithm redistributes the balls from the deleted bin among the surviving bins.*

The algorithm has two primary objectives: to minimize the total number of balls it redistributes, referred to as the (total) recourse*, and to minimize the* maximum load *of any single bin throughout the game.*

▶ Remark 1.2. As is standard in the literature on balls-and-bins, we focus on "lightweight" strategies for the algorithm, where the destination of a ball is chosen either independently of the current system state or by probing only a constant number of randomly chosen bins. Such strategies are crucial in distributed settings where querying the load of every bin may be slow or expensive.

Fine et al. [16] considered this game in the case where $T = n - 1$ (i.e., the game continues until only one bin remains). They showed that no adversary can force more than $O(n \log n)$ total recourse against the simple algorithm that redistributes balls from deleted bins uniformly at random. This is optimal for $T = n - 1$, because at any step with r remaining bins, the adversary can force a recourse of at least n/r (the average load). Thus, even over just the last $n/2$ steps, any algorithm must incur a total recourse of:

$$\sum_{r=1}^{n/2} \frac{n}{r} = n \sum_{r=1}^{n/2} \frac{1}{r} = \Theta(n \log n).$$

Note that this argument fails when the number of deletions T is smaller than $n/2$. The analysis of recourse and maximum load when the adversary removes only a subset of the bins was left open by Fine et al. [16]. (The maximum load is irrelevant when $T = n - 1$, as it is trivially n when only one bin remains.)

1.1 Our results

We analyze the recourse and the maximum load of several algorithmic strategies for the adaptive bin deletion game (Definition 1.1). First, we resolve the behavior of this game for partial deletions. For simplicity of presentation, we only discuss here $T = \frac{n}{2}$ rounds, and present the extension to $T > \frac{n}{2}$ in Section 3. We establish that after $\frac{n}{2}$ rounds, independent uniform redistribution yields optimal $O(n)$ recourse and a maximum load of $O(\frac{\log n}{\log \log n})$, matching the classical static bounds. Moreover, we show that the power of two choices carries over to this adaptive setting, reducing the maximum load to $O(\log \log n)$ and recovering the exponential improvement seen in the static case. Specifically,

▶ **Theorem 1.3** (Informal). *In the adaptive bin-deletion game, after $T = \frac{n}{2}$ rounds, with high probability,*

1. *If balls are distributed independently and uniformly at random, the recourse is $O(n)$ and the maximum load is $O(\frac{\log n}{\log \log n})$, and*
2. *If balls are distributed using the two choices allocation scheme, the recourse is $O(n)$ and the maximum load is $O(\log \log n)$.*

Theorem 1.3 assumes that a deleted bin can send every one of its balls independently into a different random (remaining) bin. However, this might sometimes be infeasible. For example, in a communication network, this might require a server to connect to a prohibitively

large number of machines. Therefore, we seek to reduce the number of target bins that a deleted bin connects to. We consider a restrictive algorithmic strategy called *d-split*: when a bin is deleted, we partition its balls among d randomly chosen bins. This strategy was suggested in [16], who asked what is the recourse of this scheme, particularly when $d = 2$. In Section 4, we answer this question when the game is played for $T = n/2$ rounds, showing that this d-split strategy suffices for guaranteeing linear recourse and nearly-optimal maximum load, even for $d = 2$. The analysis of this variant is significantly more challenging, and it may provide insights for handling adaptive inputs in other settings. Extending our result to $T = (1 - o(1))n$ rounds remains open. Note that for this variant, our bound on the maximum load holds only with constant probability.

▶ **Theorem 1.4.** *In 2-split against an adaptive adversary, after $\frac{n}{2}$ rounds, the recourse is $O(n)$ with high probability, and the maximum load is* $\mathrm{poly}(\log n)$*, with constant probability.*

As noted by [16], restricting this variant further to $d = 1$, which forces a deleted bin to send all its balls into *one* randomly chosen bin, is disastrous against an adaptive adversary: The adversary can always delete the heaviest bin, causing a snowball effect where a heavy packet of balls repeatedly merges with other bins. Already after $n/2$ rounds, this results in maximum load $\Omega(n)$ and recourse $\Omega(n^2)$.

Somewhat surprisingly, we show that this restrictive variant (with $d = 1$) is actually a solid strategy against an *oblivious* adversary that chooses the sequence of deletions in advance. This underscores the power of the adaptive adversary and sets it apart from the oblivious adversary in the context of dynamic balls-and-bins. Specifically, in Section 5 we prove the following theorem:

▶ **Theorem 1.5.** *In 1-split against an oblivious adversary, after $\frac{n}{2}$ rounds, the recourse is $O(n \log n)$ and the maximum load is $O(\log n)$, with high probability.*

To grasp the intuition behind this result, consider a random *forest* graph on n vertices constructed as follows: for each step i from 1 to $n/2$, vertex i uniformly samples a parent $j \in \{i + 1, \ldots, n\}$ and becomes a child of j. This process yields a forest with $n/2$ roots (the vertices indexed $n/2 + 1$ through n).

Critically, the recourse in our oblivious $d = 1$ game is exactly equal to the sum of the depths of all vertices in this forest, and the maximum load is the size of the largest tree. This equivalence holds because, without loss of generality, an oblivious adversary deletes bins 1 through $n/2$ sequentially. When bin i is deleted, it merges into a surviving bin $j > i$, creating the directed edge (i, j). Consequently, a ball starting at bin u incurs a movement cost exactly equal to the length of the path from u to a root; and the load of bin i is the size of the tree rooted at i. We provide a direct analysis showing that, for such a random forest, the total sum of depths is $O(n \log n)$, and the maximum tree size is $O(\log n)$ with high probability.

1.2 Technical overview

Our proofs use coupling arguments to show stochastic domination, formalized as follows.

▶ **Definition 1.6** (First-order stochastic domination)**.** *Random variable A has first-order stochastic dominance over random variable B, denoted $A \succeq B$ if, for all $x \in \mathbb{R}$,*

$$\Pr(A \geq x) \geq \Pr(B \geq x).$$

▶ **Lemma 1.7** (Theorem 4.2.3 of [28].). *For random variables A, B, we have $A \succeq B$ if and only if there exist random variables A', B', such that A' has the same distribution as A, and B' has the same distribution as B, and $A' \geq B'$. The random variables A', B' are called a monotone coupling.*

For brevity, from now on we omit the term "first-order" when referring to Definition 1.6, and omit the word "monotone" when referring to Lemma 1.7. For concreteness, suppose that the number of rounds is $n/2$, for all variants.

Uniform game

Consider the uniform algorithm, that for each ball, draws a bin uniformly and independently at random from the surviving bins, and assigns the ball to the drawn bin. We show that the recourse and maximum load in this adaptive game are stochastically dominated by the recourse and maximum load in a related *non-adaptive game*, and then bound the recourse and maximum load of the non-adaptive game using standard tools. The non-adaptive game is the following: throw balls independently and uniformly at random to n bins, until every subset of $n/2$ bins contains at least n balls. It is not difficult to show that with high probability, the number of balls in this game is at most $10n$, and the bound on the maximum load follows by classic results, for a standard balls and bins problem with $m = 10n$.

The coupling argument, which is proven in Section 3, is as follows. Whenever we want to throw a ball in the adaptive game, we do the following. In the non-adaptive game, throw a ball uniformly at random over the n bins. If the ball lands in a bin of the same index as a surviving bin in the adaptive game, place the ball in the adaptive game at that corresponding bin. Otherwise, repeat this and throw another ball in the non-adaptive game. We obtain that the configuration, at the bins which correspond to surviving bins in the adaptive game, is the same in both games. Moreover, the non-adaptive game may only end after round $n/2$ of the adaptive game, since at round $n/2 - 1$, there are $n/2 + 1$ surviving bins, which contain n balls, and so there is a set of $n/2$ bins with strictly less than n balls. Thus, the configuration in the non-adaptive game is point-wise larger than the configuration in the adaptive game, and the proof follows.

▶ Remark 1.8. It is necessary that the algorithm's coins are hidden from the adversary, at least in order to bound the maximum load. To see this, we first define a model where the algorithm's random coins are set in advance and revealed to the adversary. Suppose that every bin b holds a sequence σ_b of independent random variables drawn from the uniform distribution over $[n]$. When bin b is deleted, it sends its balls to surviving bins in σ_b, in the order of σ_b (this is basically rejection sampling).

Given the sequences of all bins, the adversary can do the following attack. Look at the first $\sqrt{n}$ random variables of the first $\sqrt{n}$ bins. With constant probability, there exists $i \in [\sqrt{n}]$ such that n appears in the first $\sqrt{n}$ random variables of i. Delete the other $\sqrt{n}$ bins indexed by random variables in σ_i, and then delete i. This yields an additional $O(1)$ expected load on bin n. Repeat $O(\sqrt{n})$ times, resulting in expected load $\Omega(\sqrt{n})$ in bin n after $n/2$ rounds.

Two choices

In the adaptive two choices paradigm, each ball draws two bins independently and uniformly over the surviving bins, and picks the least loaded bin. Our proof for this setting is similar to that of the uniform game, except that the non-adaptive game we reduce to (via coupling) is different. Specifically, we consider the following non-adaptive variant of the two choices game

(without an adversary): Start with n empty bins. Then, iteratively pick *pairs of indices* (i, j) uniformly from $[n] \times [n]$, and place a ball in the least loaded among bins i, j. The game proceeds until for every subset $S \subseteq [n]$ of size $|S| = n/2$ we have that $S \times S \subset [n] \times [n]$ contains at least n pairs. We show that the recourse and maximum load in the *adaptive* two choices game are stochastically dominated by the number of rounds and the maximum load in the *non-adaptive* two choices game, and then bound these parameters in the non-adaptive game.

2-split, bounding the recourse

Recall that with the 2-split strategy, whenever a bin is deleted, its balls are split into two packets, and each packet is independently thrown to a uniformly random surviving bin. Theorem 1.4 states that after $\frac{n}{2}$ rounds, the recourse is $O(n)$ and the maximum load is $\text{poly}(\log n)$. We first discuss the recourse bound. To this end, we relate the adaptive 2-split game to an intermediate (adaptive) game, denoted π_{pay}, where: (1) balls from deleted bins are thrown independently uniformly at random, instead of using the 2-split strategy; and (2) when a bin with k balls is deleted, the incurred recourse is $k + O(k \log k)$ instead of k. Note that the first modification "helps us" in that it makes the problem easier to analyze and the second modification "helps the adversary" as the recourse is increased.

Our analysis proceeds using two main claims: (1) The recourse in π_{pay} is at total variation distance $\frac{1}{n^8}$ from a random variable that stochastically dominates the recourse in 2-split; and (2) the recourse in π_{pay} is $O(n)$ with high probability. By a union bound, the recourse in 2-split is $O(n)$ with high probability. The proof of the second claim is very similar to the uniform game, and is omitted from this overview. The basic idea behind the first claim is that if we consider $k \geq 2$ balls that move because of a single deletion, and track their movement until each of the k balls become isolated from the other $k-1$ balls, then with high probability, they do not inflict a lot of recourse (concretely, $O(k \log k)$ recourse). Therefore, we can basically replace each deletion by paying this "cost", and throw the balls independently. This is formulated using the following toy problem and an inductive argument. In the toy problem, there are $2 \leq k \leq O(\frac{\log n}{\log \log n})$ balls, initially located at the same bin. In each round, the adversary deletes a bin that contains at least 2 balls, and the balls are split evenly to two sets that are thrown independently. The game ends when the adversary cannot delete bins. In Section 4.1, we show that with high probability, the recourse in the toy problem is $O(k \log k)$, and complete the proof using an inductive argument.

2-split, maximum load

To show that after $\frac{n}{2}$ rounds the maximum load is $\text{poly}(\log n)$, we consider the following exponential potential function. For a load vector $(L_1, \ldots, L_n)$ and a set $I \subseteq [n]$ denoting the set of surviving bins, the potential is

$$w = \sum_{i \in I} e^{\alpha L_i},$$

where $\alpha = \frac{1}{\log n}$. By tracking w, we obtain that there exists a constant $C > 1$, such that with probability at least $1/2$, when the maximum load increases by a $\log n$ factor, at least n/C rounds passed. We repeatedly apply such an argument, and obtain that every time the maximum load increases by a $\log n$ factor, with probability $1/2$, at least n/C rounds passed. The $\text{poly}(\log n)$ bound on the maximum load after $n/2$ rounds then follows by standard arguments.

2 Preliminaries

Our proofs use the following concentration bounds.

▶ **Lemma 2.1** (Hoeffding's inequality). *Let $X_1, \ldots, X_n$ be independent random variables, such that $0 \le X_i \le C$ for all i. Then,*

$$\Pr\Big(\Big|\sum_{i=1}^{n} X_i - \sum_{i=1}^{n} \mathbb{E}X_i\Big| > t\Big) \le 2\exp\Big(-\frac{2t^2}{nC^2}\Big).$$

▶ **Lemma 2.2** (Bernstein's inequality). *Let $X_1, \ldots, X_n$ be independent random variables, such that $0 \le X_i \le C$ for all i. Denote $S = \sum_{i=1}^{n} X_i$ and $V = \mathrm{var}(S)$. Then,*

$$\Pr(|S - \mathbb{E}S| > t) \le 2\exp\Big(-\frac{t^2/2}{V + Ct/3}\Big).$$

3 Uniform and two choices allocations

Recall that we consider a 2-player game between an adaptive adversary and an algorithm. Initially, there are n balls independently distributed uniformly at random over n bins. The adversary sees the assignment of balls into bins, and picks a bin to delete. The algorithm must distribute the balls from the deleted bin among the remaining bins. This game continues in this manner for T rounds. The algorithm has two objectives: to minimize the number of balls that it distributes, called recourse, and to minimize the maximum load. We first consider the algorithm that independently distributes the balls from the deleted bin uniformly at random among the remaining bins (for brevity, we simply say the balls are thrown to the remaining bins), which we call the uniform game. Previously, [16] considered this game for $T = n - 1$, i.e., the game continues until only one bin remains. They showed that the recourse is $O(n \log n)$, which is the best possible for any algorithm. We consider this game for intermediate number of rounds, and show the following.

▶ **Theorem 3.1.** *Let $T \in [n-1]$, and denote $\ell = \lceil \log \frac{n}{n-T} \rceil$. In T rounds of the uniform game, with high probability, the recourse is $O(\ell \cdot n)$ and the maximum load is*

$$\begin{cases} O(\log n \log \frac{\log \log n}{\log \log n - \ell}) & \text{if } \ell < \log \log n \text{ (corresponding to the lightly-loaded case),} \\ O(2^\ell + \log n \log \log \log n) & \text{if } \ell \ge \log \log n, \text{ (corresponding to the heavily-loaded case).} \end{cases}$$

▶ Remark 3.2. Put differently, the maximum load is

$$\begin{cases} O(\frac{\ell \log n}{\log \log n}) & \text{if } \ell \le \frac{1}{2} \log \log n, \\ O(\log n \log \frac{\log \log n}{\log \log n - \ell}) & \text{if } \frac{1}{2} \log \log n < \ell < \log \log n, \\ O(\log n \log \log \log n) & \text{if } \log \log n \le \ell < \log \log n + \log \log \log \log n, \\ O(2^\ell) & \text{if } \ell \ge \log \log n + \log \log \log \log n. \end{cases}$$

That is, for small ℓ it interpolates from the standard bound $O(\frac{\log n}{\log \log n})$ of the lightly-loaded case to $O(\log n \log \log \log n)$, and for large $\ell \ge \log \log n + \log \log \log \log n$, the maximum load is the same order as the average load. Recall that when throwing $m' = n$ balls into $n' = n/2^\ell$ bins uniformly at random, by [27], the maximum load is

$$\begin{cases} O\Big(\frac{\log n}{\log \frac{\log n}{2^\ell}}\Big) & \text{if } \ell < \log \log n \text{ (light load),} \\ 2^\ell + O(\sqrt{2^\ell \log n}) & \text{if } \ell \ge \log \log n \text{ (heavy load),} \end{cases}$$

hence our bound for the maximum load is nearly tight, for all regimes.

The recourse bound is the best possible, for any algorithm, as explained below, and matches the bound of [16] for $T = n - 1$.

The proof of Theorem 3.1 considers ℓ phases. The j-th phase, where $j \in [\ell]$, is all rounds numbered in $[n - \frac{n}{2^{j-1}} + 1, n - \frac{n}{2^j}]$, i.e., the first phase is the first $n/2$ rounds, the second phase is the next $n/4$ rounds, etc. Phase j consists of exactly $n/2^j$ rounds and begins with $n/2^{j-1}$ alive bins. Consider the balls that are moved in the j-th phase, and denote by X_j their recourse, and by A_j the maximum load they incur. Clearly, the total recourse is $X = \sum_{j=1}^{\ell} X_j$, and the maximum load is $A \leq \sum_{j=1}^{\ell} A_j$. We show that with high probability, for all $j \in [\ell]$,

- $X_j = O(n)$, and
- $A_j = \begin{cases} O\left(\frac{\log n}{\log \frac{\log n}{2^j}}\right) & \text{if } j < \log\log n \text{ (light load)}, \\ O(2^j) & \text{if } j \geq \log\log n \text{ (heavy load)}. \end{cases}$

The recourse bound is the best possible, since the average load in the j-th phase is $\Theta(2^j)$, and there are $\frac{n}{2^j}$ rounds. The maximum load matches that of throwing $O(n)$ balls to $\frac{n}{2^j}$ bins, and thus is the best possible. The proof follows by summation over the ℓ phases, which might be slightly sub-optimal for bounding the maximum load when $\omega(1) \leq \ell \leq \log\log n + \log\log\log\log n$.

The proof uses the following two lemmas. The first reduces (via coupling) each phase j to the following non-adaptive game, and the second bounds the recourse and maximum load in this non-adaptive game. In the j-th non-adaptive game, balls are thrown one at a time to $n/2^{j-1}$ bins until every subset of $n/2^j$ bins contains at least n balls. We denote by Y_j the number of inserted balls, and by B_j the maximum load (which are random variables).

▶ **Lemma 3.3.** *Let $j \in [\log n]$. Fix an adaptive adversary, and denote its recourse in the j-th phase by X_j and the load incurred in the j-th phase by A_j. Then, $Y_j \succeq X_j$ and $B_j \succeq A_j$, where Y_j and B_j are the number of inserted balls and the maximum load in the j-th non-adaptive game defined above.*

Proof. We begin by analyzing the recourse. We construct a coupling between Y_j and X_j by simulating the non-adaptive game during the $n/2^j$ rounds of the adaptive game. Abusing notation slightly, we continue to use X_j and Y_j to denote these random variables within the coupled setting.

For the non-adaptive game, let L_i^{na} denote the load of the i-th bin for $i \in [n/2^{j-1}]$. In the adaptive game, denote by $\texttt{Alive}_j \subseteq [n]$ the set of living bins right before the j-th phase starts. In particular, $|\texttt{Alive}_j| = n/2^{j-1}$, and therefore there is a one-to-one mapping between $\texttt{Alive}_j$ and $[n/2^{j-1}]$. For simplicity of presentation, we omit this mapping and simply treat every $i \in \texttt{Alive}_j$ as a number in $[n/2^{j-1}]$. Let $\texttt{Alive} \subseteq \texttt{Alive}_j$ denote the set of living bins during phase j; for each $i \in \texttt{Alive}$, let L_i^a be the load of the i-th bin incurred by balls that move in the j-th phase. We maintain the following invariant:

- **Invariant.** For every $i \in \texttt{Alive}$, we have $L_i^{na} = L_i^a$.

Initially, in the non-adaptive game there are no balls. No balls moved yet in the adaptive game. Clearly, the invariant holds.

Now, consider a round of the adaptive game. The adaptive adversary picks a bin to delete, say containing b balls. Suppose these b balls are thrown one at a time in the adaptive game, and let us simulate throwing one ball using the non-adaptive game. In the non-adaptive game, we throw a ball uniformly over all the $n/2^{j-1}$ bins. If the ball is inserted to a bin in $[n/2^{j-1}] \setminus \texttt{Alive}$, i.e., bin that was deleted in the adaptive game, we repeatedly throw another new ball to the $n/2^{j-1}$ bins, until we get a ball in some bin $i \in \texttt{Alive}$. Therefore,

for all $i' \in \texttt{Alive}, i' \neq i$, we have that $L^{na}_{i'}$ is unchanged, and $L^{na}_i \leftarrow L^{na}_i + 1$. We copy that last ball to the adaptive game, i.e., we only update $L^a_i \leftarrow L^a_i + 1$, and so the invariant holds. This process is repeated for all the b balls, and then we proceed to the next round of the adaptive game.

Crucially, we claim that the above is a simulation of the adaptive game, and it may end only after the adaptive adversary deletes $n/2^j$ bins. In the non-adaptive game, the distribution of a thrown ball, given that it lands in $\texttt{Alive}$, is uniform over $\texttt{Alive}$. Thus, the above indeed simulates the adaptive game.

Observe that right before the adaptive adversary deletes the $\frac{n}{2^j}$-th bin, we have that $|\texttt{Alive}| = \frac{n}{2^j} + 1$. Since $\sum_{i \in \texttt{Alive}} L^a_i \leq n$, there must exists a subset of $\texttt{Alive}$ of size $\frac{n}{2^j}$, whose bins in the adaptive game contain strictly less than n balls. Therefore, by the invariant, also in the non-adaptive game, there is a subset of $\frac{n}{2^j}$ bins containing strictly less than n balls, and thus the non-adaptive game didn't end. Hence, the number Y_j of balls in the non-adaptive game is at least the recourse X_j of the adaptive game in the j-th phase, i.e., $Y_j \geq X_j$.

Over the same probability space, we immediately obtain a similar result for the maximum load. The maximum load B_j in the non-adaptive game is larger than the maximum load in $\texttt{Alive}$, which by the invariant, equals the maximum load incurred by balls that move in the j-th phase of the adaptive game, and thus $B_j \geq A_j$. The proof is concluded by Lemma 1.7. ◀

▶ **Lemma 3.4.** *Consider the j-th non-adaptive game and let Y_j be the number of balls it throws. Then, $Y_j \leq 10n$ with probability at least $1 - e^{-2n}$.*

Proof. Consider the classical balls into bins problem with $10n$ balls, and each ball is thrown uniformly to $n/2^{j-1}$ bins. We show that with high probability, all subsets of $n/2^j$ bins contain at least n balls, and the claim follows.

Let $S \subset [n/2^{j-1}]$ be a subset of size $|S| = \frac{n}{2^j}$. For every $i \in [10n]$, denote by I_i an indicator that the i-th ball is in S. Thus, the number of balls in S equals $\sum_{i=1}^{10n} I_i$. Clearly, $I_i = 1$ w.p. $\frac{1}{2}$ and 0 otherwise, and all these indicators are independent. Thus, by Hoeffding's inequality,

$$\Pr\Big(\sum_{i=1}^{10n} I_i < n\Big) \leq \Pr\Big(|\sum_{i=1}^{10n} I_i - 5n| > 4n\Big) \leq 2\exp\Big(-\frac{2(4n)^2}{10n}\Big) \leq 2\exp(-3n).$$

By a union bound, the probability that there exists a set $S \subset [n]$ of size $|S| = \frac{n}{2^j}$ containing less than n balls is at most

$$\binom{n/2^{j-1}}{n/2^j} \cdot 2\exp(-3n) \leq 2^n \cdot 2\exp(-3n) \leq \exp(-2n),$$

which concludes the proof of the lemma. ◀

Proof of Theorem 3.1. By combining Lemma 3.3 and Lemma 3.4, we have that for each $j \in [\ell]$, with probability at least $1 - e^{-2n}$, the recourse is at most $10n$. By a union bound, with probability at least $1 - e^{-n}$, the total recourse is $O(\ell n)$. In standard balls and bins with $10n$ balls and $n/2^{j-1}$ bins, with probability $1 - \frac{1}{n^{11}}$, the maximum load is [27]

$$\begin{cases} O\Big(\frac{\log n}{\log \frac{\log n}{2^j}}\Big) & \text{if } j < \log\log n, \\ O(2^j) & \text{if } j \geq \log\log n. \end{cases}$$

Thus, by a union bound, with probability $1-n^{-10}$, the maximum load B_j in the non-adaptive game is bounded by that as well. Observe that

$$\sum_{j=1}^{\ell} \frac{1}{\log \frac{\log n}{2^j}} = \sum_{x=\log\log n-\ell}^{\log\log n-1} \frac{1}{x} \leq \int_{\log\log n-\ell-1}^{\log\log n} \frac{dx}{x} = O(\log \frac{\log\log n}{\log\log n-\ell}).$$

When $\ell \leq \frac{1}{2}\log\log n$, we have that $\log \frac{\log\log n}{\log\log n-\ell} = \log(1+\frac{\ell}{\log\log n-\ell}) = O(\frac{\ell}{\log\log n})$. Thus, with probability $1-n^{-10}$, the maximum load in the adaptive game is

$$\leq \sum_{j=1}^{\ell} A_j \leq \sum_{j=1}^{\ell} B_j$$

$$\leq \begin{cases} O(\log n \log \frac{\log\log n}{\log\log n-\ell}) & \text{if } \ell < \log\log n, \\ O(2^\ell + \log n \log\log\log n) & \text{if } \ell \geq \log\log n, \end{cases}$$

$$= \begin{cases} O(\frac{\ell \log n}{\log\log n}) & \text{if } \ell \leq \frac{1}{2}\log\log n, \\ O(\log n \log \frac{\log\log n}{\log\log n-\ell}) & \text{if } \frac{1}{2}\log\log n < \ell < \log\log n, \\ O(\log n \log\log\log n) & \text{if } \log\log n \leq \ell < \log\log n + \log\log\log\log n, \\ O(2^\ell) & \text{if } \ell \geq \log\log n + \log\log\log\log n, \end{cases}$$

and the proof follows. ◀

3.1 Two choices

Consider the following adaptation of the game above: whenever a ball is thrown, we pick two independent bins b_1, b_2, and place the ball at the least loaded of b_1, b_2. This is applied both to the initial configuration, and to balls thrown during the game. This is based on the well-known power of two choices, which in standard (non-adaptive) balls and bins setting, yields a maximum load of $O(\log\log n)$ when $m = O(n)$ [3, 11, 12]. We show the following.

▶ **Theorem 3.5.** *Let $T \in [n-1]$ and denote $\ell = \lceil \log \frac{n}{n-T} \rceil$. In T rounds of adaptive two choices game, the recourse is $O(\ell n)$ and the maximum load is $O(2^\ell + \ell \log\log n)$, with high probability.*

The proof is similar to that of Theorem 3.1. We reduce the problem (via coupling) to a non-adaptive game, and then bound the parameters of this non-adaptive game. The non-adaptive game is similar, only now we consider pairs of indices. For simplicity, consider $n/2$ rounds (i.e., $\ell = 1$). In this new non-adaptive game, iteratively pick two indices independently and uniformly at random over $[n]$, place a ball in the least loaded of them, and stop when every subset of size $n/2$ contains at least n pairs. Denote by Y the number of inserted balls, and by B the maximum load (which are random variables). We show in Appendix A that Lemma 3.3 still holds in this setting, using the same coupling, and the number of rounds here is still $O(n)$ with high probability. Thus, with high probability, the recourse is $O(n)$. To bound the maximum load, recall that when throwing m balls into n bins using two choices allocations, if $m \geq n$, the maximum load is at most $\frac{m}{n} + O(\log\log n)$ with high probability [3, 11]. In our case, $m = 10n$, thus the maximum load is $O(\log\log n)$, yielding Theorem 3.5. A proof is provided in Appendix A.

4 d-split problem, $d = 2$

We now consider the 2-split problem, played for $n/2$ steps. That is, when a bin is deleted, the balls inside are partitioned into two uniformly random (remaining) bins. We show that in $\frac{n}{2}$ rounds, the recourse is $O(n)$ with high probability, and the maximum load is $\text{poly}(\log n)$ with constant probability. While the constant 2 in the number of rounds is arbitrary, bounding the recourse and maximum load when the number of rounds approaches n remains open.

4.1 Bounding the recourse

▶ **Theorem 4.1.** *In $\frac{n}{2}$ rounds of the 2-split game, the recourse is $O(n)$ with probability $1-\frac{1}{n^7}$.*

As we mentioned in the introduction, our proof uses an adaptive balls into bins game, denoted π_{pay}, where there is an extra $O(k \log k)$ cost for moving $k \geq 2$ balls from a bin with k balls, and the balls are thrown independently uniformly at random.

▶ **Lemma 4.2.** *In $n/2$ rounds of π_{pay}, the total cost is $O(n)$ with probability $1-\frac{1}{n^8}$.*

▶ **Lemma 4.3.** *The total cost in $n/2$ rounds of π_{pay} stochastically dominates a RV that is at total variation distance at most $\frac{1}{n^8}$ from the recourse in $n/2$ rounds of the 2-split game.*

Theorem 4.1 follows from these two lemmas and a union bound. We first prove Lemma 4.3. The proof of Lemma 4.2 is provided in Section 4.1.3.

4.1.1 Proof of Lemma 4.3

Recall that our proof uses a toy problem, as follows. There are $k \geq 2$ balls, initially located at the same bin. In rounds, the adversary deletes a bin that contains at least 2 balls, and the balls are split evenly to two sets that are thrown independently. The game ends when the adversary cannot delete bins, that is, every bin has at most one ball.

▶ **Lemma 4.4.** *If $k = O(\log n)$, then with probability $1-\frac{1}{n^{10}}$, the recourse in the toy problem is $O(k \log k)$.*

The proof of Lemma 4.4 is given in Section 4.1.2. We now prove Lemma 4.3 using Lemma 4.4.

Proof of Lemma 4.3. To connect 2-split to π_{pay}, both played for $n/2$ rounds, we consider a sequence of hybrid games, $\pi_0, \pi_1, \ldots, \pi_{n/2}$, where:

(1) Game π_0 is exactly the 2-split game.

(2) For every $t \in [n/2]$, with high probability, it holds that the cost of π_t is at least the cost of π_{t-1}.

(3) The cost of π_{pay} stochastically dominates the cost of $\pi_{n/2}$.

Recall that in the game π_{pay}, whenever a bin with k balls is deleted we incur an extra cost of $O(k \log k)$, and the balls are thrown independently uniformly at random. The sequence of hybrid games we consider $(\pi_0, \pi_1, \ldots, \pi_{n/2})$ gradually interpolate between the 2-split game and this π_{pay} game. Intuitively, but somewhat inaccurately, in the game π_t, the first t deletions behave like in π_{pay} (balls are thrown independently and our recourse has a logarithmic blowup), and the rest of the $\frac{n}{2}-t$ deletions behave like in the 2-split game (balls are partitioned into two groups). We now make this formal, starting with the formalization of the game π_1.

The game π_1. The game π_1 is identical to the 2-split game, with one key modification regarding the balls from the *first* bin that is deleted. Suppose that the first deletion is of a bin with k balls. We pay an extra cost of $O(k \log k)$ and redistribute the k balls *independently and uniformly at random*. From now on, these k balls are special; we call these k balls "Teflon" and treat them differently throughout the rest of the game π_1. Unlike normal balls, Teflon balls do not "stick". That is, throughout the rest of the game π_1, when a bin is deleted, if this bin contains Teflon balls, then these Teflon balls are thrown independently and uniformly at random into the remaining bins. Note that "normal" balls from the deleted bin are still split into two sets and thrown as groups. Teflon balls may eventually revert to being "normal" balls based on coupling conditions we describe next between the executions of π_1 and the 2-split game.

The coupling between 2-split and π_1. Fix an adversary $\mathcal{A}$ for playing in the 2-split game (i.e., in π_0). We consider a coupled execution of 2-split and π_1 defined as follows. The initial configuration is identical in both games, obtained by throwing n balls uniformly into the n bins. The bin deletion sequence is kept identical in both games, and is determined by $\mathcal{A}$ based on the configuration of the balls in the 2-split game ($\mathcal{A}$ does not see the configuration of the balls in π_1). The first deletion made by $\mathcal{A}$ defines the identity of the Teflon balls in π_1. We stress that in the 2-split game, Teflon balls behave as any other ball. To emphasize this, whenever we refer to these balls in the 2-split game we will call them the "so-called Teflon balls". Throughout the execution, whenever a bin is deleted, we redistribute its balls as follows in each of the games:

- In both games, normal balls are split evenly and thrown to the same randomly chosen bin index.
- In π_1, Teflon balls are thrown uniformly and independently.
- In the 2-split game, Teflon balls from the deleted bin are split evenly to two sets and attached to the two sets of the normal balls. The first time when the bin of so-called Teflon-ball b is deleted in the 2-split game, and b is assigned to a set that includes no other so-called Teflon-balls, we declare b as normal (not Teflon anymore in both games), and throw its set to the bin of the same index as the bin containing b in π_1. That is, the randomness used to pick the identity of the new bin is taken from π_1. Since b was previously thrown independently in π_1, then from the viewpoint of the 2-split game, the thrown set is distributed independently, as desired.

Let X denote the total recourse that $\mathcal{A}$ achieves in $n/2$ rounds of the 2-split game, and let Y_1 denote the incurred cost in the coupled execution of π_1. We show that with high probability, $Y_1 \geq X$.

▷ Claim 4.5. With probability $1 - \frac{1}{n^9}$, $Y_1 \geq X$.

Proof. By the invariant, the recourse of the normal balls is the same. We ignore the contribution to Y_1 from the additional recourse the Teflon-balls incur in π_1. Thus, we only have to bound the recourse of the so-called Teflon balls in the 2-split game until they become normal, and compare it to the extra $O(k \log k)$ cost paid in π_1 at the first round. By standard arguments, with probability $1 - \frac{1}{n^{10}}$, the maximum load in the initial distribution of n balls into n bins is $O(\log n)$, and thus $k \leq O(\log n)$. Observe that in the special case where $k = 1$, the two games are identical, hence we consider $k \geq 2$. The recourse of the so-called Teflon-balls in the 2-split game is stochastically dominated by the recourse in the toy problem, which by Lemma 4.4 is $O(k \log k)$ with probability $1 - \frac{1}{n^{10}}$. By a union bound, we have $Y_1 \geq X$ with probability $1 - \frac{2}{n^{10}}$, which concludes the proof. ◁

The sequence of coupled games. We now inductively define the sequence of coupled games $\pi_2, \ldots, \pi_{n/2}$, where each game π_i introduces an additional set of Teflon balls, denoted T_i (where T_1 is the set of Teflon balls w.r.t. π_1 and where $T_0 = \emptyset$). For $t \geq 2$, we define the game π_t, and couple it with π_{t-1}, similar to the construction above. The two games π_{t-1} and π_t are played the same for $t-1$ rounds. In round t, we define T_t to be the set of all balls from the deleted bin that are not in $\cup_{i=1}^{t-1} T_i$. That is, T_t contains all normal balls (w.r.t. π_{t-1}) that are deleted in round t. Now, from round t onward:

- In π_{t-1}, balls that are not in $\cup_{i=1}^{t-1} T_i$ (aka normal w.r.t. π_{t-1}) are played as in 2-split, and balls in $\cup_{i=1}^{t-1} T_i$ (aka Teflon) are played as independent. Some Teflon-balls may become normal, depending on the coupling with π_i, for $i \leq t-2$.
- The only difference between π_{t-1} and π_t is about the balls in T_t, where in π_t these are played as Teflon-balls, and have extra cost $O(|T_t| \log |T_t|)$.
- In π_{t-1}, whenever a bin containing T_t-balls is deleted, we split the T_t-balls in that bin between the two sets. When a T_t-ball b is assigned to a set that contains no other T_t-ball in π_{t-1}, we throw its set to the bin of the same index as the bin containing b in π_t, and remove b from T_t. As before, from the viewpoint of π_{t-1}, this assignment is independent.

▷ Claim 4.6. Let $t \in [n/2]$. With probability $1 - \frac{1}{n^9}$, $Y_t \geq Y_{t-1}$.

Proof. This is a generalization of Claim 4.5, and the proof is similar. The only difference between Y_{t-1} and Y_t is in the cost and recourse caused by the Teflon balls T_t. We ignore the contribution to Y_t from the additional recourse the Teflon balls in T_t incur in π_t. Thus, we only compare the recourse of the balls in T_t in π_{t-1} until they become normal, with the cost $O(|T_t| \log |T_t|)$ paid in π_t.

First, observe that with probability $1 - \frac{1}{n^{10}}$, we have $|T_t| \leq O(\log n)$, by the following. For every $i \leq t-1$, the balls in a deleted bin in π_{t-1} are distributed independently. Therefore, the maximum load before round t, and hence $|T_t|$, is stochastically dominated by the maximum load in uniform adaptive balls into bins played for $n/2$ rounds. Hence, by Theorem 3.1, $|T_t| \leq O(\log n)$ with probability $1 - \frac{1}{n^{10}}$.

The recourse in π_{t-1} of the T_t-balls until they become normal, is stochastically dominated by the toy problem, with $k = |T_t|$. By Lemma 4.4 and a union bound, with probability $1 - \frac{1}{n^9}$, the recourse in π_{t-1} of the T_t-balls until they become normal is at most $O(|T_t| \log |T_t|)$. Under this same event, we have $Y_t \geq Y_{t-1}$, concluding the proof of the claim. ◁

To conclude the proof of Lemma 4.3, observe that the cost of π_{pay} stochastically dominates the cost of $\pi_{n/2}$, since the payments are only larger. (Because in $\pi_{n/2}$ we do not necessarily incur the logarithmic blowup in the cost on all the balls from a deleted bin.) By a union bound, we have that with probability $1 - \frac{1}{n^8}$, the sequence Y_t is non-decreasing, and thus the cost of π_{pay} is at least that of 2-split. ◀

4.1.2 Proof of Lemma 4.4, bounding the recourse in the toy problem

Proof of Lemma 4.4. Recall that in the toy problem, the initial configuration is that we have $2 \leq k \leq O(\log n)$ balls in one bin, and the other bins are empty. Then, in rounds, the adversary deletes a bin containing at least 2 balls, and the balls are split evenly to two sets that are thrown independently. The game ends when all bins contain at most 1 ball.

Towards analyzing the recourse, let us consider a modified variant of this toy problem, which we call π', where the adversary has the additional power to determine the initial configuration for the k balls. Furthermore, whenever a collision happens (i.e., whenever we throw a ball into a non-empty bin), the adversary can override the current configuration

and completely rearrange the k balls in the living bins. Clearly, the cost in π' stochastically dominates the recourse in the toy problem, so it suffices to bound the cost in π'. To this end, we express π' as a sequence of "mini-games" defined as follows:

Mini-game

In a mini-game, the adversary initially picks a configuration for the k balls in the living bins. Then, in every round, the adversary deletes a bin that contains at least 2 balls, and the balls are split evenly to two sets that are thrown independently. Now, if one of these sets is thrown to a non-empty bin (i.e., there is a collision), we conclude the current mini-game and start a new one. Otherwise, we play until all bins contain at most 1 ball, at which point we conclude the current mini-game without starting a new one (this corresponds to the end of π').

It is easy to see that a mini-game takes at most $O(k)$ rounds, and the actual recourse in a mini-game is bounded by $O(k \log k)$. Thus, to bound the total cost in π', it suffices to show that the number of mini-games is small with high probability. That is, we want to show that the probability that a mini-game ends (i.e., there is a collision) without π' ending is small.

Recall we have at least $n/2$ bins. Consider a round in a mini-game where the k balls are located in i bins. The adversary now deletes one of these bins, and the probability that one of the two sets we throw collide with a non-empty bin is at most $\frac{2i}{n/2} = O(\frac{k}{n})$. As there are at most $O(k)$ rounds in the mini-game, no matter what is the distribution that the adversary picked at the start of the mini-game, the probability of a collision is at most $O(\frac{k^2}{n})$.

The total cost in π' is the number of mini-games with a collision, times the cost $O(k \log k)$ of a mini-game. The number of mini-games is stochastically dominated by a geometric random variable, with success when there are no collisions, i.e., it has parameter $p = 1 - O(\frac{k^2}{n})$. Thus, the probability that there are more than 20 mini-games is at most $O(\frac{k^2}{n})^{20} \leq O(n^{-10})$. When this event does not happen, the total cost in π' is $O(k \log k)$. This concludes the proof. ◀

4.1.3 Proof of Lemma 4.2

Recall that in π_{pay}, the cost of deleting a bin with k balls is $k + O(k \log k)$, and the balls are thrown independently. Lemma 4.2 states that the cost of $n/2$ rounds of π_{pay} is $O(n)$ with high probability.

Proof of Lemma 4.2. The proof uses the same probability space as in the proof of Theorem 3.1. We consider a non-adaptive game, where balls are thrown into n bins until every subset of $n/2$ bins contains at least n balls. By the coupling in the proof of Theorem 3.1, we have a matching between deleted bin i in the adaptive game and bin i in the non-adaptive game, such that $L_i^{na} \geq L_i^a$, i.e., the load in the non-adaptive game is at least as in the adaptive game. Consider the $n/2$ heaviest loaded bins in the non-adaptive game, with loads $k_1, \ldots, k_{n/2}$. Take as cost $O\big(\sum_{i=1}^{n/2} k_i(1 + \log k_i)\big)$. By the coupling, this sum stochastically dominates the cost in π_{pay}. By Lemma 3.4, with high probability, the number of thrown balls in the non-adaptive game is at most $10n$. We now bound $\sum_{i=1}^{n/2} k_i \log k_i$ after throwing $10n$ balls, using the following.

▶ **Lemma 4.7.** *Consider standard balls into bins, with $10n$ balls and n bins. Denote the loads of the bins by $L_1, L_2, \ldots, L_n$. With high probability, $\sum_{i=1}^{n} L_i \log L_i = O(n)$.*

We defer the proof of Lemma 4.7 to Appendix B. By a union bound, after throwing $10n$ balls, the game ends and the cost is $O(n)$, which concludes the proof of Lemma 4.2. ◀

4.2 Bounding the maximum load

▶ **Theorem 4.8.** *The maximum load in the 2-split problem is* $\mathrm{poly}(\log n)$ *with constant probability. Moreover, for success probability* $1-\delta$*, the maximum load is at most* $\log^{O(\log \frac{1}{\delta})} n$*.*

Our proof uses the following lemma.

▶ **Lemma 4.9.** *Consider any assignment of* n *balls to* $m \in [n/2, n]$ *bins, with maximum load* L*. There is a constant* $C > 1$*, such that with probability* $1/2$*, the number of rounds of 2-split until the maximum load reaches* $O(L \cdot \log n)$ *is at least* $\min\{\frac{n}{C}, m - \frac{n}{2}\}$*.*

The proof of Lemma 4.9 uses the following simple claim.

▷ Claim 4.10. Let $w, n > 0$. For every $x \geq 0$, we have $(w - x^2)(1 + \frac{4x}{n}) \leq w(1 + \frac{4w}{n^2})$.

Proof. The difference satisfies

$$\begin{aligned} &w(1 + \tfrac{4w}{n^2}) - (w - x^2)(1 + \tfrac{4x}{n}) \\ &= w + \tfrac{4w^2}{n^2} - w - \tfrac{4wx}{n} + x^2 + \tfrac{4x^3}{n} \\ &= \tfrac{4w^2}{n^2} - \tfrac{4wx}{n} + x^2 + \tfrac{4x^3}{n} \\ &= (\tfrac{2w}{n} - x)^2 + \tfrac{4x^3}{n} \geq 0. \end{aligned}$$

◁

Proof of Lemma 4.9. Pick $\alpha = 1/L$. Denote the set of surviving bins at time $t \in [0, m - \frac{n}{2}]$ by $I_t \subseteq [m]$, and for every $i \in I_t$, denote the load of the i-th bin as L_i^t. When clear from context, we simply write L_i. Consider the potential function

$$w_t = \sum_{i \in I_t} e^{\alpha L_i}.$$

Initially, we have

$$w_0 = \sum_{i \in I_0} e^{\alpha L_i} \leq en.$$

Without loss of generality we may suppose that the adversary is deterministic. That is, in every step, given the current constellation H, the adversary deterministically chooses the next bin to eliminate (denoted as r). The only randomness is in picking the indices of the 2 bins to which we split r, denoted as x and y. For simplicity, we assume the algorithm enforces $x \neq y$. So going from time $t \leq m - \frac{n}{2}$ to time $t+1$, we have that w_t changes to w_{t+1} as follows:

$$\begin{aligned} w_{t+1} &= w_t - e^{\alpha L_r} + e^{\alpha L_x}\left(e^{\alpha \lceil L_r/2 \rceil} - 1\right) + e^{\alpha L_y}\left(e^{\alpha \lfloor L_r/2 \rfloor} - 1\right) \\ &\leq w_t - e^{\alpha L_r} + \left(2e^{\alpha L_r/2} - 1\right)\left[e^{\alpha L_x} + e^{\alpha L_y}\right]. \end{aligned}$$

We want to compute the expectation of this given the history H of the game until time t. The expectation is only over the choice of x, y.

$$\begin{aligned}
\mathbb{E}[w_{t+1}|H] &\leq w_t - e^{\alpha L_r} + \left(2e^{\alpha L_r/2} - 1\right) 2\mathbb{E}[e^{\alpha L_x}] \\
&\leq w_t - e^{\alpha L_r} + \left(2e^{\alpha L_r/2} - 1\right) 2 \sum_{i \in I_{t+1}} \tfrac{1}{|I_{t+1}|} e^{\alpha L_i} \\
&\underset{|I_{t+1}| \geq n/2}{\leq} w_t - e^{\alpha L_r} + \frac{2e^{\alpha L_r/2} - 1}{n/4} \left[w_t - e^{\alpha L_r}\right] \\
&= \left[w_t - e^{\alpha L_r}\right] \left(1 + \frac{2e^{\alpha L_r/2} - 1}{n/4}\right) \\
&\leq \left[w_t - e^{\alpha L_r}\right] \left(1 + \frac{2e^{\alpha L_r/2}}{n/4}\right) \\
&\leq w_t \left(1 + \frac{16 w_t}{n^2}\right),
\end{aligned}$$

The last inequality holds by Claim 4.10.

Let C be some large constant and consider the alternative random variables with an appropriate random stopping time τ defined as follows:

$$\tau = \max\{t : w_t \leq Cn\}, \qquad \text{and} \qquad \hat{w}_t = w_{t \wedge \tau},$$

where $t \wedge \tau = \min\{t, \tau\}$. Therefore,

$$\mathbb{E}[\hat{w}_{t+1}|H] \leq \hat{w}_t(1 + \tfrac{16\hat{w}_t}{n^2}) \leq \hat{w}_t(1 + \tfrac{16C}{n}),$$

and so, by the law of total expectation and since $w_0 \leq en$,

$$E[\hat{w}_{n/C}] \leq en \cdot \left(1 + \frac{16C}{n}\right)^{n/C} \leq en \cdot e^{16}.$$

By Markov's inequality,

$$\Pr[\hat{w}_{n/C} > 2e^{17} n] \leq \frac{1}{2}.$$

Set $C > 2e^{17}$. Thus, with probability at least $1/2$ we have that $\hat{w}_{n/C} \leq Cn$ in which case the stopping condition does not happen until step n/C, and so $w_{n/C} = \hat{w}_{n/C} \leq Cn$ and $\tau \geq n/C$. Observe that for every $t \leq \tau$, the maximum load is at most,

$$\tfrac{1}{\alpha} \log w_t \leq L \log(Cn),$$

which concludes the proof of Lemma 4.9. ◀

Before proceeding to the proof of Theorem 4.8, we recall useful probability statements regarding martingales (and particularly submartingales).

▶ **Definition 4.11.** *A sequence $X_1, X_2, \ldots$ of random variables with finite mean, is called submartingale if $\mathbb{E}[X_{i+1}|X_i, \ldots, X_1] \geq X_i$, for all $i \geq 1$; is called supermartingale if $\mathbb{E}[X_{i+1}|X_i, \ldots, X_1] \leq X_i$, for all $i \geq 1$; and is called martingale if it is both submartingale and supermartingale.*

We will use the following (special case of) Azuma's inequality for submartingales.

▶ **Theorem 4.12** (Azuma's inequality for submartingales). *Suppose $X_1, X_2, \ldots$ is a submartingale and $|X_{i+1} - X_i| \le c$. Then, for all $n \in \mathbb{N}$ and $t > 0$,*

$$\Pr(X_n - X_1 \le -t) \le \exp\Big(-\frac{t^2}{2nc^2}\Big).$$

Proof of Theorem 4.8. By standard arguments, the initial maximum load is $\le \log n$ with high probability (say $\ge 1 - n^{-10}$ for concreteness). Assume henceforth that this event holds. Denote by τ_i the number of rounds until the maximum load reaches $\log n \cdot \log^i Cn = O(\log^{i+1} n)$ where C is a constant satisfying the requirements of Lemma 4.9. It follows that $\tau_0 = 0$. Define the index $t^* = \max_{\tau_i \le n/2} i$, i.e., the index of the last τ_i before the $\frac{n}{2}$-th round of the game. Given the constellation at time τ_i, for $i \le t^*$, by Lemma 4.9, $\tau_i - \tau_{i-1} \ge n/C$ w.p. at least $1/2$. Denote by I_i the indicator that $\tau_i - \tau_{i-1} \ge n/C$, and $S_t = \sum_{i=1}^{t \wedge t^*} I_i - \frac{t}{2}$. We have that

$$\mathbb{E}[S_t \mid S_{t-1}, \ldots, S_1] = \begin{cases} S_{t-1} + \mathbb{E}\left[I_t - \frac{1}{2} \mid S_{t-1}, \ldots, S_1\right], & \text{if } t \le t^* \\ S_{t-1}, & \text{otherwise} \end{cases}$$
$$\ge S_{t-1}.$$

Thus, S_t is a submartingale. By Azuma's inequality,

$$\Pr[S_t \le -\tfrac{t}{4}] \le \exp(-\frac{t}{32}).$$

Assume this event does not hold.

Now, assume by contradiction that $2C < t^*$. We obtain $\sum_{i=1}^{2C} I_i = S_{2C} + \frac{2C}{2} \ge \frac{2C}{4} = \frac{C}{2}$. Thus, at least $\frac{C}{2}$ of the indicators $\{I_i\}_{i=1}^{2C}$ are equal 1, and thus $\tau_{2C} \ge \frac{C}{2} \cdot \frac{n}{C} = \frac{n}{2}$. Therefore, $2C \ge t^*$, contradiction. We thus obtained that $t^* \le 2C$. Therefore, the maximum load is $O(\log^{2C+1} n)$ with probability at least $1 - \exp(-\frac{C}{16}) - n^{-10}$. Setting $C = \max\{C' \log(1/\delta), 2e^5\}$ for an appropriate constant C' concludes the proof. ◀

5 d-split problem, $d = 1$, oblivious adversary

We now consider the d-split problem, with $d = 1$, i.e., all the balls in a deleted bin move to the same new bin; and play the game for $n/2$ steps. With adaptive adversary, this strategy is clearly bad, as the adversary can delete the heaviest bin and create a snowball effect. For example, in the initial configuration where every bin contains exactly one ball, the recourse is $\Omega(n^2)$ and the maximum load is $n/2$ (and similar bounds seem to hold for other initial configurations). Nevertheless, we establish that this strategy is solid against oblivious adversaries. Suppose the initial configuration has one ball in each bin. For simplicity of presentation, we call this variant oblivious 1-split.

▶ **Theorem 5.1.** *Consider oblivious 1-split, i.e., where all balls in a deleted bin are thrown together to a single new bin, the adversary is oblivious, and the initial configuration where every bin contains exactly one ball. After $n/2$ steps, the total recourse is $O(n \log n)$ and the max-load is $O(\log n)$, with high probability.*

Recall the intuition behind this result. Consider a random *forest* graph on n vertices constructed as follows: for each step i from 1 to $n/2$, vertex i uniformly samples a parent $j \in \{i+1, \ldots, n\}$ and becomes a child of j. This process yields $n/2$ trees $T_1, \ldots, T_{\frac{n}{2}}$, whose roots are the vertices indexed $n/2 + 1$ through n. As explained right after Theorem 1.5, the maximum load in oblivious 1-split equals the size of the largest tree in this forest, and the recourse equals the sum of depths of all vertices in this forest.

5.1 Bounding the recourse

We first bound the recourse of oblivious 1-split by $O(n \log n)$ with high probability. Recall that Y is a geometric RV with parameter $\frac{1}{2}$ if $\Pr(Y = j) = 2^{-j}$ for every integer $j \geq 1$.

▷ Claim 5.2 (Lemma 5 of [16]). For every $i \leq n/2$, the recourse of the ball that started in the i-th bin is stochastically dominated by a geometric random variable with parameter $\frac{1}{2}$.

Therefore, for each $i \in [n]$, with probability $1 - n^{-10}$, the recourse of the i-th ball is $O(\log n)$. By a union bound, with probability $1 - n^{-9}$, the recourse of the i-th ball is $O(\log n)$ for all $i \in [n/2]$. Thus, the overall recourse is $O(n \log n)$ with probability $1 - n^{-9}$.

5.2 Bounding the max-load

We now show that the size of each of the trees $T_1, \ldots, T_{\frac{n}{2}}$ is stochastically dominated by a Galton-Watson Process (aka branching process), which yields the $O(\log n)$ bound on the maximum tree size.

▶ **Definition 5.3** (Galton-Watson Process). *A stochastic process $\{X_i\}_{i \in \mathbb{N}}$ is called Galton-Watson (GW) if it follows a recurrence formula $X_1 = 1$ and $X_{i+1} = \sum_{j=1}^{X_i} Y_j^i$, where Y_j^i are iid natural numbered RVs. The distribution μ of the Y_j^i is called the offspring distribution. The total progeny of the process is $\sum_{i=1}^{\infty} X_i$.*

Consider a random variable that is a sum of $n/2$ independent Bernoulli random variables, with success probabilities $\frac{1}{n/2}, \frac{1}{n/2+1}, \ldots, \frac{1}{n-1}$, and denote its distribution by μ.

▶ **Lemma 5.4.** *Let T be one of the trees defined above. The size of T is stochastically dominated by the total progeny of a Galton-Watson Process $\{X_i\}_{i \in \mathbb{N}}$ with offspring distribution μ.*

Proof. Without loss of generality, let T be the random tree rooted at $n/2 + 1$, where every node $i \leq n/2$ chooses a parent $parent(i)$ uniformly and independently from $\{i + 1, \ldots, n\}$. We introduce a coupling of the size of T to the total progeny of a GW Process $\{X_i\}_{i \in \mathbb{N}}$ with offspring distribution μ. Observe that a GW process can be defined by a tree T^{GW} s.t. the number of nodes in level i is X_i, and the number of children of the j-th node in level i is Y_j^i. The total progeny of the GW process is the size of T^{GW}.

In our coupling, we enforce $T \subseteq T^{GW}$ by making each node in T produce fewer or equal children than its counterpart in T_{GW} under this coupling. The number of children of the roots of T and T^{GW} are distributed according to μ, so coupling them is trivial (we use the same random coins).

Traverse T from right to left, and denote the subtree we observed so far by T_{now}. That is, initially T_{now} is just the root node $n/2 + 1$. In an inductive manner, suppose T_{now} is a subtree also of T^{GW}. We now add new nodes of T to T_{now}, and match them with nodes of T^{GW}. Denote by i the leaf of T_{now} with the maximum index. Every children u of i is chosen only from available indices (i.e., $u \notin T_{now}$), and must satisfy $u < i$. We denote the set of potential children of i by U_{now}, i.e., $U_{now} = \{u < i : u \notin T_{now}\}$. By construction, the set of potential parents of a node $u \in U_{now}$ equals $[u + 1, i] \cup ([i + 1, n] \setminus T_{now})$, i.e., vertices in $[u + 1, n]$ that are not internal nodes of T_{now} (since i is the leaf of T_{now} with the maximum index). Denote $P = [i, \frac{n}{2}] \setminus T_{now}$.

Given T_{now}, the number of children of i is a sum of $|U_{now}|$ independent Bernoulli random variables with success probabilities

$$\frac{1}{\frac{n}{2} + |P| + i - u}, \qquad u \in U_{now}.$$

Recall that the offspring distribution μ in T^{GW} is defined by a sum of independent Bernoulli's with success probabilities $\frac{1}{\frac{n}{2}+j}$ for $j \in [0, n/2-1]$. Observe that $|P| \leq \frac{n}{2} - i$. Thus, we can match the $|U_{now}|$ Bernoulli variables describing i's children to the corresponding Bernoulli variables in T^{GW} that have identical success probabilities. This forces the number of children of i in T to be stochastically bounded by the number of children of i in T^{GW}. The remaining Bernoulli variables in T^{GW} simply utilize another independent source of randomness. This concludes the inductive step.

We thus obtained a coupling between T and T^{GW}, s.t. $T \subseteq T^{GW}$. Therefore, $|T| \leq |T^{GW}|$, concluding the proof. ◀

We now bound the size of T^{GW} (or equivalently, the total progeny of the GW process) using Bernstein's inequality (Lemma 2.2). We first bound the expectation and variance of $Y \sim \mu$.

▶ **Lemma 5.5.** *Let $Y \sim \mu$. The following hold.*

- $\mathbb{E}Y < 0.7$*, and*
- $\operatorname{var} Y < 0.7$.

To prove Lemma 5.5, we use the following claim.

▷ Claim 5.6.

$$\sum_{i=1}^{n/2} \tfrac{1}{n-i} \leq \ln 2 + O(\tfrac{1}{n}).$$

Proof. Denote the n-th harmonic number by $H_n = \sum_{k=1}^{n} \frac{1}{k}$. Using the asymptotic expansion $H_n = \ln n + \gamma + \frac{1}{2n} + O(n^{-2})$ (where γ is the Euler-Mascheroni constant),

$$H_{n-1} - H_{n/2-1} = (\ln n + \gamma) - (\ln(n/2) + \gamma) + O(\tfrac{1}{n}) = \ln 2 + O(\tfrac{1}{n}).$$ ◁

Proof of Lemma 5.5. We have, $\mathbb{E}Y = \sum_{i=1}^{n/2} \frac{1}{n-i}$. By Claim 5.6, $\mathbb{E}Y \leq \ln 2 + O(\frac{1}{n})$. As $\ln 2 \approx 0.693$, this concludes the proof of the first bullet. Denote by I_i a Bernoulli random variable with success probability $\frac{1}{n+i}$, for $i = 1, \ldots, n/2$. We have

$$\operatorname{var} Y = \sum_{i=1}^{n/2} \operatorname{var} I_i \leq \sum_{i=1}^{n/2} \mathbb{E}I_i^2 = \sum_{i=1}^{n/2} \mathbb{E}I_i = \mathbb{E}Y < 0.7,$$

which concludes the proof. ◀

Let us now bound the total progeny of the GW process.

▶ **Lemma 5.7.** *With probability $1 - n^{-10}$, the total progeny of a GW process with offspring distribution μ is $O(\log n)$.*

Proof. Enumerate the nodes of the tree using a search order (e.g., Breadth-First Search). Let ξ_i be the number of children of the i-th node visited. Since nodes reproduce independently, the sequence $\xi_1, \xi_2, \ldots$ consists of i.i.d. random variables distributed according to μ. Let S_k be the number of unexplored nodes after visiting k nodes. We have the following recurrence: Start with one root, $S_0 = 1$, and at each step i, remove the current node and add its children

$$S_i = S_{i-1} - 1 + \xi_i.$$

Thus,

$$S_k = 1 + \sum_{i=1}^{k} (\xi_i - 1).$$

The process stops when there are no nodes to explore ($S_k = 0$). The total progeny Z is exactly the smallest index k such that $S_k = 0$. Therefore, the event that the tree size is large ($Z \geq k$) implies that $S_i \geq 1$ for all $0 \leq i \leq k$. A loose but sufficient condition for $Z \geq k$ is that the sum of offspring is at least the number of parents processed (minus the initial root),

$$Z \geq k \implies \sum_{i=1}^{k} \xi_i \geq k - 1.$$

Recall that each ξ_i is a sum of $\frac{n}{2}$ Bernoulli random variables (with different distributions), thus $\sum_{i=1}^{k} \xi_i$ is in fact a sum of $kn/2$ Bernoulli random variables. Hence, by Lemma 5.5 and Bernstein's bound,

$$\Pr(\sum_{i=1}^{k} \xi_i \geq k - 1) \leq 2\exp(-\tfrac{(0.3k)^2}{0.7k+0.3k/3}).$$

Taking $k = O(\log n)$, we obtain that the total progeny $Z \leq k = O(\log n)$ w.p. $1 - n^{-10}$, as desired. ◀

We are now ready to bound the max-load in Theorem 5.1, and thus conclude its proof.

Proof of Theorem 5.1, max-load. By Lemma 5.4, the load of a bin is dominated by the size of a GW process with offspring distribution μ. By Lemma 5.7, its size is $O(\log n)$ with probability $1 - n^{-10}$. A union bound over the $n/2$ trees concludes the proof. ◀

A Uniform two choices game

In this section, we prove Theorem 3.5, which states that if the algorithm uses the two choices allocation scheme, then after $n - n/2^\ell$ rounds of adaptive game, the recourse is $O(\ell n)$ and the maximum load is $O(2^\ell + \ell \log\log n)$.

The proof is similar to that of Theorem 3.1. It uses the following non-adaptive games that use the two choices allocation scheme. In the j-th non-adaptive game, we begin with $n/2^{j-1}$ empty bins. Then, we iteratively draw a pair of indices (i, i') uniformly over $[n/2^{j-1}]^2$, and place a ball in the least loaded among bins i, i'. The game proceeds until every subset $S \subset [n/2^{j-1}]$ of size $|S| = n/2^j$ contains the two indices of at least n pairs. We denote by Y_j the number of inserted balls, and denote by B_j the maximum load of a bin at the end of the game.

▶ **Lemma A.1.** *Let $j \in [\log n]$. Fix an adaptive adversary, and denote the recourse it obtains against two choices allocations in the j-th phase by X_j, and its maximum load in the j-th phase by A_j. Then, $Y_j \succeq X_j$ and $B_j \succeq A_j$, where Y_j and B_j are the number of inserted balls and the maximum load in the j-th non-adaptive game defined above.*

Proof. The proof is similar to the single choice (uniform) game of Lemma 3.3. We first analyze the recourse. We create a coupling between Y_j and X_j, by simulating the non-adaptive game during the $n/2^j$ rounds of the adaptive game. Abusing notation slightly, we continue to use X_j and Y_j to denote these random variables within the coupled setting.

For the non-adaptive game, let L_i^{na} denote the load of the i-th bin for $i \in [n/2^{j-1}]$. In the adaptive game, denote by $\texttt{Alive}_j \subseteq [n]$ the set of living bins right before the j-th phase starts. In particular, $|\texttt{Alive}_j| = n/2^{j-1}$, and therefore there is a one-to-one mapping between $\texttt{Alive}_j$ and $[n/2^{j-1}]$. For simplicity of presentation, we omit this mapping and simply treat every $i \in \texttt{Alive}_j$ as a number in $[n/2^{j-1}]$. Let $\texttt{Alive} \subseteq \texttt{Alive}_j$ denote the set of living bins during phase j; for each $i \in \texttt{Alive}$, let L_i^a be the load of the i-th bin incurred by balls that move in the j-th phase. We maintain the following invariant.

- **Invariant.** For every $i \in \texttt{Alive}$, we have $L_i^{na} \geq L_i^a$.

Initially, in the non-adaptive game there are no balls. No balls moved yet in the adaptive game. Clearly, the invariant holds.

Now, consider a round of the adaptive game. The adaptive adversary picks a bin to delete, say containing b balls. Suppose these b balls are thrown one at a time in the adaptive game, and let us simulate throwing one ball using the non-adaptive game. In the non-adaptive game, to throw a ball, we independently draw two indices $i, i' \in [n/2^{j-1}]$, and allocate the ball to the bin with smaller load (i.e., bin i if $L_i^{na} \leq L_{i'}^{na}$, and bin i' otherwise). If $(i, i') \notin \texttt{Alive}^2$, i.e., bin i or i' were deleted in the adaptive game, we repeatedly throw another new ball to the $n/2^{j-1}$ bins, until we get two indices in $(i, i') \in \texttt{Alive}$. The process of repeatedly throwing new balls may increase the load over $\texttt{Alive}$ in the non-adaptive game, but this doesn't damage the invariant. When obtaining two indices $i, i' \in \texttt{Alive}$, let us assume without loss of generality that $L_i^{na} \geq L_{i'}^{na}$, and so we allocate the ball in bin i' in the non-adaptive game. If $L_i^a \geq L_{i'}^a$ as well, we allocate the ball in bin i' also in the adaptive game, and the invariant holds. Otherwise, $L_i^a < L_{i'}^a$, so we must allocate the ball in bin i in the adaptive game. Before allocating the ball, we have by the invariant, $L_i^a < L_{i'}^a \leq L_{i'}^{na} \leq L_i^{na}$, and since the loads are integers, $L_i^a \leq L_i^{na} - 1$. Thus, the invariant still holds after adding this one ball to bin i in the adaptive game (which increases L_i^a by 1). This process is repeated for all the b balls, and then we proceed to the next round of the adaptive game.

Crucially, we claim that the above is a simulation of the adaptive game, and it may end only after the adaptive adversary deletes $n/2^j$ bins. In the non-adaptive game, the distribution of a pair of indices i, i', given that both land in $\texttt{Alive}$, is uniform over $\texttt{Alive}^2$. Thus, the above indeed simulates the adaptive game.

Observe that right before the adaptive adversary deletes the $\frac{n}{2^j}$-th bin, we have that $|\texttt{Alive}| = \frac{n}{2^j} + 1$. Since $\sum_{i \in \texttt{Alive}} L_i^a \leq n$, there must exists a subset S of $\texttt{Alive}$ of size $\frac{n}{2^j}$, whose bins in the adaptive game contain strictly less than n balls. Hence, in the adaptive game, there were strictly less than n pairs of indices both in S. Therefore, by the construction, since $S \subset \texttt{Alive}$, there were strictly less than n pairs of indices in S also in the non-adaptive game, and thus the non-adaptive game didn't end. Hence, the number Y_j of balls in the non-adaptive game is at least the recourse X_j of the adaptive game in the j-th phase, i.e., $Y_j \geq X_j$.

Over the same probability space, we immediately obtain a similar result for the maximum load. The maximum load B_j in the non-adaptive game is larger than the maximum load in $\texttt{Alive}$, which by the invariant, is larger than the maximum load incurred by balls that move in the j-th phase of the adaptive game, and thus $B_j \geq A_j$. The proof is concluded by Lemma 1.7. ◀

▶ **Lemma A.2.** *Consider the j-th two choices non-adaptive game and let Y_j be the number of balls it throws. Then, $Y_j \leq 24n$ with probability at least $1 - e^{-n}$.*

Proof. The proof is similar to the proof of Lemma 3.4. Consider throwing $24n$ pairs of indices independently and uniformly over $[n/2^{j-1}]^2$. We show that with high probability, all subsets of $n/2^j$ bins contain at least n pairs, and the claim follows.

Let a set $S \subset [n/2^{j-1}]$ of size $|S| = \frac{n}{2^j}$. For every $i \in [24n]$, denote by I_i an indicator that the i-th pair is in S^2. Thus, the number of pairs in S equals $\sum_{i=1}^{24n} I_i$. Clearly, $I_i = 1$ w.p. $\frac{1}{4}$ and 0 otherwise, and all these indicators are independent. Thus, by Hoeffding's inequality,

$$\Pr\Big(\sum_{i=1}^{24n} I_i < n\Big) \leq \Pr\Big(|\sum_{i=1}^{24n} I_i - 6n| > 5n\Big) \leq 2\exp\Big(-\frac{2(5n)^2}{24n}\Big) \leq 2\exp(-2n).$$

By a union bound, the probability that there exists a set $S \subset [n/2^{j-1}]$ of size $|S| = \frac{n}{2^j}$ containing less than n balls is at most

$$\binom{n/2^{j-1}}{n/2^j} \cdot 2\exp(-2n) \leq 2^n \cdot 2\exp(-2n) \leq \exp(-n),$$

which concludes the proof of the lemma. ◀

Proof of Theorem 3.5. By combining Lemma A.1 and Lemma A.2, we have that for each $j \in [\ell]$, with probability at least $1 - e^{-n}$, the recourse is at most $24n$. By a union bound, with probability at least $1 - e^{-n/2}$, the total recourse is $O(\ell n)$. In standard two choices allocations with $10n$ balls and $n/2^{j-1}$ bins, by [11], with probability $1 - \frac{1}{n^{11}}$, the maximum load is $B_j = O(2^j + \log\log n)$.

Thus, by a union bound, with probability $1 - n^{-10}$, the maximum load in the non-adaptive game is

$$\leq \sum_{j=1}^{\ell} A_j \leq \sum_{j=1}^{\ell} B_j \leq O(2^\ell + \ell \log\log n),$$

and the proof follows. ◀

B Proof of Lemma 4.7

To prove Lemma 4.7, we apply McDiarmid's inequality.

▶ **Lemma B.1** (McDiarmid's inequality). *Suppose a function $f : \mathbb{R}^n \to \mathbb{R}$ satisfies for all $i \in [n]$, and $x_1, \ldots, x_n \in \mathbb{R}$,*

$$\sup_{x_i' \in \mathbb{R}} \left| f(x_1, \ldots, x_i, \ldots, x_n) - f(x_1, \ldots, x_i', \ldots, x_n) \right| \leq c.$$

Let $X_1, \ldots, X_n \in \mathbb{R}$ be independent random variables. For all $t > 0$,

$$\Pr\left(|f(X_1, \ldots, X_n) - \mathbb{E}f(X_1, \ldots, X_n)| \geq t\right) \leq 2\exp\Big(-\frac{2t^2}{nc^2}\Big).$$

Recall that in Lemma 4.7, $10n$ balls are thrown to n bins, the bins loads are denoted by $L_1, L_2, \ldots, L_n$, and the claim is that with high probability, $\sum_{i=1}^n L_i \log L_i = O(n)$. Denote $F = \sum_{i=1}^n L_i \ln L_i$, which is $O(1)$ factor from the desired sum. We view F as a function of the locations of the $10n$ balls. Consider the effect of changing the location of one ball, say, by changing its location from bin i to bin j. Then F changes by

$$\begin{aligned}
&\left|(L_i - 1)\ln(L_i - 1) + (L_j + 1)\ln(L_j + 1) - L_i \ln L_i - L_j \ln L_j\right| \\
&= |L_i \ln(\tfrac{L_i - 1}{L_i}) + L_j \ln(\tfrac{L_j + 1}{L_j}) - \ln(L_i - 1) + \ln(L_j + 1)| \\
&\leq 2\ln(10n) + |L_i \ln(\tfrac{L_i - 1}{L_i})| + |L_j \ln(\tfrac{L_j + 1}{L_j})| \\
&\leq 2\ln(10n) + 2,
\end{aligned}$$

where the last inequality is since $\ln(1 + x) \leq x$ for $x > -1$.

▷ Claim B.2. We have $\mathbb{E}F \leq n \cdot 10 \ln 11 < 25n$.

Proof of Lemma 4.7. By McDiarmid's inequality,

$$\begin{aligned}\Pr(F > 100n) &\le \Pr(F - \mathbb{E}(F) > 75n)\\ &\le 2\exp\Big(-\frac{2(75n)^2}{10n(2\ln(10n+2)+2)^2}\Big) \le e^{-\sqrt{n}}.\end{aligned}$$

◀

Proof of Claim B.2. By linearity of expectation, $\mathbb{E}F = n \cdot \mathbb{E}(L_1 \ln L_1)$. Observe that $L_1 \sim Bin(10n, \frac{1}{n})$, i.e., it is a binomial random variable with $10n$ experiments and success probability $\frac{1}{n}$. Therefore,

$$\begin{aligned}\mathbb{E}L_1 \ln L_1 &= \sum_{k=1}^{10n}\binom{10n}{k}\Big(1-\frac{1}{n}\Big)^{10n-k}\frac{1}{n^k}\cdot k\ln k\\ &= \sum_{k=1}^{10n}\frac{10n}{k}\binom{10n-1}{k-1}\Big(1-\frac{1}{n}\Big)^{10n-k}\frac{1}{n^k}\cdot k\ln k && \text{since } k\binom{m}{k} = m\binom{m-1}{k-1}\\ &= 10\sum_{k=1}^{10n}\binom{10n-1}{k-1}\Big(1-\frac{1}{n}\Big)^{10n-k}\frac{1}{n^{k-1}}\cdot \ln k\\ &= 10\sum_{k=0}^{10n-1}\binom{10n-1}{k}\Big(1-\frac{1}{n}\Big)^{10n-1-k}\frac{1}{n^k}\cdot \ln(k+1) && \text{change of index}\\ &= 10\cdot\mathbb{E}\ln(X+1) && \text{where } X\sim Bin(10n-1,\tfrac{1}{n})\\ &\le 10\ln(\mathbb{E}X+1) && \text{by Jensen's inequality}\\ &\le 10\ln 11 < 25.\end{aligned}$$

Arboricity Matters in Triangle Counting with Random Edges

Arijit Bishnu

Gopinath Mishra
Institute of Mathematical Sciences, Chennai, India

Abstract

Given a simple, unweighted, undirected graph $G = (V, E)$ with $|V| = n$ and $|E| = m$, and parameters $0 < \varepsilon, \delta < 1$, along with `Degree`, `Neighbour`, `Pair` and `RandomEdge` query access to G, we provide a query-based randomized algorithm to generate an estimate $\widehat{T}$ of the number of triangles T in G, such that $\widehat{T} \in [(1-\varepsilon)T, (1+\varepsilon)T]$ with probability at least $1-\delta$. The query complexity of our algorithm is $\widetilde{O}\left(m\alpha \log(1/\delta)/\varepsilon^3 T\right)$, where α is the arboricity of G. Our work can be seen as a natural progression to the line of recent works [Eden et al., SIAM J Comp., 2017; Assadi et al., ITCS 2019; Eden et al., SODA 2020] that considered subgraph or triangle counting with or without the use of `RandomEdge` query. Of these works, Eden et al. [SODA 2020] considers the role of arboricity. Our work is the first to consider how `RandomEdge` query can leverage the structural property of arboricity. Furthermore, continuing in the line of work of Assadi et al. [APPROX/RANDOM 2022], we also provide a lower bound of $\widetilde{\Omega}\left(m\alpha \log(1/\delta)/\varepsilon^2 T\right)$ that matches the upper bound exactly on arboricity, δ, and almost on ε.

1 Introduction

Counting the number of triangles present in graphs is a classical problem [20, 5, 53, 4, 10]. Researchers in the streaming (sub-linear space) community have studied this problem for the last two decades; see [10, 11, 35, 2, 17, 6, 36, 18, 22, 55, 41] for a sample of such works. The problem has also been studied by researchers in the property testing (sub-linear time) community in the last decade [26, 48, 39, 11, 13, 28, 35]. Here, graphs can be accessed only through certain queries. On the other hand, starting with the work of [20], the graph parameter called arboricity has also found its use in triangle counting [28]. Our work shows the use of arboricity in triangle counting where the graph can be accessed through random edge queries along with other standard queries like `Degree`, `Neighbour` and `Pair`.

Counting triangles has been a well-motivated problem with applications across various domains like optimizing query size in database join problems [10, 9, 7], computing clustering coefficients, transitivity ratio [1, 46, 60, 44], studying structures in web graphs [25, 23] etc. For a more thorough overview, see the surveys [3, 57]. The parametrization based on arboricity is also of practical interest due to the occurrence of low-arboricity graphs in various real-world scenarios [24, 42, 50, 31, 12, 23, 54].

Formally, we are given a simple, unweighted, undirected graph $G = (V, E)$ with $|V| = n$, and $|E| = m$. The neighbours of v is denoted $\mathsf{N}(v) = \{u | (u, v) \in E\}$ and the degree of the vertex v is denoted $\deg_v = |\mathsf{N}(v)|$. We are given the following queries to access the graph:

- `Degree`(v): Given a vertex v, return $\deg_v$.
- `Neighbour`(v, i): Given a vertex $v \in V$ and $i \in [n]$, return the i-th vertex $u \in \mathsf{N}(v)$ if it exists; otherwise, we get $\perp$.
- `Pair`(u, v): Given two vertices $u, v \in V$, return 1 if $(u, v) \in E$, and 0, otherwise.
- `RandomEdge`: Return an edge $e \in E$ uniformly at random.

We will call the `Degree`, `Neighbour` and `Pair` queries taken together to be *local queries* [7]. Now, we formally state our problem:

Triangle Estimation:
Given ε, δ with $0 < \varepsilon, \delta < 1$, obtain an estimate $\widehat{T}$ of the number of triangles T in the graph G, such that $\widehat{T} \in [(1-\varepsilon)T, (1+\varepsilon)T]$ with probability at least $1 - \delta$.

From now on, we refer $\widehat{T}$ to be an (ε, δ) estimate of T. One of the graph parameters that has been relevant to quantify the complexity of triangle counting algorithms within the context of RAM model [20], streaming model [13], distributed model [34, 56, 30, 45] and query model [29], is the arboricity of the graph G, denoted α. The arboricity of a graph can be seen as a measure of the density of the graph.

▶ **Definition 1** (Arboricity(α)). *The arboricity of a graph $G = (V, E)$, denoted α, is the minimum number of spanning forests that E can be partitioned into.*

Recent works have established various ways to construct lower bounds incorporating the impact of ε and δ both in graph property testing [8] and other problems [58]. Our lower bounds will also involve ε and δ. To illustrate the dependence of ε, δ, and polylog terms on the query complexity of our algorithm, we will use two notations at times in place of $O(\bullet)$ – $\widetilde{O}(\bullet)$ hides polylog factors only but shows dependence on ε and δ, whereas $\widetilde{O}_{\varepsilon,\delta}(\bullet)$ hides both ε, δ and polylog terms.

1.1 Our results

In this section, we present the main results of this work.

Upper bound

We show that using random edge queries in addition to local queries, we can obtain an (ε, δ) estimate of T where the query complexity is parametrized by arboricity apart from the usual parameters of edge, vertex, the number of triangles, ε, and δ. The work of [20] established the role of arboricity in the problem of triangle counting giving an $O(m\alpha)$ time algorithm to exactly count the number of triangles T in the RAM model. In recent works in the property testing model, [26] gave an algorithm that uses local queries and requires $\widetilde{O}_{\varepsilon,\delta}\left(\frac{n}{T^{1/3}} + \min\left\{m, \frac{m^{3/2}}{T}\right\}\right)$ queries to obtain an (ε, δ) estimate $\widehat{T}$ of T. Using `RandomEdge` in addition to the local queries, [7] proposed an algorithm that uses $\widetilde{O}\left(\frac{m^{3/2}\log(1/\delta)}{\varepsilon^2 T}\right)$ queries. Following this, [28] was introduces the parameter of arboricity to triangle counting in the query based setup. They proposed an algorithm that uses $\widetilde{O}\left(\frac{n}{T^{1/3}} + \frac{m\alpha\log^3(1/\delta)}{\varepsilon^5 T}\right)$ local queries to obtain an (ε, δ) estimate $\widehat{T}$ of T. Our work follows in the line of the works of [26, 7, 28], where we use `RandomEdge` in addition to *local* queries to obtain an algorithm that uses $\widetilde{O}\left(\frac{m\alpha\log(1/\delta)}{\varepsilon^3 T}\right)$ queries (see the last row in Table 1). Formally,

▶ **Theorem 2** (Upper bound). *Given a simple, unweighted and undirected graph $G = (V, E)$ with $|V| = n$, $|E| = m$ and arboricity α, and access to the graph via* `Degree`, `Neighbour`, `Pair` *and* `RandomEdge` *queries, an (ε, δ) estimate $\widehat{T}$ of T can be obtained using $\widetilde{O}\left(\frac{m\alpha \log(1/\delta)}{\varepsilon^3 T}\right)$ queries.*

A constant-pass $\widetilde{O}\left(\frac{m\kappa}{\varepsilon^4 T}\right)$ space streaming algorithm was proposed in [13] for obtaining an (ε, δ)-estimate of the number of triangles in a graph, where κ is the degeneracy of the graph. Our algorithm can be directly extended to a constant pass streaming algorithm using $\widetilde{O}\left(\frac{m\alpha}{\varepsilon^3 T}\right)$ space. By the fact that $\alpha \leq \kappa \leq 2\alpha$, our algorithm's space complexity is as good as the algorithm of [13] in terms of the graph parameters, and asymptotically better in terms of the approximation factor ε.

Lower bound

We also establish a lower bound involving the arboricity and the parameters ε and δ. Reductions from communication complexity is a well studied method to establish lower bound results in terms of query complexity [15, 29, 32]. Using only `Degree` and `Neighbour` queries, triangle counting requires $\Omega(m)$ queries [33]. Including `Pair` with the previous two queries, [26] established a lower bound of $\Omega\left(\frac{n}{T^{1/3}} + \frac{m^{3/2}}{T}\right)$ queries which matches their upper bound up to $poly\left(\frac{\log(n/\delta)}{\varepsilon}\right)$ factors. Later, a simpler proof was proposed for the same bound through reduction from communication complexity problems [29]. This was subsequently extended to incorporate arboricity with a bound of $\Omega\left(\frac{n}{T^{1/3}} + \frac{m\alpha}{T}\right)$ queries [28] which again matched their proposed upper bound up to $poly\left(\frac{\log(n/\delta)}{\varepsilon}\right)$ factors. If `RandomEdge` query is allowed along with all three local queries, the above lower bounds of $\Omega\left(\frac{n}{T^{1/3}} + \frac{m^{3/2}}{T}\right)$ and $\Omega\left(\frac{n}{T^{1/3}} + \frac{m\alpha}{T}\right)$ become $\Omega\left(m^{3/2}/T\right)$ [29] and $\Omega(m\alpha/T)$ [28], respectively. [1] As we have mentioned, for general graphs, there is an algorithm that makes $\widetilde{O}\left(\frac{m^{3/2}\log(1/\delta)}{\varepsilon^2 T}\right)$ queries, where each query is either a local query or a `RandomEdge` query [7]. Recently, in [8], it has been shown that the algorithm of [7] is optimal (up to $poly(\log(n))$ factors) in terms of all parameters including ε and δ through a lower bound of $\Omega\left(\frac{m^{3/2}\log(1/\delta)}{\varepsilon^2 T}\right)$ queries for obtaining an (ε, δ) estimate of T using local and `RandomEdge` queries. However, this does not consider the dependency of the query complexity on arboricity of the graph. Like our upper bound, the lower bound of our work also captures the role of arboricity and the parameters ε, and δ when the queries allowed are the local and the `RandomEdge` queries. Moreover, our lower bound combines the parametrization of [8] and [28] in terms of ε, δ, and α, respectively, to establish an improved lower bound.

▶ **Theorem 3** (Lower bound). *Given a simple, unweighted and undirected graph $G = (V, E)$ with $|V| = n$, $|E| = m$ and arboricity α, and access to the graph via* `Degree`, `Neighbour`, `Pair` *and* `RandomEdge` *queries, obtaining an (ε, δ) estimate $\widehat{T}$ of T requires $\Omega\left(\frac{m\alpha \log(1/\delta)}{\varepsilon^2 T}\right)$ queries.*

Table 1 describes the upper and lower bounds across different query accesses and parametrization for the triangle counting problem, with our contributions in this work highlighted with an asterisk $(*)$ mark. Table 1 shows that it is only natural to study the problem of

[1] Though [28] does not mention about $\Omega(m\alpha/T)$ explicitly, it is not difficult to see it from their construction. Also, this lower bound of $\Omega(m\alpha/T)$ matches with our upper bound (stated in Theorem 2) in terms of dependence on m, T, and α.

triangle estimation with the use of `RandomEdge` and arboricity as a parameter after the works of [26, 28, 7, 8]. We believe our work also raises some new questions: (a) it opens up the question of quantifying the impact of α to count other subgraphs (e.g., k-cliques) using `RandomEdge` and other local queries; (b) there remains a small gap of $1/\varepsilon$ between our upper and lower bounds that remain to be resolved.

1.2 Related work in other models

The problem of triangle counting is a problem that has been extensively studied across various models of computation. Here, we discuss the works in RAM and streaming models.

RAM model. The work of [20] proposed an $O\left(\frac{m\alpha}{T}\right)$ algorithm in the RAM model that remains the best known till date. Recent works have shown it to be conditionally optimal under the 3SUM [43] and APSP hypotheses [59].

Streaming model. In the data streaming model, a long line of work [51, 52] has culminated in an $\widetilde{O}\left(\frac{m}{T}\left(\Delta_E + \sqrt{\Delta_V}\right)\right)$-space one-pass streaming algorithm for insertion only model [39] that has been shown to be optimal through the combined lower bounds proposed in [16, 39]. Here, Δ_E (Δ_V) denote the maximum number of triangles incident on an edge e (a vertex v) in the graph G. There have been works on triangle counting in multi-pass setup as well as in other streaming models (e.g., turnstile, cash-register etc.) [48, 11, 39, 37, 38, 40, 13].

1.3 Paper organization

Section 2 discusses a broad overview of the techniques we use, and contextualizes it with respect to the relevant prior works. Section 3 sets up the preliminaries for our proofs, including the structural results involving arboricity of a graph. Section 4 discusses the query-based algorithm by breaking the discussion into several parts: a weight function (Section 4.1), an oracle based algorithm (Sections 4.2) and its implementation (Section 4.3) and the final algorithm (Section 4.4). The lower bounds are discussed in Section 5. Some of the proofs are deferred to the Appendix. We have also included the full version of the paper in the Appendix.

2 Technical overview

In this section, we give a broad overview of the techniques used in this work. We denote by T_e the number of triangles incident on the edge e, and the degree of an edge by $\deg_e = \deg_{(u,v)} = \min\{\deg_u, \deg_v\}$.

2.1 Upper bound

Our starting point is to use `RandomEdge` queries to obtain S, a random sample of edges of size s and try to estimate the number of triangles T incident on the edges of S. As the `RandomEdge` query samples edges uniformly at random, the expected number of triangles each sampled edge participates in is $\frac{T}{m}$. Hence, an obvious approach to estimate T would be to count the number of triangles T_e each edge e participates in, and take their average for the sampled edges and scale it appropriately. However, there are two issues with this approach.

Firstly, counting the number of triangles an edge e participates in exactly would require $\Omega(\deg_e)$ *local* queries. Therefore, we have to sample sufficiently many neighbour vertices for each edge e and check if it forms a triangle or not to obtain a good estimate of T_e.

Secondly, even though the expected number of triangles incident on each edge is $\frac{T}{m}$, individual edges e can participate in a large number of triangles, i.e., T_e can be $\Omega(T)$. This makes the variance of the estimate too high, and requires s to be large to obtain a good estimate. To work around this issue, we fix a threshold τ based on the arboricity α of the graph, that has a connection to the number of triangles in the graph. We call edges that participates in more than τ triangles *τ-heavy edges*. Correspondingly, any edge that participates in less than τ triangles is called *τ-light edges*. For now, assume we are given access to an oracle `Heavy` to decide whether an edge is light or heavy. We call the triangles consisting exclusively of heavy edges as *heavy triangles*, and the remaining triangles as *light triangles*. The threshold τ is set at an appropriate multiple of α so that heavy triangles constitute only ε fraction of the triangles. Thus, we can forget about the *τ-heavy edges* and focus only on counting the light triangles. This brings us to the issue of sampling light triangles uniformly at random. We define a weight function on the edges that assigns each light triangle to one of its constituent light edges. The weight function is defined to be the number of light triangles assigned to the edge, with each heavy edge being assigned a value of 0.

Now the algorithm's objective is to estimate this weight function, which cannot be accessed or sampled directly. Observe that there can be multiple assignments of the light triangles to the edges, and consequently multiple weight functions. It suffices for the algorithm to estimate any one of them. In that regard, for all the light edges in our sample S, we maintain a partial non-conflicting assignment. Such an assignment can be extended to a valid assignment, and consequently, a valid weight function. Based on this assignment, we obtain an estimate of the corresponding weight function, which, given an appropriately fixed threshold $\tau = \Theta\left(\frac{\alpha}{\varepsilon}\right)$, and setting s to $\widetilde{O}\left(\frac{m\alpha}{\varepsilon^3 T}\log\frac{1}{\delta}\right)$ will give an (ε, δ) estimate of T.

To design the oracle `Heavy` for a given edge e, we estimate the number of triangles each edge participates in. We can estimate it by sampling each triangle independently through the corresponding neighbouring vertex of e. The probability of obtaining a triangle for an edge e through a random neighbour is $\frac{T_e}{\deg_e}$. Hence, for the heavy edges where $T_e \geq \tau$, T_e can be estimated using sufficiently small number of queries. For the light edges where $T_e \leq \tau$, the probability of obtaining a triangle through a random neighbour can be arbitrarily low. However, note that the lower probability of obtaining triangles allows for high approximation error. We then design a bucketing trick to exploit this trade-off to implement an efficient algorithm to decide whether an edge is heavy or light. For full details, see Section 4.

2.2 Lower bound

Several lower bounds for triangle counting problems based on reductions from the *disjointness* problem in communication complexity [29, 7, 28] are often close to the best possible upper bounds. It is not clear whether this approach can give tight bounds involving ε and δ. Recently, Assadi and Nguyen [8] showed that any algorithm to find an (ε, δ)-estimate of the number of triangles T must make at least $\Omega\left(\frac{m^{3/2}\log(1/\delta)}{\varepsilon^2 T}\right)$ queries, where each query is either a local query or a `RandomEdge` query.[2] To prove the lower bound, they introduced a new query problem called the *Popcount Thresholding Problem* (`PTP`), and gave reductions from this problem to triangle estimation, instead of using disjointness. We also show a reduction from `PTP`. In particular, we show that for any value of arboricity α, we can design a graph G with arboricity α such that finding an (ε, δ)-estimate in it using $\Omega\left(\frac{m\alpha\log(1/\delta)}{\varepsilon^2 T}\right)$ queries would violate the lower bound of `PTP`.

In the $\texttt{PTP}_{M,k,\gamma}$ problem, we are given query access to a binary string $x \in \{0,1\}^M$ and must decide whether it was generated from one of two similar distributions. In the first distribution, denoted $\mathcal{D}_0$, each bit of the string is independently set to 1 with probability $(1-2\gamma)k/M$; in the second distribution, denoted $\mathcal{D}_1$, each bit is independently set to 1 with probability $(1+2\gamma)k/M$. The objective is to distinguish between these two cases by adaptively querying bits of x. For suitable choice of k,γ, and δ, with probability at least $1-\delta$, a string from $\mathcal{D}_0$ will have fewer than $(1-\gamma)k$ 1s and a string from $\mathcal{D}_1$ will have more than $(1+\gamma)k$ 1s. Hence, to distinguish whether x is generated from $\mathcal{D}_0$ or $\mathcal{D}_1$, it suffices to estimate the number of 1s present in x, i.e. $\|x\|_1$ upto multiplicative approximation factor γ. Assadi et al. [8] showed that (under suitable choice of parameters) $\Omega\left(\frac{M\log(1/\delta)}{\gamma^2 k}\right)$ queries to x are needed to distinguish between the case whether $x \sim \mathcal{D}_0$ and $x \sim \mathcal{D}_1$ with probability $1-\delta$.

We now describe the hard graph instance $G_x(V_x, E_x)$ used in the reduction. The core structure of V_x consists of three vertex sets: A, B, and R, where $|A| = |B| = \Theta(m/\alpha)$ and $|R| = \Theta(\alpha)$. Every vertex in $A \cup B$ is connected to all vertices in R, forming a bipartite clique between $A \cup B$ and R. The subgraph induced by $A \cup B$ contains $\Theta(m)$ edges, with each vertex having degree at most $O(\alpha)$. We associate each index $i \in [M]$ from the $\texttt{PTP}_{M,k,\gamma}$ instance with a potential edge between A and B, and include the edge if and only if $x_i = 1$. Thus, the number of edges between A and B equals $\|x\|_1$, and the total number of triangles in the graph G_x is $\|x\|_1 \cdot |R|$. By choosing parameters such that $M = \Theta(m)$, $k = \Theta(T/\alpha)$, and $\gamma = \Theta(\varepsilon)$, distinguishing whether x is drawn from $\mathcal{D}_0$ or $\mathcal{D}_1$ becomes equivalent to distinguishing whether the number of triangles in the graph is at most $(1-\varepsilon)T$ or at least $(1+\varepsilon)T$. To complete the reduction, we show that each local query and `RandomEdge` query to G_x can be simulated using only a constant number of queries to x. To enable this, we extend the construction by introducing two additional disjoint vertex sets A' and B', resulting in five disjoint sets: A, B, R, A', and B'. All triangles in the graph are confined to the sets A, B, and R, while the sets A' and B' are added to ensure that the degree of each vertex in V_x remains identical regardless of whether x is drawn from $\mathcal{D}_0$ or $\mathcal{D}_1$. With this construction, every allowable query to the graph can be simulated with $O(1)$ queries to x. For full details, see Section 5.

[2] Note that this lower bound matches exactly with the corresponding upper bound in [7].

2.3 Contextualizing with relevant prior work

Our work follows as a natural progression to the works of [26, 7, 28] in the property testing framework. So, let us review the algorithmic techniques at play in them.

We start by describing a simple randomized algorithm due to Assadi et al. [7] for estimating the number of triangles in a graph when we have access to queries like `Degree`, `Neighbour`, `Pair`, and `RandomEdge`. First, pick a random edge $\{u, v\}$ and let $\deg_u \leq \deg_v$. If $\deg_u \leq \tau_d$, pick a random neighbour w of u and check if $\{u, v, w\}$ forms a triangle in the correct order, i.e., in the increasing degree sequence. The probability of sampling a triangle in this case is $\frac{1}{2m} \cdot \frac{1}{\deg_u} \cdot \frac{\deg_u}{\tau_d} = \frac{1}{2m\tau_d}$. If $\deg_u > \tau_d$, pick a vertex w at random with probability proportional to its degree. This is possible because `RandomEdge` allows sampling vertices proportional to their degrees. The probability of sampling a triangle in this case is $\frac{1}{2m} \cdot \frac{\deg_w}{2m} \geq \frac{\tau_d}{4m^2}$. By setting $\tau_d = \sqrt{2m}$, we can ensure that the algorithm works effectively. This process finds a triangle with probability $\Omega(T/m^{3/2})$. Finally, by repeating this process $\widetilde{O}(m^{3/2} \log(1/\delta)/\varepsilon^2 T)$ times, we can estimate the total number of triangles.

The setting $\tau_d = \Theta(\sqrt{m})$ seems to be the optimal choice for the general case. We do not see a way to generalize the above idea when parametrized by arboricity. In bounded arboricity graphs, the structure and degree distribution of the graph may not align with this approach. So, a different strategy would be required for graphs with bounded arboricity to achieve the desired bound of $\widetilde{O}(m\alpha \log(1/\delta)/\varepsilon^3 T)$.

Our approach is more closely aligned with the framework of triangle counting developed by Eden et al. [26] with access to local queries only. The algorithm by Eden et al. [26] starts by picking a small set of vertices at random and for each sampled vertex, the algorithm tries to estimate the number of triangles it participates in. Some vertices appear in many triangles and are called heavy, while others are called light. To keep the estimate as desired, the algorithm limits the contribution of heavy vertices and focuses mainly on light ones. It gives more weight to triangles that have more light vertices. Since the number of triangles a vertex participates in cannot be obtained directly, the algorithm estimates this by sampling edges incident on the sampled vertices and checking if they close triangles with neighbouring vertices of those edges. The above framework has also been subsequently extended for clique counting in general graphs [28] and that in bounded arboricity graphs [28].

In summary, the idea of dividing the triangles in terms of their constituent edges or vertices into heavy and light, and dealing with them separately has been a long-standing technique for subgraph counting in sublinear models [48, 26, 11, 27, 38, 28, 13]. The algorithmic techniques vary on how to set and leverage this thresholding behaviour for the specific problems and models. Furthermore, allowing `RandomEdge` queries has yielded simpler algorithms for subgraph counting problems [7]. The usage of `RandomEdge` enables us to design a simple algorithm that uses the structural parameter of arboricity.

The lower bounds for the triangle counting problem in the query model have come from indistinguishability arguments [26] or reduction from communication problems, particularly *set-disjointness* [29, 7, 28] with [28] establishing arboricity-sensitive lower bounds. On the other hand, several recent works [14, 8] have established lower bounds for property testing problems through reductions to query problems that are sensitive to ε and δ. In this work, we extend the ε, δ-sensitive lower bound of [8] to the triangle counting problem for any value of arboricity α.

3 Preliminaries

3.1 Notations

The set of positive integers $\{1, 2, \ldots, x\}$ is denoted $[x]$. The set of triangles in G is denoted Δ, and individual triangles are denoted $\mathtt{t}$. (v, e) denotes a triangle formed by the vertices v and the endpoints of the edge e. $\text{Unif}(S)$ denotes an element of S is chosen uniformly at random.

3.2 Arboricity and its properties

As arboricity plays a crucial role in our work, we put together all the structural results that involve arboricity here. Let us restate the definition once more.

▶ **Definition 4** (Arboricity(α)). *The arboricity of a graph $G = (V, E)$, denoted by α_G, is the minimum number of spanning forests that E can be partitioned into.*

The arboricity of a graph can be seen as a measure of the density of the graph. α_G can be at least $\lceil m/(n-1) \rceil$. Also, $\alpha_G \geq \alpha_H$ where H is any subgraph of G. We will write α instead of α_G when the underlying graph is understood. We introduce the following result due to [20] on the sum of edge degrees over all edges in the graph.

▶ **Lemma 5** (Sum of deg_e [20]). *Given a graph $G = (V, E)$ with arboricity α and $|E| = m$, $\sum_{e \in E} deg_e \leq 2m\alpha$.*

The following result due to [28] builds on the work of [20] to bound the number of triangles based on the number of edges m and arboricity α.

▶ **Lemma 6** (Triangle upper bound [28]). *Given a graph $G = (V, E)$ with arboricity α and $|E| = m$, the graph G has at most $m\alpha$ triangles.*

Note that this upper bound is also tight, i.e., there exists graphs that contain m edges and $\Omega(m\alpha)$ triangles. Additionally, arboricity α can be at most $O(\sqrt{m})$ [28]. Thus, all our results can be reformulated by plugging in this upper bound.

3.3 Chernoff bounds

We will be using the following variation of the Chernoff bound that bounds the deviation of the sum of independent Poisson trials [49].

▶ **Lemma 7** (Multiplicative Chernoff bound). *Given i.i.d. random variables $X_1, X_2, ..., X_t$ where $\Pr[X_i = 1] = p$ and $\Pr[X_i = 0] = (1 - p)$, define $X = \sum_{i \in [t]} X_i$. Then, we have:*

$$\Pr[X \leq (1-\varepsilon)\,\mathbb{E}[X]] \leq \exp\left(-\frac{\mathbb{E}[X]\,\varepsilon^2}{3}\right) \qquad 0 \leq \varepsilon < 1$$

$$\Pr[X \geq (1+\varepsilon)\,\mathbb{E}[X]] \leq \exp\left(-\frac{\varepsilon^2\,\mathbb{E}[X]}{2+\varepsilon}\right) \qquad 0 \leq \varepsilon$$

4 Algorithm

This section describes the algorithm and its related concepts. Section 4.1 formally defines the weight function for edges and associated structural results. Section 4.2 describes the algorithm assuming access to an idealized oracle that can decide if an edge is heavy or light

(based on whether the edge has many or few incident triangles). Section 4.3 describes how to actually implement this oracle within the problem setup. Section 4.4 puts everything together to develop the final algorithm.

4.1 Weight function

In this section, we formalize the ideas of heavy and light edges and weight function for the edges.

Heavy and light edges and triangles

First, we define heavy and light edges and correspondingly, heavy and light triangles.

▶ **Definition 8** (τ-heavy and τ-light edges). *An edge $e \in E$ is defined to be a τ-heavy (resp. τ-light) edge if it participates in more than τ (resp. $\leq \tau$) triangles.*

▶ **Definition 9** (τ-heavy and τ-light triangles). *A triangle $\mathsf{t} \in \Delta$ is called a τ-heavy triangle if all its three edges are τ-heavy edges. A triangle that is not τ-heavy is a τ-light triangle.*

We denote by T_L^τ and T_H^τ the number of τ-light and τ-heavy triangles in the graph G, respectively. The following lemma bounds the number of τ-heavy triangles in a graph using the parameter of arboricity.

▶ **Lemma 10** (Upper bound on T_H^τ). *Given a graph $G = (V, E)$ with T triangles, the number of τ-heavy triangles is at most $\frac{3T\alpha}{\tau}$.*

Proof. Note that the graph $G = (V, E)$ has T triangles containing at most $3T$ edges. By Definition 9, τ-heavy triangles have all three of their edges to be τ-heavy edges, τ or more triangles incident on each of them. Hence, the number of τ-heavy edges in G is at most $\frac{3T}{\tau}$.

Now consider the subgraph $H = (V_H, E_H)$ of G induced by the τ-heavy edges in G. We know, $E_H \leq \frac{3T}{\tau}$. Also, $\alpha_H \leq \alpha_G = \alpha$ (see Section 3.2). Hence, by Lemma 6, we know that H contains at most $\frac{3T\alpha}{\tau}$ triangles. ◀

The following corollary follows from Lemma 10 and the fact that $T = T_L^\tau + T_H^\tau$.

▶ **Corollary 11** (Lower bound on T_L^τ). *Given a graph $G = (V, E)$, there are at least $(1 - \frac{3\alpha}{\tau})T$ τ-light triangles.*

Weight function for the edges

Now, we define a weight function for the edges. As a triangle is incident to multiple edges, the objective of a weight function is to charge each of the light triangles to exactly one of its participating light edges. To ensure this, we do not charge any light triangle to any heavy edge that it may be incident on. Each light edge e can be charged by at most T_e triangles, i.e., all the triangles the edge e participates in. To avoid over-counting, we ensure that the sum of the weight function over all edges is equal to the number of light triangles, T_L^τ. (t, e) denotes that the triangle t is charged to the edge e.

▶ **Definition 12** (Triangle weight function (w)). *We define a function $w : E \to \mathbb{N}$ to be a triangle weight function if it satisfies the following two conditions:*

$$\begin{aligned} &\textit{Condition (1)}: \quad w(e) \quad \leq \quad \begin{cases} T_e & \textit{if } e \textit{ is a light edge} \\ 0 & \textit{if } e \textit{ is a heavy edge} \end{cases} \\ &\textit{Condition (2)}: \quad \sum_{e \in E} w(e) \quad = \quad T_L^\tau \end{aligned}$$

Observe that there are multiple such weight functions (e.g., a triangle with 3 light edges can be assigned to any one of these 3 edges). Henceforth, we denote the set consisting of valid triangle weight functions by $\mathcal{W}$. We now state a property of valid weight functions. Note that this property is true for any $w \in \mathcal{W}$.

▶ **Lemma 13** (Expectation of $w(e)$)**.** *Consider any triangle weight function $w \in \mathcal{W}$. If we select an edge $e \in E$ uniformly at random, then the expected value of $w(e)$ is $\frac{T_L^\tau}{m}$, i.e., $\mathbb{E}_{e\sim \mathrm{Unif}(E)} w(e) = \frac{T_L^\tau}{m}$.*

Proof. Given that the edges have been chosen uniformly at random and the condition of the triangle weight function (Definition 12), we have:

$$\mathop{\mathbb{E}}_{e\sim \mathrm{Unif}(E)} w(e) \;=\; \sum_{e\in \mathrm{Unif}(E)} \frac{1}{m} w(e) \;=\; \frac{1}{m}\sum_{e\in E} w(e) \;=\; \frac{T_L^\tau}{m}. \qquad \blacktriangleleft$$

4.2 Oracle based algorithm

Our algorithm, due to its usage of the *triangle weight function*, requires knowledge of whether an edge is *heavy* or *light*. The problem of deciding whether an edge is heavy is non-trivial as it directly relates to number of triangles the edge participates in. In this section, we assume black-box access to an oracle `HeavyOracle` that helps us determine if an edge is heavy.

$$\texttt{HeavyOracle}(e,\alpha,\varepsilon) = \begin{cases} 1 & \text{if edge } e \text{ is a } \dfrac{h\alpha}{\varepsilon}\text{-heavy edge, i.e., } \tau = \dfrac{h\alpha}{\varepsilon} \\ 0 & \text{if edge } e \text{ is a } \dfrac{l\alpha}{\varepsilon}\text{-light edge, i.e., } \tau = \dfrac{l\alpha}{\varepsilon} \end{cases}$$

Here h and l ($h > l$) are constants to be determined later. We will discuss an efficient implementation of this oracle later.

Let us first consider the case where we are given an oracle that given an edge e, returns the exact value of a weight function, $w(e)$. Given we can sample edges uniformly at random through the `RandomEdge` query, we can compute $\mathbb{E}_{e\sim \mathrm{Unif}(E)}[w(e)] = T_L^{\frac{l\alpha}{\varepsilon}}$ using this oracle on the sampled edges. However, no such oracle exists in our model. Hence, we try to simulate one through an empirical estimate of the weight function, $\widehat{w}(e)$. Recall the fact that there are many valid weight functions, each being characterized by every light triangle being charged to one of its constituent light edges. Our algorithm will work if the empirical weight function $\widehat{w}$ estimates any one of these weight functions. We achieve this by ensuring that a triangle is not sampled through more than one edge (see Line 17 of Algorithm 1). Thus, the assignments that we consider can be extended to a valid weight function w, and our algorithm can be thought of as estimating this weight function through $\widehat{w}$. We develop our initial algorithm (Algorithm 1) assuming $\widetilde{T}$, an estimate of T satisfying $\widetilde{T} \le 2T$.

In Algorithm 1, we assume that we know m exactly. In fact, our algorithm and analysis work even if we have a constant factor approximation of m. This can be achieved by using $\widetilde{O}_{\varepsilon,\delta}(1)$ queries [7].

We now state and analyse the algorithm.

▶ **Lemma 14** (Expectation of Algorithm 1)**.** *Algorithm 1 ensures that $\mathbb{E}[\widehat{w}(e_i)] = T_L^{\frac{l\alpha}{\varepsilon}}/m$, and $\mathbb{E}\left[\widehat{T}\right] = T_L^{\frac{l\alpha}{\varepsilon}}$.*

Proof. Let $\mathcal{E}_i$ be the event that the edge e is chosen as the i-th edge sample. We proceed with the proof by considering two different cases: $\deg_e < \alpha$ and $\deg_e \ge \alpha$.

Algorithm 1 Triangle Counting Algorithm - with access to `Heavy`, and knowledge of $\widetilde{T}$.

Require: `Degree`, `Neighbour`, `Pair`, and `RandomEdge` query access to a graph G. Parameters $\widetilde{T}, \alpha, \varepsilon, m$ and oracle access to `HeavyOracle` with threshold constants l, h

$s \leftarrow c(1+h)\varepsilon^{-3}(m\alpha/\widetilde{T})\log n$
$S \leftarrow \emptyset$ ▷ S is the set of random edges sampled. $|S|$ grows up to s
$S_\Delta \leftarrow \emptyset$ ▷ S_Δ is the set of light triangles sampled through the edges in S
for $i \in [s]$ **do**
  $e_i \leftarrow$ `RandomEdge`
  $S \leftarrow S \cup e_i$
  Let $e_i = (v_i, x)$ where $\deg_{v_i} < \deg_x$ ▷ Requires two `Degree` queries
  if (`HeavyOracle`$(e_i, \alpha, \varepsilon) = 0$) **then** ▷ e_i is a $\frac{l\alpha}{\varepsilon}$-light edge
    $r_{e_i} \leftarrow 0$ ▷ r_e denotes the number of queries for each edge e
    if $\deg_{v_i} \leq \alpha$ **then**
      set $r_{e_i} \leftarrow 1$ with probability $\frac{\deg_{v_i}}{\alpha}$
    else
      set $r_{e_i} \leftarrow \left\lceil \frac{\deg_{v_i}}{\alpha} \right\rceil$
    for $j \in [r_{e_i}]$ **do**
      Choose $k \leftarrow \text{Unif}\left(\{1, 2, ..., \deg_{v_i}\}\right)$
      $u \leftarrow$ `Neighbour`(v_i, k)
      if (`Pair`$(u, x) = 1$ and $\mathtt{t} = (\mathtt{u}, \mathtt{e_i})$ is not in S_Δ through another edge e') **then**
        $S_\Delta \leftarrow S_\Delta \cup \mathtt{t}$
  ▷ A triangle $\mathtt{t}$ may occur in S_Δ multiple times, but each time it will be through the same edge e
  else
    $r_{e_i} \leftarrow 0$
for $i \in [s]$ **do**
  if $r_{e_i} > 0$ **then**
    $\widehat{w}(e_i) = \frac{1}{r_{e_i}} \sum_{(\mathtt{t}, \mathtt{e_i}) \in \mathtt{S}_\Delta} \max\left(\alpha, \deg_{e_i}\right)$
  else
    $\widehat{w}\left(e_i\right) = 0$
return $\widehat{T} = \frac{m}{s} \sum_{i \in s} \widehat{w}(e_i)$

Case I: ($\deg_e < \alpha$). When $\deg_e < \alpha$, r_e is set to 0 with probability $1 - \deg_e/\alpha$ and 1 with probability $\deg_e/\alpha$, and $\widehat{w}(e)$ is evaluated through a single query. Thus,

$$\mathbb{E}[\widehat{w}(e_i)|\mathcal{E}_i] = \frac{\deg_e}{\alpha} \sum_{k \in [w(e)]} \frac{1}{\deg_e}\alpha + \left(1 - \frac{\deg_e}{\alpha}\right) \cdot 0 = w(e) \tag{1}$$

Case II: ($\deg_e \geq \alpha$). On the other hand, when $\deg_e \geq \alpha$, let $Z_j, j \in [r_e]$ be the contribution of each r_e queries made for the edge e to the weight function estimate. Then,

$$\mathbb{E}[Z_j|\mathcal{E}_i] = \sum_{k \in [w(e)]} \frac{1}{\deg_e} \deg_e = w(e) \tag{2}$$

Correspondingly, we have by linearity of expectation and Equation (2):

$$\mathbb{E}\left[\widehat{w}(e_i)|\mathcal{E}_i\right] = \frac{1}{r_e}\sum_{j\in[r_e]}\mathbb{E}\left[Z_j|\mathcal{E}_i\right] = \mathbb{E}\left[Z_j|\mathcal{E}_i\right] = w(e) \tag{3}$$

Given that we draw each edge $e \in S$ uniformly at random, we now have by Equations (1), (3), and Lemma 13:

$$\mathbb{E}\left[\widehat{w}(e_i)\right] = \mathop{\mathbb{E}}_{e\sim\mathrm{Unif}(E)} w\left(e\right) = T_L^{\frac{l\alpha}{\varepsilon}}/m$$

By linearity of expectations, we obtain

$$\mathbb{E}\left[\widehat{T}\right] = \mathbb{E}\left[\frac{m}{s}\sum_{i\in s}\widehat{w}(e_i)\right] = T_L^{\frac{l\alpha}{\varepsilon}}$$ ◀

Note that Lemma 14 holds irrespective of whether the assumption $\widetilde{T} \leq 2T$ is satisfied or not. Next, we turn our attention to the variance of $\widehat{w}(e)$.

▶ **Lemma 15** (Variance of Algorithm 1). *Algorithm 1 ensures that* $\mathrm{Var}[\widehat{w}(e_i)] \leq \frac{(1+h)\alpha}{\varepsilon} \cdot \mathbb{E}_{e\sim\mathrm{Unif}(E)}[w(e)]$.

Proof. Again, we consider two different cases as in the proof of Lemma 14.

Case I: ($\deg_e < \alpha$). When $\deg_e < \alpha$, Algorithm 1 makes at most 1 query as $r \leq 1$. As $\widehat{w}(e) \leq \alpha$, we have

$$\mathrm{Var}[\widehat{w}(e_i)|\mathcal{E}_i] \leq \mathbb{E}[\widehat{w}(e_i)^2|\mathcal{E}_i] \leq \alpha\,\mathbb{E}\left[\widehat{w}\left(e_i\right)|\mathcal{E}_i\right] \tag{4}$$

Case II: ($\deg_e \geq \alpha$). Now we consider the case $\deg_e \geq \alpha$ which is more involved as $r \geq 1$. We first estimate the variance of each Z_j individually as defined in Lemma 14. We condition on the event that edge e is chosen as the i-th edge sample, denoted by $\mathcal{E}_i$. If $\texttt{HeavyOracle}(e,\alpha,\varepsilon) = 1$, then $Var[Z_j] = 0, \forall j \in [r]$. Hence, we condition on the event that $\texttt{HeavyOracle}(e,\alpha,\varepsilon) = 0$ from now on. As $Z_j \leq \deg_e$,

$$\mathrm{Var}[Z_j|\mathcal{E}_i] \leq \mathbb{E}[Z_j^2|\mathcal{E}_i] \leq \deg_{e_i}\mathbb{E}[Z_j|\mathcal{E}_i] \tag{5}$$

After having bounded the variance of the contribution of each query, we now obtain the variance of the weight estimate of the edge.

$$\begin{aligned}
\mathrm{Var}[\widehat{w}(e_i)|\mathcal{E}_i] &= \mathrm{Var}\left[\frac{1}{r_{e_i}}\sum_{j\in r_{e_i}} Z_j|\mathcal{E}_i\right] \\
&= \frac{1}{r_{e_i}^2}\sum_{j\in r_{e_i}}\mathrm{Var}\left[Z_j|\mathcal{E}_i\right] && (Z_j \text{ are i.i.d. given } \mathcal{E}_i) \\
&= \frac{\deg_{e_i}}{r_{e_i}}\sum_{j\in r_{e_i}}\frac{1}{r_{e_i}}\mathbb{E}[Z_j|\mathcal{E}_i] && (\text{by Equation (5) and linearity of expectation}) \\
&\leq \alpha\,\mathbb{E}[\widehat{w}(e_i)|\mathcal{E}_i] && \left(\text{as } r_{e_i} = \left\lceil\frac{\deg_e}{\alpha}\right\rceil\right)
\end{aligned} \tag{6}$$

Now, we remove the conditioning on $\mathcal{E}_i$ using the law of total variance:

$$\begin{aligned}
\mathrm{Var}[\widehat{w}(e_i)] &= \mathop{\mathbb{E}}_{e_i}[\mathrm{Var}[\widehat{w}(e_i)|\mathcal{E}_i]] + \mathop{\mathrm{Var}}_{e_i}[\mathbb{E}[\widehat{w}(e_i)|\mathcal{E}_i]] && \text{(by the law of total variance)}\\
&\leq \mathop{\mathbb{E}}_{e_i}[\alpha\,\mathbb{E}[\widehat{w}(e_i)|\mathcal{E}_i]] + \mathop{\mathbb{E}}_{e_i}[\mathbb{E}[\widehat{w}(e_i)|\mathcal{E}_i]^2] && \text{(by Equations (4) and (6))}\\
&\leq \alpha \mathop{\mathbb{E}}_{e_i}[\mathbb{E}[\widehat{w}(e_i)|\mathcal{E}_i]] + \frac{h\alpha}{\varepsilon}\cdot\mathop{\mathbb{E}}_{e_i}[\mathbb{E}[\widehat{w}(e_i)|\mathcal{E}_i]] && \text{(as } \texttt{HeavyOracle}(e)=0,\ \frac{h\alpha}{\varepsilon}\geq|T_e|)\\
&\leq \frac{(1+h)\alpha}{\varepsilon}\cdot\mathbb{E}[w(e)] && \blacktriangleleft
\end{aligned}$$

▶ **Theorem 16** (Performance guarantees of Algorithm 1). *Algorithm 1 makes* $c(1+h)\varepsilon^{-3}(m\alpha/\widetilde{T})\log n$ *queries, and* $c(1+h)\varepsilon^{-3}(m\alpha/\widetilde{T})\log n$ *calls to* `HeavyOracle`*, and given* $\widetilde{T}$ *satisfying the assumption that* $\widetilde{T}\leq 2T$*, returns* $\widehat{T}$ *such that* $\Pr(|\widehat{T}-T_L^{\frac{l\alpha}{\varepsilon}}|\geq\varepsilon T_L^{\frac{l\alpha}{\varepsilon}})\leq\frac{1}{c\log n}$.

Proof. The algorithm calls `HeavyOracle` for each of the s edges in S, resulting in a total of $c(1+h)\varepsilon^{-3}(\log n)(m\alpha/\widetilde{T})$ calls.

The algorithm makes s `RandomEdge` queries, $2s$ `Degree` queries, and $2r_e$ `Neighbour` query for each edge $e\in S$. All edges in S are sampled uniformly at random from E. Hence, the expected number of `Neighbour` queries made are:

$$\mathop{\mathbb{E}}_{e\sim\mathrm{Unif}(E)}\left[\left\lceil\frac{\deg_e}{\alpha}\right\rceil\right]=\sum_{e\in E}\frac{1}{m}\left\lceil\frac{\deg_e}{\alpha}\right\rceil\leq\frac{1}{m}\sum_{e\in E}1+\frac{\deg_e}{\alpha}=1+\frac{1}{m}\sum_{e\in E}\frac{\deg_e}{\alpha}\leq 1+\frac{2m\alpha}{m\alpha}=3$$

The last inequality in the above step follows from Lemma 5. Hence, the algorithm makes at most $9s=c(1+h)\varepsilon^{-3}(m\alpha/\widetilde{T})\log n$ queries in expectation. Here the inequality is due to the fact that for a heavy edge e in S, $r_e=0$. Furthermore, we bound the variance of the estimate $\widehat{T}$ as:

$$\mathrm{Var}[\widehat{T}]=\mathrm{Var}\left[\frac{m}{s}\sum_{i\in s}\widehat{w}(e_i)\right]\leq\frac{(1+h)\alpha m^2\,\mathbb{E}[w(e)]}{\varepsilon s}\leq\frac{(1+h)m\alpha\,\mathbb{E}[\widehat{T}]}{\varepsilon s}.$$

The last two steps follow from Lemma 15 and the fact that $\mathbb{E}\left[\widehat{T}\right]=m\,\mathbb{E}\left[w(e)\right]$. We now use Chebyshev's inequality on $\widehat{T}$:

$$\begin{aligned}
\Pr\left(|\widehat{T}-\mathbb{E}[\widehat{T}]|\leq\varepsilon\,\mathbb{E}[\widehat{T}]\right)&\leq\frac{\mathrm{Var}[\widehat{T}]}{\varepsilon^2\,\mathbb{E}[\widehat{T}]^2} && \text{(Chebyshev's inequality)}\\
&\leq\frac{(1+h)m\alpha}{\varepsilon^3 s\,\mathbb{E}[\widehat{T}]} && \text{(by Lemma 15)}\\
&\leq\frac{(1+h)m\alpha}{\varepsilon^3\cdot 4c\,(1+h)\,\varepsilon^{-3}(m\alpha/\widetilde{T})\log n\cdot T_L^{\frac{l\alpha}{\varepsilon}}} && \text{(by Lemma 14)}\\
&\leq\frac{1}{c\log n} && \text{(as } T_L^{\frac{l\alpha}{\varepsilon}}>T/2\geq\widetilde{T}/4)
\end{aligned}$$

where the last inequality uses the fact $T/2\geq\widetilde{T}/4$ due to the assumption that $\widetilde{T}\leq 2T$. ◀

4.3 Implementing the oracle

Rather than the exact oracle (`HeavyOracle`) that we assumed in Algorithm 1, we would design an oracle (called `Heavy`) that given arboricity α, and parameters ε and δ, accepts edges participating in at most $\frac{\alpha}{2\varepsilon}$ triangles as light, and rejects edges participating in at least

$\frac{2\alpha}{\varepsilon}$ triangles as heavy, with probability at least $1-\delta$. The algorithm works by estimating the number of triangles each edge participates in. However, in this case, each `Neighbour` and `Pair` queries generate i.i.d. random variables denoting the existence of triangle through that neighbouring vertex. Thus, our analysis uses the multiplicative Chernoff bound to obtain high probability guarantees for each individual edge.

Algorithm 2 `Heavy`$(e, \alpha, \varepsilon, \delta)$.

Require: `Degree`, `Neighbour`, `Pair`, and `RandomEdge` query access to a graph G

$r \leftarrow \left\lceil \frac{16\varepsilon \deg_e}{\alpha} \log\left(\frac{1}{\delta}\right) \right\rceil$ ▷ r denotes the number of queries for each edge e
Let $e = (u, x)$ where $\deg_u < \deg_x$ ▷ Requires 2 `Degree` queries
$Y \leftarrow 0$
for $i \in [r]$ **do**
  Choose $k \leftarrow \text{Unif}(\{1, 2, ..., \deg_u\})$
  $v_i \leftarrow$ `Neighbour`(u, k) ▷ Requires 1 `Neighbour` query
  if `Pair`$(v_i, x) = 1$ **then** ▷ Requires 1 `Pair` query
    $Y_i \leftarrow 1$ ▷ Found triangle (v_i, e)
  else
    $Y_i \leftarrow 0$
  $Y \leftarrow Y + Y_i$
$Y \leftarrow \frac{Y}{r}$
if $Y \geq \frac{\alpha}{\varepsilon \cdot \deg_e}$ **then**
  return 1
else
  return 0

▶ **Lemma 17** (Estimation guarantee of `Heavy`). *The algorithm* `Heavy`$(e, \alpha, \varepsilon, \delta)$ *satisfies the following properties with probability at least* $1-\delta$*: (i) returns* 1 *edge* e *if it is* $\frac{2\alpha}{\varepsilon}$*-heavy; (ii) returns* 0 *edge* e *if it is* $\frac{\alpha}{2\varepsilon}$*-light.*

Proof. For (i), we only consider edges that have at least $\frac{2\alpha}{\varepsilon}$ triangles. In this case, the random variables Y_i (Y_i as in Algorithm 2; $Y_i = 1$ if v_i and e form a triangle; 0, otherwise) are i.i.d. Bernoulli random variables taking value 1 with probability at least $\frac{2\alpha}{\varepsilon \deg_e}$. Hence, we have the following using linearity of expectation: $\mathbb{E}[Y] = \mathbb{E}\left[\frac{1}{r}\sum_{i\in[r]} Y_i\right] = \mathbb{E}[Y_i] > \frac{2\alpha}{\varepsilon \deg_e}$

As $Y = \frac{1}{r}\sum_i Y_i$, we can upper bound the probability of the algorithm returning 0 for the edge e, by a multiplicative Chernoff bound (Lemma 7) as follows:

$$\begin{aligned}
\Pr\left[Y \leq \frac{\alpha}{\varepsilon \deg_e}\right] &\leq \Pr\left[Y \leq \left(1-\frac{1}{2}\right)\mathbb{E}[Y]\right] && \left(\mathbb{E}[Y] > \frac{2\alpha}{\varepsilon \deg_e}\right) \\
&\leq \exp\left(-\frac{r\,\mathbb{E}[Y]}{12}\right) && \text{(by multiplicative Chernoff bound)} \\
&\leq \exp\left(-\frac{r\alpha}{6\deg_e \varepsilon}\right) && \left(\mathbb{E}[Y] > \frac{2\alpha}{\varepsilon \deg_e}\right) \\
&\leq \delta && \left(r = \frac{16\varepsilon \deg_e}{\alpha}\log\left(\frac{1}{\delta}\right)\right)
\end{aligned}$$

For (ii), we do not have a lower bound on the probability of success ($Y_i = 1$) in general and hence we cannot obtain a lower bound on $\mathbb{E}[Y]$. Now, observe that for the edges that participate in very few triangles, the probability of finding triangles (i.e., getting $Y_i = 1$) is

low. However, such light edges can still tolerate a high approximation error to be accepted (as a light edge). To account for the trade-off between the lower bound on the probability of $Y_i = 1$ and the upper bound on the approximation factor, we divide the edges participating in at most $\frac{\alpha}{2\varepsilon}$ triangles into $\left\lceil \log(\frac{\alpha}{\varepsilon}) \right\rceil$ buckets with each bucket being defined as the set of edges $\mathcal{B}_k = \left\{ e | \frac{\alpha}{2^{k+1}\varepsilon} \leq T_e < \frac{\alpha}{2^k \varepsilon} \right\}$. For each of these buckets, observe that when `Heavy` is called for an edge belonging to the bucket, we have $\Pr[Y_i = 1] = \frac{\mathsf{t_e}}{\deg_e} \geq \frac{\alpha}{2^{k+1}\varepsilon \deg_e}$, and hence $\mathbb{E}[Y] = \mathbb{E}[Y_i] \geq \frac{\alpha}{2^{k+1}\varepsilon \deg_e}$.

On the other hand, we have $\mathbb{E}[Y] < \frac{\alpha}{2^k \varepsilon \deg_e}$, and hence, $\left(1 + 2^{k-1}\right)\mathbb{E}[Y] < \frac{\alpha}{\varepsilon \deg_e}$. Using these observations, we complete the proof by considering any e in these buckets:

$$
\begin{aligned}
\Pr\left[Y \geq \frac{\alpha}{\varepsilon \deg_e} \right] &\leq \Pr\left[Y \geq \left(1 + 2^{k-1}\right)\mathbb{E}[Y] \right] && \left(\left(1 + 2^{k-1}\right)\mathbb{E}[Y] < \frac{\alpha}{\varepsilon \deg_e} \right) \\
&\leq \exp\left(- \frac{2^{2k-2} r \, \mathbb{E}[Y]}{2 + 2^{k-1}} \right) && \text{(by multiplicative Chernoff bound)} \\
&\leq \exp\left(- \frac{2^{2k} r \, \mathbb{E}[Y]}{2^{k+3}} \right) && (k \geq 1) \\
&\leq \exp\left(- \frac{r\alpha}{16\varepsilon \deg_e} \right) && \left(\mathbb{E}[Y] > \frac{\alpha}{2^{k+1}\varepsilon \deg_e} \right) \\
&\leq \delta && \left(r = \frac{16\varepsilon \deg_e}{\alpha} \log\left(\frac{1}{\delta}\right) \right) \quad \blacktriangleleft
\end{aligned}
$$

Lemma 17 shows that Algorithm 2 can decide whether an edge is heavy or not with probability at least $1 - \delta$ using $\frac{16\varepsilon}{\alpha} \deg_e \log\left(\frac{1}{\delta}\right)$ iterations; making 2 `Degree`, 1 `Neighbour` and 1 `Pair` queries in each iteration. For an individual edge, $\deg_e$ can be at most $n - 1$, and hence the subroutine might contribute to additional queries for each edge. However, as part of Algorithm 1, `Heavy` is called on a set of edges drawn uniformly at random. Hence, in the following lemma, we bound the expected number of queries made by `Heavy` when called on edges that were drawn uniformly at random.

▶ **Lemma 18** (Query complexity of `Heavy`). *`Heavy`$(e, \alpha, \varepsilon, \delta)$ makes $c\varepsilon \log\left(\frac{1}{\delta}\right)$ queries in expectation on an edge $e \sim \mathrm{Unif}(E)$.*

Proof. For edge e, `Heavy`$(e, \alpha, \varepsilon, \delta)$ makes $\left\lceil \frac{16\varepsilon \deg_e}{\alpha} \log\left(\frac{1}{\delta}\right) \right\rceil$ iterations with each iteration making 4 queries. Hence, the expected number of queries is:

$$
\begin{aligned}
\mathop{\mathbb{E}}_{e \sim \mathrm{Unif}(E)} \left[4 \left\lceil \frac{16\varepsilon \deg_e}{\alpha} \log\left(\frac{1}{\delta}\right) \right\rceil \right] &\leq \frac{64\varepsilon}{\alpha} \log\left(\frac{1}{\delta}\right) \mathop{\mathbb{E}}_{e \sim \mathrm{Unif}(E)} [\deg_e] + 4 \\
&= \frac{64\varepsilon}{\alpha} \log\left(\frac{1}{\delta}\right) \frac{1}{m} \sum_{e \in E} \deg_e + 4 \\
&\leq \frac{64\varepsilon}{\alpha} \log\left(\frac{1}{\delta}\right) \frac{1}{m} 2m\alpha + 4 && \text{(by Lemma 5)} \\
&\leq 132\varepsilon \log\left(\frac{1}{\delta}\right) && \left(\varepsilon \log\left(\frac{1}{\delta}\right) \geq 1 \right) \quad \blacktriangleleft
\end{aligned}
$$

4.4 Finalizing the algorithm

In this section, we combine the algorithms discussed above to obtain our final algorithm. Our goal is to call `Heavy` with appropriate parameters instead of `HeavyOracle` so that the approximation error due to the heavy triangles not being counted remains small. We also derive the query complexity of the algorithm including the queries made through `Heavy`.

4.4.1 Algorithm with an estimate $\widetilde{T}$

Algorithm 3 Triangle Counting Algorithm - with $\widetilde{T}$.

Require: `Degree`, `Neighbour`, `Pair`, and `RandomEdge` query access to a graph G. Parameters $\widetilde{T}, \alpha, \varepsilon, m$

1: Call Algorithm 1 with parameters $\widetilde{T}, \alpha, \varepsilon/2$, and thresholds $l = 6$, and $h = 24$. We also implement the oracle $\texttt{HeavyOracle}(e, \alpha, \varepsilon)$ through $\texttt{Heavy}\left(e, \alpha, \varepsilon/6, \frac{1}{mn}\right)$. ▷
Due to Algorithm 1 being called with parameter $\varepsilon/2$ and the implementation of `Heavy` as stated, the threshold parameters are evaluated w.r.t. call to `Heavy` with parameter $l = 6$ and $h = 24$

▶ **Theorem 19** (Performance guarantees of Algorithm 3)**.** *Algorithm 3 makes at most* $c\varepsilon^{-3}(m\alpha/\widetilde{T})\log^2 n$ *queries in expectation and returns* $\widehat{T}$ *such that* $\Pr\left[\widehat{T} \in [(1-\varepsilon)T, (1+\varepsilon)T]\right] \geq 1 - \frac{1}{c\log n}$.

Proof. Algorithm 3 will make the same number of calls to `Heavy` as did Algorithm 1 to `HeavyOracle`. By Theorem 16, Algorithm 3 makes $c(1+h)\varepsilon^{-3}(m\alpha/\widetilde{T})\log n$ queries and $c(1+h)\varepsilon^{-3}\log(n)(m\alpha/\widetilde{T})$ calls to `Heavy`. By Lemma 18, each call to `Heavy` requires $c\varepsilon\log n$ queries in expectation. Combining with the fact that we have $h = 24$, the algorithm requires $(c + c\varepsilon\log n)\left(\varepsilon^{-3}(m\alpha/\widetilde{T})c\log n\right) \leq c\varepsilon^{-3}(m\alpha/\widetilde{T})\log^2 n$ queries in expectation.

By Lemma 17, we can use $\texttt{Heavy}\left(e, \alpha, \varepsilon/6, \frac{1}{mn}\right)$ as an implementation of the idealized $\texttt{HeavyOracle}(e, \alpha, \varepsilon)$. This ensures that a $\frac{6\alpha}{\varepsilon}$-light edge is accepted and a $\frac{24\alpha}{\varepsilon}$-heavy edge is rejected with probability at least $1 - \frac{1}{mn}$. By union bound, the algorithm accepts all $\frac{6\alpha}{\varepsilon}$-light edges and rejects all $\frac{24\alpha}{\varepsilon}$-heavy edges in S with probability at least $1 - \frac{1}{n}$. Hence, by Corollary 11 and Lemma 14, we have,

$$\mathbb{E}\left[\widehat{T}\right] = T_L^{\frac{6\alpha}{\varepsilon}} \in [(1-\varepsilon/2)T, T] \tag{7}$$

By Theorem 16, we have that:

$$\Pr\left[\widehat{T} \in \left[(1-\varepsilon/2)T_L^{\frac{6\alpha}{\varepsilon}}, (1+\varepsilon/2)T_L^{\frac{6\alpha}{\varepsilon}}\right]\right] \geq 1 - \frac{1}{c\log n} \tag{8}$$

Combining Equations (7) and (8) and using union bound on the event that all oracle calls were executed correctly, for large enough n:

$$\Pr\left[\widehat{T} \in [(1-\varepsilon)T, (1+\varepsilon)T]\right] \geq 1 - \frac{1}{c\log n}$$ ◀

4.4.2 Getting rid of the assumption on $\widetilde{T}$

In this section, we describe the steps to obtain Theorem 22 from Theorem 19. First, we remove the assumption on the knowledge of $\widetilde{T}$ for Algorithm 3. To achieve that, we search for an appropriate choice of $\widetilde{T}$ starting from $\bar{t} = n^3$ and halving it each time we fail to find a $\widetilde{T}$ satisfying the assumption that $\widetilde{T} \leq 2T$. We must also bound the probability of $\bar{t}$ deviating significantly below T. To ensure that, for each value of $\bar{t}$, we run Algorithm 3 using values of $\widetilde{T}$ as $n^3, n^3/2, ..., \bar{t}$.

First we bound the probability that the Algorithm 4 terminates at a choice of $\widetilde{T}$ that does not satisfy the assumption that $\widetilde{T} \leq 2T$.

Algorithm 4 Triangle Counting Algorithm.

Require: `Degree`, `Neighbour`, `Pair`, and `RandomEdge` query access to a graph G. Parameters α, ε, m

1: **for** $\bar{t}$ in $\left[n^3, n^3/2, ..., 1\right]$ **do**
2: **for** $\widetilde{T}$ in $\left[n^3, n^3/2, ..., \bar{t}\right]$ **do**
3: **for** $i \in [2\log(c\log(n))]$ **do**
4: $X_i \leftarrow$ Solution to Algorithm 3 with parameters $\widetilde{T}, \alpha, \varepsilon$
5: $X \leftarrow \min_i X_i$
6: **if** $X \geq \widetilde{T}$ **then**
7: **return** X

▶ **Lemma 20** (Termination bound of Algorithm 4). *When $\widetilde{T} > 2T$, the algorithm terminates with probability at most $\frac{1}{c\log^2 n}$.*

Proof. By Lemma 14, we have from Markov's inequality:

$$\Pr\left[\widehat{T} > 2T\right] \leq \frac{\mathbb{E}\left[\widehat{T}\right]}{2T} \leq \frac{1}{2}$$

Now, we have $\Pr\left[X \geq \widetilde{T}\right] \leq \Pr\left[\cap_i X_i \geq \widetilde{T}\right] \leq \frac{1}{c\log^2 n}$ ◀

▶ **Lemma 21** (Lower bound of $\bar{t}$ for Algorithm 4). *The algorithm reaches a value of $\bar{t} \leq T/2^k$ $(k \geq 1)$ with probability at most $\frac{1}{(c\log n)^k}$.*

Proof. For every such value of $\bar{t}$, we have a $\widetilde{T}$ in Line 2 of Algorithm 4 such that $\widetilde{T} \leq T/2$. By Theorem 19, the algorithm returns an estimate $X_i \geq T/2 \geq \widetilde{T}$ with probability at least $1 - \frac{1}{c\log n}$. Taking a union bound over possible values of $i \in [2\log(c\log n)]$, we have Algorithm 4 returning an X such that $X \geq T/2 \geq \widetilde{T}$ with probability at least $1 - \frac{1}{c\log n}$, and the algorithm terminates.

Hence, to get to a $\bar{t} \leq \frac{T}{2^k}$, Algorithm 4 must have failed to terminate for all previous values of $\bar{t}$, which happens with probability at most $\frac{1}{(c\log n)^k}$. ◀

Finally we combine Lemmas 20 and 21 to obtain the following theorem quantifying the estimation guarantees and query complexity of Algorithm 4. The following theorem formalizes the Theorem 2 of Section 1.1.

▶ **Theorem 22** (Upper bound - Formal). *There exists an algorithm that makes $\widetilde{O}\left(\frac{m\alpha\log\frac{1}{\delta}}{\varepsilon^3 T}\right)$ queries in expectation, and returns $X \in [(1-\varepsilon)T, (1+\varepsilon)T]$ with probability at least $1-\delta$.*

Proof. The algorithm runs through at most $\log^2 n$ values of $\widetilde{T}$ such that $\widetilde{T} > 2T$. By Lemma 20, the algorithm terminates in each such case with probability at most $1/c\log^2 n$. For each value of $\bar{t} \leq 2T$, by Theorem 19, the algorithm returns a wrong value with probability at most $1/c\log n$. There are at most $3\log n$ such values of $\bar{t}$. Taking an union bound and fixing the constant c appropriately, the algorithm returns a correct output with probability at least $5/6$.

For each $\bar{t}$ in Line 1 of Algorithm 4, by Theorem 19, the algorithm makes $\widetilde{O}\left((m\alpha/\varepsilon^3\bar{t})\right)$ queries. Hence, till $\bar{t} \leq T/2$, the algorithm makes $\widetilde{O}\left((m\alpha/\varepsilon^3 T)\right)$ queries. Additionally, by Lemma 21, the queries beyond $\bar{t} \leq T$ can be bounded as:

$$\sum_{i\in\log(n)} \frac{1}{(c\log n)^k} \cdot 2^k \cdot \widetilde{O}\left(\frac{m\alpha}{\varepsilon^3 T}\right) = \widetilde{O}\left(\frac{m\alpha}{\varepsilon^3 T}\right)$$

By the well-known median trick [19], the median of $O\left(\log\frac{1}{\delta}\right)$ independent runs of Algorithm 4 establishes the result. ◀

5 Lower bound

In this section, we prove a lower bound that accounts for ε, δ, and the arboricity α of the graph by extending the ideas proposed in [8]. Our lower bound almost matches our proposed upper bound stated in Theorem 22. We first state the problem Popcount Thresholding Problem (referred to as PTP) in the query framework:

▶ **Definition 23** ($\texttt{PTP}_{M,k,\gamma}$). *Given a string $x \in \{0,1\}^M$, the problem $\textit{PTP}_{M,k,\gamma}$ is to distinguish whether x is generated by i.i.d. samples from $\mathcal{D}_0$ or $\mathcal{D}_1$ defined as follows:*

- $\boldsymbol{\mathcal{D}_0}$ *: For all $i \in [M]$, x_i is set to 1 with probability $(1-2\gamma)\frac{k}{M}$, and set to 0, otherwise.*
- $\boldsymbol{\mathcal{D}_1}$ *: For all $i \in [M]$, x_i is set to 1 with probability $(1+2\gamma)\frac{k}{M}$, and set to 0, otherwise.*

The problem is to decide if x is generated from $\mathcal{D}_0$ or $\mathcal{D}_1$ by querying x at any of its M bits.

We state the following lemma [8] quantifying the query complexity of $\texttt{PTP}_{M,k,\gamma}$.

▶ **Lemma 24** (PTP Query Lower Bound [8]). *For any $\gamma \in (0,1/4)$, $\delta \in (0,1/100)$, and integers $M \geq 1$, $\log(1/\delta)\cdot 12/\gamma^2 \leq k \leq M/6$, $R_\delta(\textit{PTP}_{M,k,\gamma}) \geq \frac{M\log(1/4\delta)}{24\gamma^2 k}$ where $R_\delta(\textit{PTP}_{M,k,\gamma})$ is the randomized query complexity to decide $\textit{PTP}_{M,k,\gamma}$ problem with probability at least $1-\delta$.*

We also state the following lemma, establishing bounds on the ℓ_1-norm of x, which was partially proved in [8].

▶ **Lemma 25.** *In $\textit{PTP}_{M,k,\gamma}$, for any $\gamma \in (0,1/4)$, $\delta \in (0,1/100)$, and integers $M \geq 1$, $\log(1/\delta)\cdot 12/\gamma^2 \leq k \leq M/6$, let $\|x\|_1$ denote the number of 1's in the string x, then:*

(i) $\Pr[\|x\|_1 > (1-\gamma)\cdot k \,|\, x \sim \mathcal{D}_0] \leq \delta$;

(ii) $\Pr[\|x\|_1 < (1+\gamma)\cdot k \,|\, x \sim \mathcal{D}_1] \leq \delta$;

(iii) $\Pr[\|x\|_1 < (1-4\gamma)\cdot k] \leq \delta$;

In [8], (i) and (ii) have been shown using Chernoff bound. (iii) can also be shown by using Chernoff bound. We combine two results to obtain the result. First we state the lemma due to [8]:

▶ **Lemma 26** ([8]). *In $\textit{PTP}_{M,k,\gamma}$, for any $\gamma \in (0,1/4)$, $\delta \in (0,1/100)$, and integers $M \geq 1$, $\log(1/\delta)\cdot 12/\gamma^2 \leq k \leq M/6$,*

(i) $\Pr[\|x\|_1 > (1-\gamma)\cdot k \mid x \sim \mathcal{D}_0] \leq \delta$;

(ii) $\Pr[\|x\|_1 < (1+\gamma)\cdot k \mid x \sim \mathcal{D}_1] \leq \delta$

where $\|x\|_1$ denotes the number of 1's in the string x.

We introduce another lemma to lower bound the ℓ_1 norm of x for $\mathcal{D}_0$.

▶ **Lemma 27.** *In $\textit{PTP}_{M,k,\gamma}$, for any $\gamma \in (0,1/4)$, $\delta \in (0,1/100)$, and integers $M \geq 1$, $\log(1/\delta)\cdot 12/\gamma^2 \leq k \leq M/6$, $\Pr[\|x\|_1 < (1-4\gamma)\cdot k \mid x \sim \mathcal{D}_0] \leq \delta$*

Proof. By definition of $\mathcal{D}_0$ and linearity of expectations, we have:

$$\mathbb{E}[\|x\|_1] = \sum_{i\in[M]} \mathbb{E}[x_i] = (1-2\gamma)\,k$$

Now, given the independence of each x_i, we can use Chernoff bound (Lemma 7) to obtain:

$$\begin{aligned}
&\Pr\left[\|x\|_1 < (1-4\gamma)\,k\right] \\
&= \Pr\left[\|x\|_1 - \mathbb{E}\left[\|x\|_1\right] > \frac{2\gamma}{1-2\gamma}\,\mathbb{E}\left[\|x\|_1\right]\right] \\
&\leq \exp\left(-\frac{4\gamma^2\,\mathbb{E}\left[\|x\|_1\right]}{3\,(1-2\gamma)^2}\right) && \text{(by Chernoff bound)} \\
&\leq \exp\left(-\frac{48\gamma^2\log\left(1/\delta\right)}{3\gamma^2\,(1-2\gamma)}\right) && \left(\mathbb{E}\left[\|x\|_1\right] = (1-2\gamma)\,k, k \geq \log(1/\delta)\cdot 12/\gamma^2\right) \\
&\leq \delta && (\gamma < 1/4)\ \blacktriangleleft
\end{aligned}$$

Combining Lemma 26 and 27, we obtain the desired result.

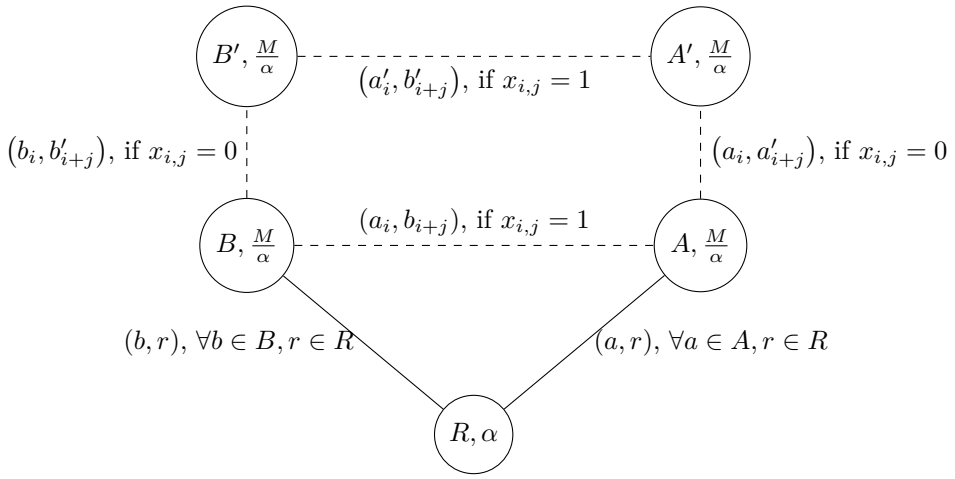

Figure 1 Lower Bound Graph Construction.

The following theorem formalizes the Theorem 3 of Section 1.1.

▶ **Theorem 28** (Lower bound - Formal). *Any algorithm that solves triangle estimation problem with $\varepsilon \leq \frac{1}{8}$ using* `Degree`, `Neighbour`, `Pair` *and* `RandomEdge` *for any graph with m edges, T triangles, and arboricity α such that $T = \Omega\left(\frac{\alpha\log(1/\delta)}{\varepsilon^2}\right)$ requires $\Omega\left(\frac{m\alpha\log(1/\delta)}{\varepsilon^2 T}\right)$ queries.*

Proof. We want to show that given a graph G, it takes $\Omega\left(\frac{m\alpha\log(1/\delta)}{\varepsilon^2 T}\right)$ queries to obtain an estimate $\widetilde{T}$ such that $\widetilde{T} \in (1\pm\varepsilon)T$ with probability at least $1-\delta$. For a contradiction, let us assume that there exists an algorithm $\mathcal{A}_T$ that, for some arboricity α, computes an estimate $\widetilde{T}$ such that $\widetilde{T} \in (1\pm\varepsilon)T$ with probability at least $1-\delta$ using $o\left(\frac{m\alpha\log(1/\delta)}{\varepsilon^2 T}\right)$ queries.

To show the contradiction, we design an algorithm that solves $\mathtt{PTP}_{M,k,\gamma}$ in less than $\frac{M\log(1/4\delta)}{24\gamma^2 k}$ queries using $\mathcal{A}_T$. Given an instance of x generated from $\mathtt{PTP}_{M,k,\gamma}$, we consider a graph $G_x = (V_x, E_x)$ defined as:

The vertex set V_x. The vertex set V_x consists of 5 sets of disjoint and independent set of vertices A, A', B, B', and R, with $|A| = |A'| = |B| = |B'| = M/\alpha$, and $|R| = \alpha$. Vertices of A, A', B and B' will be named as a, a', b and b', respectively.

The edge set E_x. There exists an edge between every vertex in $A \cup B$ to every vertex in R. Observe that this makes sure that the arboricity of G_x is at least the average degree of the subgraph induced by $A \cup B \cup R$, i.e., $\Omega(\alpha)$. If a bit of x is 1 (resp. 0), there will be an edge from a vertex in A (resp. A) to a vertex in B (resp. A'), and an edge from a vertex in A' (resp. B) to a vertex in B' (resp. B').

We index the problem instance x of length M as $\left[\frac{M}{\alpha}\right] \times [\alpha]$, denoting $x_{(i-1)\times\alpha+j}$ as $x_{i,j}$, where $i \in \left[\frac{M}{\alpha}\right]$ and $j \in [\alpha]$. We add an edge $\left(a_i, a'_{i+j}\right)$, and an edge $\left(b_i, b'_{i+j}\right)$ if $x_{i,j} = 0$. We add an edge (a_i, b_{i+j}), and an edge $\left(a'_i, b'_{i+j}\right)$ if $x_{i,j} = 1$. All $(i+j)$ additions here are modulo $\left[\frac{M}{\alpha}\right]$.

Consider the orientation of edges such that all edges from R is oriented outwards, and other edges are oriented arbitrarily. This gives a DAG with the out-degree of each edge being bounded by 2α. As a DAG with out-degree at most α ensures that the arboricity of the graph G_x is at most α[28, 47, 21], the graph has arboricity at most 2α. Hence, the arboricity of G_x is $\Theta(\alpha)$, as we have already shown it to be $\Omega(\alpha)$.

From the construction, observe that the number of edges between A and B is $\|x\|_1$. Moreover, each edge between A and B adds α triangles. Hence, the number of triangles in G_x is exactly $\|x\|_1 \alpha$. Also note that we have added $2M$ edges between $A \cup B$ and R, and further $2M$ edges (in the subgraph induced by $V_x \setminus S$) according to the entries of x, 2 for each bit x_i. Hence, we have $m = 4M$, and we fix $\varepsilon = \gamma$.

We now describe $\mathcal{A}_T^{\mathtt{PTP}}$ an algorithm that uses $\mathcal{A}_T$ to solve $\mathtt{PTP}_{M,k,\gamma}$ using less than $\frac{M \log(1/4\delta)}{24\gamma^2 k}$ queries. Given a string x, we generate G_x and estimate the number of triangles $\widehat{T}$ by calling $\mathcal{A}_T$ using $\frac{m \log(1/4\delta)}{200\varepsilon^2 k} = \frac{M \log(1/4\delta)}{50\gamma^2 k}$ queries. If $\widehat{T} < \left(1-\gamma^2\right) k\alpha$, it outputs $x \sim \mathcal{D}_0$; otherwise, it outputs $x \sim \mathcal{D}_1$. Also, observe that by Lemma 25, we have $T = \alpha \|x\|_1 \geq \alpha(1-4\gamma)k \geq \frac{\alpha k}{2}$ with probability at least $1-\delta$, where the last inequality follows from the fact that $\gamma = \varepsilon \leq \frac{1}{4}$. Lemma 25 is applicable due to the fact that $T = \Omega\left(\frac{\alpha \log(1/\delta)}{\varepsilon^2}\right)$. Hence, we have $\frac{m \log(1/4\delta)}{200\varepsilon^2 k} \geq \frac{m\alpha \log(1/4\delta)}{200\varepsilon^2 T}$. Thus, $\mathcal{A}_T$ is allowed to make $o\left(\frac{m\alpha \log(1/\delta)}{\varepsilon^2 T}\right)$ queries under the given query bound.

By Lemma 25, to distinguish between whether x is generated from $\mathcal{D}_0$ or $\mathcal{D}_1$ with probability at least $1-\delta$, it suffices to show that we can use $\mathcal{A}_T$ to distinguish between the instance where $\|x\|_1 > (1+\gamma)\,k$ and the instance where $\|x\|_1 < (1-\gamma)\,k$ instance with probability at least $1-\frac{\delta}{2}$. We now show that $\mathcal{A}_T^{\mathtt{PTP}}$ outputs $\mathcal{D}_1$ with probability at least $1-\frac{\delta}{2}$ given $\|x\|_1 > (1+\gamma)\,k$, and outputs $\mathcal{D}_0$ with probability at least $1-\frac{\delta}{2}$ given $\|x\|_1 < (1-\gamma)\,k$. We consider the two cases separately:

Case I: $(\|x\|_1 > (1+\gamma)\,k)$. Our construction ensures that the number of triangles in G_x is $T = \|x\|_1 \alpha > (1+\gamma)\,k\alpha = (1+\varepsilon)\,k\alpha$. Additionally, by our assumption on $\mathcal{A}_T$, it outputs an estimate $\widehat{T} \geq (1-\varepsilon)T$ with probability $1-\frac{\delta}{2}$. Thus, we have $\widetilde{T} \geq \left(1-\varepsilon^2\right) k\alpha$ with probability at least $1-\frac{\delta}{2}$.

Case II: $(\|x\|_1 < (1-\gamma)\,k)$. Our construction ensures that the number of triangles in G_x is $T = \|x\|_1 \alpha < (1-\gamma)\,k\alpha = (1-\varepsilon)\,k\alpha$. Additionally, by our assumption on $\mathcal{A}_T$, it outputs an estimate $\widehat{T} \leq (1+\varepsilon)T$ with probability $1-\frac{\delta}{2}$. Thus, we have $\widetilde{T} \leq \left(1-\varepsilon^2\right) k\alpha$ with probability at least $1-\frac{\delta}{2}$.

Now we state how to simulate the required queries used by the algorithm:

- **`Degree`(v):** For a vertex $v \in A \cup B \cup A' \cup B'$, return α, and for a vertex $v \in R$, return $\frac{2M}{\alpha}$. Hence, for `Degree` queries, no queries are made to the string.
- **`Neighbour`(v, i):** For a vertex $v \in A \cup B \cup A' \cup B'$, w.l.o.g assume v to be $a_j \in A$. Return a'_{i+j} if $x_{i,j} = 0$, and b_{i+j} otherwise. For a vertex $v \in R$, if $i \leq \frac{m}{\alpha}$, return a_i, else return $b_{i-\frac{m}{\alpha}}$. Hence, for `Neighbour` queries, a single query is made to the string.

- **`Pair`(u, v):** Given a vertex pair (v, u), there can be 3 cases: (a) If the vertex $v \in A \cup B$, w.l.o.g assume v to be $a_i \in A$, if $u \in R$, return 1, else if $u = b_j \in B$ and $x_{i,j-i} = 1$, return 1, else if $u = a'_j \in A'$ and $x_{i,j-i} = 0$, return 1, else return 0. (b) If a vertex $v \in A' \cup B'$, w.l.o.g assume the v to be $a'_i \in A'$, if $u = a_j \in A$, return 1 if $x_{j,i-j} = 0$, else if $u = b'_j \in B'$, return 1 if $x_{j,i-j} = 1$, else return 0. If $v \in R$, return 1 if $u \in A \cup B$, else return 0. (c) If a vertex $v \in R$, return 1 if $u \in A \cup B$, return 0 otherwise. Hence, for `Pair` queries, a single query is made to the string.
- **`RandomEdge`:** Sample a vertex v with probability $\frac{\deg_v}{4M}$. Choose $i \in \deg_{(v)}$ uniformly at random, query $u =$ `Neighbour`(v, i) and return (v, u). Hence, for `RandomEdge` queries, a single query is made to the string for the `Neighbour` query. ◀

The following corollary is a direct implication from Theorem 28 due to the fact that we consider a weaker model (without access to `RandomEdge` queries) compared to Theorem 28.

▶ **Corollary 29** (Lower Bound for Local Queries). *Any algorithm that solves triangle estimation problem with $\varepsilon \leq \frac{1}{4}$ using `Degree`, `Neighbour`, and `Pair` requires $\Omega\left(\frac{m\alpha \log(1/\delta)}{\varepsilon^2 T}\right)$ queries.*

6 Conclusion

In this paper, we present an almost optimal algorithm for triangle counting in graphs of bounded arboricity, assuming access to both local queries and `RandomEdge` queries. In particular, the query complexity of our algorithm is $O(m\alpha/T)$.[3] Extending our result to clique counting remains an interesting open question. Eden et al. [28] showed that the number of k-cliques can be estimated using $O\left(n/T_k^{1/k} + m^{k/2}/T_k\right)$ local queries, where T_k denotes the number of k-cliques in the graph. When `RandomEdge` queries are also available, Assadi et al. [7] established a bound of $O\left(m^{k/2}/T_k\right)$. For graphs with arboricity bounded by α, Eden et al. [28] showed that $O\left(n/T_k^{1/k} + m\alpha^{k-2}/T_k\right)$ local queries suffice. We believe that, when `RandomEdge` queries are available in addition to local queries, the bound can be improved to $O\left(m\alpha^{k-2}/T_k\right)$. However, establishing the complexity of clique counting (when `RandomEdge` is available along with local queries) remains an open question. A similar open question was posed in the streaming model by Bera and Seshadri [13].

An Improved Construction of Variety-Evasive Subspace Families

Robert Andrews

Abhibhav Garg
Cheriton School of Computer Science, University of Waterloo, Canada

Abstract

We study the question of explicitly constructing variety-evasive subspace families, a pseudorandom primitive introduced by Guo (Computational Complexity 2024) that generalizes both hitting sets and lossless rank condensers. Roughly speaking, a variety-evasive subspace family $\mathcal{H}$ is a collection of subspaces such that for every algebraic variety V in a fixed family $\mathcal{F}$, there is some subspace $W \in \mathcal{H}$ that is in general position with respect to V.

We give an explicit construction of a subspace families that evade all degree-d varieties in an n-dimensional affine or projective space. Our construction improves on the size of the variety-evasive subspace families constructed by Guo and, for varieties of degree $n^{1+\Omega(1)}$, is polynomially close to Guo's lower bound on the size of any such variety-evasive subspace family. Our variety-evasive subspace families rely on an improved construction of hitting sets for Chow forms of algebraic varieties.

1 Introduction

1.1 Background

The probabilistic method is a powerful tool with widespread use throughout mathematics. Many objects of interest throughout combinatorics and computer science, such as Ramsey graphs and randomness extractors, can be shown to exist via the probabilistic method, often with excellent parameters. While probabilistic arguments excel at demonstrating existence, they fall short of providing an efficient, deterministic means of constructing the object of interest. One of the main goals of pseudorandomness is to obtain explicit constructions of objects that exhibit properties similar to those enjoyed by a randomly-chosen object. Not only are explicit constructions interesting in their own right, but they are all the more important in algorithmic applications such as derandomization, where the aim is to reduce or eliminate the use of randomness as an algorithmic resource.

Over time, the theory of pseudorandomness has developed into a rich area of theoretical computer science that studies a variety of objects, including expander graphs, list-decodable codes, randomness extractors, pseudorandom generators, and the numerous connections and relationships between them [14]. More recently, a parallel theory of linear-algebraic pseudorandomness has also appeared. This theory studies collections of linear maps that

satisfy various pseudorandom properties, including rank extractors and rank condensers, subspace designs, dimension expanders, and subspace-evasive sets, where the dimension of vector spaces plays a role analogous to that of min-entropy in classical pseudorandomness.

In this work, we study the construction of *variety-evasive subspace families*, a linear-algebraic pseudorandom object introduced by Guo [7]. Roughly speaking, a variety-evasive subspace family $\mathcal{H}$ is a collection of linear or affine spaces such that for any algebraic variety V of interest, there is some subspace $W \in \mathcal{H}$ that is in general position with respect to V. For example, if V is a curve in the plane and $\mathcal{H}$ is a collection of lines, then there should be some line $W \in \mathcal{H}$ such that the intersection $V \cap W$ is nonempty and zero-dimensional. More generally, when the variety V is fixed, most linear spaces (and in fact, most varieties) W will satisfy $\operatorname{codim}(V \cap W) = \operatorname{codim}(V) + \operatorname{codim}(W)$, and a variety-evasive subspace family must contain a subspace W that intersects V in a manner similar to a random subspace. This is the sort of behavior captured by the notion of one variety evading another, defined below.

▶ **Definition 1.1** (Evasiveness). *Let V and W be irreducible subvarieties of $\mathbb{P}^n$ or $\mathbb{A}^n$. We say that W* evades *V if*

$$\dim(V \cap W) \leq \dim(V) + \dim(W) - n.$$

If V and W are affine varieties, we say that W strongly evades *V if the above holds with equality whenever the right-hand side is nonnegative. If V is a reducible variety, we say that W* (strongly) evades *V if W (strongly) evades each irreducible component of V.*

When V and W are affine varieties, it may be the case that $V \cap W = \varnothing$, even though $\operatorname{codim}(V) + \operatorname{codim}(W)$ is not large enough to force this intersection to be empty in general. The notion of W strongly evading V adds the constraint that the intersection $V \cap W$ should have the expected codimension of $\operatorname{codim}(V) + \operatorname{codim}(W)$ whenever this is possible.

As a matter of notational convenience, we also define the notion of a k-subspace family.

▶ **Definition 1.2** (k-Subspace family). *For $0 \leq k \leq n$, a* k-subspace family *is a finite collection of k-dimensional subspaces of $\mathbb{P}^n$. Similarly, an* affine k-subspace family *is a finite collection of k-dimensional affine subspaces of $\mathbb{A}^n$.*

We can now define variety-evasive subspace families, the main object of study in this work.

▶ **Definition 1.3** (Variety-evasive subspace families [7]). *Let $\mathcal{F}$ be a family of subvarieties of $\mathbb{P}^n$ (or of $\mathbb{A}^n$) and let $\mathcal{H}$ be a k-subspace (or affine k-subspace) family.*

1. *We say that the family $\mathcal{H}$ is* (strongly) $\mathcal{F}$-evasive *if for every $V \in \mathcal{F}$, there is some $W \in \mathcal{H}$ that (strongly) evades V. In the case where $\mathcal{F}$ is the family of all degree-d subvarieties, we say that $\mathcal{H}$ is* (strongly) (n, d)-evasive.
2. *We say that $\mathcal{H}$ is* (strongly) $(\mathcal{F}, \varepsilon)$-evasive *if for every $V \in \mathcal{F}$, a randomly-chosen $W \in \mathcal{H}$ (strongly) evades V with probability at least $1 - \varepsilon$. When $\mathcal{F}$ is the family of all degree-d subvarieties, we say that $\mathcal{H}$ is* (strongly) (n, d, ε)-evasive.

As observed by Guo [7], variety-evasive subspace families are a common generalization of two natural problems in algebraic pseudorandomness. The first such problem is the construction of hitting sets for arithmetic circuits, a common approach to derandomizing algorithms for the polynomial identity testing problem. A hitting set $\mathcal{H} \subseteq \mathbb{F}^n$ is a collection of points such that for every nonzero polynomial $f \in \mathcal{C}$ in a circuit class $\mathcal{C}$ of interest, there is some point $\boldsymbol{\alpha} \in \mathcal{H}$ such that $f(\boldsymbol{\alpha}) \neq 0$. The point $\boldsymbol{\alpha}$ witnesses the fact that f is nonzero

as a polynomial. An efficient, deterministic construction of such a hitting set immediately implies a deterministic algorithm with similar complexity for testing polynomials $f \in \mathcal{C}$. Geometrically, one can view a hitting set as a set of points $\mathcal{H}$ such that for every hypersurface V defined by a polynomial $f \in \mathcal{C}$, there is a point $\boldsymbol{\alpha} \in \mathcal{H}$ such that $\boldsymbol{\alpha} \notin V$. Taking $\mathcal{F}_{\mathcal{C}}$ to be the family of hypersurfaces defined by polynomials in $\mathcal{C}$, a hitting set is precisely a $\mathcal{F}_{\mathcal{C}}$-evasive 0-subspace family.

The second task generalized by variety-evasive subspace families is the construction of lossless rank condensers. Rank condensers, first appearing in the work of Gabizon and Raz [6], are another of the myriad objects studied in linear-algebraic pseudorandomness. A lossless rank condenser $\mathcal{E} \subseteq \mathbb{F}^{r \times n}$ is a collection of linear maps $\mathbb{F}^n \to \mathbb{F}^r$ such that for every r-dimensional subspace V, there is some map $E \in \mathcal{E}$ where the image of V under E remains r-dimensional. Dualizing, this is precisely the same as requiring the kernel of E to only intersect V at the origin, or equivalently, that the linear spaces in projective space $\mathbb{P}^{n-1}$ corresponding to $\ker E$ and V have empty intersection. Thus, a lossless rank condenser is exactly the same object as an $(n-r-1)$-subspace family in $\mathbb{P}^{n-1}$ that evades all dimension-$(r-1)$ linear spaces.

Besides their generalization of other tasks in algebraic pseudorandomness, explicitly constructing variety-evasive subspace families is a natural task from the point of view of algebraic geometry. For example, as we will see later, variety-evasive subspace families can easily be used to construct Noether normalizing maps for algebraic varieties.

Guo [7] gives the only known construction of variety-evasive subspace families. To describe his result, we need the following function. For $n, d \in \mathbb{N}$ and $k \in \{0, 1, \ldots, n-1\}$, let $N(k, d, n)$ be the function given by

$$N(k,d,n) \coloneqq \min\left(\binom{(k'+1)(n'+1+d)}{(k'+1)d}, \binom{(n-k)(n'+1+d)}{(n-k)d}\right)$$

where $k' \coloneqq \min(k, d-2)$ and $n' \coloneqq n - (k - k')$. Guo [7, Theorem 1.7] constructed (n, d, ε)-evasive k-subspace families of size

$$\operatorname{poly}\left(N(k,d,n), n, \varepsilon^{-1}\right).$$

Moreover, this construction is explicit and can be carried out in time polynomial in the size of the variety-evasive subspace family $\mathcal{H}$ (and $\log p$ if the field $\mathbb{F}$ has characteristic $p > 0$). Guo's work complements this with a lower bound that shows any (n, d)-evasive k-subspace family $\mathcal{H}$ must have size at least

$$|\mathcal{H}| \geq \begin{cases} (n-k)(k+1)+1 & \text{if } d = 1, \\ \max\left(d(n-k)(k+1)+1, \binom{d+n-k}{d} + (n-k+1)k\right) & \text{if } d > 1. \end{cases}$$

This lower bound is tight in the sense that there is a non-explicit construction of a variety-evasive k-subspace family whose size precisely matches the lower bound [7, Section 4].

1.2 Our results

We give an improved construction of (n, d, ε)-evasive k-subspace families. Just like Guo's construction, ours is explicit and can be carried out in time polynomial in the size of the evasive subspace family $\mathcal{H}$ (and $\log p$, if $\mathbb{F}$ has characteristic $p > 0$).

▶ **Theorem 1.4.** *Let $n, d \in \mathbb{N}$, $k \in \{0, 1, \ldots, n-1\}$, and $0 < \varepsilon < 1$. There is an explicit (n, d, ε)-evasive k-subspace family (resp. strongly (n, d, ε)-evasive affine k-subspace family) $\mathcal{H}$ of size $\operatorname{poly}(((n-k)d+1)^{n-k}, \varepsilon^{-1})$. Moreover, there is a deterministic algorithm that on input (n, d, ε) runs in time $\operatorname{poly}(|\mathcal{H}|)$ and prints defining equations of the subspaces in $\mathcal{H}$.*

To compare our construction with that of Guo, we use the simplified bound from [7, Theorem 1.7], which asserts an explicit construction of an (n, d, ε)-evasive k-subspace family of size $\mathrm{poly}(n^{\min(k+1,n-k,d)d}, d, \varepsilon^{-1})$. In contrast, we construct explicit (n, d, ε)-evasive k-subspace families of size $\mathrm{poly}(((n-k)d+1)^{n-k}, \varepsilon^{-1})$. This improves the dependence on d, which may be exponentially larger than n and k; for example, a variety cut out by $n/2$ quadratic equations will generally have degree $2^{n/2}$.

Guo's work shows that in order to construct an (n, d)-evasive k-subspace family (and similarly an (n, d, ε)-evasive k-subspace family), it suffices to construct a hitting set for *Chow forms* of equidimensional projective varieties of dimension $n-k-1$ (see Definition 3.3 for the precise definition). The Chow form of such a variety is a polynomial in $n-k$ sets of $n+1$ variables each, which are thought of as encoding $n-k$ linear equations. The Chow form has the remarkable property that it evaluates to zero exactly when these linear equations have a solution lying on the variety; equivalently, the Chow form is nonzero exactly when the subspace defined by these linear equations evades the variety. If the underlying projective variety has degree d, then the Chow form will be a polynomial of degree d in each set of $n-k$ variables, for a total degree of $(n-k)\cdot d$. Using this bound on the degree, Guo [7] bounds the sparsity of the Chow form and uses the work of Klivans and Spielman [10] to construct a hitting set for Chow forms. To construct (n, d, ε)-evasive subspace families, Guo [7] invokes a result of Agrawal, Gurjar, Korwar, and Saxena [1] that provides a stronger guarantee than a hitting set: they construct an explicit set of points $\mathcal{H}$ such that for all polynomials f of a given sparsity bound, a $1-\varepsilon$ fraction of points in $\mathcal{H}$ hit f. Applying this to Chow forms results in (n, d, ε)-evasive subspace families.

Our Theorem 1.4 stems from an improved construction of hitting sets for Chow forms: we reduce the number of variables from $(n-k)(n+1)$ down to $n-k$ while only increasing the degree by a factor of n. This allows us to construct (n, d)-evasive k-subspace families using hitting sets for polynomials of individual degree dn in $n-k$ variables, resulting in the improved parameters of Theorem 1.4. To obtain (n, d, ε)-evasive k-subspace families, we proceed in the same manner as Guo, applying the work of Agrawal, Gurjar, Korwar, and Saxena [1] to the variable-reduced Chow form.

We also give a simple construction of (n, d)-evasive k-subspace families that eliminates the polynomial overhead appearing in Theorem 1.4 and does not rely on the notion of Chow forms.

▶ **Theorem 1.5.** *Let $n, d \in \mathbb{N}$ and $k \in \{0, 1, \ldots, n-1\}$. There is an explicit (n, d)-evasive k-subspace family (resp. strongly (n, d)-evasive affine k-subspace family) $\mathcal{H}$ of size at most $(nd+1)^{n-k}$. Moreover, there is a deterministic algorithm that receives n, d, and k as input and prints the subspace family $\mathcal{H}$ in time $(nd+1)^{O(n-k)}$.*

When $d \geq n^{1+\varepsilon}$ for some constant $\varepsilon > 0$, Theorem 1.5 is polynomially close to Guo's lower bound on the size of (n, d)-evasive k-subspace families. To see this, observe that we can bound the size of the (n, d)-evasive k-subspace family constructed in Theorem 1.5 by $\left(d^{\frac{2+\varepsilon}{1+\varepsilon}}+1\right)^{(n-k)} \approx d^{\frac{2+\varepsilon}{1+\varepsilon}(n-k)}$. On the other hand, Guo showed that any such k-subspace family must have size at least

$$\binom{d+n-k}{n-k} \geq \left(1+\frac{d}{n-k}\right)^{n-k} \geq \left(1+\frac{d}{n}\right)^{n-k} \geq d^{\frac{\varepsilon}{1+\varepsilon}(n-k)}.$$

As an application of our main result, we give an explicit construction of Noether normalizing maps. Noether normalization is a useful basic result in commutative algebra. In geometric language, the Noether normalization lemma states that for every r-dimensional

affine variety $V \subseteq \mathbb{A}^n$, there is a surjective finite morphism $\pi : V \to \mathbb{A}^r$. Finite morphisms are particularly nice maps of algebraic varieties: every subvariety of V is mapped to a subvariety of $\mathbb{A}^r$, and the preimage $\pi^{-1}(p)$ of any point $p \in \mathbb{A}^r$ will be a finite set.

Over an infinite field, a randomly-chosen linear map $\pi : \mathbb{A}^n \to \mathbb{A}^r$ will be Noether normalizing with high probability. Guo [7, Theorems 1.12 and 1.13] observed that Noether normalizing maps can easily be constructed from an (n, d)-evasive subspace family. As a corollary of Theorem 1.4, we obtain the following explicit construction of Noether normalizing maps.

▶ **Corollary 1.6.** *Let $n, d \in \mathbb{N}$, $r \in \{0, 1, \ldots, n\}$, $k \coloneqq n - r - 1$, and let $\varepsilon > 0$. There is an explicit collection $\mathcal{L}$ of linear maps $\mathbb{A}^n \to \mathbb{A}^r$ of size $\mathrm{poly}(((n-k)d)^{n-k}, \varepsilon^{-1})$ and computable in time $\mathrm{poly}(|\mathcal{L}|)$ such that the following hold.*

1. *For every projective variety $V \subseteq \mathbb{P}^n$ of dimension $r-1$ and degree at most d, at least a $1-\varepsilon$ fraction of maps $\pi \in \mathcal{L}$ induce a surjective finite morphism from V to $\mathbb{P}^{r-1}$.*
2. *For every affine variety $V \subseteq \mathbb{A}^n$ of dimension r and degree at most d, at least a $1-\varepsilon$ fraction of maps $\pi \in \mathcal{L}$ restrict to a surjective finite morphism from V to $\mathbb{P}^r$.*

The proof of Corollary 1.6 is exactly the same as [7, Theorems 1.12 and 1.13], but using the (n, d, ε)-evasive subspace families of Theorem 1.4 instead of the subspace families constructed by Guo, so we omit further details.

2 Preliminaries

Throughout this work, we use $\mathbb{F}$ to denote an algebraically closed field. The ring of polynomials in $n+1$ variables is denoted $\mathbb{F}[x_0, \ldots, x_n]$. We use bold letters for vectors, whose length will be clear from context. We use vector notation to denote monomials: given $\mathbf{a} \in \mathbb{N}^{n+1}$, we write $\mathbf{x}^{\mathbf{a}}$ for the monomial $x_0^{a_0} \cdots x_n^{a_n}$. We use $\mathbb{A}^n$ and $\mathbb{P}^n$ to denote n-dimensional affine and projective spaces, respectively.

2.1 Algebraic geometry

We assume basic algebraic geometry at the level of [13]. For us, an *algebraic variety* is a Zariski-closed subset of $\mathbb{A}^n$ or $\mathbb{P}^n$; in particular, a variety may be reducible. We adopt the convention that the degree of a variety is the sum of the degrees of all of its irreducible components. For this notion of degree, the following inequality holds, which we call Bézout's inequality.

▶ **Lemma 2.1** (Bézout's inequality)**.** *For any two varieties V and W, we have* $\deg(V \cap W) \leq \deg V \cdot \deg W$.

A proof of the affine version of Lemma 2.1 is given in [9, Theorem 1], while a proof of the projective version follows immediately from [5, Chapter 2.3].

We also need the following lemma, which shows that varieties of small degree and dimension are contained in linear subspaces of small dimension.

▶ **Lemma 2.2.** *For every projective variety V, there exists a linear subspace L of dimension at most $(\dim V + 1) \cdot \deg V - 1$ such that $V \subseteq L$.*

Proof. First, suppose V is irreducible. Let $L \subseteq \mathbb{P}^n$ be a minimal linear subspace such that $V \subseteq L$. By [8, Corollary 18.12], we can deduce that V has codimension at most $\deg V - 1$ within L. It follows that L has dimension at most $\dim V + \deg V - 1$.

Now let V be an arbitrary projective variety and let $V_1, \ldots, V_t$ be the irreducible components of V. Each V_i is contained in a linear subspace L_i of dimension at most $\dim V_i + \deg V_i - 1$. Let L be the smallest linear subspace that contains $\bigcup_{i=1}^{t} L_i$. Since each irreducible component V_i is contained in L, the variety V is likewise contained in L. We have

$$\dim L \leq \sum_{i=1}^{t} (\dim L_i + 1) - 1 \leq \sum_{i=1}^{t} (\dim V_i + \deg V_i) - 1.$$

By Bézout's inequality, we have $\sum_{i=1}^{t} \deg V_i \leq \deg V$ and $t \leq \deg V$. Combined with the fact that $\dim V_i \leq \dim V$, the required statement follows. ◀

2.2 Variety-evasive subspace families

In this subsection, we gather some preparatory lemmas for the construction of variety-evasive k-subspace families. In particular, we will see that to construct (n, d, ε)-evasive k-subspace families, it suffices to construct a k-subspace family that evades degree-d varieties of dimension $n - k - 1$, and that we may further assume these varieties live in an ambient space of dimension $(n - k - 1)d$. In addition to this, we will see that an (n, d, ε)-evasive k-subspace family automatically yields an (n, d, ε')-evasive affine k-subspace family with only a mild loss in ε'.

We first cite a lemma of Guo [7] that shows constructing an (n, d, ε)-evasive k-subspace family reduces to the task of constructing a k-subspace that ε-evades equidimensional subvarieties of dimension $n - k - 1$ and degree d.

▶ **Lemma 2.3** ([7, Lemma 3.1]). *Let $\mathcal{F}$ be the family of equidimensional projective subvarieties of $\mathbb{P}^n$ of dimension $n-k-1$ and degree at most d. Suppose $\mathcal{H}$ is an $(\mathcal{F}, \varepsilon)$-evasive k-subspace family. Then $\mathcal{H}$ is (n, d, ε)-evasive.*

Next, we show that the dimension of the ambient space can be reduced. As a consequence of Lemma 2.2, it suffices to construct variety-evasive subspace families when the ambient dimension n is at most $\deg V \cdot \dim V$. Essentially the same reduction is used in the constructions of Guo [7]. We give a proof for completeness.

▶ **Lemma 2.4.** *Let $r := n - k - 1$ and let $\mathcal{H}$ be a given $(rd + d - r - 2)$-subspace family of linear subspaces of $\mathbb{P}^{rd+d-1}$ of size T.*

1. *If $\mathcal{H}$ is $(rd + d - 1, d)$-evasive, then we can construct an (n, d)-evasive k-subspace family of size* $\operatorname{poly}(T, n, d)$ *in time* $\operatorname{poly}(T, n, d)$.
2. *If $\mathcal{H}$ is $(rd + d - 1, d, \varepsilon)$-evasive, then we can construct an $(n, d, 2\varepsilon)$-evasive k-subspace family of size* $\operatorname{poly}\left(T, n, d, \varepsilon^{-1}\right)$ *in time* $\operatorname{poly}\left(T, n, d, \varepsilon^{-1}\right)$.

Proof. We first carry out the construction of an (n, d)-evasive k-subspace family in detail. After this, we briefly remark how to modify the construction to obtain an (n, d, ε)-evasive k-subspace family.

We begin by constructing an $(n, 1)$-evasive $(n - rd - d)$-subspace family $\widehat{\mathcal{H}}$. By Lemma 2.3, it suffices to build a collection $W_1, \ldots, W_s$ of linear subspaces in $\mathbb{P}^n$ such that for any linear subspace $L \subset \mathbb{P}^n$ of dimension $rd + d - 1$, there is some W_i such that $L \cap W_i = \emptyset$. Such a family of subspaces W_i is precisely the nullspaces of the matrices in a *rank extractor*. Forbes and Shpilka [4], together with the improved analysis of Forbes, Saptharishi, and Shpilka [3], gave an explicit construction of such a rank extractor of size $s = (rd + d - 1)(n - rd - d + 1) + 1$. For each $i \in [s]$, we pick points $v_{i,0}, \ldots, v_{i,n} \in \mathbb{P}^n$ such that $\operatorname{span}(v_{i,0}, \ldots, v_{i,n}) = \mathbb{P}^n$ and $\operatorname{span}(v_{i,rd+d}, \ldots, v_{i,n}) = W_i$.

Let $\mathcal{H} = \{Y_1, \ldots, Y_T\} \subseteq \mathbb{P}^{rd}$ be the given $(rd+d-1, d)$-evasive $(rd+d-r-2)$-subspace family. For each Y_i, we pick $rd+d-r-1$ points $u_{i,0}, \ldots, u_{i,rd+d-r-1} \in \mathbb{P}^{rd+d-1}$ that span Y_i.

Now we define linear subspaces $Z_{i,j} \subseteq \mathbb{P}^n$ for every $1 \leq i \leq s$ and $1 \leq j \leq T$ that will form the required (n,d)-evasive k-subspace family. Let $\phi_i : \mathbb{P}^{rd+d-1} \to \mathbb{P}^n$ be the linear map that sends the point e_ℓ to $v_{i,\ell}$, where e_ℓ denotes the point in $\mathbb{P}^{rd+d-1}$ whose ℓ-th coordinate is 1 and whose remaining coordinates are zero. We take $Z_{i,j}$ to be the k-subspace given by

$$Z_{i,j} \coloneqq \operatorname{span}\left(v_{i,rd+d}, \ldots, v_{i,n}, \phi_i(u_{j,0}), \ldots, \phi_i(u_{j,rd+d-r-2})\right).$$

Given the subspace families $\mathcal{H}$ and $\widehat{\mathcal{H}}$, it is clear that we can construct the subspaces $Z_{i,j}$ in $\operatorname{poly}(T, n, d)$ time by iterating over the product set $\mathcal{H} \times \widehat{\mathcal{H}}$.

It remains to show that the k-subspace family $\{Z_{i,j} : i \in [s], j \in [T]\}$ is (n,d)-evasive. To this end, let $V \subseteq \mathbb{P}^n$ be an equidimensional variety of dimension r and degree d. By Lemma 2.2, there is a linear subspace X of dimension $rd+d-1$ that contains V. Since $\widehat{\mathcal{H}} = \{W_1, \ldots, W_s\}$ is $(n,1)$-evasive, there is some W_i such that $W_i \cap X = \varnothing$; without loss of generality, we may assume that $W_1 \cap X = \emptyset$. For each $0 \leq i \leq rd+d-1$, the intersection $\operatorname{span}(W_1, v_{i,1}) \cap X$ consists of a single point in $\mathbb{P}^n$, which we denote by a_i. Comparing dimensions, we see that $\operatorname{span}(a_0, \ldots, a_{rd+d-1}) = X$. Let $\psi : \mathbb{P}^{rd+d-1} \to \mathbb{P}^n$ denote the linear map that maps e_i to a_i. Since $v_{1,i} \in \operatorname{span}(W_1, \psi(e_i))$, it follows that $\operatorname{span}(W_1, \psi(e_i)) = \operatorname{span}(W_1, \phi_1(e_i)) = \operatorname{span}(W_1, v_{i,1})$.

The image of the map ψ is exactly X, and so ψ is an isomorphism between $\mathbb{P}^{rd+d-1}$ and X. Since $V \subseteq X$, the preimage of V under ψ is also a variety of dimension r and degree d. Because $\mathcal{H} = \{Y_1, \ldots, Y_T\}$ is $(rd+d-1, d)$-evasive, there is some Y_j such that $Y_j \cap \psi^{-1}(V) = \varnothing$; without loss of generality, we may assume that Y_1 does not intersect $\psi^{-1}(V)$. The choice of the map ψ implies that $Z_{1,1} = \operatorname{span}(W_1, \psi(Y_1))$. Now suppose towards a contradiction that there is a point $b \in V \cap Z_{1,1}$. The point b lies in $\operatorname{span}(\psi(c), w)$, for some $c \in Y_1$ and $w \in W_1$. Since $b, \psi(c) \in X$ and $X \cap W_1 = \emptyset$, we deduce $b = \psi(c)$ in $\mathbb{P}^n$. This contradicts the fact that $Y_1 \cap \psi^{-1}(V) = \emptyset$.

Since V was an arbitrary equidimensional variety, we can invoke Lemma 2.3 to conclude that the constructed k-subspace is (n,d)-evasive. To construct an (n,d,ε)-evasive k-subspace family, the only part of the construction that changes is that the $(n,1)$-evasive subspace family used in the first step must be replaced by an $(n,1,\varepsilon)$-evasive subspace family. The Forbes–Shpilka construction of rank extractors also produces this $(n,1,\varepsilon)$-evasive subspace family, incurring only a $1/\varepsilon$ multiplicative increase in the size of the subspace family. ◀

Finally, we show that any (n,d,ε)-evasive k-subspace family immediately yields an (n,d,ε')-evasive affine k-subspace family with only a small loss in the parameter ε'.

▶ **Lemma 2.5.** *Let $\mathcal{H}$ be an (n,d,ε)-evasive k-subspace family. Let $\mathcal{H}' \subseteq \mathcal{H}$ be the subfamily of subspaces not contained in the hyperplane at infinity. Then the restriction of $\mathcal{H}'$ to the affine chart of points at finite distance is a strongly $(n,d,2\varepsilon/(1-\varepsilon))$-evasive affine k-subspace family.*

Proof. Since $\mathcal{H}$ is (n,d,ε)-evasive, at most ε fraction of the elements of $\mathcal{H}$ are contained in $\mathrm{V}(x_0)$, the hyperplane at infinity, so $|\mathcal{H}'| \geq (1-\varepsilon)|\mathcal{H}|$. For the rest of this proof, let $\varepsilon' \coloneqq \varepsilon/(1-\varepsilon)$. The family $\mathcal{H}'$ is (n,d,ε')-evasive.

Let $\mathcal{H}_\infty$ be the restriction to $\mathrm{V}(x_0)$ of those subspaces in $\mathcal{H}'$. This is a $(k-1)$-subspace family of size at least $(1-\varepsilon)|\mathcal{H}|$. Let $V \subseteq \mathbb{P}^{n-1}$ be any variety of degree at most d. We can identify $\mathbb{P}^{n-1}$ with the hyperplane at infinity in $\mathbb{P}^n$. This way, V can be viewed as a variety in $\mathbb{P}^n$. All except $\varepsilon|\mathcal{H}|$ elements in $\mathcal{H}'$ evade V. Therefore, $\mathcal{H}_\infty$ is a $(n-1,d,\varepsilon')$-evasive subspace family.

We now show that the restriction of $\mathcal{H}'$ to the affine chart is strongly $(n, d, 2\varepsilon')$-evasive for affine varieties. Let $V \subseteq \mathbb{A}^n$ be an affine variety of degree d. Identifying $\mathbb{A}^n$ with the affine chart, we can consider $V \subseteq \mathbb{P}^n$. Let $\overline{V}$ be the projective closure of V, and let V_∞ denote $\overline{V} \cap \mathrm{V}(x_0)$. Both $\overline{V}$ and V_∞ have degree at most d.

Suppose $H \in \mathcal{H}'$ is such that H evades $\overline{V}$ and $H \cap \mathrm{V}(x_0)$ evades V_∞. Let W be an irreducible component of V, let $\overline{W}$ be the projective closure of W, and let W_∞ denote $\overline{W} \cap \mathrm{V}(x_0)$. By assumption, every component of $\overline{W} \cap H$ has dimension $\dim \overline{W} + k - n$. If $\dim \overline{W} + k - n < 0$, then this intersection is empty. In this case, $W \cap H \cap \mathbb{A}^n$ is also empty, and therefore $H \cap \mathbb{A}^n$ evades W. Otherwise, we have $\dim \overline{W} + k - n \geq 0$.

To show that $H \cap \mathbb{A}^n$ evades W, it suffices to show that $\overline{W} \cap H \not\subseteq \mathrm{V}(x_0)$. This will guarantee that $W \cap H \cap \mathbb{A}^n$ is nonempty and has the correct dimension. To this end, note that $\dim W_\infty = \dim W - 1$. Since $H \cap \mathrm{V}(x_0)$ evades W_∞, every component of $\overline{W} \cap H \cap \mathrm{V}(x_0)$ has dimension $\dim \overline{W} + k - n - 1$. Since every component of $\overline{W} \cap H$ has dimension $\dim \overline{W} + k - n$, no component of $\overline{W} \cap H$ lies completely in the hyperplane at infinity, completing the proof that $H \cap \mathbb{A}^n$ evades W. Since this holds for every component W of V, we deduce that $H \cap \mathbb{A}^n$ evades V.

Because $\mathcal{H}'$ and $\mathcal{H}_\infty$ are (n, d, ε')-evasive and $(n-1, d, \varepsilon')$-evasive, respectively, the fraction of hyperplanes in $\mathcal{H}'$ such that either H does not evade $\overline{V}$ or such that $H \cap \mathrm{V}(x_0)$ does not evade V_∞ is at most $2\varepsilon'$. Therefore, the restriction of $\mathcal{H}'$ to the affine chart is a strongly $(n, d, 2\varepsilon')$-evasive affine k-subspace family. ◀

3 Construction of variety-evasive subspace families

We give two constructions of variety-evasive subspace families. The first is a simple construction meant to illustrate our main technical observation. The second is a more involved construction that allows us to obtain improved epsilon variety-evasive subspace families.

3.1 Basic construction

Let $V \subseteq \mathbb{P}^n$ be an projective variety of dimension r. The intersection of V with a general hyperplane is a variety of dimension $r - 1$. Typically, to obtain an effective version of this fact, one picks a point on each irreducible component of V and controls the probability that a randomly-chosen hyperplane H does not pass through the chosen points. If H does not pass through these points, then H properly intersects each component of V, so the intersection $V \cap H$ will have dimension exactly $r - 1$.

We implement this argument in the following lemma. Here, the coefficients of the hyperplane H are not picked independently, but are instead chosen from points of the form $(1, \gamma, \gamma^2, \ldots, \gamma^n)$ for $\gamma \in \mathbb{F}$. When we invoke this lemma in the proof of Theorem 1.5, we will need to choose a hyperplane H that properly intersects a collection of irreducible varieties that need not be the irreducible components of a single variety. For example, one variety in the given collection may be properly contained in another.

▶ **Lemma 3.1.** *Let $V_1, \ldots, V_t \subseteq \mathbb{P}^n$ be irreducible projective varieties. There exists a polynomial $P \in \mathbb{F}[z]$ of degree nt such that for any γ with $P(\gamma) \neq 0$, every hyperplane section $V_i \cap \mathrm{V}\left(\sum_{j=0}^n \gamma^j x_j\right)$ has dimension $\dim V_i - 1$.*

Proof. From each variety V_i of V, we pick a point p_i. Consider the polynomial $Q(\mathbf{x}, z) \coloneqq \sum_{i=0}^n z^i x_i$. The evaluation $Q(p_i, z)$ is a nonzero polynomial in z, since the point p_i has at least one nonzero coordinate. Set $P(z) \coloneqq \prod_{i=1}^t Q(p_i, z)$.

It is clear that P is a polynomial of degree nt. To show that P satisfies the claimed property, let $\gamma \in \mathbb{F}$ be a point such that $P(\gamma) \neq 0$ and consider the linear form $L(\mathbf{x}) \coloneqq \sum_{i=0}^{n} \gamma^i x_i$. By construction, we have that $L(p_i) = Q(p_i, \gamma)$. Because $P(\gamma) \neq 0$, it follows that $Q(p_i, \gamma) \neq 0$. In particular, the linear form L does not vanish identically on V_i. Therefore $V_i \cap \mathrm{V}(L)$ has dimension $\dim V_i - 1$ by [2, Chapter 9, Section 4, Corollary 4]. ◀

We can also deduce a similar statement for affine varieties.

▶ **Lemma 3.2.** *Let $V_1, \ldots, V_t \subseteq \mathbb{A}^n$ irreducible affine varieties of degree $d_1, \ldots, d_t$, respectively. There exists a polynomial $P \in \mathbb{F}[z]$ of degree at most $n \sum_{i=1}^{t} d_i$ such that for any γ with $P(\gamma) \neq 0$, every hyperplane section $V_i \cap \mathrm{V}\left(1 + \sum_{j=1}^{n} \gamma^j x_j\right)$ has dimension $\dim V_i - 1$.*

Proof. Let $\overline{V}_i$ denote the projective closure of the variety V_i, which is an irreducible projective variety. Because the variety $\overline{V}_i$ is irreducible, we have $\dim(\overline{V}_i \cap \mathrm{V}(x_0)) = \dim \overline{V}_i - 1$. For each i such that $\dim \overline{V}_i \geq 1$, and for each irreducible component $\overline{V}_{i,j}$ of $\overline{V}_i \cap \mathrm{V}(x_0)$, pick a point $p_{i,j} \in \overline{V}_{i,j}$. For those i such that $\dim \overline{V}_i = 0$, let $p_{i,1}$ be the single point of $\overline{V}_i$.

Consider the polynomial $Q(\mathbf{x}, z) \coloneqq \sum_{i=0}^{n} z^i x_i$. If we evaluate at $p_{i,j}$, we get $Q(p_{i,j}, z)$, which is a nonzero polynomial in $\mathbb{F}[z]$, since $p_{i,j}$ has at least one nonzero coordinate. Set $P(z) \coloneqq \prod_{i,j} Q(p_{i,j}, z)$. The fact that $P(z)$ has degree at most $n \sum_{i=1}^{t} d_i$ follows from the fact that each factor $Q(p_{i,j}, z)$ is a polynomial of degree n, together with the fact that there is one factor of $P(z)$ per component of $\overline{V}_i$, of which there are at most $d_i = \deg V_i$. If we pick $\gamma \in \mathbb{F}$ such that $P(\gamma) \neq 0$, then the linear form $L(\mathbf{x}) \coloneqq \sum_{i=0}^{n} \gamma^i x_i$ is nonzero at every $p_{i,j}$. From this, we can deduce that $\dim(\overline{V}_i \cap \mathrm{V}(L, x_0)) = \dim \overline{V}_i - 2$ for every variety $\overline{V}_i$ of dimension at least one. Therefore, for any such variety, we must have $\dim(V_i \cap \mathrm{V}(\ell)) = \dim V_i - 1$, where $\ell(\mathbf{x}) \coloneqq L(1, x_1, \ldots, x_n)$. For the zero-dimensional varieties V_i, we can also deduce that $V_i \cap \mathrm{V}(\ell) = \emptyset$, since L does not vanish at the single point of V_i. ◀

Applying Lemma 3.1 to the irreducible components of a projective variety allows us to construct a set $\mathcal{H}$ of $nd + 1$ hyperplanes such that for any projective variety $V \subseteq \mathbb{P}^n$ of degree d, there is some $H \in \mathcal{H}$ that properly intersects V. Lemma 3.2 does the same for affine varieties. By iterating this construction k times, we can obtain an (n, d)-evasive (affine) k-subspace family. We remark that this solves [7, Open Problem 7], which asked for an explicit construction of a polynomial-size (n, d)-evasive k-subspace family when $n - k = O(1)$.

▶ **Theorem 1.5.** *Let $n, d \in \mathbb{N}$ and $k \in \{0, 1, \ldots, n-1\}$. There is an explicit (n, d)-evasive k-subspace family (resp. strongly (n, d)-evasive affine k-subspace family) $\mathcal{H}$ of size at most $(nd+1)^{n-k}$. Moreover, there is a deterministic algorithm that receives n, d, and k as input and prints the subspace family $\mathcal{H}$ in time $(nd+1)^{O(n-k)}$.*

Proof. We start by establishing the projective version of the theorem. Fix pairwise disjoint subsets $B_1, \ldots, B_{n-k} \subseteq \mathbb{F}$, each of size $nd+1$ and not containing 0. For each $\alpha \in \mathbb{F}$, let $L_\alpha(\mathbf{x})$ denote the linear form $x_0 + \alpha x_1 + \cdots + \alpha^n x_n$. For each $\boldsymbol{\gamma} \in \mathbb{F}^{n-k}$, let $H_{\boldsymbol{\gamma}} \subseteq \mathbb{P}^n$ denote the linear subspace $\mathrm{V}\left(L_{\gamma_1}, \ldots, L_{\gamma_{n-k}}\right)$. Let $\mathcal{H}$ denote the collection of subspaces $H_{\boldsymbol{\gamma}}$ where $\boldsymbol{\gamma}$ varies over elements in $B_1 \times \cdots \times B_{n-k}$. Finally, let $\mathcal{H}'$ denote the restriction of each element of $\mathcal{H}$ to the affine chart $x_0 = 1$. We claim that $\mathcal{H}$ and $\mathcal{H}'$ are the required (n, d)-evasive k-subspace and affine k-subspace families, respectively. The bound on the sizes of $\mathcal{H}$ and $\mathcal{H}'$ are clear from construction. To algorithmically produce $\mathcal{H}$ and $\mathcal{H}'$, we simply iterate over the set $B_1 \times \cdots \times B_{n-k}$ and print the subspace $H_{\boldsymbol{\gamma}}$ for every $\boldsymbol{\gamma} \in B_1 \times \cdots \times B_{n-k}$.

To see why $\mathcal{H}$ is (n, d)-evasive, let $V \subseteq \mathbb{P}^n$ be any variety of degree d. By applying Lemma 3.1 to the irreducible components $V_1 \cup \cdots \cup V_t$ of V, there exists a polynomial $P_1 \in \mathbb{F}[z]$ of degree $nt \leq nd$ such that for any $\gamma_1 \in \mathbb{F}$ satisfying $P_1(\gamma_1) \neq 0$, the intersection of V_i and $\mathrm{V}(L_{\gamma_1})$ has dimension $\dim V_i - 1$ for every irreducible component V_i of V. Since the set B_1 has size $nd + 1$, we can find such an element $\gamma_1 \in B_1$. Fix this choice of γ_1.

Let d_i be the degree of the component V_i. By Bézout's inequality (Lemma 2.1), the intersection $V_i \cap \mathrm{V}(L_{\gamma_1})$ has degree at most d_i, and thus consists of at most d_i irreducible components. We again apply Lemma 3.1 to the collection of varieties consisting of the irreducible components of $V_1 \cap \mathrm{V}(L_{\gamma_1}), \ldots, V_t \cap \mathrm{V}(L_{\gamma_1})$, of which there are at most $d_1 + \cdots + d_t = d$. This gives us a polynomial P_2 of degree at most nd whose non-roots define hyperplanes that properly intersect each of these components. Because $|B_2| = nd + 1$, we can find a nonroot γ_2 of P_2 that lies in B_2. Moreover, since B_1 and B_2 are disjoint, we are guaranteed that γ_2 is different from γ_1. This implies that the intersection $V_i \cap \mathrm{V}(L_{\gamma_1}) \cap \mathrm{V}(L_{\gamma_2})$ has dimension $\dim V_i - 2$ for every irreducible component V_i of V. Continuing in this manner, we obtain $(\gamma_1, \ldots, \gamma_{n-k}) \in B_1 \times \cdots \times B_{n-k}$ such that the subspace $H_{\boldsymbol{\gamma}}$ evades V.

The affine version for $\mathcal{H}'$ follows the same argument, invoking Lemma 3.2 in place of Lemma 3.1. The fact that no B_i contains 0 implies that each affine subspace in $\mathcal{H}'$ has dimension k. ◀

3.2 Constructing (n, d, ε)-evasive subspace families

Theorem 1.5 constructs an (n, d)-evasive k-subspace family by building the subspaces iteratively, intersecting $n - k$ hyperplanes one at a time. To improve this to a construction of an (n, d, ε)-evasive k-subspace family, one natural approach is to ensure that at each step, the probability of picking a hyperplane that does not properly intersect a variety V is bounded by $\frac{\varepsilon}{n-k}$. Applying a union bound over the $n - k$ choices of hyperplanes implies that at most an ε fraction of subspaces fail to evade V. However, this enlarges the number of hyperplanes chosen at each step by a factor of $\frac{n-k}{\varepsilon}$, which leads to a $(1/\varepsilon)^{n-k}$ factor in the final size of the subspace family.

By arguing about the $n - k$ hyperplanes as a whole instead of one at a time, we can improve this $(1/\varepsilon)^{n-k}$ factor to $(1/\varepsilon)^{O(1)}$. To do this requires the notion of the Chow form of a variety, which we now define. The definition and facts we use about the Chow form are classical. The following statements appear in [11, Section 2.1.1], and proofs can be found in [12, Chapter 1].

▶ **Definition 3.3.** *Let $V \subseteq \mathbb{P}^n$ be an equidimensional variety of dimension r and degree d. Let $\mathbf{u}_0, \ldots, \mathbf{u}_r$ be sets of variables, each of size $n+1$. The* Chow form of V, *denoted $\mathcal{C}_V$, is a polynomial in $\mathbb{F}[\mathbf{u}_0, \ldots, \mathbf{u}_r]$ with the following properties.*

- *For every choice of $\boldsymbol{\gamma}_0, \ldots, \boldsymbol{\gamma}_r \in \mathbb{F}^{n+1}$, the linear subspace $\mathrm{V}\left(\sum_{j=0}^n \gamma_{0,j} x_j, \ldots, \sum_{j=0}^n \gamma_{r,j} x_j\right)$ has a point in V if and only if $\mathcal{C}_V(\boldsymbol{\gamma}_0, \ldots, \boldsymbol{\gamma}_r) = 0$.*
- *The polynomial $\mathcal{C}_V$ squarefree and homogeneous of degree d in each set of variables $\mathbf{u}_i$.*

In other words, the Chow form of a variety characterizes those linear subspaces of dimension at least $n - r + 1$ that intersect V. The following is an easy corollary of Lemma 3.1.

▶ **Corollary 3.4.** *Let $V \subseteq \mathbb{P}^n$ be an equidimensional variety of dimension r and degree d with Chow form $\mathcal{C}_V \in \mathbb{F}[\mathbf{u}_0, \ldots, \mathbf{u}_r]$. Let $v_0, \ldots, v_r$ be new variables and let $\phi : \mathbb{F}[\mathbf{u}_0, \ldots, \mathbf{u}_r] \to \mathbb{F}[\mathbf{v}]$ be the map defined by $\phi(u_{i,j}) = v_i^j$. Then $\phi(\mathcal{C}_V) \neq 0$.*

Proof. Let $\gamma_0 \in \mathbb{F}$ be such that $V_1 \coloneqq V \cap \mathrm{V}(x_0 + \gamma_0 x_1 + \cdots + \gamma_0^n x_n)$ is equidimensional of dimension $r - 1$. Such an element exists by Lemma 3.1. The variety V_1 is now equidimensional of dimension $r - 1$, and we can invoke Lemma 3.1 again to find a $\gamma_1 \in \mathbb{F}$ such that $V_2 \coloneqq V_1 \cap \mathrm{V}(x_0 + \gamma_1 x_1 + \cdots + \gamma_1^n x_n)$ is equidimensional of dimension $r - 2$. Repeating this, we find $\gamma_0, \ldots, \gamma_r$ such that $V \cap \mathrm{V}\left(\sum_{j=0}^n \gamma_0^j x_j, \ldots, \sum_{j=0}^n \gamma_r^j x_j\right)$ is empty. By Definition 3.3, we have $\phi(\mathcal{C}_V)(\gamma_0, \ldots, \gamma_r) \neq 0$, which shows in particular that $\phi(\mathcal{C}_V)$ is nonzero. ◀

In the notation of Corollary 3.4, the polynomial $\phi(\mathcal{C}_V)$ is a nonzero polynomial of individual degree nd in $r+1$ variables with the property that the subspace defined by the linear forms with coefficients $\boldsymbol{\gamma}_0, \ldots, \boldsymbol{\gamma}_r$ evades V if $\phi(\mathcal{C}_V)(\boldsymbol{\gamma}_0, \ldots, \boldsymbol{\gamma}_r) \neq 0$. The construction of Theorem 1.5 can be thought of as a construction of a hitting set for the restricted Chow form $\phi(\mathcal{C}_V)$. To obtain (n, d, ε)-evasive k-subspace families, we instead apply an ε-hitting set to the restricted Chow form $\phi(\mathcal{C}_V)$. An *ε-hitting set* has exactly the guarantee we need: it is a finite set $\mathcal{H}$ such that a $1-\varepsilon$ fraction of points $(\boldsymbol{\gamma}_0, \ldots, \boldsymbol{\gamma}_r) \in \mathcal{H}$ satisfy $\phi(\mathcal{C}_V)(\boldsymbol{\gamma}_0, \ldots, \boldsymbol{\gamma}_r) \neq 0$. We make this observation precise in the following corollary.

▶ **Corollary 3.5.** *Suppose $\mathcal{P}$ is an ε-hitting set for polynomials of individual degree nd in $n-k$ variables. Then there exists a (n, d, ε)-evasive k-subspace family $\mathcal{H}$ of size at most $|\mathcal{P}|$. Moreover, there is a deterministic algorithm that takes $\mathcal{P}$ as input, prints the set $\mathcal{H}$, and runs in time* $\mathrm{poly}(n, |\mathcal{P}|)$.

Proof. The evasive family of subspaces is constructed as follows. For each point $\boldsymbol{\mu} \in \mathcal{P}$, let $H_{\boldsymbol{\mu}}$ be the linear subspace defined by the linear forms $x_0 + \mu_i x_1 + \cdots + \mu_i^n x_n$ for $i \in [n-k]$. Let $\mathcal{H}'$ be the resulting family of subspaces.

Let V be an arbitrary equidimensional variety of dimension $n-k-1$ and degree d, and let $\mathcal{C}_V$ be its Chow form. Let ϕ be the map defined in Corollary 3.4, so $\phi(\mathcal{C}_V)$ is a nonzero polynomial of individual degree nd in $n-k$ variables. Since $\mathcal{P}$ is a ε-hitting set for such polynomials, for all except $\varepsilon|\mathcal{P}|$ elements in $\mathcal{P}$, we have $\phi(\mathcal{C}_V)(\boldsymbol{\mu}) \neq 0$. Therefore, for all except $\varepsilon|\mathcal{H}'|$ of the subspaces $H \in \mathcal{H}'$, we have $V \cap H = \emptyset$.

Note that the exceptional set of $\varepsilon|\mathcal{H}'|$ vector spaces $H \in \mathcal{H}'$ such that $V \cap H \neq \emptyset$ contains all those subspaces in $\mathcal{H}'$ that are not k-dimensional. Therefore, if we define $\mathcal{H}$ to be the set of k-dimensional subspaces in $\mathcal{H}'$, then all except $\varepsilon|\mathcal{H}|$ elements in $\mathcal{H}$ evade V. Since V was an arbitrary equidimensional variety of dimension $n-k-1$ and degree d, we can invoke Lemma 2.3 to deduce that $\mathcal{H}$ is (n, d, ε)-evasive.

It is clear that the set $\mathcal{H}'$ can be obtained in polynomial time from the ε-hitting set $\mathcal{P}$. To prune $\mathcal{H}'$ to the (n, d, ε)-evasive k-subspace family $\mathcal{H}$, we need to remove from $\mathcal{H}'$ those subspaces that are not k-dimensional. This is a basic linear algebra calculation that can be performed in $\mathrm{poly}(n)$ time for each element of $\mathcal{H}'$. ◀

Finally, we need an explicit construction of ε-hitting sets. We do this using a construction of Agrawal, Gurjar, Korwar, and Saxena [1], as instantiated by Guo [7]. The version we state here is adapted to polynomials of bounded individual degree instead of bounded total degree, but follows exactly the same proof as [7, Lemma 2.3].

▶ **Lemma 3.6** ([7, Lemma 2.3], [1, Lemma 4])**.** *For every $d, n \in \mathbb{N}$ and $\varepsilon \in (0,1)$, there exists an ε-hitting set $\mathcal{P}$ for the set of all polynomials of individual degree d in n variables. The set $\mathcal{P}$ has size and bit complexity* $\mathrm{poly}\left((d+1)^n, \varepsilon^{-1}\right)$ *and can be constructed in time* $\mathrm{poly}(|\mathcal{P}|)$.

Combining Corollary 3.5, Lemma 3.6, and the reductions in Section 2, we obtain our final construction of (n, d, ε)-evasive subspaces.

▶ **Theorem 1.4.** *Let $n, d \in \mathbb{N}$, $k \in \{0, 1, \ldots, n-1\}$, and $0 < \varepsilon < 1$. There is an explicit (n, d, ε)-evasive k-subspace family (resp. strongly (n, d, ε)-evasive affine k-subspace family) $\mathcal{H}$ of size* $\mathrm{poly}(((n-k)d+1)^{n-k}, \varepsilon^{-1})$. *Moreover, there is a deterministic algorithm that on input (n, d, ε) runs in time* $\mathrm{poly}(|\mathcal{H}|)$ *and prints defining equations of the subspaces in $\mathcal{H}$.*

Proof. We start by constructing an (n, d, ε)-evasive k-subspace family. First suppose $n \leq (n-k)d$. Then the required (n, d, ε)-evasive k-subspace family can be constructed by using Corollary 3.5 instantiated with the ε-hitting set from Lemma 3.6. The resulting variety-evasive subspace family has size and bit complexity $\mathrm{poly}\left((nd+1)^{n-k}, \varepsilon^{-1}\right) \leq \mathrm{poly}\left(((n-k)d+1)^{n-k}, \varepsilon^{-1}\right)$, since $n \leq (n-k)d$.

Now suppose $n > (n-k)d$. Let $r := n-k-1$. Using Lemma 3.6 and Corollary 3.5, we can construct an $(rd, d, \varepsilon/2)$-evasive $(rd-r-1)$-subspace family. This family has size $\text{poly}\left((rd+1)^r, \varepsilon^{-1}\right) \leq \text{poly}\left(((n-k)d+1)^{n-k}, \varepsilon^{-1}\right)$. We can now invoke Lemma 2.4 to obtain the required (n, d, ε)-evasive subspace family. The size of the resulting family is also bounded by $\text{poly}\left(((n-k)d+1)^{n-k}, \varepsilon^{-1}\right)$.

To construct a strongly (n, d, ε)-evasive affine k-subspace family, we first pick ε' such that $\varepsilon = 2\varepsilon'/(1-\varepsilon')$. We construct a (n, d, ε')-evasive k-subspace family using the above construction and then invoke Lemma 2.5 to obtain the required (n, d, ε)-evasive affine k-subspace family. ◀

Abstract

We initiate the study of *unate distributions* over $\{\pm 1\}^n$ – a natural analogue of unate Boolean functions – by considering two basic testing problems that parallel well-studied questions for monotone distributions:

- **Uniformity Testing of Unate Distributions:** We show that $\widetilde{\Theta}(n^{3/2})$ samples are sufficient and necessary, in contrast to the $\widetilde{\Theta}(n)$ sample complexity of the analogous problem for monotone distributions (Rubinfeld and Servedio, STOC 2005; Adamaszek, Czumaj, and Sohler, SODA 2010).
- **Unateness Testing of Arbitrary Distributions:** We give a tester that uses $\widetilde{O}(n^{3/2})$ conditional samples in the subcube conditional model. On the other hand, every tester that draws conditional samples in a similar fashion, namely from $O(1)$-dimensional subcubes, must have an $\widetilde{\Omega}(n^{2/3})$ complexity. In the same model, the complexity of monotonicity testing was recently shown to be $\widetilde{\Theta}(n)$ (Chakrabarty et al., STOC 2025).

Our algorithms for both problems significantly outperform the naive approach of reducing to the monotone case, which would incur $\Omega(n^2)$ sample complexity. Our uniformity tester relies on a subroutine that "weakly" learns the hidden orientations of a unate distribution, together with a new correlation bound for these estimates. Both tools may be of independent interest in studying monotonicity and unateness over $\{\pm 1\}^n$.

1 Introduction

Many fundamental distribution testing tasks – uniformity testing being the canonical example – become infeasible in high dimensional settings such as the Boolean hypercube $\{\pm 1\}^n$, requiring exponentially many samples in the dimension [15, 18]. A central theme in the field has therefore been to identify *structured* settings that admit efficient testers: examples include Bayesian networks [17, 35], Markov random fields [34, 8], and structured truncations [36, 37].

Among such structural assumptions, one of the most extensively studied is *monotonicity*, the distributional analogue of the classical Boolean function property.[1] In the Boolean function setting, monotonicity has played a central role in sublinear algorithms for nearly three decades: it was among the first properties studied in Boolean function testing and continues to be actively investigated to this day [14, 38, 22, 29, 41, 43, 26, 11, 44, 25]. In the distributional setting, monotonicity has similarly been studied in depth, leading to tight upper and lower bounds for tasks such as uniformity testing and property testing under various access models [6, 51, 2, 9, 1, 4, 52, 12, 21].

A closely related property in the Boolean function setting is *unateness*. Informally, a Boolean function is unate if each coordinate is either always non-decreasing or always non-increasing. The problem of testing unateness of Boolean functions was introduced alongside monotonicity testing in [38], and has since received considerable attention [42, 23, 31, 32, 30, 5]. Both monotonicity and unateness are fundamental structural properties that arise naturally across many domains, for example in social choice (where we can view a Boolean function f as a voting rule), economics, learning theory, and circuit design.

Despite extensive work on unate functions, the analogous notion for distributions has, to the best of our knowledge, not been studied. In this work, we initiate the study of *unate distributions* over $\{\pm 1\}^n$. The motivation for this is twofold:

- The study of monotone distributions has a well-developed literature precisely because monotonicity is a natural structural constraint arising in settings ranging from social choice to learning theory. Unateness is a strict and natural generalization – it captures the same "directional" structure without fixing a canonical orientation – and we believe its study for distributions will prove equally fruitful.
