The instability follows the same mechanism exposed by the clean baseline. When the agent changes the predicted-vulnerable rate, a small non-semantic edit can be enough to move a borderline trace to the other side of the decision boundary. DeepSeek increases from 0.157 FR at C1 to 0.219 at C2 with $p < 0.001$, and gpt-5.4 increases from 0.199 to 0.259 with $p < 0.001$. Qwen3.6-27B, DS-Coder-V2-Lite, and Qwen2.5-Coder-14B reach still higher C2 FR levels of 0.353, 0.398, and 0.355, respectively. The accuracy change under these perturbations is small or negative, so the flips are not mainly benign corrections. These flips indicate unstable verdicts under label-preserving repository changes.

The perturbation profile explains why this happens. P3 and P4 insert vulnerability-looking but non-causal code; P5 only changes presentation. Yet at C2, P5 alone flips roughly one fifth to one third of decisions on four base models, and P3/P4 are frequently the strongest perturbations for the code-specialized models. In the raw traces, flipped cases often show the agent reusing the same tools but shifting the rationale from the target data flow to a newly salient surface cue, such as an unused helper or an unreachable block. The added context thus appears to provide more non-causal anchors for the answer.

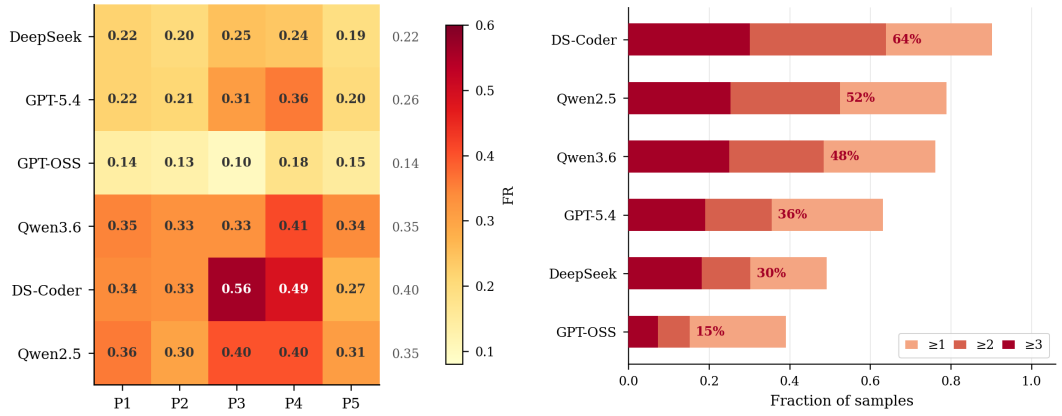

**Figure 2** RQ1 robustness under repository-synchronized semantics-preserving perturbations. The left panel reports C2 flip rates by perturbation family P1–P5, and the right panel reports the concentration of repeated flips under C2. The low FR for gpt-oss-120b should be read together with its safe-collapse in Table 5.

**Table 6** Flip rate stratified by ground-truth label, averaged over P1–P5 and pooled across difficulty strata. $N$ is the number of matched instances per GT class; ΔFR is relative to the same base model's C1 row. Bold cells mark the largest C1→C2 jump in both GT classes.

Self-review does not consistently reduce this failure mode. C3 raises FR above C2 on five of six base models rather than dampening it. That pattern is consistent with self-review reopening the same unstable boundary instead of adding independent evidence. SV-TrustEval-C provides a semantic-change sanity check: the condition-level changes are small, mostly within about three points, so the RQ1 result is specific to repository-scale semantics-preserving edits that introduce plausible but non-causal security cues.

**Ground-truth-stratified flip rate.** To separate instability from shifts in the predicted-vulnerable rate, we also stratify perturbation flips by the ground-truth label of the perturbed instance. Each JITVUL pair contributes one vulnerable instance and one patched-safe instance, giving a balanced, exogenous conditioning variable for each base-model–condition cell. Table 6 reports pooled P1–P5 flip rates for the GT-vulnerable and GT-safe subsets.

This control strengthens the robustness result. On five of six base models, C1→C2 FR increases in both GT classes simultaneously. The increases are +0.037/ + 0.088 for DeepSeek-V3.2 and +0.157/ + 0.150 for DS-Coder-V2-Lite on GT-vulnerable and GT-safe instances. A pure predicted-vulnerable-rate shift would tend to move the two class-conditional flip rates in opposite directions. Here, they rise together. The exception, gpt-oss-120b, nearly always predicts `safe` at C2, leaving few flip opportunities in either class.

**Finding 1: Agent verdicts become easier to flip without semantic change.** Semantics-preserving edits raise flip rates on most base models, and the increase appears in both vulnerable and safe classes on the same five of six base models. Within this model pool, the agent loop is therefore associated with additional boundary instability beyond a shifted predicted-vulnerable rate.

## 5.3 RQ2: Resistance to Misleading Non-Causal Context

**Result.** In the adversarial opposite-label prompt-cue stress test, agents are more vulnerable to prompt-level misleading context than to repository distractors. At C2, D2 has a higher flip rate than D1 on every non-collapsed base model, and it does so in the most damaging direction: correct verdicts are much easier to destroy than wrong verdicts are to repair under this cue design.

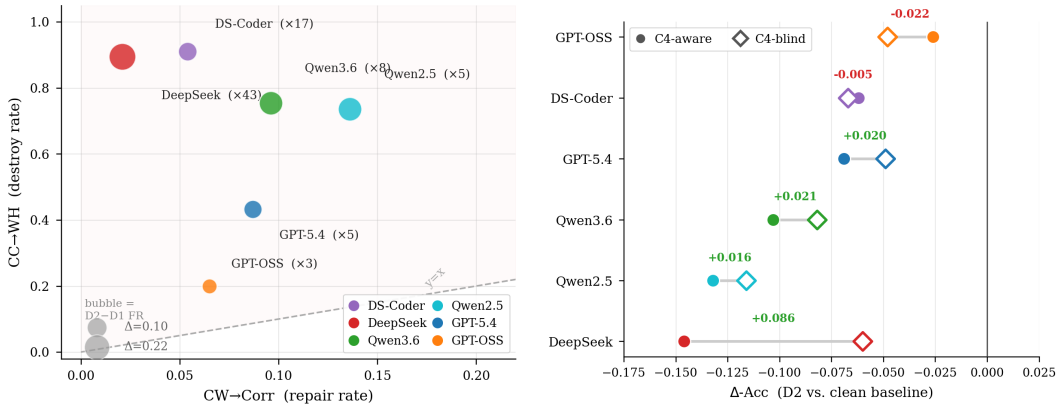

**Figure 3** RQ2 misleading-context effects. Under D2 at C2, the left panel shows that the destruction of clean-correct verdicts greatly exceeds the repair of clean-wrong verdicts. The right panel compares C4-aware and C4-blind accuracy loss under D2; blind verification reduces the damage by isolating the verifier from the cue.

The asymmetry is large enough to be visible without relying on aggregate accuracy. Under D2 at C2, the share of clean-correct verdicts turned wrong is 0.895 for DeepSeek-V3.2, 0.754 for Qwen3.6-27B, 0.736 for Qwen2.5-Coder-14B, and 0.910 for DS-Coder-V2-Lite; the corresponding repair rates for clean-wrong verdicts are only 0.021, 0.096, 0.136, and 0.054. The opposite-label prompt cue therefore does not simply add noise. It creates a directed reversal in this stress test: the cue can override code evidence when the model is right but rarely repairs a wrong verdict.

The mechanism is exposure order in this stress test. D2 frames the analysis before tool observations are interpreted, whereas D1 must first be retrieved and connected to the target. D2 therefore produces larger FR than D1 in the matched DeepSeek and gpt-5.4 tests at C2, with $p < 0.001$ and $p = 0.015$; gpt-oss-120b again collapses toward `safe`.

The C4 verifier separates two possible explanations. If verification helped because a second model pass reasons more carefully, then an aware verifier that sees the same D2 cue should recover. It does not. The recovery appears when the verifier is blind to the cue. On DeepSeek-V3.2, the D2 flip rate drops from 0.454 with aware verification to 0.302 with blind verification, with $p < 0.001$; the accuracy loss is reduced from $-0.411$ to $-0.251$. The same direction holds on five of six base models. Stratified by difficulty, the DeepSeek

blind-minus-aware accuracy gap under D2 grows from +0.105 on Easy to +0.173 on Medium and +0.202 on Hard. The hardest cases benefit most because they are precisely where the initial agent is most susceptible to using the prompt cue as a tie-breaker.

**Finding 2: Opposite-label prompt cues create directed reversals; blind verification limits them.** Prompt-level opposite-label cues mostly destroy clean-correct verdicts rather than repair clean-wrong ones. Verification helps only when the verifier is cue-blind, implicating controlled exposure rather than an additional reasoning round.

## 5.4 RQ3: Grounding of Vulnerability Predictions

**Result.** No condition provides consistent evidence that the aggregate performance gain lifts grounding above the low baseline observed in these metrics. CWE classification remains low, statement-level evidence F1 stays near the floor on SecVulEval, and patch-replacement consistency is decoupled from the C1→C2 pAcc change. The agent often produces more elaborate explanations, but the additional explanation surface is not accompanied by reliably better localization of the causal vulnerable lines.

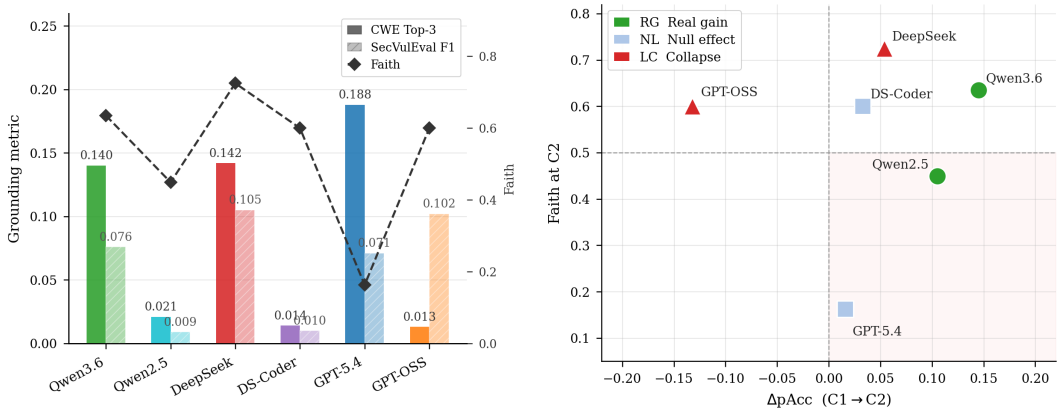

**Figure 4** RQ3 grounding diagnostics. The left panel reports C2 CWE Top-3, best SecVulEval statement-level evidence F1, and C2 Faith. The right panel compares C1→C2 pAcc change with C2 Faith. Detection change and grounding diagnostics are not aligned across base models.

At C2, CWE Top-3 accuracy is at most 0.188 and is near zero for the two smaller code models. It does not track pAcc: gpt-5.4 falls from 0.287 at C1 to 0.188 at C2, while Qwen2.5-Coder-14B remains at 0.021 despite a pAcc gain. On SecVulEval, no complete pipeline (C2–C5) exceeds evidence F1 0.105; the decline in DeepSeek precision from 0.081 at L1 to 0.029 at C4 is consistent with over-citation rather than better causal localization.

Statement-level evidence on SecVulEval gives a stricter test of this observable grounding signal. Among complete agent pipelines (C2–C5), no condition exceeds evidence F1 0.105 in the main evidence evaluation. DeepSeek reaches the strongest complete-pipeline score at C2, but precision falls from L1 to C4 from 0.081 to 0.029, with C2 and C3 at 0.074 and 0.060. The trace pattern is consistent with over-citation: iterative passes cite more plausible lines, but these additional citations do not consistently become more causal.

**Table 7** SecVulEval soft-overlap F1 on vulnerable samples with non-empty evidence predictions, pooled across difficulty strata. $F1_{\pm k}$ matches citations within $\pm k$ lines of the labeled lines; $N$ is the number of evaluated samples.

| Model | Cond. | $N$ | $\pm0$ | $\pm1$ | $\pm3$ | $\pm5$ | Model | Cond. | $N$ | $\pm0$ | $\pm1$ | $\pm3$ | $\pm5$ |

| | C2 | 33 | 0.086 | 0.162 | 0.226 | 0.282 | | C2 | 16 | 0.000 | 0.000 | 0.000 | 0.000 |
| gpt-oss | C3 | 31 | 0.090 | 0.180 | 0.248 | 0.297 | Qwen2.5 | C3 | 16 | 0.000 | 0.000 | 0.000 | 0.000 |
| | C4 | 22 | 0.098 | 0.198 | 0.277 | 0.312 | | C4 | 14 | 0.001 | 0.002 | 0.005 | 0.007 |
| | C5 | 21 | 0.022 | 0.089 | 0.106 | 0.166 | | C5 | 16 | 0.001 | 0.001 | 0.003 | 0.004 |

**Soft-overlap and audit.** Because strict evidence F1 can miss adjacent citations, we also report soft overlap within $\pm k$ lines, for $k \in \{0, 1, 3, 5\}$, and complement it with a manual audit. Table 7 shows that at $\pm3$, F1 rises by about 2.5−4×, but all scores remain below 0.40 even at $\pm5$. L1 matches or exceeds C2 at $\pm3$ for DeepSeek-V3.2, gpt-5.4, and gpt-oss-120b, while the two smaller code models remain near zero.

The 20-trace inspection attributes the remaining gap to three patterns: *off-by-block citation*, where the cited block ends next to the labeled bug; *over-citation around the bug*, where the agent cites a wide block containing the label but with low precision; and *evidence/verdict mismatch*, where the cited lines overlap the bug but the final verdict is still `safe`. Thus, relaxed matching shows that strict evidence F1 understates some near misses, but it does not overturn the grounding result.

**Exploratory causal-grounding audit on 50 traces.** Soft overlap measures proximity, not whether the rationale identifies the causal vulnerability mechanism. We therefore manually rated 50 vulnerable C2 traces from the four base models with non-trivial evidence emission, stratified by Easy, Medium, and Hard. The sample contains 13 traces each from DeepSeek-V3.2, gpt-5.4, and gpt-oss-120b, plus 11 traces from Qwen3.6-27B. A trace is *causal* if the cited evidence reaches the labeled line or its $\pm1$ neighborhood and the rationale matches the true mechanism; *adjacent* if it localizes nearby code or a related mechanism; and *irrelevant* otherwise. One author rated each trace using the cited lines, SecVulEval `changed_lines`, rationale text, and CWE predictions. We use the resulting audit as qualitative support for interpreting the quantitative grounding analyses.

Table 8 summarizes the exploratory sample: 15 of 50 traces (30%) were rated causal, 19 (38%) adjacent, and 16 (32%) irrelevant. The descriptive causal shares range from 27% to 31% across the four represented models. The audited cases also illustrate a divergence between verdict correctness and grounding: 8 of 21 correct vulnerable predictions were rated causal, while 7 of 29 missed bugs still cited the bug lines.

Three rated cases illustrate the audit categories. A causal DeepSeek-V3.2 trace on CVE-2017-14064 (function `cState_space_set` in the Ruby `json` extension) identifies the allocator/deallocator mismatch even though one endpoint is adjacent rather than exactly cited. An adjacent trace on CVE-2019-19275 (function `ast2obj_slice` in `typed_ast`) cites a 20-line

**Table 8** Exploratory manual three-way grounding rating on 50 vulnerable C2 traces. Right blocks split by predicted verdict; all audited inputs are GT-vulnerable, so "pred. vul." is a correct verdict and "pred. safe" is a missed bug. C/A/I denotes causal, adjacent, irrelevant.

| | | All audited | | | Pred. vul., correct | | | | Pred. safe, missed | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| **Model** | $N$ | C | A | I | $n$ | C | A | I | $n$ | C | A | I |
| DeepSeek-V3.2 | 13 | 4 | 7 | 2 | 9 | 3 | 5 | 1 | 4 | 1 | 2 | 1 |
| gpt-5.4 | 13 | 4 | 4 | 5 | 2 | 1 | 0 | 1 | 11 | 3 | 4 | 4 |
| gpt-oss-120b | 13 | 4 | 5 | 4 | 4 | 2 | 1 | 1 | 9 | 2 | 4 | 3 |
| Qwen3.6-27B | 11 | 3 | 3 | 5 | 6 | 2 | 2 | 2 | 5 | 1 | 1 | 3 |
| **Total** | 50 | 15 | 19 | 16 | 21 | 8 | 8 | 5 | 29 | 7 | 11 | 11 |
| **Share** | – | 30% | 38% | 32% | – | 38% | 38% | 24% | – | 24% | 38% | 38% |

block around the bug, recovering the neighborhood but not isolating the causal statements. An irrelevant gpt-oss-120b trace on CVE-2015-2778 (function `CoreUserInputHandler::handleSay` in `quassel`) cites header lines and a distant helper but misses the actual bug.

Read with the soft-overlap table, the manual rating provides qualitative context for the grounding result. The audited cases illustrate how strict evidence F1 can miss nearby evidence and how longer traces may cite plausible but non-causal code. The quantitative grounding conclusion rests on the full evidence-localization and patch-based analyses.

**Denominators behind the grounding metrics.** Faith and evidence F1 are subset-dependent. At C2, empty `evidence_lines` rates range from 0.7% to 60.6% across base models, the soft-overlap evidence denominators range from 117 to 296 emitted-evidence instances, and the patch-replacement-eligible subsets range from 10 to 120 instances. We therefore treat patch-replacement consistency as an auxiliary diagnostic rather than a basis for ranking base models; its cross-model association with C1→C2 pAcc gain is near zero. The descriptive correlation is $r = +0.10$ over the six base models.

**Finding 3: Longer traces do not lift grounding above the observed floor.** Relaxed line matching shows that strict evidence F1 understates some near misses, while the exploratory manual ratings illustrate causal, adjacent, and irrelevant evidence patterns. Across the quantitative diagnostics, the full agent does not consistently lift grounding signals above the matched-context baseline, and patch-replacement consistency does not track clean pair-level gain.

**Cost note.** Table 9 reports the full cost and latency results. On DeepSeek-V3.2, C2 and C4 cost about 9× and 15× C1, respectively, while much of the C1→C2 pAcc change is already present in L1. Thus, the generic ReAct loop is costly for its residual clean-task benefit; blind verification is the clearer exception because it limits cue exposure.

## 6 Discussion

**Lessons learned.** Three lessons emerge: aggregate gains require attribution because trace replay and prediction-rate shifts can explain much of the change; additional orchestration does not consistently improve robustness, resistance, or grounding; and under D2, blind verification helps by controlling cue exposure.

**Research implications.** Researchers and benchmark designers should pair aggregate metrics with matched trace-replay controls, pair-level accuracy, predicted-vulnerable rate, and behavioral probes. Reporting eligible denominators alongside replay-recoverable and residual effects makes gains easier to interpret.

**Practical implications.** Tool builders should require measured behavioral gains to justify agent cost; keep retrieved evidence, verifier exposure, and decision aggregation auditable; and validate cue-isolated verification on natural inputs before deployment.

**Threats to validity.** *Construct validity.* Robustness, resistance, and grounding are operational probes, and L1 effects are conditional on the C2-selected trace. *Internal validity.* Prompt wording, tool behavior, provider variability, and implementation may affect outcomes despite matched controls; overlapping difficulty-voting and evaluation models restrict strata to within-model contrasts. *External validity.* JITVUL chiefly supports paired repository-level detection, the evaluated conditions do not cover all agent architectures, and weaker natural cues may differ from D2. *Conclusion validity.* Evidence F1 and Faith use varying eligible subsets. The 50-trace, one-author audit is qualitative; conclusions rely on matched effects, confidence intervals, and cross-model consistency.

## 7 Conclusion

This paper presented a matched measurement framework for auditing LLM vulnerability-detection agents beyond aggregate accuracy. By holding the C2-selected tool trace fixed, the framework separates change recoverable from replaying the selected tool trace from the residual ReAct-loop effect over that same context, and evaluates the same conditions on robustness, resistance, and grounding.

Across six base models, aggregate agent gains reproduce in some settings but do not consistently imply better measured vulnerability reasoning. The clearest positive lesson is controlled independence: blind verification can reduce susceptibility to misleading prompt cues. Future vulnerability-detection agents should therefore demonstrate gains on robustness, resistance, and grounding, not only on aggregate detection metrics.

## Data Availability Statement

The replication package is publicly available at `https://github.com/cielverse/llm-vuln-agent-reasoning-eval`. It contains the implementation, data, prompts, model-output records, and reproduction instructions. API keys and provider-side logs are excluded; runs that depend on external services must be regenerated following the documented procedures.

# Balancing Green and Clean Code: Prompting for LLM-Based Refactoring

**Feray Gulu-zada**
University of Tartu, Estonia

**Hina Anwar**
University of Tartu, Estonia

## Abstract

**Background.** LLMs are increasingly used for code refactoring, but their effects on multiple software quality dimensions remain unclear. Green coding targets energy efficiency, while clean coding emphasizes readability and maintainability. These objectives may interact or conflict, making LLM-based refactoring a multi-objective problem.

**Aims.** This study investigates whether prompting can guide LLM-based refactoring toward balanced green and clean code outcomes. We examine how different prompting strategies affect energy consumption, runtime performance, and maintainability.

**Method.** We conduct a controlled empirical study on 15 human-written Python scripts using four LLMs and five prompting strategies: clean, green, multi-objective, clean-to-green staged, and green-to-clean staged prompting. Generated refactorings are validated for correctness before analysis. Valid outputs are evaluated using CPU energy consumption, runtime, maintainability index, cyclomatic complexity, source lines of code, and Halstead volume. We analyze results using descriptive statistics, statistical tests, correlation analysis, bootstrap confidence intervals, and Pareto-efficiency analysis.

**Results.** Of 300 generated refactorings, 267 passed validation. Among valid outputs, 53.18% (142 of 267) reduced energy consumption, but the overall energy effect was small, variable, and not statistically significant across prompting strategies. Energy and runtime changes showed a moderate positive correlation, while maintainability showed weaker relationships with efficiency metrics. Prompting strategies significantly affected maintainability but not energy or runtime. Clean and multi-objective prompting produced the most balanced Pareto outcomes, though these differences were mainly driven by maintainability.

**Conclusions.** LLM-based refactoring can sometimes reduce energy consumption without necessarily degrading maintainability, but its effects are inconsistent and depend on model choice, prompt design, and correctness validation. Prompting is useful for steering LLM-based refactoring, but current evidence supports cautious, validated use rather than assuming reliable multi-objective optimization.

## 1 Introduction

Large Language Models (LLMs) are increasingly used in software engineering tasks such as code generation, refactoring, and optimization. Their growing adoption positions them not only as productivity tools, but also as automated agents that can influence software

© Feray Gulu-zada and Hina Anwar;

quality attributes such as maintainability, performance, and energy efficiency. As developers increasingly rely on LLM-generated code transformations, it becomes important to understand not only whether these transformations improve code, but also which quality attributes they improve and which they may degrade.

Software quality has traditionally been associated with *clean code*, which emphasizes readability, simplicity, and maintainability [13]. More recently, *green software* has emerged as a complementary concern, focusing on reducing energy consumption as one contributor to the environmental impact of software systems [33]. As software systems scale, even small inefficiencies in frequently executed code can accumulate into substantial energy costs. Sustainability, therefore, represents an increasingly important dimension of software quality, particularly for code that is executed repeatedly or deployed at scale.

However, clean and green code objectives are not always aligned. Optimizations that improve runtime or energy efficiency may reduce readability or maintainability, while refactorings that improve clarity may introduce computational overhead [5, 26, 23]. This creates a multi-objective refactoring problem in which improving one quality attribute may come at the expense of another. Such trade-offs are especially relevant for LLM-based refactoring, where developers may accept generated changes without fully understanding their effects across multiple quality dimensions.

Existing research has investigated LLMs for code generation, repair, refactoring, performance optimization, and maintainability improvement. In parallel, empirical software engineering research has studied energy-aware programming and trade-offs among performance, readability, and maintainability. However, these lines of work remain only partially connected. Existing studies often evaluate clean-code or green-code objectives separately, leaving limited empirical evidence on whether LLM-based refactoring can be guided to balance these objectives simultaneously. In particular, it remains unclear how prompting strategies affect trade-offs among energy consumption, runtime performance, and maintainability.

Prompting provides a lightweight mechanism for steering LLM behavior. Prior work shows that prompt structure, context, and stated objectives can substantially influence generated code [36, 20, 23]. Unlike fine-tuning or specialized optimization tools, prompting can be applied directly across models without modifying their internals, making it a practical intervention for studying multi-objective LLM-based refactoring. Nevertheless, LLM-generated transformations are useful only if they preserve the behavior of the original program. Therefore, functional correctness must be treated as a prerequisite before assessing non-functional quality changes.

The goal of this paper is to empirically evaluate how LLMs behave when asked to refactor existing Python programs under different optimization objectives. We use the term *refactoring* to refer to LLM-generated code transformations intended to preserve input-output behavior while improving non-functional properties. We conduct a controlled study using 15 human-written Python scripts, four LLMs, and five prompting strategies: clean, green, multi-objective, clean-to-green staged prompting, and green-to-clean staged prompting. The generated outputs are first validated for correctness and then evaluated using CPU energy consumption, runtime, maintainability index, cyclomatic complexity, source lines of code, and Halstead volume metrics. We analyze the resulting trade-offs using descriptive statistics, statistical tests, correlation analysis, bootstrap confidence intervals, and Pareto-efficiency analysis. This study makes the following contributions:

- an empirical evaluation of LLM-generated refactorings across energy consumption, runtime performance, and maintainability;
- a comparison of single-objective, multi-objective, and staged prompting strategies for steering LLM-based refactoring;

- an analysis of trade-offs among clean and green code objectives, showing how model choice, prompt design, and correctness validation shape sustainable and maintainable LLM-based refactoring.

The remainder of this paper is organized as follows. Section 2 reviews related work on LLM-based refactoring, green-code optimization, and prompting. Section 3 describes the study design, including research questions, dataset, models, prompts, metrics, validation, and analysis. Section 4 presents the results, Section 5 discusses the findings, Section 6 addresses threats to validity, and Section 7 concludes the paper.

## 2 Related Work

This section summarizes prior work on LLM-based refactoring, energy-aware code generation, and prompt engineering for code improvement. Prior studies were identified through database search and backward/forward snowballing.

### 2.1 LLM-Based Clean-Code Refactoring

LLMs have shown promise for automated refactoring and maintainability improvement. Prior studies report that Copilot resolved 87.1% of Python code smells [36], GPT improved code quality by 20% [15], produced effective refactorings for most Java code segments [9], and matched human recommendations in 63.6% of cases [14]. Structured and multi-agent LLM systems further improve reliability: CORE achieved up to 76.8% fix rates while reducing unintended changes by 25.8% [34], a Haskell-based multi-agent system reduced complexity by 11% and improved quality by 22% [30], and RefAgent achieved a 90% unit-test pass rate while reducing code smells by 52.5% [19]. These studies show that LLMs can support clean-code refactoring, but their effectiveness varies across models, tasks, and evaluation settings.

### 2.2 LLM-Based Green-Code Optimization

Research on LLMs for energy-efficient code reports more mixed results. Studies evaluating Copilot, GPT-4o, o1-mini, Code Llama, DeepSeek-v3, Gemini-1.5-Pro, and related models show that LLM-generated code often underperforms human-written baselines in runtime or energy consumption, although occasional parity or marginal gains appear under specific conditions [31, 32, 10, 33, 7, 1]. Prompt-based energy optimization is similarly inconsistent: general efficiency prompts often yield negligible improvements [33, 3, 7, 1], while structured, tagged, or iterative prompting can improve efficiency in some cases [27, 2, 23, 12, 11]. However, iterative energy optimization may also reduce correctness when not guided by execution feedback [35]. These findings suggest that LLMs do not reliably optimize energy efficiency without explicit guidance and validation.

### 2.3 Prompt Engineering for Code Improvement

Prompt engineering is central to LLM-based code improvement because small changes in task framing, constraints, role specification, examples, and feedback can substantially affect generated code. In refactoring studies, iterative, role-based, contextual, constrained, few-shot, and task-specific prompts have been shown to reduce complexity, lines of code, code smells, and maintainability issues, while also improving correctness, runtime efficiency, and memory usage in some settings [29, 6, 30, 14, 18, 36]. Prior work also shows that prompt formulation and task framing strongly affect LLM refactoring performance [20, 22].

For energy-oriented tasks, prompting evidence is less stable. Generic requests for efficient or green code often produce negligible gains, whereas more structured prompts, prompt tags, iterative refinement, and explicit optimization cues can improve energy or runtime in specific contexts [33, 3, 7, 1, 27, 2, 23, 12, 11]. However, these gains may come with correctness risks when outputs are not validated [35]. This motivates treating prompt design and functional validation as linked concerns in empirical studies of LLM-based refactoring.

Prior work shows that LLMs can improve maintainability and, in some settings, runtime or energy efficiency. However, these objectives are typically studied separately, despite potential trade-offs between clean and green code. Although prompting, constraints, feedback, and multi-agent coordination affect LLM-based code improvement [14, 18, 36, 6, 29, 4, 30, 34, 8, 28, 21], limited evidence exists on how prompting strategies shape trade-offs among maintainability, runtime, and energy efficiency in refactoring. This study addresses that gap by comparing single-objective, multi-objective, and staged prompting strategies across clean and green code metrics.

# 3 Methodology

This section describes the empirical study used to evaluate whether LLM-based refactoring can improve energy efficiency, runtime performance, and maintainability of existing Python programs. We present the research questions, study design, dataset, models, prompts, validation procedure, metrics, measurement setup, and analysis methods.

## 3.1 Research Questions

The following research questions guide this study:

- **RQ1:** To what extent can LLM-based refactoring improve the energy efficiency of existing Python code?
- **RQ2:** How do prompting strategies affect trade-offs among energy consumption, runtime performance, and maintainability?
- **RQ3:** Which prompting strategies yield the most balanced outcomes across green and clean code metrics?

RQ1 focuses on energy changes, RQ2 on interactions among efficiency and maintainability metrics, and RQ3 on identifying prompting strategies with favorable multi-objective trade-offs.

## 3.2 Study Design

We conduct a controlled empirical study in which existing Python programs are refactored using multiple LLMs under different prompting strategies. Each original program serves as its own baseline. The independent variables are the LLM and prompting strategy; the dependent variables are energy consumption, runtime performance, and maintainability-related metrics. Functional correctness is treated as a prerequisite for metric comparison.

Figure 1 summarizes the experimental pipeline. For each script, we collect baseline measurements, generate refactored versions using each model and prompt, validate correctness, measure valid outputs, and compare the resulting metrics against the baseline.

## 3.3 Dataset and Task Definition

The dataset consists of 15 human-written Python scripts manually selected from public GitHub repositories containing standalone implementations of classical algorithms and data structures. Repositories were manually inspected, and scripts satisfying the predefined

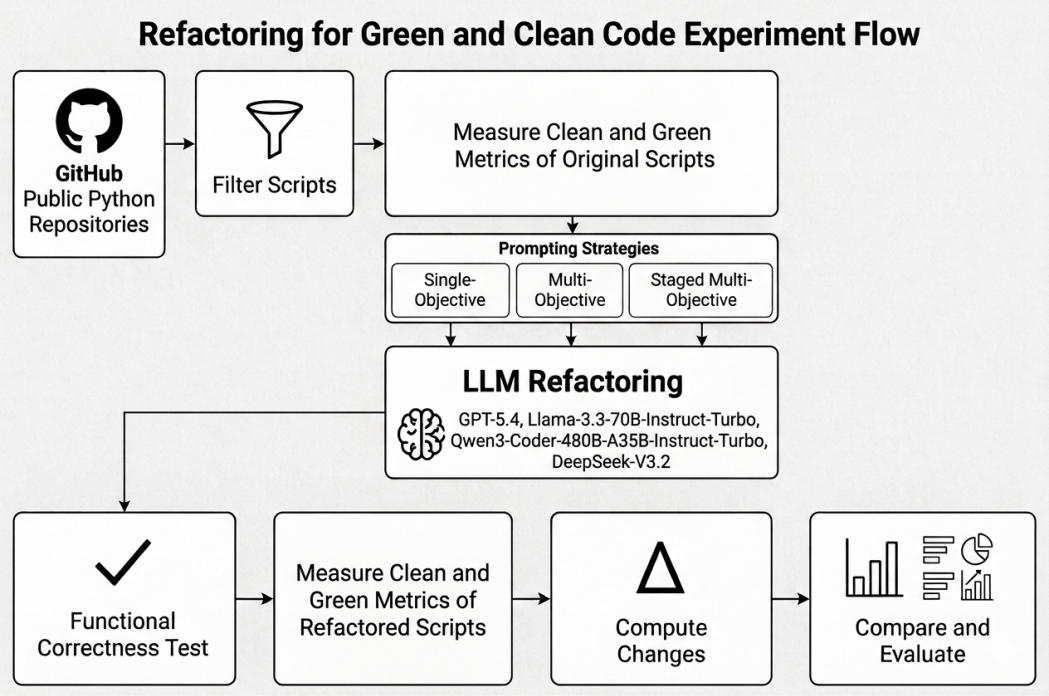

**Figure 1** Overview of the experimental pipeline.

inclusion criteria were selected for the study. The scripts implement classical data structures and algorithms (e.g., trees, graph algorithms, dynamic programming, and search algorithms), providing deterministic computational workloads with varying control flow and algorithmic complexity. These characteristics make them suitable for controlled comparisons of runtime, CPU energy consumption, and maintainability. Scripts were selected to satisfy the following inclusion criteria: they contained 50–200 lines of code, three to eight user-defined functions, at least one conditional branch and one iterative construct, implemented computationally significant tasks (e.g., graph algorithms, data structure manipulation, dynamic programming, recursive algorithms, or search algorithms), and exhibited at least one maintainability issue, such as elevated cyclomatic complexity, a low Maintainability Index, or code smell warnings reported by Pylint. Scripts that require external dependencies, interactive input, external services, or complex runtime environments were excluded to reduce measurement noise. The dataset size was kept modest to support controlled, repeated energy measurements and correctness validation.

For scripts without a fixed entry point or predefined inputs, we added a standardized `main()` function and deterministic input values. These execution harnesses enabled automated execution, correctness validation, and consistent runtime and energy measurement.

We use *refactoring* to refer to LLM-generated code transformations intended to preserve input-output behavior while improving non-functional properties. Since LLMs may alter behavior, all generated outputs are validated before metric analysis.

## 3.4 LLMs

We evaluate four transformer-based LLMs representing instruction-tuned and code-oriented models:

- **Instruction-tuned models:** GPT-5.4 and Llama-3.3-70B-Instruct-Turbo.
- **Code-oriented models:** Qwen3-Coder-480B-A35B-Instruct-Turbo and DeepSeek-V3.2.

**Table 1** Prompting strategies evaluated in the study.

| Strategy | Type | Primary objective |
|---|---|---|
| clean | Single-objective | Maintainability/readability |
| green | Single-objective | Runtime/energy efficiency |
| multi | Multi-objective | Maintainability, runtime, energy |
| stagedcg | Staged | Clean → green |
| stagedgc | Staged | Green → clean |

GPT-5.4 was accessed through the OpenAI API, while the remaining models were accessed through DeepInfra. All generations were conducted between April 15 and May 8, with the temperature set to 0.0 to reduce randomness in generation.

## 3.5 Prompting Strategies

Prompting is the main experimental treatment. We evaluate five strategies representing single-objective, multi-objective, and staged optimization. Each strategy asks the model to preserve input-output behavior, avoid external dependencies, and return only refactored code. The prompting strategies evaluated in this study are summarized in Table 1.

The `clean` strategy targets structural quality by reducing complexity, unnecessary lines of code, and Halstead Volume. The `green` strategy targets runtime and CPU energy consumption. The `multi` strategy combines both objective sets into a single prompt. The staged strategies apply the objectives in a sequential order: `stagedcg` applies clean then green optimization, while `stagedgc` applies the reverse order. Only the final second-stage output is included in the main analysis; intermediate outputs are retained for traceability.

All prompts share a common structure: role definition, task description, optimization goals, behavior-preservation and dependency constraints, and an output-format instruction. The complete set of prompt templates is available in the replication package.

```
You are a software engineer specializing in [objective].
Task: Refactor the code to improve [target qualities].
Constraints:
- Do not add external dependencies.
- Preserve input-output behavior.
- Limit changes to internal computation logic.
Optimization goals: [strategy-specific goals]
Output: Return ONLY the refactored code.
Code to refactor: [code]
```

## 3.6 Correctness Validation

Before measuring non-functional properties, each refactored program is validated against the corresponding original implementation. Both versions are executed using the same deterministic inputs, which were fixed before model generation and reused across all model–prompt combinations for a given script. A refactoring is valid only if it executes successfully and produces output equivalent to the baseline.

Generated outputs are excluded if they fail correctness validation. The number of generated, excluded, and valid refactorings is reported in Section 4.

**Table 2** Metrics used to evaluate original and refactored programs.

| Category | Metric | Tool | Unit | Improvement Direction |
|---|---|---|---|---|
| Green | Runtime | `time.perf_counter()` | seconds | Lower |
| Green | CPU energy | Intel RAPL/`pyRAPL` | $\mu$J | Lower |
| Clean | Maintainability Index | `Custom Calculation` | score (0–100) | Higher |
| Clean | Cyclomatic Complexity | `Lizard` | count | Lower |
| Clean | SLOC | `Radon` | lines | Lower |
| Clean | Halstead Volume | `Radon` | – | Lower |

## 3.7 Metrics

We evaluate each original and refactored program using green and clean code metrics. Green metrics capture execution efficiency, while clean metrics capture structural maintainability. Table 2 summarizes the metrics, tools, and optimization direction.

Maintainability Index is computed as follows:

$$MI = \max\left(0, \frac{171 - 5.2\ln(HV) - 0.23 \cdot CC_{\text{total}} - 16.2\ln(SLOC)}{171} \times 100\right) \tag{1}$$

where $HV$ is Halstead Volume, $CC_{\text{total}}$ is the total Cyclomatic Complexity, calculated as the sum of the per-function complexity values reported by Lizard, and $SLOC$ is Source Lines of Code. We use the normalized Maintainability Index formulation adopted by Microsoft Visual Studio, which yields values on a 0–100 scale, with higher values indicating better maintainability [17].

## 3.8 Static Analysis Tools

We use three static analysis tools to extract code quality metrics from the original and refactored programs. `Radon` is a Python code analysis tool used to compute Source Lines of Code (SLOC) and Halstead Volume [25]. `Lizard` is a complexity analysis tool used to measure Cyclomatic Complexity of the analyzed programs [16]. `Pylint` is a Python static analysis tool used to identify maintainability-related warnings [24].

## 3.9 Execution Environment

All experiments were executed on a single HP EliteBook 8 G1i 14-inch notebook running Ubuntu 24.04.4 LTS, with an Intel(R) Core(TM) Ultra 5 228V processor, 8 logical cores, 30 GB RAM, 8 GB swap, and Intel integrated graphics. To reduce measurement noise, the machine was connected to power, non-essential applications and network-intensive tasks were closed, and automatic updates were disabled.

## 3.10 Runtime and Energy Measurement

Runtime and energy consumption were measured for both original and refactored programs. Each execution was pinned to a single physical CPU core using Linux CPU affinity through `taskset`. Each script was executed 30 times, and the complete measurement procedure was repeated five times per script. A 60-second cooldown interval was enforced between measurement repetitions. Final runtime and energy values were computed using the mean across repeated runs.

## 3.11 Analysis Method

For each metric, percentage change is computed relative to the original implementation:

$$\Delta M = \frac{M_{\text{refactored}} - M_{\text{original}}}{M_{\text{original}}} \times 100 \tag{2}$$

For energy consumption, runtime, Cyclomatic Complexity, SLOC, and Halstead Volume, negative values indicate improvement. For the Maintainability Index, positive values indicate improvement.

We summarize the results using the mean, median, and standard deviation, grouped by model and prompting strategy. Spearman's rank correlation coefficients were used to analyze relationships among changes in energy, runtime, and maintainability. Spearman's method was selected because the percentage-change variables exhibited skewed distributions and contained outliers, making a rank-based correlation more appropriate. We use the Kruskal–Wallis test to compare prompting strategies. When significant effects are observed, we perform post-hoc pairwise comparisons using Dunn's test with Holm correction to adjust for multiple testing. Uncertainty in the estimates is assessed using bootstrap confidence intervals for mean percentage changes across strategies.

To identify balanced solutions, we perform Pareto-efficiency analysis. A refactoring is Pareto-efficient if no other refactoring improves at least one objective without worsening another.

All analyses were conducted in Python using NumPy, Pandas, SciPy, Matplotlib, and Seaborn.

# 4 Results

This section reports the results for 300 generated refactorings. We first summarize validation outcomes and failure patterns, then present the results for each research question. Only refactorings that passed correctness validation and completed measurement are included in the energy, runtime, maintainability, and Pareto analyses, consistent with the validation procedure described in Section 3.6.

Table 3 summarizes the validation outcomes. Out of 300 generated refactorings, 267 passed validation and were included in the final analysis. The remaining 33 outputs were excluded: 31 failed correctness validation, one timed out during correctness evaluation, and one timed out during energy measurement.

**Table 3** Validation outcomes for generated refactorings.

| Outcome | N (%) |
|---|---|
| Valid refactorings | 267 (89.0) |
| Correctness failures | 31 (10.3) |
| Correctness timeout | 1 (0.3) |
| Energy timeout | 1 (0.3) |
| Total | 300 (100.0) |

## 4.1 Correctness Failures

Before analyzing non-functional quality changes, we examine invalid outputs by model, prompting strategy, and base script to identify where correctness-preserving refactoring was most difficult. As shown in Figure 2, invalid outputs are unevenly distributed across models. LLaMA accounts for the largest share, followed by DeepSeek, Qwen, and GPT, indicating higher instability in LLaMA-generated refactorings.

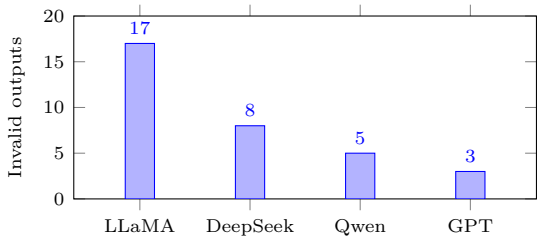

**Figure 2** Invalid outputs across models, including correctness failures and timeouts.

Figure 3 shows that failures are relatively balanced across prompting strategies, although staged strategies, especially `stagedgc` and `stagedcg`, account for more failures. LLaMA shows consistently higher failure rates across prompting strategies, whereas GPT, DeepSeek, and Qwen remain more stable with generally low error rates.

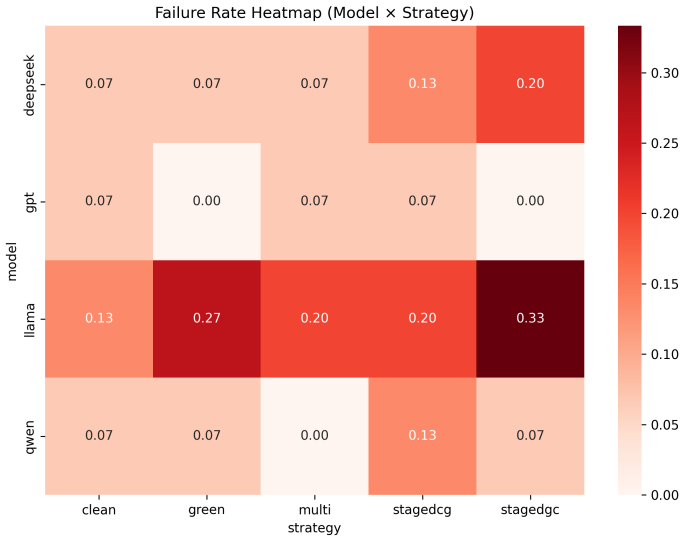

**Figure 3** Failure-rate heatmap across models and prompting strategies.

At the base-script level, Figure 4 shows that failures are concentrated in computationally complex tasks such as `priority_queue` and `satisfiability`. This suggests that algorithmic complexity affects the likelihood of correctness-preserving refactoring.

Overall, the validation results indicate that model choice and task complexity contribute more strongly to failure patterns than prompting strategy alone. This supports treating functional correctness as a prerequisite for non-functional metric analysis.

## 4.2 RQ1: Energy Efficiency Improvements

RQ1 asks to what extent LLM-based refactoring improves the energy efficiency of existing code. We analyze percentage changes in energy consumption relative to the original implementations across the 267 valid refactorings.

Overall, 53.18% (142 of 267) of valid refactorings reduced energy consumption. However, the effect size is small and highly variable: the mean energy change is 0.50%, the median is -0.11%, and the standard deviation is 11.59 percentage points. Thus, slightly more than half of the valid refactorings reduce energy consumption, but the overall effect remains close to zero.

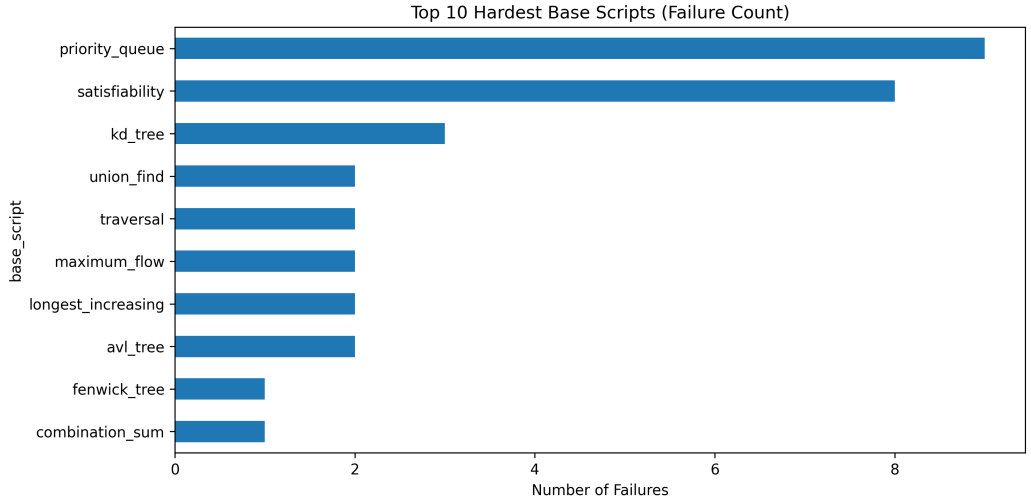

**Figure 4** Top 10 most failure-prone base scripts.

Figure 5 shows the distribution of energy change by model. DeepSeek achieves the strongest average reduction (-1.46%), followed by GPT (-0.36%). Qwen is approximately neutral (0.28%), while LLaMA shows the largest average increase in energy consumption (4.23%), with several extreme positive outliers.

Figure 6 shows the corresponding distribution by prompting strategy. The `stagedgc` strategy achieves the strongest average reduction (-1.45%), followed by `green` (-0.96%) and `multi` (-0.49%). In contrast, `clean` (1.92%) and `stagedcg` (3.56%) increase energy consumption on average. This suggests that prompts with explicit efficiency objectives are more likely to reduce energy consumption than maintainability-only prompts.

Figure 7 shows the interaction between the model and the prompting strategy. The best-performing combinations include Qwen with `multi` prompting (-5.11%) and `stagedgc` prompting (-4.59%), and DeepSeek with `clean` prompting (-4.17%) and `green` prompting (-3.80%). However, the widespread combinations indicate that energy outcomes depend on both model choice and prompt design. The boxplots also show several outliers, highlighting substantial variability within combinations, indicating that energy outcomes are highly sensitive to both model choice and prompting strategy, even when they passed correctness validation.

To assess whether energy differences across prompting strategies are statistically significant, we apply a Kruskal-Wallis test. The result is not significant ($p = 0.52$), indicating that energy variations across strategies are not statistically distinguishable. Bootstrap confidence intervals further indicate high variability, with most intervals crossing zero.

**Summary of RQ1.** LLM-based refactoring reduces energy consumption in a slight majority of valid cases, but the overall effect is small, highly variable, and not statistically significant across prompting strategies. Model choice matters descriptively, with DeepSeek and GPT showing lower mean energy consumption than Qwen and LLaMA.

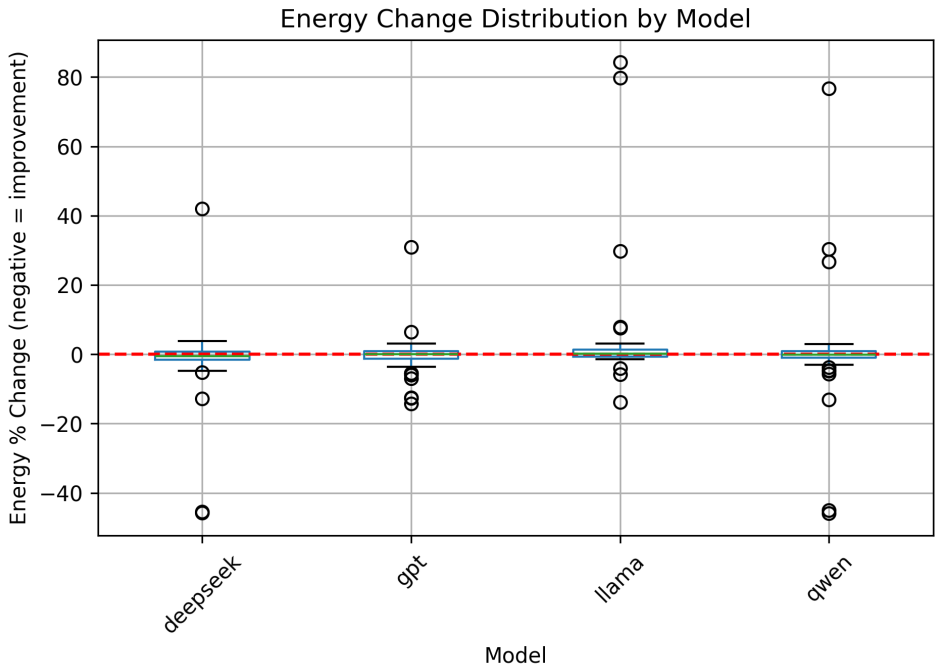

**Figure 5** Distribution of energy change by model. Negative values indicate reduced energy consumption relative to the original implementation.

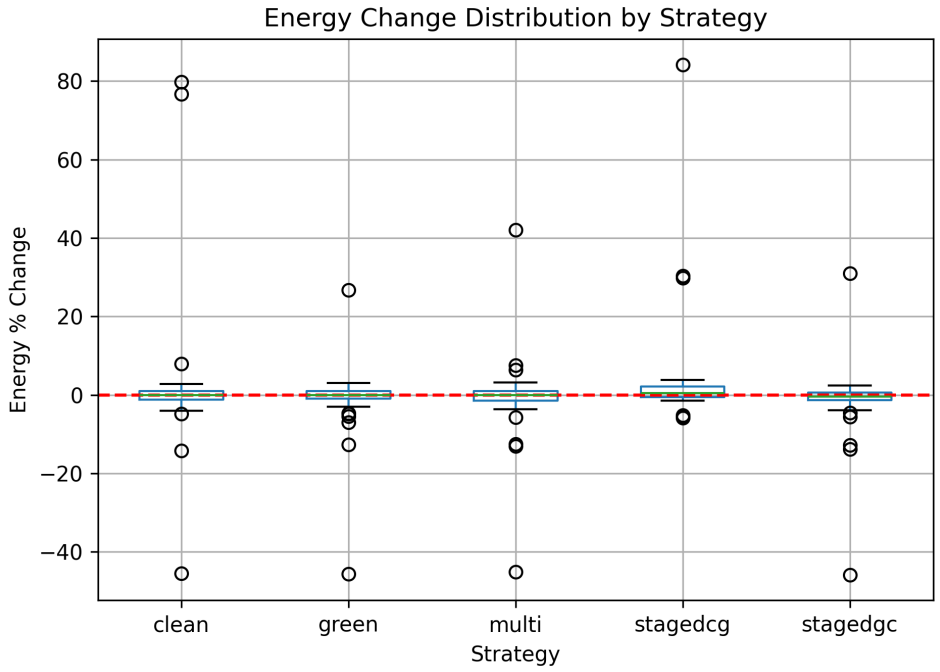

**Figure 6** Distribution of energy change by prompting strategy. Negative values indicate reduced energy consumption relative to the original implementation.

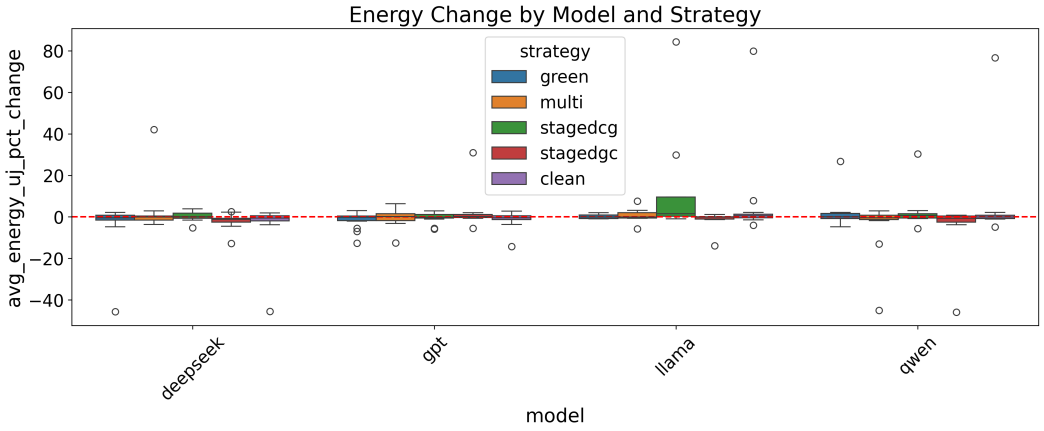

**Figure 7** Distribution of energy change by model and prompting strategy. Negative values indicate reduced energy consumption relative to the original implementation.

## 4.3 RQ2: Trade-offs Between Metrics

RQ2 examines how prompting strategies affect trade-offs among energy consumption, runtime performance, and maintainability. Table 4 compares the median values of the strategies across the three dimensions. Following the metric directions defined in Section 3.7, lower values indicate improvement for energy and runtime, while higher values indicate improvement for maintainability.

**Table 4** Median Energy, Runtime, and Maintainability Changes by Prompting Strategy.

| Strategy | Energy ↓ | Runtime ↓ | Maintainability Index ↑ |
|---|---|---|---|
| clean | -0.10 | 0.14 | 0.37 |
| multi | -0.51 | -0.03 | 0.27 |
| green | -0.085 | 0.355 | -2.82 |
| stagedcg | 0.19 | 0.37 | -2.295 |
| stagedgc | -0.05 | 0.41 | -2.22 |

Table 4 shows that `multi` prompting reduces both energy consumption (approximately -0.51) and runtime (approximately -0.03), while achieving moderate maintainability improvement (approximately 0.27). Clean-only prompting yields the highest maintainability gain (0.37), suggesting a trade-off between efficiency and structural quality.

Figure 8 illustrates the relationship between changes in energy consumption and runtime. Spearman's rank correlation indicates a moderate positive association ($\rho = 0.50$). Because reductions in both energy consumption and runtime are represented by negative percentage changes, this result suggests that refactorings that reduce runtime also tend to reduce energy consumption. In contrast, Figure 9 shows a weak negative association between changes in energy consumption and maintainability ($\rho = -0.27$). Since lower energy consumption and higher Maintainability Index values both represent improvements, the negative correlation indicates a weak tendency for energy-efficient refactorings to improve maintainability as well. However, the small magnitude of the correlation suggests that this relationship is limited and that improvements in the two dimensions are not strongly coupled.

Overall, multi-objective prompting tends to yield comparatively balanced outcomes while preserving a moderate level of structural quality. Clean prompting primarily improves maintainability, whereas green and staged strategies more often reduce maintainability.

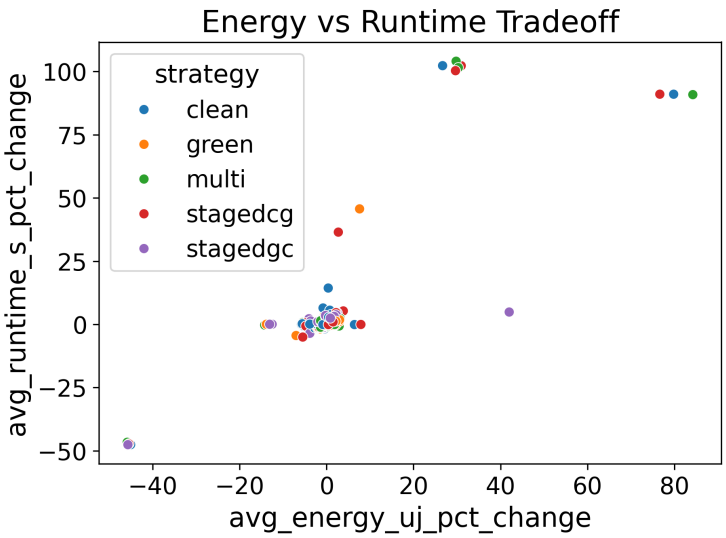

**Figure 8** Trade-off between energy and runtime. Negative values indicate improvements relative to the original implementation.

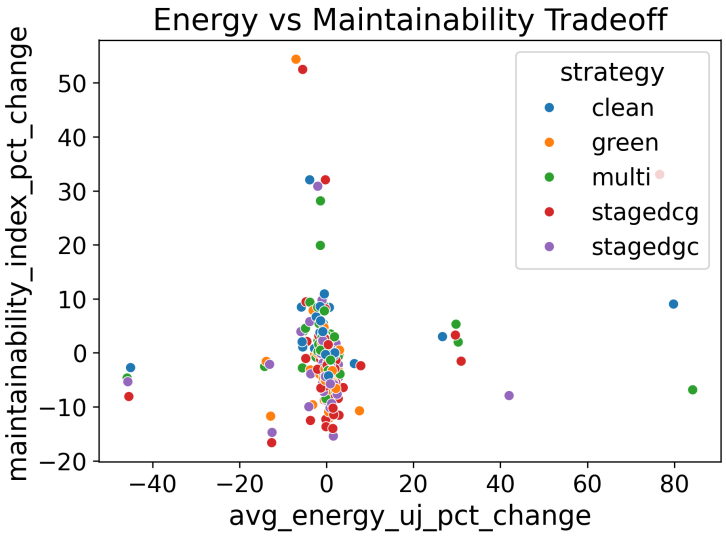

**Figure 9** Trade-off between energy and maintainability. Negative energy values indicate reduced energy consumption, while positive maintainability values indicate improved maintainability.

These results suggest that energy/runtime optimization and maintainability improvement are only weakly related, and that explicitly balancing objectives may help avoid extreme degradation in either dimension.

Kruskal–Wallis tests show no significant differences across prompting strategies for energy consumption ($p = 0.52$) or runtime ($p = 0.68$), but maintainability differs significantly ($p < 0.001$). Post hoc pairwise comparisons using Dunn's test with Holm correction indicate that significant differences in maintainability are primarily observed for `clean` and `multi` prompting compared with the remaining prompting strategies.

Figure 10 shows bootstrap confidence intervals across prompting strategies. The intervals indicate high uncertainty in energy and runtime estimates, with multiple intervals crossing zero. Runtime exhibits particularly wide intervals, while maintainability shows more consistent directional shifts.

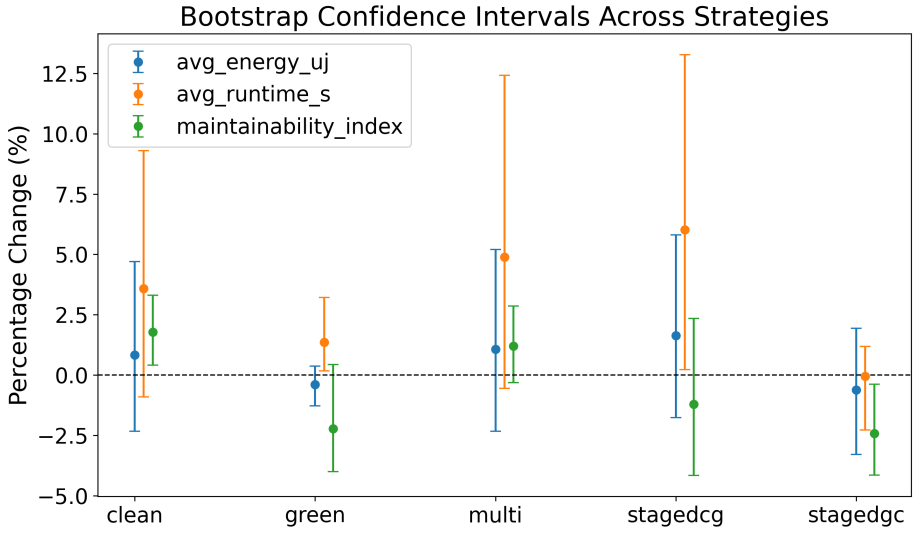

**Figure 10** Bootstrap confidence intervals across prompting strategies. Intervals crossing zero indicate uncertainty about the direction of the effect.

**Summary of RQ2.** Energy and runtime improvements tend to occur together, showing a moderate association, while maintainability is only weakly related to energy outcomes. Prompting strategies significantly affect maintainability, while their effects on energy and runtime are descriptive rather than statistically significant.

## 4.4 RQ3: Balanced Outcomes (Pareto Analysis)

RQ3 examines which prompting strategies yield the most balanced outcomes across green and clean code metrics. We evaluate balance using Pareto efficiency across energy, runtime, and maintainability. Pareto efficiency is used as a descriptive measure of trade-offs between objectives.

As shown in Figure 11, clean prompting achieves the highest Pareto-efficiency rate (0.84), followed by multi-objective prompting (0.76). In contrast, `stagedcg` (0.48), `green` (0.44), and `stagedgc` (0.39) show lower rates of non-dominated solutions.

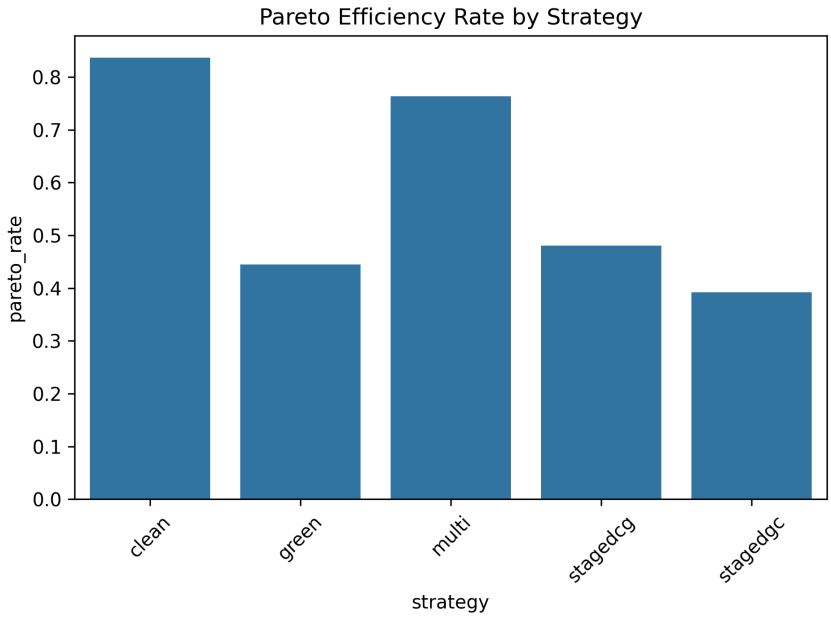

**Figure 11** Pareto efficiency across prompting strategies. Higher values indicate a larger proportion of non-dominated refactorings.

Although Pareto differences are observable, the statistical tests in RQ2 indicate that these differences are mainly driven by maintainability rather than consistent improvements in energy or runtime. Therefore, Pareto rankings should be interpreted as descriptive summaries of multi-objective behavior rather than definitive performance hierarchies.

Across the observed model-level results, clean prompting appears comparatively stable, while multi-objective prompting performs competitively but with higher variance, particularly in maintainability outcomes. Green and staged strategies generally underperform across models. No single prompting strategy dominates all objectives, but clean and multi-objective prompting provide the most consistently balanced trade-offs.

**Summary of RQ3.** Clean and multi-objective prompting provide the most balanced Pareto outcomes. However, because the strongest differences are driven by maintainability rather than energy or runtime, these results should be interpreted descriptively rather than as statistically definitive rankings.

## 5 Discussion

This study examined whether prompting strategies can guide LLM-based refactoring toward balanced improvements in energy efficiency, runtime performance, and maintainability. The results show a distinction between structural code quality and execution-level efficiency. Energy consumption and runtime showed limited and statistically non-robust differences across prompting strategies, whereas maintainability was more consistently affected. Although slightly more than half of the valid refactorings reduced energy consumption, the overall effect was small, highly variable, and not statistically significant across prompting strategies. This suggests that LLM-based refactoring can sometimes improve energy efficiency, but such improvements are not reliable enough to be assumed from prompting alone. The

validation outcomes also show that correctness remains a practical barrier: 33 generated outputs were excluded due to correctness failures or timeouts. This reinforces the need to treat LLM-generated refactorings as candidates requiring validation before non-functional improvements are assessed.

The moderate positive association between energy and runtime changes suggests that these two efficiency metrics are related in our experimental setting. Refactorings that reduced execution time also tended to reduce CPU energy consumption. However, both metrics showed high variability across models, prompts, and scripts. A likely explanation is that energy and runtime are shaped primarily by algorithmic structure, input behavior, and execution-level effects rather than by surface-level code restructuring. Small syntactic or structural changes introduced by LLMs may therefore have inconsistent performance consequences, especially when they do not alter the underlying algorithm.

In contrast, maintainability metrics responded more clearly to prompting. This is expected because LLMs are trained on large corpora of human-written code where naming conventions, modular structure, idiomatic style, and common refactoring patterns are strongly represented. Maintainability-oriented prompts, therefore, align more closely with the models' learned capabilities than energy-oriented prompts. The significant differences in maintainability across strategies suggest that prompt design is useful for steering structural code improvements, even when it is less effective for controlling runtime or energy behavior.

Model-specific differences were also observed. DeepSeek and GPT produced lower average energy consumption than Qwen and LLaMA, while LLaMA generated the highest number of invalid refactorings and the largest average increase in energy consumption. These observations suggest that model selection is an important factor alongside prompt design when applying LLM-based refactoring in practice.

These findings have important implications for multi-objective LLM-based refactoring. Prompt engineering alone appears insufficient for reliably optimizing energy efficiency, especially when no execution feedback is provided during generation. Multi-objective and staged prompts can encourage more balanced outputs, but they do not guarantee improvements across all objectives. In practice, developers should treat LLM-generated refactorings as candidates that require validation, measurement, and review rather than as automatically improved versions of the original code. Correctness validation is particularly important, since invalid outputs cannot meaningfully be evaluated for non-functional quality.

The results are consistent with prior work showing that LLMs are effective at improving readability and maintainability-related aspects of code, but less reliable for performance- and energy-oriented optimization. Our study extends this evidence by showing that even structured prompting does not fully resolve the challenge of jointly optimizing clean and green code objectives. More reliable green refactoring may require approaches that combine prompting with execution feedback, profiling information, search-based optimization, or tool-assisted validation. In our setting, LLMs appear better suited for maintainability-oriented refactoring than for standalone energy optimization.

## 6 Threats to Validity

Several threats may affect the interpretation and generalizability of our findings. First, LLM outputs can be non-deterministic. We mitigated this by setting the temperature to 0.0, the lowest available setting for each API, but minor variations may still occur. Second, energy measurements based on Intel RAPL can be affected by background activity and hardware state. To reduce this threat, all experiments were run in a controlled environment with

minimal background processes, and each script was executed repeatedly across multiple measurement runs. Third, results may be sensitive to the wording of the prompt. We mitigated this by using standardized prompt templates and varying only the controlled elements required by each prompting strategy.

The external validity of the results is limited by the dataset and model selection. Our dataset consists of curated Python scripts focused on algorithmic tasks, so the findings may not generalize to other programming languages, larger software systems, or industrial codebases with complex dependencies and architectures. We evaluated four current LLMs: GPT-5.4, Llama-3.3-70B-Instruct-Turbo, Qwen3-Coder-480B-A35B-Instruct-Turbo, and DeepSeek-V3.2. Although these models represent relevant current capabilities, newer or differently configured models may produce different results.

Construct validity is mainly affected by the metrics used to approximate maintainability and energy efficiency. Maintainability Index and related static metrics are widely used, but they do not fully capture human-perceived readability or long-term maintainability. Similarly, Intel RAPL measures CPU energy consumption, but not full-system energy use or GPU-related workloads. Therefore, our results should be interpreted as evidence about CPU-level execution energy and static maintainability indicators rather than complete measures of software sustainability or maintainability. Functional correctness was assessed using a predefined test input, which may not capture behavioral differences across all possible inputs. Thus, some refactorings may pass validation while still failing on untested edge cases or boundary conditions.

The statistical conclusions are limited by the relatively small sample size and substantial variability in energy changes, which may reduce the power to detect small differences between prompting strategies. Accordingly, non-significant results should be interpreted as a lack of statistically detectable evidence rather than evidence of no effect.

## 7 Conclusion

This paper investigated whether prompt engineering can guide LLM-based refactoring to improve energy efficiency, runtime performance, and maintainability. We evaluated multiple LLMs under single-objective, multi-objective, and staged prompting strategies and analyzed the resulting refactorings using green- and clean-code metrics.

The results show that LLM-based refactoring does not produce statistically robust or consistent improvements in energy consumption or runtime across prompting strategies. Although some refactorings reduce energy consumption, the effects are small, highly variable, and not statistically significant. In contrast, maintainability is more consistently influenced by prompting, suggesting that prompt design has a stronger impact on structural code quality than on execution-level performance.

Overall, the findings highlight a relative separation between maintainability-oriented and efficiency-oriented optimization in LLM-based refactoring. Prompt engineering can support maintainability improvements, but it is insufficient on its own for reliable energy or runtime optimization. Robust multi-objective LLM-based refactoring will likely require approaches that combine prompting with correctness validation, runtime feedback, profiling, or other tool-supported optimization mechanisms. Future work should evaluate these approaches across larger, more diverse codebases, additional programming languages, and more complex software systems.

## Abstract

**Background.** Performance antipatterns are well known for degrading the responsiveness of microservice-based systems. However, although their impact on latency has been widely studied, their relationship with energy consumption remains largely unexplored.

**Aims.** This study empirically investigates whether ten widely recognized performance antipatterns, as defined by Smith and Williams, affect power consumption and energy-related behavior in containerized environments.

**Method.** We implemented ten antipatterns as isolated containerized services and evaluated them under controlled load conditions. For each antipattern, we conducted 30 repeated runs and collected measurements of response time, CPU and DRAM power consumption, and resource utilization.

**Results.** While all injected antipatterns degraded performance as expected, only a subset showed a statistically significant positive relationship between increased response time and higher power consumption. Some antipatterns exhibited a clear association between performance degradation and increased power demand. In contrast, others reached CPU saturation early, such that power draw remained nearly constant despite rising response times. In these cases, additional slowdowns primarily increased total execution time rather than instantaneous power demand.

**Conclusions.** Performance antipatterns do not affect power and energy-related behavior uniformly. This study provides a systematic foundation for characterizing how different performance flaws are associated with power and energy-related behavior, offering actionable insights for architects aiming to design more energy-aware software systems.

## 1 Introduction

Software systems often experience recurring conditions that negatively affect their performance. Recognizing, avoiding, and resolving these issues is vital for maintaining high performance and ensuring software sustainability over time and across contexts. Since their formalization in 2002 by Smith et al. [39], software performance antipatterns have been the subject of extensive study across different domains of software engineering. Current

research emphasizes early detection of antipatterns during the software engineering process, especially at the architectural level, to reduce future issues and avoid costly refactoring in production [15, 7, 25, 33, 6, 42].

Despite the recognized importance of antipatterns for performance optimization, *research on their effects on software energy efficiency remains limited*, as also shown by [5]. Architectural decisions, however, can substantially influence energy efficiency [47]. The authors of [47] describe a complex interplay between energy consumption and performance in microservice architectures. Specifically, finer service granularity tends to increase both energy usage and response time compared to coarser designs. Moreover, higher workloads, represented as higher request rates, further amplify both energy consumption and performance impact. The study underscores that the relationship between energy efficiency and performance, shaped by service granularity and system scale, must be carefully evaluated during the design phase.

At the current stage, *it remains unclear whether performance antipatterns are also harmful to software energy efficiency* [26]. Establishing such evidence would be valuable for software architects, enabling them to assess performance-energy tradeoffs during the design phase. Performance indicators may be independent of energy use, with the former being favored in contexts where performance is assessed primarily through output quality or throughput rather than energy efficiency. In this context, *power* represents the instantaneous rate of energy use, whereas total *energy* is obtained by integrating power over the measurement interval. Analysing power separately allows us to determine whether performance degradation is accompanied by an increase in instantaneous demand [4]. However, stable power does not necessarily imply stable energy efficiency, because a slower system may complete less useful work during the same interval.

Our **goal** is to investigate whether and to what extent performance antipatterns are associated with different power-consumption behaviors. We design and conduct a controlled experiment on the ten performance antipatterns described by Connie Smith [40]. These antipatterns are manually implemented as isolated containerized services and profiled under a fixed workload and observation period of 20 minutes. This experimental setup enables us to examine the relationship between performance and energy-related metrics while controlling potential confounding factors, such as thermal variability and background operating system activity. We collect response time, power consumption, and resource utilization, and we use CPU utilization as a control metric. The resource utilization data allow us to verify whether the observed behavior aligns with the antipattern definitions, as the original descriptions provide no implementation guidelines and are intended to remain implementation-agnostic.

Our **results** show that the occurrence of performance antipatterns does not necessarily lead to energy waste. The Ramp, God Class, and Traffic Jam show increases in both response time and power consumption, while also saturating CPU usage. In these scenarios, the prolonged response time can increase the energy required to complete a given amount of useful work, even when instantaneous power remains stable. For the other antipatterns, power consumption is not significantly associated with response time. In such cases, response time remains stable, while power and CPU resources are still unnecessarily drained. The Unnecessary Processing antipattern exemplifies this behavior.

The **main contributions** of this study are as follows: (i) an empirical analysis of the relationship between response time and power consumption in the presence of performance antipatterns; (ii) an in-depth discussion of the findings, emphasizing the trade-offs between energy efficiency and software performance; and (iii) a replication package containing the raw data, analysis scripts, and source code to facilitate full reproducibility of the study (see [3]).

Our findings reveal that performance antipatterns are not inherently detrimental to energy efficiency. Consequently, software architects should carefully assess the trade-offs between performance and energy consumption during design-time. For researchers, the study underscores the importance of treating response time and energy efficiency as independent dimensions of analysis. Finally, our work bridges the two communities, illustrating how insights from software performance evaluation can enrich software architecture design.

## 2 Related Work

The term *Antipattern* was coined by Andrew Koenig in 1995 to describe solutions to recurring problems that superficially look like good solutions but later reveal disadvantages, making them poor solutions [36]. Smith and Williams [39] proposed a catalog of recurring performance antipatterns, covering processing imbalance, unnecessary work, ramp effects, inefficient database retrieval, excessive parallelism, god classes, excessive allocation, costly lookup chains, serialization bottlenecks, and backlog-related degradation. *Performance antipatterns* have been studied as multi-level software pathologies [38], through design-time models such as Queuing Networks [33, 13], and via runtime multivariate detection for CI/CD pipelines [6].

*Software energy consumption* can be measured using physical power meters, via on-chip energy counters, or by means of software-only estimators based on analytical or statistical models [23]. The introduction of RAPL in modern CPU architectures has significantly increased the possibility of collecting fine-grained energy data in software and attributing it to specific workloads or software components [19]. Building on this capability, several recent works focus on software, server, and container-level observability of energy and power consumption [32, 1, 16].

*The relationship between performance and energy efficiency* in server-side systems is non-trivial. From a software engineering perspective, empirical studies show that design decisions impact energy and performance differently: [28] show that design patterns often increase energy consumption despite performance intentions, while refactoring code smells can improve energy efficiency by 49% or increase it by 70% depending on the smell type [43]. [35] demonstrate that best practices making CPU usage more energy-proportional can reduce consumption up to 25%, but parallel execution improves the energy-performance trade-off compared to sequential execution. Across different contexts, researchers find discrepancies between energy and performance metrics. Code smell refactoring shows mixed results [43], while microservice techniques present complex trade-offs: reducing energy by up to 5.6% can increase latency by 25.9% in some cases, while decreasing it by 72.5% in others [45]. Architectural choices also affect these metrics, as demonstrated by microservice granularity studies [47]. These results suggest that performance problems and energy inefficiencies are often correlated but not perfectly aligned, motivating an explicit analysis of software performance antipatterns from the energy-consumption perspective.

*Recent research establishes energy as a first-class quality attribute* in software architecture, requiring explicit consideration throughout the design process [9]. Foundational work demonstrates that energy-aware architectural abstractions and design principles are essential for system-level optimization. A key observation is that energy-optimal resource allocation configurations often diverge significantly from performance-optimal solutions [46], necessitating dedicated energy-aware resource management strategies. Industrial empirical studies validate the effectiveness of architectural tactics in practice: [17] demonstrate that deployment model selection and granular auto-scaling can achieve energy reductions ranging from 21-50% under typical loads. In microservice contexts, balancing energy efficiency with

failure resilience remains a critical concern [34]. While evidence confirms that energy-aware design is broadly applicable across diverse application domains, adoption barriers persist in industrial practice due to limited measurement transparency and the need for systematic decision-making.

*Performance antipattern detection* employs multiple approaches across abstraction levels. Model-based frameworks like PADRE [14] identify antipatterns at design time through UML analysis with automated refactoring; runtime statistical methods [6] enable CI/CD integration. *Energy measurement* is based on two main methodologies: monitoring (for CPU, DRAM and GPU) or estimation (which can also include Network and Disk) [31]. Monitoring relies on Intel's Running Average Power Limit (RAPL) which is a hardware interface built into modern Intel processors that provides fine-grained energy consumption measurements at runtime for CPU, uncore components, and DRAM through model-specific registers [22]. Various tools are available based on RAPL with varying levels of granularity, such as Scaphandre [20], which provides per-process attribution across bare metal and containerized environments; Powerjoular [27], which enables process-level Linux monitoring; PowerLetrics [18], which offers real-time energy footprints; and JoularJX [27], which targets Java-level granularity. However, [26] reveals a critical phenomenon: seven of the studied object-oriented and mobile antipatterns improve energy efficiency of an Android app when removed, while two paradoxically worsen it, indicating that performance optimization and energy efficiency are not perfectly aligned. Despite mature detection tools for performance and a comprehensive measurement infrastructure for energy, no integrated approach combines both perspectives to detect energy-specific antipatterns, particularly in microservice contexts where granularity and resource allocation create novel energy-performance trade-offs.

## 3 Study Design

This work investigates whether and how much the presence of performance antipatterns impacts energy efficiency beyond degrading system performance. To this end, we analyse how power consumption evolves over time under a controlled workload.

This analysis enables a deeper understanding of power/response time trade-offs by characterizing the degree and conditions of their correlation. When a strong positive relationship is observed, increasing response time is accompanied by increasing power demand. When the relationship is weak or absent, response time cannot be used as a reliable proxy for power behavior. When the correlation is weak or absent, which can occur due to parallelism, performance optimization may be insufficient or even counterproductive for energy efficiency.

Formulated as a GQM goal [10], this study aims to analyze the performance and power-consumption behavior of ten established performance antipatterns for the purpose of characterizing the relationship between performance degradation and instantaneous power demand, with respect to response time, CPU power, DRAM power, throughput, and CPU utilization, from the viewpoint of software architects and software engineering researchers, in the context of isolated containerized applications executed under controlled workloads.

From this reasoning, we derive the following research question: *how does the presence of performance antipatterns affect the power consumption of containerized software?*

Figure 1 depicts the research methodology followed in this study: we begin with hypothesis formulation (see Sect. 3) and the study of the related work (see Sect. 2). As a next step, we identify the software antipatterns we want to evaluate and implement them (see Sect. 4). An empty application was executed under the same conditions as an environmental control to characterize background power consumption and identify temporal effects introduced by

the testbed or measurement setup. For each execution, the initial stable period was used to normalize the temporal evolution of response time and power consumption. We then assess whether the antipattern implementations exhibit the expected performance degradation. Valid implementations are subsequently used to evaluate the hypotheses in Sect. 7.

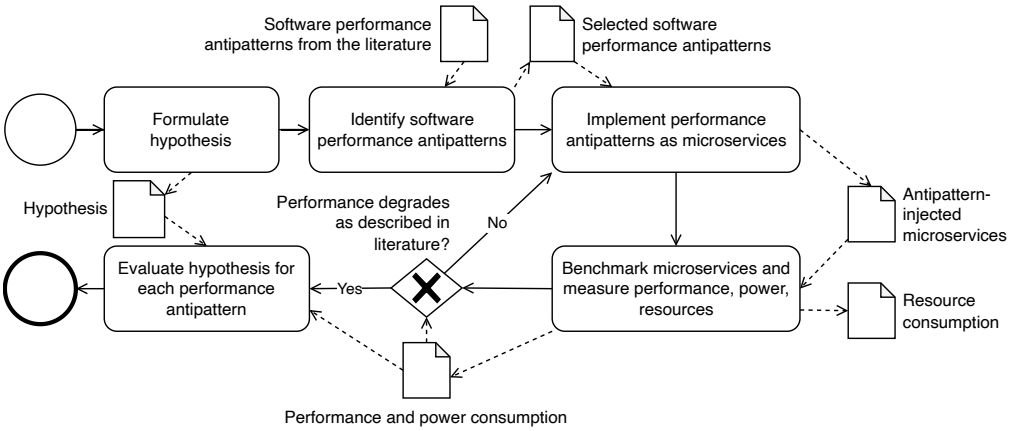

**Figure 1** Research Process (in BPMN [29] notation).

To investigate whether microservices that experience performance degradation also exhibit higher power consumption, we formulate the following hypotheses. The **null hypothesis ($H_0$)** states that no significant relationship exists between system performance and power usage; in other words, variations in response time do not correspond to meaningful changes in power consumption. The **alternative hypothesis ($H_1$)** posits a significant relationship, whereby higher response times are associated with increased or decreased power demand.

## 4 Performance Antipatterns Implementation

This section presents the selected performance antipatterns. We base our implementations on the antipatterns described by Smith and Williams [40], whose catalog is widely recognized in the performance engineering community. To the best of our knowledge, there are no self-contained implementations of these performance antipatterns suitable for controlled experimentation in microservice settings. Existing occurrences are typically embedded in larger systems, introducing confounding factors that hinder isolated analysis.

The implementations follow these principles: execution restricted to one CPU core, implementation as a single endpoint within a Python Flask [30] application, faithful reproduction of the antipattern's described behavior, and deployment within a single container. A SQLite port of the Northwind database [21] was used only for the Circuitous Treasure Hunt, Excessive Dynamic Allocation, God Class, and Sisyphus Retrieval experiments. In the following, we describe the implementation of each antipattern. Antipattern implementations and diagrams are provided in the replication package.

We implement the ten antipatterns as follows. In **Unbalanced Processing**, redundant transformations and an unbounded in-memory store are placed on one processing path. As a result, concurrent requests are processed sequentially. **Unnecessary Processing** performs CPU- and memory-intensive operations that do not provide a functional benefit. In **The Ramp**, each request searches and sorts a continuously growing collection. Therefore, the processing cost increases with the system state. **Sisyphus DB Retrieval** processes complete database tables before it returns only the requested subset. **More is Less** creates several

CPU-bound threads, for which the coordination and contention overhead is higher than the benefit of parallel execution. **God Class** combines validation, hashing, caching, storage, and database access in one handler. **Excessive Dynamic Allocation** repeatedly creates and discards short-lived containers, strings, and nested data structures. **Circuitous Treasure Hunt** retrieves related data through a sequence of nested database queries. **One-Lane Bridge** holds a global lock during expensive computations. This forces concurrent requests into a waiting queue. Finally, **Traffic Jam** alternates between normal and heavy CPU work and creates a backlog that also affects later requests.

## 5 Experiment Design

We design the experiment using a *within-subject design* [44], where each subject (in this case, each antipattern implementation) is exposed to different conditions, namely a set of concurrent users in our setting. The number of concurrent users corresponds to our unique **independent variable**, which we set to a single treatment level.

This value is chosen based on CPU usage induced by the number of concurrent users requesting the service. To ensure that the performance antipattern can actually manifest during experimentation, the system must operate under a sufficiently high CPU load. For this reason, we select a number of concurrent users that drives CPU utilization to at least 25% and does not lead to any execution errors. This threshold provides the necessary level of system saturation for revealing behaviors that typically arise under medium or high load, such as slowdowns. For all antipatterns, 50 concurrent users were selected, except Unbalanced Processing (10 users), Unnecessary Processing (30 users), and Traffic Jam (30 users); this choice depends on the available hardware configuration, which is described in Sect. 6.

The considered **dependent variables** are power consumption and performance. Power consumption refers to the power consumed by the container from the CPU and memory, measured in Watts (W). Performance is assessed through response time in milliseconds (ms). CPU usage, memory consumption, disk activity, and network utilization are collected not as performance metrics, but to verify the correctness of the antipattern implementation and to confirm its alignment with the descriptions found in the literature. The tools used in the study, together with their roles and deployment locations, are listed in Tab. 1. The collected metrics are presented in Tab. 2, along with their measurement unit and scope, an indication of whether each metric is directly collected or derived, and whether it is a point or cumulative metric.

Each trial, which includes a specific antipattern and number of concurrent users, is repeated 30 times to ensure measurement consistency and mitigate random variation caused by the execution environment, such as unintentionally active background operating-system processes.

Each experiment consists of a 20-minute test phase. Between experiments, we reset the environment by wiping all Docker containers, restarting the Docker service, waiting for 10 seconds, deploying the solution, and waiting an additional 10 seconds. After each test, we include a 30-second cooldown period. The workload is generated with a spawn rate of 10 users per second. Considering these timings, the total duration of the complete experimental campaign can be expressed as $(20\,\text{min} + \text{setup and cool-down}) \times 10\,\text{antipatterns} \times 30\,\text{repetitions}$, which results in approximately 110 hours (4.58 days) of execution time.

**Table 1** Components, Role, and Deployment Location.

| Tool | Role | Installation location: Driver, Testbed |
|---|---|---|

## 6 Experiment Execution

The experimental infrastructure consists of two separate machines, as illustrated in Figure 2: a *driver* and a *testbed*.

The testbed is a machine equipped solely with the software required for data collection and for executing the software under test. Docker containers are constrained to a single virtual CPU (vCPU) and 1 GB of RAM to ensure consistent resource allocation across all experiments. During each experiment, only the application container is running, and Docker services are restarted between consecutive trials to eliminate residual process states and prevent measurement contamination. The number of concurrent users is ramped up to the target count in under two minutes, establishing a steady load. Following standard performance-measurement practice, data collected during the first two minutes (the warm-up period) are excluded from the analysis to allow the system to reach a stable state.

For the baseline, we deploy the minimal endpoint in a container and drive it with 50 concurrent users, using the same spawn rate and duration as in the other experiments. We record power traces for the same duration as a standard trial.

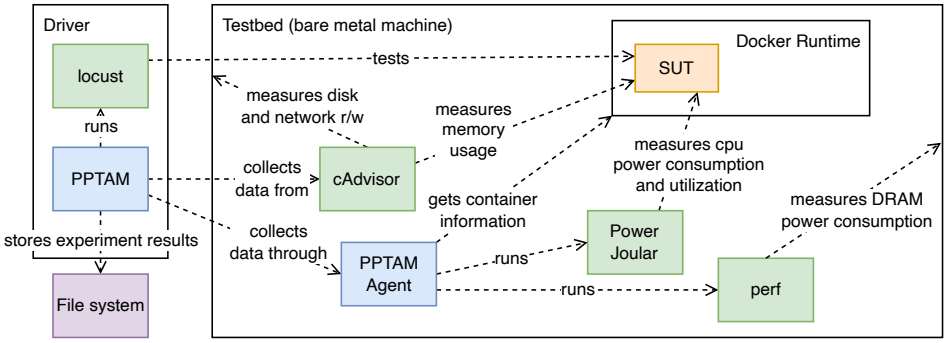

**Figure 2** Container diagram of the experimental infrastructure (C4 notation [12]). Blue containers indicate data collection and experiment coordination containers; green containers indicate data collection tools; orange containers indicate the software under test (SUT); and violet containers indicate external systems.

We operationalize the dependent variables from Sect. 5 by collecting the metrics listed in Tab. 2. Response time is measured in milliseconds (ms), CPU usage in percent, memory, disk and network usage in bytes, later converted to mebibytes (MiB) or gibibytes (GiB).

The **testbed** is a Lenovo X1 Yoga 3rd Gen with an Intel Core i5-8250U CPU and 8 GB of RAM. The software stack consists of Ubuntu 24.04 LTS, Powerjoular 0.4, cAdvisor 0.53, perf 6.8.12, Docker 29.0.2, and the PPTAM *agent* used to collect measurements. The ambient room temperature during the experiments was approximately 25°C, with a variability of ±2°C.

We measure power consumption using two complementary tools: Powerjoular for process-level CPU power consumption and perf for DRAM energy consumption. Both tools derive their measurements from Intel RAPL counters exposed through the Linux powercap interface [41]. Power readings are collected at 1-second intervals throughout each trial, with CPU power and DRAM power expressed in Watts (W).

At runtime, we convert consecutive energy readings from perf into average power by computing the change in energy over the corresponding time interval. This yields the average power between the two readings, expressed in Watts.

CPU utilization is reported as a fraction of the total system CPU capacity. Containers are limited to a single vCPU in Docker. Since the machine has four CPU cores, a value of 0.25 corresponds to 100% utilization of a single vCPU. The CPU frequency governor is set to *powersave* to reduce variability caused by frequency scaling.

The **driver** machine is a virtual machine running on Proxmox VE 8.4.14 with 8 vCPUs and 20 GB of RAM. The software installed on this VM includes Ubuntu 24.04 LTS, PPTAM to orchestrate tests and collect data, and Docker 29.0.2. PPTAM internally uses locust.io 2.42.2. During the experiments, the VM has exclusive access to its allocated resources.

On both machines, unnecessary services and background processes are identified and disabled, and network access is limited to minimize external interference and measurement noise.

## 7 Data Analysis

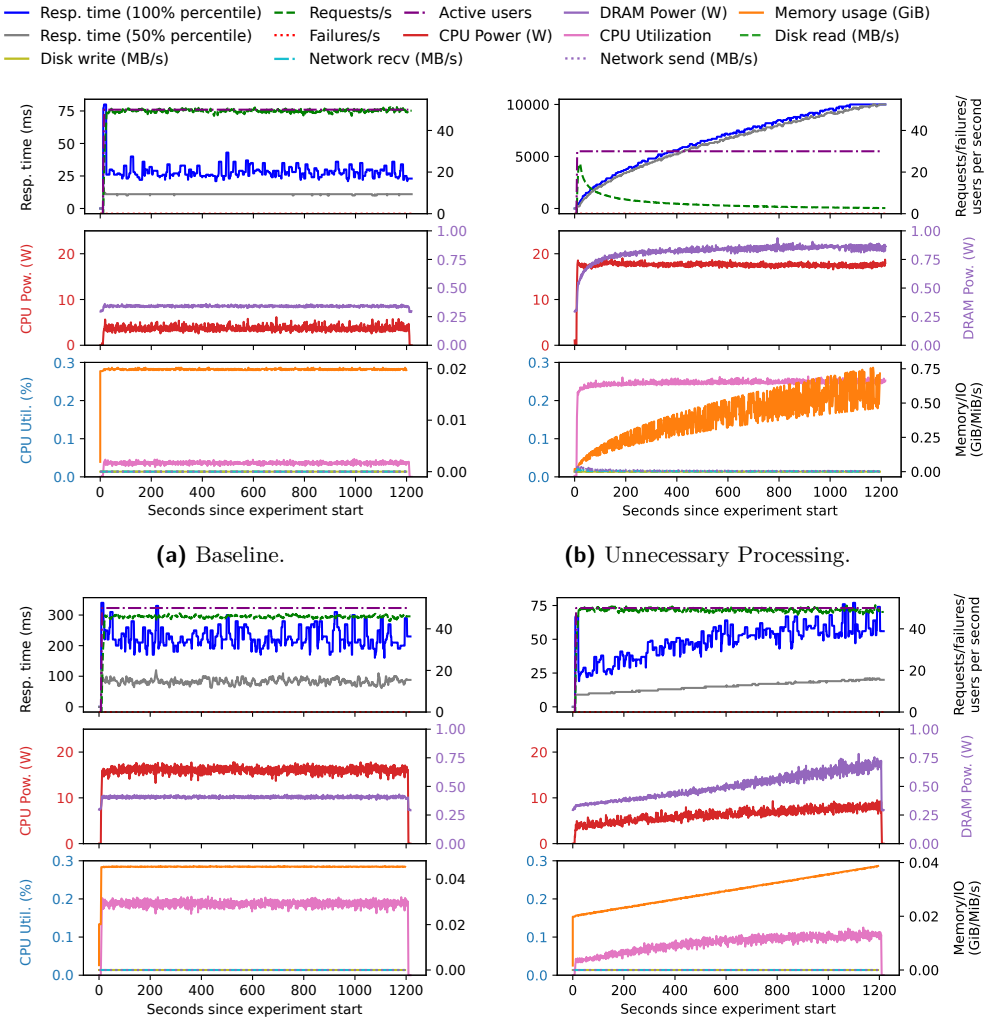
Our analysis proceeds in five steps. First, we conduct a sanity check through trace visualization by plotting the three measurement groups (performance, energy consumption, and resource utilization) for each experiment. This enables us to visually inspect the data, detect

measurement anomalies, and verify that each antipattern exhibits the characteristic behavior reported in prior work. Second, we perform a descriptive analysis by computing mean, minimum, and maximum values of power consumption and response time for each antipattern and generating box plots to obtain an initial view of their distributions.

Third, we compare each antipattern against the baseline using run-level distributions of power consumption. Since Shapiro-Wilk tests indicate non-normality for several condition-metric pairs, we use Wilcoxon rank-sum tests with Holm correction. The complete baseline-comparison results, including percentage changes with respect to the baseline, are reported in the replication package.

We then assess the association between response time and power consumption through Pearson and Spearman correlation coefficients, capturing both linear and monotonic relationships. Finally, we fit multiple linear regression models for each antipattern experiment, with CPU or DRAM power as the dependent variable. The CPU model includes response time, request rate, CPU utilization, and the interaction between response time and CPU utilization. The DRAM model additionally controls for memory usage. Response time and CPU utilization are mean-centered before computing the interaction term. Using heteroskedasticity-robust (HC3) standard errors, we test whether the response-time and interaction coefficients differ significantly from zero at $\alpha = 0.05$.

## 8 Results



Beginning with *Sanity Check via Trace Visualization*, in Fig. 3 we illustrate examples of collected metrics during the respective experiments. The complete set of plots for every antipattern is available in the replication package [3].

The baseline serves two purposes. First, it supports measurement stability assessment, as CPU and DRAM power remain approximately constant over time with no systematic trend across the 30 runs, as shown in Figure 3a. Second, it provides a minimal reference condition for comparing the power consumption observed under each antipattern.

According to our experimental design, the failure rate remains at zero over the entire execution time, and the CPU utilization reaches at least 0.075, which in our testbed corresponds to approximately 25% of a single vCPU. In Figure 3b, we observe that even with a significant drop in requests per second, no corresponding increase is observed in the number of errors. This substantial reduction in throughput therefore has no impact on the error rate, and for this reason the results of this experiment are considered valid. During the Circuitous Treasure Hunt antipattern (Figure 3c), the response time fluctuates, while the error rate remains zero. We also observe a small fluctuation in the number of requests per second, which is consistent with the expected behavior of this antipattern.

The Ramp antipattern in Figure 3d exhibits the characteristic pattern of steadily increasing metric values, which is precisely how this antipattern is expected to manifest. Nevertheless, in this case as well, both the error rate and CPU utilization satisfy our validity conditions. These observations collectively support the faithfulness of our Python implementation of the considered antipatterns.

Proceeding to *Descriptive analysis*, Table 3 summarizes the average, minimum, and maximum values of response time, CPU power, and DRAM power consumption across all antipattern experiments. The results reveal substantial variability in response time characteristics. Several antipatterns, such as Unbalanced Processing, God Class, and Excessive Dynamic Allocation, exhibit high average response times (7–14 s), while The Ramp and

**(a)** Baseline.

**(b)** Unnecessary Processing.

**(c)** Circuitous Treasure Hunt.

**(d)** The Ramp.

**Figure 3** Trace Visualization of Unnecessary Processing, Circuitous Treasure Hunt, and The Ramp.

Circuitous Treasure Hunt show response times that remain well below 300 ms. Maximum response time values follow the same pattern, with the most severe antipatterns reaching up to 17 s.

CPU power shows a narrower range across experiments. Mean CPU load typically falls between 14–19 W, with peak values consistently reaching 22–25 W, indicating that most antipatterns drive the system close to full CPU usage during the workload's high-load phases.

DRAM power consumption exhibits moderate variability. Mean DRAM power remains low for most experiments (approximately 0.29–0.40 W), but some antipatterns such as Unnecessary Processing and Sisyphus DB Retrieval show markedly higher average values (above 0.70 W). Maximum DRAM power ranges from 0.43 W (More Is Less) up to 1.65 W (Unnecessary Processing), suggesting that certain antipatterns cause more pronounced memory-side energy demands.

**Table 3** Average, minimum, and maximum values of power consumption and response time for each antipattern. Minimum response time and minimum CPU omitted since they are always 0.

| | Response time (ms) | | Power (W) CPU | | DRAM | | |
|---|---|---|---|---|---|---|---|

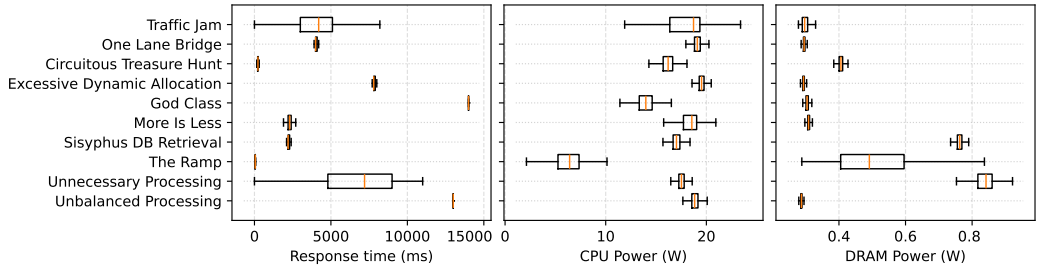

**Figure 4** Response time, CPU and DRAM power box plots across all 30 runs for every studied antipattern; boxes show median/IQR, whiskers show central spread, mean marked (outliers hidden).

Overall, the results indicate that while CPU utilization is relatively similar across antipatterns, response time and DRAM power consumption vary considerably, suggesting that different performance antipatterns impose distinct types and intensities of resource stress on the system. Fig. 4 illustrates the box plots across all experiments for response time, CPU power, and DRAM power.

The results of the *Correlation analysis* are reported in Tab. 4. Pearson's correlation measures the linear association between two variables, indicating how strongly they vary in a proportional, straight-line manner. Spearman's rank correlation captures monotonic relationships, detects consistent increasing or decreasing trends even when they are nonlinear, and is less sensitive to outliers. Using both metrics provides complementary insight: agreement between them suggests a stable relationship, whereas divergence indicates potential nonlinearity or the influence of extreme values. We indicate agreement using underlined values.

Across the experiments, the correlations between response time and power consumption vary substantially, reflecting the heterogeneous behavior of different antipatterns. Several cases (including The Ramp, Unbalanced Processing, and Excessive Dynamic Allocation) show positive CPU–response time correlations, consistent with increased computational effort accompanying higher response times. In contrast, DRAM correlations are more mixed: some antipatterns (e.g., Unnecessary Processing) exhibit strong positive associations, while others show weak or even negative relationships, indicating that memory activity is not uniformly coupled with response time across patterns. Agreement between Pearson and

**Table 4** Pearson and Spearman correlations between CPU and DRAM power and response time for each experiment (30-run aggregates); Underlined values indicate that both correlations share the same sign.

Spearman coefficients (highlighted by underlined values) suggests that, for those experiments, the relationship is both monotonic and directionally stable, whereas divergences point to non-linear or irregular interactions between performance degradation and power usage.

At this point we proceed to *Regression modeling and hypothesis testing*. We estimate the relationship between response time and power consumption using two ordinary least squares (OLS) regression models for each antipattern experiment, aggregating data across 30 repeated runs. OLS quantifies how a dependent variable changes as a linear function of a set of predictors, such that each regression coefficient represents the average marginal effect of its predictor while holding the remaining variables constant. Both models include an intercept and are fitted only on steady-state samples, excluding a 120-second warm-up interval and ignoring negative power readings. This filtering ensures that transient initialization effects and instrumentation artifacts do not bias the estimated relationship between response time and power consumption, allowing the models to capture behavior that is representative of the system's stable operating mode.

To account for the possibility that the association between response time and power depends on processor load, we include a response-time $\times$ CPU-utilization interaction term. Response time and CPU utilization are mean-centered within each experiment before constructing the interaction. Consequently, the response-time main effect represents its association with power at the experiment's mean CPU utilization, while the interaction coefficient indicates how this association changes as CPU utilization increases.

Because system-level performance measurements are typically noisy and exhibit load-dependent variability (see e.g., [37]), the assumption of homoskedastic residuals (i.e., constant variance in the regression errors) is unlikely to hold. In line with this expectation, the Anderson-Darling test [2] rejected normality for all experiments; the Breusch-Pagan test [11] rejected the null hypothesis of homoskedasticity for every antipattern in at least one of the two regression models (CPU or DRAM power). Specifically, all antipatterns except *Unnecessary Processing* showed heteroskedasticity in the CPU–power model, while for DRAM power the null was rejected for all but *More Is Less*, *God Class*, *Excessive Dynamic Allocation*, and *One Lane Bridge*. Thus, each antipattern showed evidence of heteroskedasticity in one or the other analysis.

As a consequence, we employ HC3 heteroskedasticity-consistent (robust) standard errors [24]. HC3 adjusts the estimated uncertainty of regression coefficients in the presence of outliers or non-uniform noise, yielding more reliable inference than classical OLS standard errors when homoskedasticity does not hold. Using HC3 enables valid hypothesis testing even when measurement variability increases over time.

For the CPU power model, we regress CPU power on mean-centered response time, request rate, mean-centered CPU utilization, and their response-time × CPU-utilization interaction. These predictors are chosen to isolate the contribution of response time to CPU energy usage while accounting for factors that directly influence CPU power. Request rate captures the volume of work offered to the system, and CPU utilization reflects the degree of processor saturation; both variables typically rise and fall with workload intensity and may correlate with response time. By including them, the model controls for load-induced variation in CPU power, ensuring that the estimated response time coefficient represents the effect of performance degradation rather than changes in system demand or CPU occupancy. The goal is thus to obtain an estimate of whether higher response time is associated with increased CPU power consumption under otherwise comparable conditions.

For the DRAM power model, we use the same predictors and interaction term and additionally control for memory usage. The same workload controls (request rate and CPU utilization) are included to account for load-induced changes in memory traffic, while memory usage is added because it directly determines the volume of active DRAM state and is a primary driver of DRAM power draw. Including these predictors addresses potential confounding: DRAM activity may rise due to increased memory pressure or higher throughput, independently of response time. By selecting variables with clear mechanistic relevance to DRAM behavior, the model remains parsimonious while enabling a more accurate assessment of whether increased response time, after controlling for workload and memory demand, is associated with higher DRAM power consumption.

For each experiment (with sample sizes $N > 32{,}000$ in all cases), we report the response-time coefficient and the response-time × CPU-utilization interaction coefficient with their HC3 $p$-values. Because the predictors are mean-centered, the response-time coefficient describes its association with power at average CPU utilization. A significant interaction indicates that this association changes with CPU utilization.

The goal of this analysis is to assess whether increased response time corresponds to higher instantaneous power and whether this relationship depends on CPU utilization. A significant positive interaction indicates that the response-time–power relationship becomes more positive as CPU utilization increases; a significant negative interaction indicates that it becomes less positive or more negative. The detailed results are shown in Tab. 5.

The relationship between response time and power depends on CPU utilization for only a subset of antipatterns. For CPU power, this relationship is significant for Unnecessary Processing, The Ramp, God Class, and Traffic Jam. For DRAM power, it is significant for The Ramp, God Class, Circuitous Treasure Hunt, and Traffic Jam. For the remaining cases, we find no statistically significant evidence that CPU utilization modifies the response-time–power relationship.

These results provide a more nuanced interpretation of the relationship between performance and power. For Unnecessary Processing and The Ramp, the positive interaction indicates that the response-time–power association becomes more positive as CPU utilization increases. For God Class and Traffic Jam, the negative interaction indicates that this association weakens as CPU utilization rises, which is consistent with power approaching a saturation region while response time can continue to increase. Circuitous Treasure Hunt

**Table 5** Regression results for CPU and DRAM power. For each power metric, the decision tests whether response time is associated with power at mean CPU utilization. The interaction term tests whether this association changes with CPU utilization.

exhibits this conditional relationship only for DRAM power, suggesting that its memory-side behavior depends on processor load even though its CPU-power interaction is not significant. Thus, response time does not have a constant association with power across all utilization levels, reinforcing our overall conclusion that the coupling between response time and power is antipattern-dependent.

## 9 Discussion

**Our results show that antipatterns affect power consumption non-uniformly. Increases in power are mainly driven by workload intensity rather than response time alone.** We observe that power consumption growth is primarily influenced by workload intensity rather than by the accumulated execution time alone. For instance, the Circuitous Treasure Hunt antipattern, illustrated in Figure 3c, quickly increases CPU utilization to around 80%, capping power draw at an upper bound, even as response time holds steady in a range below 300 ms.

This case shows that increasing *response time is not accompanied by increasing instantaneous power*. However, the resulting energy efficiency also depends on the amount of useful work completed during the measurement interval.

Consistent with this profile, the regression analysis in Table 5 provides no significant evidence that CPU utilization changes the relationship between response time and CPU power.

The Circuitous Treasure Hunt scenario therefore illustrates that response time and instantaneous power do not necessarily change together.

Despite a CPU usage spike of around 80 %, this antipattern is not primarily CPU-intensive. The observed response time is therefore likely influenced by its implementation. Specifically, our implementation performs multiple sequential database calls, which primarily stress disk and memory resources rather than the CPU. As a result, the way data is retrieved and joined across different tables has a major impact on response time. Optimizing query batching or introducing asynchronous requests could further reduce unnecessary CPU activity while maintaining the intended functionality and response time characteristics of the scenario.

This behavior differs from that of Unnecessary Processing, shown in Figure 3b. Like Circuitous Treasure Hunt, it operates close to CPU saturation and exhibits a relatively stable overall power profile. However, the significant positive interaction indicates that the response-time–CPU-power association becomes more positive as CPU utilization increases. However, response time increases steadily throughout the observation period. The system therefore exhibits stable power after reaching CPU saturation, while response time continues to increase. Unlike Circuitous Treasure Hunt, this antipattern performs CPU-intensive operations, repeatedly carrying out redundant hash computations and input validations. It also continuously allocates and reorders data in memory, resulting in a sequence of superfluous operations whose footprint gradually expands over time. This ongoing growth in unnecessary processing causes increasing response time, resembling a mild instance of The Ramp antipattern. This observation suggests that, depending on the implementation, *multiple antipatterns may manifest simultaneously.*

Our implementation of The Ramp also provides additional insights for practitioners. Figure 3d shows a typical Ramp situation: both CPU and DRAM power consumption increase steadily over time, and this trend is mirrored by the growth in response time. By definition, The Ramp antipattern is characterized by a workload that becomes progressively heavier during the observation window. In our case, as more data are accumulated in memory, each new request must process a larger in-memory dataset. In the concrete implementation, this behaviour is caused by continuously storing additional data structures and then performing search and ordering operations on them. As the in-memory collections grow, these operations become increasingly expensive, both in terms of computation and memory access. Consequently, the application performs more work per request, leading to longer response times and a gradual increase in CPU and DRAM power consumption, consistent with the expected profile of The Ramp antipattern. The significant positive interactions for both CPU and DRAM power further indicate that this coupling becomes stronger as CPU utilization increases. The pattern implies long-term scalability and capacity issues: since each request becomes more expensive as the system accumulates data, the system will not only slow down but also show decreasing throughput over time, which is a defining characteristic of The Ramp antipattern. This means that adding hardware itself will not solve the problem sustainably, because the fundamental per-request work keeps increasing with dataset size. *This indicates that refactoring data structures or choosing algorithms whose computational complexity grows more slowly with dataset size, such as indexed access, partitioning, or batching, is at least as important as restructuring the workload over time.*

We suggest that practitioners prioritize those antipatterns that are associated not only with degraded system performance, but also with increased power consumption. In particular, *The Ramp* deserves attention because it increases energy usage over time as the system state grows. Although this behaviour may not be entirely removed in every case, optimizing the corresponding code path remains worthwhile to improve the sustainability of the software. *Excessive Dynamic Allocation* also represents an important target, as the repeated creation and disposal of short-lived objects increases memory activity and contributes to additional

CPU and energy demand over time. A similar concern emerges for *Traffic Jam*, where energy consumption increases during phases of backlog accumulation and recovery, reflecting the extra overhead imposed by congestion and repeated scheduling activity rather than productive work. Finally, *God Class* is particularly relevant from a design perspective, since the concentration of multiple responsibilities may amplify inefficiencies similar to those observed in other antipatterns, thereby contributing to both poor performance and increased energy consumption. More generally, our results suggest that optimization strategies should not focus on response time alone. Some antipatterns exhibit relatively stable power profiles despite substantial performance degradation, whereas others show a clearer coupling between latency and power demand. For this reason, practitioners should evaluate the trade-offs among response time, CPU usage, and power consumption in order to identify hidden operational computational complexity more effectively.

We observe that the fixed-duration executions show different total energy measurements across antipattern implementations. Although total energy consumption is not the primary focus of this study, it depends on contextual factors such as the number of users, the hardware platform, and the specific implementation of each antipattern. This work seeks to examine the relationship between power consumption, response time, and resource utilization. Notably, our findings indicate that antipatterns executed under similar conditions exhibit distinct energy loads, *offering a promising foundation for further investigation into the energy implications of performance antipatterns*. Table 6 presents the average energy consumption associated with each antipattern, computed by applying the trapezoidal rule to the power measurements. We notice that antipatterns executed with the same number of concurrent users (50), that is, all except Unbalanced Processing (10), Unnecessary Processing (30), and Traffic Jam (30), demonstrate different CPU and DRAM consumption. Excessive Dynamic Allocation results in the highest CPU energy usage, while Unnecessary Processing yields the greatest DRAM energy load. These findings are valuable for practitioners evaluating whether mitigating a given antipattern can help achieve a more balanced trade-off between energy efficiency and performance. For instance, God Class and The Ramp introduce significantly lower energy overhead compared to the other antipatterns.

**Table 6** Average CPU and DRAM energy consumption.

| | Energy (kJ) | | | Energy (kJ) | |
|---|---|---|---|---|---|
| **Experiment** | **CPU** | **DRAM** | **Experiment** | **CPU** | **DRAM** |
| Unbalanced Processing | 21.93 | 0.31 | God Class | 17.95 | 0.33 |
| Unnecessary Processing | 20.52 | 0.90 | Excessive Dynamic Allocation | 22.72 | 0.32 |
| The Ramp | 10.62 | 0.56 | Circuitous Treasure Hunt | 19.25 | 0.44 |
| Sisyphus DB Retrieval | 19.95 | 0.83 | One Lane Bridge | 22.22 | 0.32 |
| More Is Less | 20.98 | 0.33 | Traffic Jam | 20.83 | 0.32 |

## 10 Threats To Validity

**Internal Validity.** Each performance antipattern is manually implemented and may introduce unintended effects. We mitigate this threat by visually validating the behavior of every antipattern against its description in [40] using line plots of response time, CPU utilization, and power consumption (see Fig. 3d). Between each experiment, applications containing the antipattern are uninstalled, the entire Docker environment is restarted, and the applications are reinstalled.

**External Validity.** Our results are obtained from Python-based containers running on a single hardware configuration equipped with an Intel Core i5-8250U CPU. This controlled setup improves reproducibility but limits generalizability to other platforms, languages, and deployment environments. Real-world systems often exhibit more heterogeneous workloads and resource variability, which may influence the observed effects. We mitigate this risk by providing the implemented antipatterns together with all collected data in the form of a replication package [3].

**Construct Validity.** Because [40] describes performance antipatterns only conceptually, their exact implementations are not specified. We mitigate this risk by confirming that each container exhibits the expected resource-usage and response time patterns and by providing the rationale for their implementation in section 4. The minimal reference service characterises background power consumption and possible temporal effects of the testbed. Comparisons with this control describe deviations from background conditions rather than the overhead that could be removed through refactoring.

**Conclusion Validity.** Measurement accuracy and statistical inference represent additional threats. DRAM power readings, collected via RAPL, reflect system-wide consumption and cannot be isolated at the container level, though we eliminate competing workloads to limit noise. Each experiment is repeated 30 times, warm-up periods are excluded, and HC3 robust standard errors are used to account for non-normality and heteroskedasticity in the residuals. Furthermore, Section 4 documents the concrete implementation choices and their rationale for each antipattern, enabling verification, replication, and adaptation of our implementations by other researchers.

## 11 Conclusion and Future Work

Software performance antipatterns are recurring situations in software design that are known to degrade system performance. Although these antipatterns are well recognized, limited evidence exists regarding their impact on software energy efficiency. This study investigates how response time relates to instantaneous power consumption and energy-related behavior. . We conducted a controlled experiment using the ten performance antipatterns presented by [39]. Each antipattern is implemented as a containerized service, exercised under a fixed workload, and profiled to measure performance and power metrics. The results show that performance antipatterns do not exhibit uniform power behaviour, and these differences can have distinct implications for total energy consumption and energy efficiency. In some cases, performance issues that increase response time are also associated with increasing power demand and may imply higher energy use for the same amount of useful work, such as in The Ramp antipattern. The relationship between response time and power is also conditional on CPU utilization for some antipatterns. In Unnecessary Processing, for example, the average response-time coefficient is not significant, but the positive interaction indicates that its association with CPU power becomes more positive as CPU utilization increases. We encourage practitioners to consider response time, power consumption, and total energy as related but distinct metrics when evaluating software performance. As future work, we plan to inject these antipatterns into established microservice benchmarks (e.g., Train Ticket, TeaStore) and replicate the study at the system level and across different platforms. This will enable the identification of design patterns that promote better trade-offs between performance and energy efficiency.

## Data Availability Statement

Experimental artifacts, datasets, antipattern implementations, and analysis scripts are available in the replication package [3]. The package includes a README file with instructions for reproducing the study.

# How Students Construct Human–AI Boundaries in Software Engineering Teamwork

**Isabella Graßl**
Technical University of Darmstadt, Germany

## Abstract

**Background.** Software engineering is a sociotechnical discipline in which teamwork is central, even as AI tools are integrated into professional and educational practice. While prior research has primarily examined AI as an individual productivity tool, we know little about how software teams position AI within collaboration.

**Aims.** Drawing on boundary work theory, we explore how students integrate AI into project-based software engineering teamwork and how they construct boundaries between AI and human collaboration.

**Method.** We conducted a qualitative multiple-case study across seven software engineering courses, collecting interviews ($n = 27$) and reflections ($n = 89$) from 116 students.

**Results.** Students construct explicit human–AI boundaries within software engineering teamwork. They draw *complementary* boundaries, using AI to support individual preparation and thereby improving the conditions *around* collaboration, and *competitive* boundaries, actively excluding AI from interpersonal aspects of teamwork that they reserve for humans, grounded in concerns about accountability, trust, and relational value. We found no evidence in students' accounts that they perceived AI as a *co-evolving* collaborative partner.

**Conclusions.** We argue that students actively construct AI as infrastructural support rather than as a social collaborator, thereby preserving human responsibility, empathy, and trust within software engineering teamwork. These findings contribute to emerging discussions on human–AI collaboration and the evolving role of software engineers in this era.

## 1 Introduction

Software engineering is a collaborative discipline [37] that requires communication, coordination, negotiation, and shared responsibility between team members [25, 39]. Yet, collaboration is not easy to learn: professional and student teams alike often face unequal participation, communication breakdowns, and interpersonal conflict [20, 12]. In the last few years, professional and educational software engineering [47, 42] has been adapting to AI tools such as GitHub Copilot and ChatGPT [40]. They support (future) developers with coding and documentation, often boosting perceived individual productivity [23, 32].

Most software engineering research has treated AI as an individual tool, leaving its role in teamwork largely unexplored. Studies in social sciences and HCI suggest that AI can influence team communication, commitment, and perceived productivity [31, 15, 2], but these insights have not been systematically examined in software engineering, where interpersonal skills are often undervalued [35, 24], and students must learn to collaborate, share responsibility, and build trust [18]. This is especially important since students are not only learning technical

licensed under Creative Commons License CC-BY 4.0

practices, but are also developing professional norms and expectations regarding collaboration, responsibility, and the role of AI in software engineering work. Understanding how students integrate AI into teamwork may therefore provide insight into broader sociotechnical shifts emerging in software engineering practice.

To investigate this, we draw on boundary work theory [21], which examines how people define and maintain distinctions between domains of responsibility and legitimacy. We draw on three forms of human–AI boundary work from recent work [17]: *complementary boundaries*, where AI and humans take on distinct but supporting roles; *competitive boundaries*, where humans actively resist AI involvement in domains they consider their own; and *co-evolving boundaries*, where AI is treated as a partner that develops together with humans over time [17]. This perspective enables us to explore how they position AI in relation to human collaboration [39, 32].

By analysing interviews and written reflections from 116 students from project-based software engineering courses, we investigate how students use AI in project-based teamwork (RQ1), what functional and practical changes emerge (RQ2), and how they conceptually position AI in relation to humans (RQ3):
**RQ1:** How do students integrate AI tools into their software engineering teamwork?
**RQ2:** How do students perceive the practical and functional impact of AI tools on collaboration within their software engineering teamwork?
**RQ3:** How do students normatively position AI tools in relation to their human teammates in software engineering teamwork?

Our findings show that students draw a consistent line between AI supporting the conditions *around* collaboration and AI participating *within* it. They position AI as support for individual preparation and productivity rather than as part of their collaboration itself. While AI improved conditions around teamwork, students actively reserved interpersonal, emotional, and accountable aspects of collaboration for humans. According to our data, students did not perceive AI as an evolving collaborative partner within their teamwork. Instead, they maintained clear human responsibility within their teamwork, even when relying on AI tools for technical support. We argue that the adoption of AI tools depends not only on technical skills but also on *values* about what work should remain human, emphasising that while tools evolve, the social character of software teamwork is still a central aspect.

## 2 Background and Related Work

Software engineering is a sociotechnical discipline in which communication, coordination, and shared responsibility are central to software development [37]. Thus, software engineering must prepare its students not only for technical implementation but also for teamwork [37]. However, teamwork in software engineering courses is often challenging [20]. Prior work reports recurring issues including unequal participation, ineffective communication, coordination difficulties, poor planning, and interpersonal conflict [18, 30, 26, 12]. These challenges disproportionately affect underrepresented groups, including female and international students [12]. Technologies can support coordination, but may also reinforce inequalities when access, confidence, or digital literacy differ [27]. With the presence of AI, this challenge becomes even more urgent [29], as software systems must now address fairness, transparency, diversity, and accountability alongside traditional quality goals [3].

## 2.1 AI in Software Engineering (Teamwork)

Generative AI tools such as ChatGPT and GitHub Copilot are increasingly integrated into software engineering education and practice [19, 29]. Prior research has primarily examined AI as an individual productivity tool, focusing on coding support, debugging, assessment, and learning outcomes [13, 32, 29]. Studies suggest that students perceive AI as useful for idea generation, programming support, and productivity gains, while also expressing concerns regarding overreliance, responsibility, and reduced critical thinking [38, 13].

More recently, research has begun to examine AI within collaborations. Prior studies in other disciplines suggest that AI can shape communication patterns, collective attention, and team interaction [15, 49]. Trust and the alignment of shared goals in a task play a key role since misunderstandings with AI reduce trust, communication, and perceived performance [9, 2, 36]. Human–AI teams may show lower commitment and motivation than all-human teams, weakening collaboration despite technical assistance [45].

In software engineering specifically, a recent mapping study finds that human–machine teaming remains rare in software engineering practice [33], and position papers have begun to sketch AI as a future collaborator in student software teams [16]. At the individual level, developers describe AI as a subordinate helper, a junior colleague or teacher [48], and trust in tools such as Copilot shifts over the course of individual use [36].

However, developers in pair programming treat AI contributions differently from human input, reacting less critically, which may shift norms of responsibility and judgement in collaboration [44]. Despite growing interest in human-AI collaboration, empirical understanding of how software engineering teams socially position AI within teamwork remains limited.

## 2.2 Boundary Work in Human-AI Collaboration

Abrahão et al. [1] project AI as a future teammate in software engineering, which raises the question of whether students already treat AI this way, or whether a tool-based view remains the norm. To examine how our future software engineers position AI within teamwork, we draw on boundary work theory [21]. Boundary work describes how actors define and maintain distinctions between domains of responsibility, legitimacy, and practice. In the context of generative AI, Kim et al. [17] describe three forms of human-AI boundary work. *Complementary boundaries* position AI and human work as distinct but mutually supportive, where AI assists selected tasks while humans retain responsibility for others. *Competitive* boundaries emerge when actors resist AI participation in domains perceived as fundamentally human or socially important. *Co-evolving* boundaries arise when humans and AI are treated as developing collaborative partners over time. These three boundary types are not mutually exclusive and may operate simultaneously across different domains of practice. This framework enables us to move beyond describing AI use towards analysing how students construct (un)acceptable forms of AI participation in software engineering teamwork. This matters for software engineering education, where the question is not only what AI can or cannot do, but what students believe it should and should not do, and why.

# 3 Methods

The aim of this study is to understand how students use AI tools in project-based software engineering courses and how they perceive the role of AI in their collaboration. We used a qualitative multiple case study design [46], which allowed us to systematically explore the practices in educational settings by combining multiple data sources [46]. This design also enabled us to compare across contexts, hence different universities and course settings with the same overall aim and structure.

## 3.1 Cases: Course Contexts

We studied seven project-based courses in software engineering across three public universities: one lab course at the University of Victoria in Canada (*North America, NA*), two lab courses at the University of Passau in Germany (*Europe, EU1*), and two lab courses plus two seminar courses at the Technical University of Darmstadt in Germany (*Europe, EU2*). Each course represents one case ($n = 7$ cases). All courses followed a project-based learning approach, which connects learning to real-world issues and makes tasks more meaningful. This approach includes improving students' agency, meaning they *own* their projects from topic selection to presentation. They began with theoretical input at the beginning of the term, and then worked in teams to apply research methods and software engineering principles to their projects. Across courses, students produced outputs such as papers, reports, proposals, peer reviews, and posters.

All courses required students to work in teams over one academic term (four to five months), and to produce concrete outcomes. Team sizes ranged from four to six students in all courses with the same credit points, which makes these courses suitable cases for studying AI use in teamwork. All courses focused on human-centred software development, where user needs and human-focused research play a central role. The main difference between formats lies in the focus: labs emphasised implementation, while seminars emphasised conducting research as a practical contribution.

**Human-centred software development lab.** Students developed a software solution for a real or simulated client, implemented a prototype, and wrote a short report. While technical implementation was important (e.g. architecture and testing), user needs formed the core of the project. The course followed design thinking principles. Teams also worked with agile practices: they organised their own schedules, task allocation, and feature planning. In the final report, students explained how they addressed diverse user needs and justified their technical design and testing decisions.

**Human-centred software development seminar.** Student teams developed a research idea in software engineering, implemented a prototype, and wrote a research report. Students received an initial set of research papers in human-centred software engineering, which served as starting points for topic development and discussion. The seminar placed stronger emphasis on reflection, academic writing, and critical discussion than the lab format.

All courses were elective and open to both Bachelor and Master students. The mix of Bachelor and Master students in the same courses meant participants had varying levels of programming and teamwork experience as well as professional and personal maturity. However, the focus on human-centred software development created common ground. We found no systematic differences in AI collaboration perceptions between Bachelor and Master students in our analysis. The first author taught all courses except the lab in *NA*, where she was not the formal course instructor but co-supervised the student teams.

All three universities at the time had adopted standard institutional policies on AI use, similar to ACM guidelines: students must acknowledge AI use and avoid copy-pasting without attribution. Within courses, we applied no additional restrictions. Students were informed that any directly copied AI-generated code or text must be clearly marked as such, but they remained free to use AI as they wish for their learning and project work. This approach allowed us to observe their authentic AI use patterns rather than keeping strict rules.

## 3.2 Data Collection and Participants

We used two complementary data sources: written reflections and semi-structured interviews. This combination supports data triangulation and strengthens the credibility of our study [28].

### 3.2.1 Interviews and Reflections

The written reflections and interview guide followed the same core questions. Interviews allowed us to get further insights, ask for clarification, and concrete examples. We designed the interviews following established guidelines [34].

1. **Background Information (optional).** Gender, study program.
2. **Practical AI Use in Teamwork (maps to RQ1).** *For which activities have you used AI tools in this project and which tools did you use? Please elaborate on whether they were helpful or not for your team and provide examples.*
3. **Perceived Impact of AI on Teamwork (maps to RQ2).** *How has using AI tools affected your collaboration with your team partners, if at all? Please provide examples.*
4. **Comparison Between Human and AI Collaboration (maps to RQ3).** *How did you experience collaborating with AI compared to collaborating with your team partners?*
5. **Broader Teamwork Experiences (context for all RQs).** *Reflect on your team dynamics in this course. What has been challenging? What has been easy?*

The same mappings of the research questions apply to the reflection instrument. We transcribed all interviews using *Otter.ai* and *Notta.ai*, and manually checked and corrected the transcripts. Written reflections were already available in textual form. We imported all transcribed data into *Atlas.ti* for the reflexive thematic analysis.

### 3.2.2 Recruitment

We invited all students enrolled in the selected courses to participate. Participation in reflections and interviews was voluntary, took place at the end of each course, and had no influence on grading, as all grades had already been submitted. We distributed the link to the online reflection form and the invitation to participate in interviews at the end of each course, coinciding with the end of term. Students completed the reflections online.

We conducted interviews only in the NA and EU1 contexts due to practical constraints; data from EU2 consist entirely of written reflections. This approach ensured that all participants could contribute in a format appropriate to their context. Data collection took place between January 2024 and December 2025. All interviews were conducted in person and audio-recorded with participants' informed consent.

For reflections, we achieved a 46% response rate (89 responses from 193 enrolled students). For interviews, all invited students participated (27 of 27). We collected 89 individual written reflections across four courses in *EU2*. The completion time for reflections ranged from 8 to 18 minutes. We conducted 27 semi-structured interviews, with durations ranging from 21 to 43 minutes. Of these participants, 16 were from *EU1* and 11 from *NA*.

### 3.2.3 Participants

Our dataset includes perceptions from 116 students. 31% of students identified as female and 69% as male; no participants identified as non-binary. Most participants studied Computer Science (83%), with the remaining in Business Informatics. The majority were undergraduate students (74%, Bachelor, 26% Master). We did not systematically capture students' prior

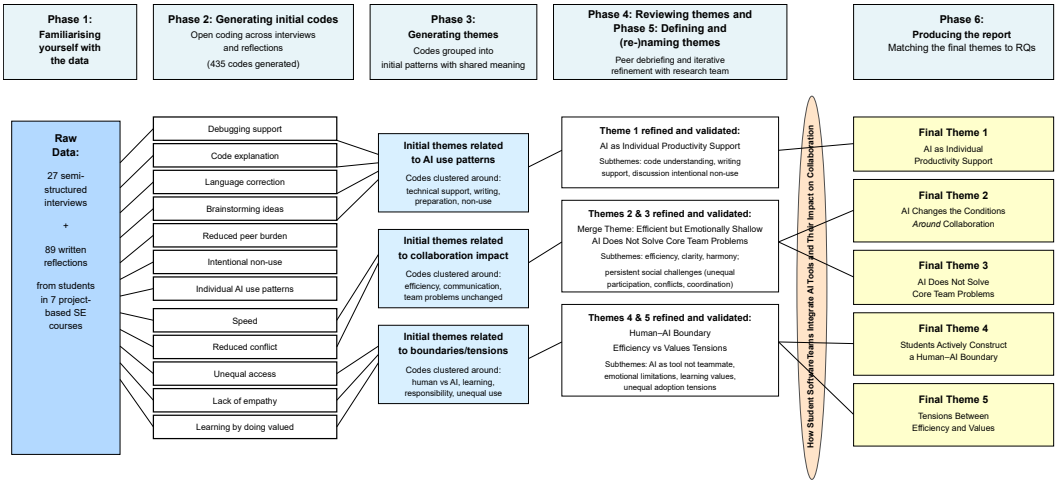

**Figure 1** Overview of the reflexive thematic analysis process from raw data to final themes. The figure illustrates how data from 116 participants were analysed through the six phases of reflexive thematic analysis [4], resulting in five themes.

experience with, frequency of use of, or confidence in generative AI tools before the course; all participants stated that they are familiar with AI tools and have already used them within their studies. We obtained ethics approval from the committee for interviews in Canada. In the German context, formal approval was not required; however, we followed standard ethical guidelines in both settings, including informed consent, voluntary participation, and anonymisation. We obtained consent from all participants. All data were stored securely using *GitLab* on German servers. We replaced all participant identifiers with pseudonyms (e.g., NA-01, EU1-02) during transcription.

## 3.3 Data Analysis

We analysed the data using reflexive thematic analysis, following Braun and Clarke's established approach [7]. This approach conceptualises the coding process as an interpretative, researcher-positioned practice [6] and aims to capture the range of meanings present in the data, rather than to produce a definitive model [34]. Consistent with Braun and Clarke's philosophy, we emphasise that qualitative research treats *"researcher subjectivity as a resource rather than a threat to knowledge production"* [5]. In order to verify our analytical process, we followed best practices for qualitative software engineering [22] and documented the COREQ [41] checklist in our replication package.

### 3.3.1 Reflexive Thematic Analysis

Figure 1 provides an overview of the process. One researcher (the corresponding author) conducted the initial open coding and theme generation across the full dataset (Phases 1–3); a second researcher (research assistant) acted as peer debriefer in Phases 4–5, reviewing the coding and thematic structure and challenging interpretations, without independently coding the raw data. Interviews and reflections were coded within the same coding frame in *Atlas.ti* and treated as a single combined dataset per case; we compared emerging patterns across the two sources during Phase 4 rather than analysing them as separate strands.

In the first phase of reflexive thematic analysis, we familiarised ourselves with the data by reading all transcripts *actively* [4].

In the second phase, one researcher conducted open coding across the entire dataset. We adopted an inductive approach, meaning that codes were derived directly from the data rather than from predefined categories [4]. The coding combined semantic and latent approaches [5]. This involved line-by-line coding with close attention to participants' wording. In line with Braun and Clarke's guidance [7], we kept initial codes close to the original expressions used by students. This process resulted in 435 initial codes.

In the third phase, we iteratively refined codes and grouped them into higher-level categories, thereby *generating* initial themes. As Braun and Clarke emphasise, themes are not passively located *in* the data but are actively constructed by researchers through interpretation and abstraction [5]. Accordingly, our themes do not represent topic summaries but patterns of *shared meaning* across the dataset [5]. This phase also involved repeated comparison across participants and data sources, resulting in seven initial themes.

In the fourth phase, we refined the themes by identifying the *essence* of each theme: clarifying what *story* each theme tells and how it is distinct from the others. We used peer debriefing to strengthen rigour [14]. A research assistant reviewed the coding and thematic structure, challenged interpretations (e.g., by questioning overlaps between themes), and discussed alternative readings [5]. This process led to further refinement: we merged one theme with another and renamed two themes. The full analytic trail, including refinements and revisions, is documented in our replication package. During this phase, we also finalised sub-themes, which provide internal structure and nuance within each theme [4]. We compared themes across both data sources (interviews and reflections) and found consistent patterns, which strengthened confidence in the findings. Interviews provided richer contextual detail, while reflections offered broader coverage across participants.

Finally, we structured the themes in relation to the three research questions. Themes addressing how and for what purposes students use AI tools correspond to RQ1 (*Theme 1*, Figure 1). Themes addressing perceived effects on communication and collaboration correspond to RQ2 (*Theme 2*, *Theme 3*). Themes addressing how students distinguish between AI tools and human collaborators correspond to RQ3 (*Theme 4*, *Theme 5*).

Consistent with reflexive thematic analysis, we did not aim for interrater reliability, as coding is understood as an interpretative act shaped by researchers' perspectives rather than an objective process to be standardised [7]. Instead, we ensured rigour through peer debriefing, critical discussion, and sustained reflexive engagement throughout the analytic process [6]. Following Braun and Clarke's guidance [7], we do not report or interpret these counts, but they are visible in our replication package through *Atlas.ti*.

We selected illustrative quotes from all available and consented data. One researcher compiled an initial set of candidate quotes, and the research assistant reviewed these selections. In cases of disagreement, both researchers discussed the selection. The first researcher typically deferred to the second researcher's judgement, as the latter had greater analytic distance from the data collection process.

## 3.4 Trustworthiness

Consistent with interpretive qualitative principles of reflexive thematic analysis, we evaluate the quality of our study using the framework of trustworthiness.

**Credibility and Confirmability.** The corresponding author, who conducted all interviews and led the coding, identifies as a white European woman, is a first-generation academic, and has several years of experience in software engineering research and education. Her attitude

towards AI tools can be described as cautiously sceptical yet open. This positioning may have influenced how the data were interpreted and presented. Through ongoing discussions within the research team, where some colleagues hold very positive views of AI and are frequent users of AI tools, we aimed to balance this influence and critically reflect on our own assumptions. We also acknowledge that the first author's dual role as teacher and researcher may have influenced student responses. However, we collected data only after final grades were submitted, and participants expressed diverse and sometimes critical perspectives on AI use, suggesting they felt able to share their views openly.

We triangulated two data sources (reflections and interviews) and examined whether themes appeared consistently across both. We kept codes close to participants' wording to remain grounded in the data. Some question phrasing may still have shaped responses; we mitigated this risk by basing one question on prior work and by jointly discussing and refining all questions within the research team. Participation in reflections and interviews was voluntary, which may introduce self-selection bias, particularly given the human-centred focus of the lab and seminar. The study relies on self-reported data; participants may not accurately recall their AI use or may describe their behaviour in socially desirable ways. Qualitative analysis also involves interpretation. To reduce the risk that findings reflect only one researcher's perspective, we used iterative coding, peer debriefing, and critical discussion within the research team. For instance, during peer debriefing, the research assistant questioned the initial separation of what became Theme 2 and Theme 3, arguing that *efficiency gains* and *unresolved team problems* described the same underlying tension from two angles; this discussion led us to merge the two initial themes and reframe them as complementary outcomes of the same boundary.

**Transferability.** We aim to offer theoretically meaningful insights rather than representativeness. We provide detailed descriptions of the context, participants, and themes to support readers in judging transferability to their own settings. We note that our data capture individual students' accounts of AI use within team contexts; claims about team-level dynamics are inferential. Including multiple courses across different universities and countries strengthens relevance beyond a single local context. At the same time, the findings represent a snapshot from January 2024 to December 2025; students' practices and perceptions may evolve as tools develop and educational norms around AI use continue to stabilise. All courses shared a human-centred pedagogical orientation; this may have primed students to value human interaction and could sharpen the boundaries reported here relative to other software engineering course contexts. In addition, since participation, though voluntary, took place within an academic setting, some competitive boundaries may partly reflect institutional norms around originality and independent learning rather than AI's capabilities as such, as illustrated by students' concerns about plagiarising and learning progress. Practitioners may draw these boundaries differently; we return to this as a direction for future work.

**Dependability.** We documented and provide the full analytical circle, including the generation of codes and themes, as well as the COREQ checklist.

## 4 Results

We developed five themes across interviews and written reflections (Table 1). All themes appeared across all seven courses; the main variation was in emphasis, as lab courses more often discussed AI in relation to coding, and seminar courses in relation to writing and idea development. We provide a cross-case comparison table in the replication package.

**Table 1** Overview of themes from the reflexive thematic analysis.

| Theme | Subthemes | Codes (examples) |
|---|---|---|
| 1: AI as Individual Productivity Support | AI to understand and debug code | debugging support; explanation of code; refactoring |
| | AI to improve written communication | language correction; documentation; post-processing |
| | AI to prepare for brainstorming and discussions | brainstorming; idea generation; pre-meeting preparation |
| | Selective and critical AI use | trust concerns; low-quality output; team contracts |
| 2: AI Changes the Conditions *Around* Collaboration | Experiencing efficiency gains and availability | time savings; speed; AI availability; reliability |
| | Using AI for clarity and communication | language barrier support; reduced peer burden |
| | Valuing AI's harmony and predictability | emotionally stable; low-friction; less conflict; agreeable |
| 3: AI Does Not Solve Core Team Problems | Communication issues | not speaking up; difficulty motivating; defensive reactions |
| | Unequal workload distribution | unequal participation; compensation for others |
| | Scheduling and coordination | conflicting schedules; different priorities; job scheduling |
| | Interpersonal conflict and feedback | criticism as personal; defensiveness; unresolved tensions |
| | Diversity-related conflict | not taken seriously; disrespect; lack of integration |
| 4: Students Actively Construct a Human–AI Boundary | Treating AI as tool, not teammate | cognitive offloading; distrust; one-sided relationship |
| | Recognising AI's emotional limitations | missing support; lack of empathy; trauma bonding |
| | Reserving empathy and support for humans | categorical rejection for interpersonal problems |
| | Human responsibility and accountability | human judgement; trust in humans; overreliance |
| 5: Tensions Between Efficiency and Values | Tensions from unequal AI adoption | authenticity of work; uniformity; unequal access |
| | Prioritising human learning over efficiency | learning by doing; value of effort and struggle; dependency |
| | Emotions and purpose as human values | meaningful discussion; shared emotional experience |

## 4.1 RQ1: AI Usage in Software Teams

Students described AI as functioning as preparatory infrastructure that strengthens individual readiness before collaboration. They view AI tools as support for their individual work rather than a shared team resource (*Theme 1*, Table 1). They explained AI as helping them *individually* to brainstorm, code, document, organise, and prepare for meetings, but rarely as something that is directly used in their collective work.

### 4.1.1 Theme 1: AI as Individual Productivity Support

**AI as preparatory infrastructure.** Students used AI to explain unfamiliar code, debug errors, refactor implementations, and support technical understanding. Rather than directly copying outputs, they described AI as helping them reason through problems independently to *understand why using exactly this code* (NA-12). This explanatory function became particularly important when teams worked with unfamiliar technologies:

> "*Thank God for ChatGPT. As none of us has used the framework Flutter or the language Dart, we needed this app coded basically in a month. We got to learn now really quick and apply it. Flutter is really new and doesn't have helpful documentation.*" – NA-10

Students also used AI for writing support, including documentation, grammar correction, and report writing. They explained that they do not have to worry about *describing code details or structuring formal sentences* (EU2-50), since those are tasks they are bored with or

find challenging. Support for communication was particularly relevant for students working in a second language. However, even when collaborative artefacts were produced, AI use remained individualised since work was divided between team members.

Beyond implementation and writing, students described AI as useful for brainstorming and meeting preparation. AI-supported preparation enabled students to arrive at discussions with more structured ideas and clearer proposals. This preparation had an indirect positive effect on team meetings since, instead of arriving at discussions unprepared, they used AI to develop outlines, ideas, and options beforehand:

> "*I used AI to help brainstorm in preparation for our team discussions and standups. Before a project meeting, I gathered a list of possible approaches from AI chats and shared them with the team. Having those options ready meant we could start the conversation with a clear direction and immediately, get everyone involved faster, and focus on improving the ideas together, which was positive.*" – EU2-16

**Selective and critical AI use.** Students did not adopt AI uncritically as they described careful, selective, or even deliberate non-use of AI. They emphasised the need to edit AI output, verify correctness, and apply their own judgement. Some teams introduced explicit rules in their team contracts at the beginning of the term, while others avoided AI for personal or ethical reasons. They framed teamwork itself as inherently human:

> "*We did not use AI tools, and it did not occur to me to use it once. Team work relies on human participation, so how could those help us?*" – EU2-30

Students with professional experience were particularly sceptical about overreliance on AI-generated code, using it rather as *last resort* (EU1-02), and preferred human-validated resources such as Stack Overflow as they valued the collective human knowledge:

> "*ChatGPT just gives you code, but you don't know where to put it or how it works. You need to ask more and more questions. I don't wanna go down this rabbit hole, it's just annoying.*" – EU1-11

**RQ1.** Students use AI not *within* the team, but *individually* to strengthen personal preparation and productivity before contributing to collaborations.

## 4.2 RQ2: Impact of AI on Collaboration

While students reported several positive impacts, these related to efficiency, preparation, and clarity, improving the conditions for collaboration without transforming the collaborative process itself; hence, AI influenced collaboration indirectly (*Theme 2*, Table 1). Some core team problems remained unaddressed despite the use of AI tools (*Theme 3*).

### 4.2.1 Theme 2: AI Changes the Conditions *Around* Collaboration

**Reducing coordination and communication friction.** Students valued AI for its speed, availability, and predictability. AI enabled them to access support immediately without depending on teammates' schedules or availability, as with *AI it is easier, because it is always available when you ask for it.* (EU2-43). This saved them time they would otherwise have spent arranging a meeting to *just clarify a single line of code* (EU1-10), whereas *AI tools allow for faster feedback cycles* (EU2-16). Beyond scheduling, students also valued that AI has no mental or emotional limitations:

> "*AI tools are always available, not only scheduling wise but also mentally. There is no bad day for them so you have to work around that or postpone mentally taxing work to accomodate for e.g. a bad nights sleep.*" – EU2-08

In this context, students contrasted AI interaction with human collaboration, describing AI as emotionally neutral and less socially demanding:

> "*With an LLM there is no conflict to resolve, as they follow what you tell it to do. That way we could focus on implementation rather than on small things.*" – EU2-22

In its enhanced form, students used AI to soften emotionally charged communication before interacting with teammates:

> "*I also used it when I was once again absolutely disappointed by the team, and then typed a very aggressive message into Discord and thought to myself, I can't send this like this. Then I put it into ChatGPT and said, "Please rewrite this in a factual and unemotional way, or maybe a little friendlier." Only then did I send it.*" – EU1-03

Students also reported that AI supported clearer communication, particularly for international students and those with lower confidence in English. In these cases, AI reduced some of the communicative barriers surrounding teamwork:

> "*As a foreigner, I believe that, due to the language barrier, using AI tools has made communication more efficient by helping me understand things I couldn't or correcting mistakes in my speech, and looking up unfamiliar words, so I did not feel so awkward around the team.*" – EU2-04

Some of these effects operated primarily at the individual level: reduced awkwardness or increased confidence describe how a student experienced participating in the team, rather than a change in what the team did together. We report these because they shaped students' willingness to engage, but distinguish them from effects such as faster feedback cycles or reduced peer burden, which more directly altered team-level coordination.

### 4.2.2 Theme 3: AI Does Not Solve Core Team Problems

Despite reported benefits, students expressed core teamwork problems as fundamentally interpersonal rather than technical. Unequal participation, scheduling conflicts, communication difficulties, and interpersonal tensions persisted regardless of their AI use. Students did not describe AI as capable of addressing these issues as they *can't even imagine that the machine can help solve the problems between people* (NA-08).

*Communication issues* stayed central to team difficulties. Students described situations in which team members avoided discussing problems, withdrew from conversations, or reacted defensively to criticism. Unequal workload distribution, inconsistent participation, and a lack of open communication created additional frustration and resentment within teams:

> "*It was challenging. Teammates do not communicate that a task is too hard, and then wait for others to ask them about it. It delays the sprint not because someone is incapable, but because the person feels shame.*" – EU2-77

Students described situations where team members were *ghosting without notice to the team* (EU2-76) or contributed significantly more than others. These imbalances are connected to *scheduling*, different levels of time availability and priorities. On top of that, *interpersonal conflict and feedback* created emotional challenges as students struggled with how team members received criticism as

> "*constructive criticism was rather seen as a personal attack against someone and instead of accepting feedback and suggestions for change, some people got mad and defensive.*" – EU2-19

Some students, particularly women, also described experiences of exclusion and disrespect that affected their sense of belonging within the team environment:

*Diversity-related conflict* emerged for some students, particularly women. They reported feeling excluded or disrespected by their teammates, to an extent where a woman reported that their team mates *were so disrespectful, that they made me cry* (EU2-02). These experiences went beyond task-related disagreements to affect students' sense of belonging and psychological safety:

> "*I had the feeling that the others are not interesting, but we are a team. It was a horrible feeling, because what was happening is that, not to make it a gender thing, I was left out of quite a bit of conversations. At some point, I truly felt like the crazy lady.*" – EU1-01

**RQ2.** AI improved conditions *surrounding* collaboration, but did not address core interpersonal challenges within teamwork.

## 4.3 RQ3: Socio-technical Relationship

As a recurring pattern across our data, students maintained a clear distinction between AI systems and human collaborators (*Theme 4*, Table 1). While AI was accepted as cognitive and technical support, students reserved social, emotional, and accountable aspects of teamwork for humans (*Theme 5*). That an AI system lacks empathy might be an unsurprising starting point; what we report below is how students translate this into specific exclusions: which situations, tasks, and relationships they withhold from AI, and why.

### 4.3.1 Theme 4: Constructing a Human–AI Boundary

**AI as tool, not teammate.** Students explicitly positioned AI as a tool rather than as a collaborative partner. They accepted AI support for technical and cognitive tasks, while rejecting the idea that AI could meaningfully participate in interpersonal collaboration *because human brain is not a computer and what happens there is way too complicated for a language model to grasp* (EU1-05).

> "*If AI wouldn't help with code, it wouldn't help with people, interaction, and human things. We call it artificial intelligence, but in reality, it's still not intelligence. It is just a a very profound and cutting edge piece of software.*" – EU1-10

Students expressed distrust towards AI in sensitive contexts. They raised concerns about bias and the lack of contextual understanding in AI systems:

> "*We didn't use it for anything indigenous-related in the design sprint, because there's a lot of bias, and AI inherently has white supremacy built into it. I trust my team mates.. or at least they would not do any damage with this kind of information. I wouldn't trust any silicon company to knowing properly about how to interact with indigenous people.*" – NA-02

**Recognising AI's emotional limitations.** Students emphasised that while AI can be useful and efficient, it cannot replace the emotional and social qualities of teamwork. They described human collaboration as more meaningful, motivating, and emotionally rich. Students stated the emotional aspect, as *talking to humans requires empathy* (EU2-29), which the AI lacks.

> "*AI couldn't provide emotional support, resolve conflicts, or offer real empathy during stressful moments. For me personally, it is this shared stress management that made my team experience unique.*" – EU2-34

Others contrasted the value of human discussion with AI support, emphasising that the social dimension of teamwork cannot be replicated:

> "*The support from the team, especially when you are stuck with a topic, is much more valuable. And working in person and discussing with each other and also having fun as a group is something that AI can't replace.*" – EU2-43

Students described that human interaction allows richer understanding because relationships, also in professional settings, matter:

> "*with my team partner i want to find a solution, because i have to work with them in the future or even like them as humans. this is complicated but also more rewarding.*" – EU2-73

**Reserving empathy and support for humans.** Students strongly rejected the idea of using AI for emotional or interpersonal problems. They emphasised that empathy, trust, encouragement, and understanding belong to human relationships.

> "*I like to evaluate what's going on with people on my own, like reading social clues. I would ask a real person, not a language model.*" – EU1-07

Students especially emphasised the value of human feedback and mentorship. When facing difficulties, they turned to teammates or instructors rather than AI:

> "*I'd be more likely to just whenever [Team member] and I couldn't get over like, a hurdle. We would bring in [Mentor]. I would never, like never ever, asked chatgpt. It's not human, and I don't trust it with this kind of stuff.*" – NA-06

Students also valued the critical perspective that only humans can provide in order to get diverse perspectives:

> "*But of course AI cannot replace critical pushback from humans which is necessary to avoid being trapped in an echo chamber.*" – EU2-15

**Maintaining human responsibility and accountability.** Students also expressed that responsibility should remain with humans. They worried about errors, misleading output, and overreliance, and emphasised that human judgement remains essential, and their trust in human partners. They did not feel comfortable relying on AI in ways that would shift accountability away from themselves or their team members:

> "*At the end of the day a developer is the pilot of the project, not the LLM.*" – EU2-22

Even in contexts where students engaged with online communities, they trusted collective human intelligence on platforms like Stack Overflow more than AI-generated solutions:

> "*When I have a problem, I'm going always to Stack Overflow, or whatever, because when you find a solution there, it will be rated. People have tested it. People have responded. You can feel the feedback, feel if it's working or not.*" – EU1-10

### 4.3.2 Theme 5: Tensions Between Efficiency and Values

Students described emerging tensions within teams related to different levels of AI adoption and different attitudes towards *appropriate* use. These differences became visible in *poor final work* (EU2-44), created concerns about fairness, and revealed disagreements about learning versus productivity gains. This created challenges for technical aspects, e.g. affecting code review, coding style and coherence and making it difficult to maintain consistency across the team's work:

> "*It's not very good if you are doing homework with GPT, and it's plagiarizing and it's gonna make your coding style look very, very weird. You're not gonna have your own coding style, because GPT is just gonna generate code based on whatever like it finds on internet.*" – NA-05

Rather than valuing efficiency alone, students associated learning with effort, discussion, and shared struggle, and worried that AI could weaken this process.

> "*I want to learn, right? With GPT, you get everything ready for you, you're not really learning efficiently. When you learn new words, it's better to see them in sentences and try to figure out the idea... Same with coding. If you get a piece of code that is written for you... you are not putting your effort into thinking of the logic behind this.*" – EU1-09

They appreciated having discussions and disagreements, since they reported this is the key aspect of teamwork, exchanging perspectives and arguments. Students emphasised this benefit by noting that intentional non-use of AI led to more team interaction:

> "*The decision not to use any AI tools was a good one, it led to much more exchange and interaction within the team, even though it was getting a little bit heated, but we got really good ideas out of it.*" – EU2-14

They associated meaningful learning with human interaction, especially when it comes to creativity, e.g. when asking for app names, the AI delivered *just kind of generated, random ones. It was like very cliche and gross. Once we had a proper sitdown with the team, we were super creative* (NA-10).

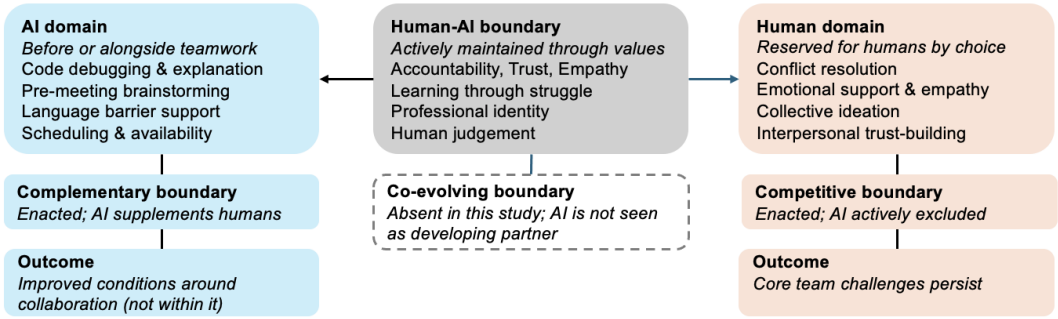

**Figure 2** Boundary work in student AI–human software teamwork based on Kim et al. [17] boundary types. Enacted boundaries shown solid, absent boundary dashed.

Overall, students accepted AI as support for individual cognition and preparation while maintaining clear boundaries around human responsibility, emotional engagement, and collaborative legitimacy. In their explanations, real discourse and emotional engagement only happen between humans:

> "*In the team, genuine discourse takes place, where ideas are developed and questioned together. In my opinion, emotional aspects such as motivation, mutual support, and creative engagement arise exclusively through teamwork, not through AI.*" – EU2-39

**RQ3.** Students valued AI for cognitive support while reserving socially meaningful collaboration for humans.

## 5 Discussion

Our findings reveal a dichotomy of the perception of AI-human relationships: students across our cases described adopting AI tools (*RQ1*), and reported tangible benefits (*RQ2*), yet actively resist treating AI as part of their collaborations (*RQ3*). We frame these findings within boundary work and discuss their implications for software engineering.

### 5.1 AI Supports Collaboration Indirectly

The central contribution of this study is the distinction between AI supporting *around* collaboration versus *within* collaboration. Our contribution lies not in showing that students treat AI as a tool, which might be an expected outcome given current AI capabilities, but in specifying where and why they draw the line: which tasks they hand to AI, and which they actively withhold and why. As a recurring pattern across our data, students enacted complementary boundaries [17] by using AI for drafting, debugging, organising, brainstorming, and communication support *before* entering collaborations (Figure 2). Students described AI as functioning as preparatory infrastructure that strengthened individual readiness and reduced coordination friction surrounding teamwork.

At the same time, students draw strong competitive boundaries around empathy [8], responsibility [43], learning, and trust [36], rejecting AI for conflict resolution, emotional support, or collective accountability. AI benefits occur *before* or *alongside* teamwork, not *during* it. AI was therefore perceived as useful for supporting technical and cognitive work, but not for replacing socially accountable collaboration. These competitive boundaries were not uniform in kind. Some rested on accountability: students located responsibility for

outcomes in human judgement, treating AI participation as a threat to who could be held answerable for a decision (EU2-22) [43]. Others rested on trust: students questioned whether AI could be relied upon in contexts involving values, bias, or lived experience, preferring the tested judgement of human peers (NA-02, EU1-10). A third group of justifications was relational and emotional: students described qualities such as empathy, shared struggle, and motivation as constitutively human rather than technically absent from current AI (EU2-29, EU2-73) [8]. These grounds for exclusion are distinct and may not be equally durable: accountability-based boundaries could weaken as AI systems become more auditable and traceable, whereas relational boundaries are tied to what students consider collaboration to mean and may prove more resistant to changes in AI capability alone.

We found no evidence in students' accounts that they perceived AI as a co-evolving collaborative partner [17] (Figure 2). Kim et al. [17] studied individual use of generative AI (e.g. as a writing aid) and found that co-evolving boundaries can emerge over time. Our team setting did not reproduce this: unlike individual use, teamwork carries collective accountability and interpersonal stakes, which may make a co-evolving, partner-like framing of AI harder to sustain. Our students framed AI as a static support tool. Our findings therefore suggest that, within student software teams, AI is currently positioned more as infrastructural support than as a socially legitimate collaborator (Figure 2). As our design relies on retrospective interviews and reflections rather than longitudinal observation, this finding describes an absence in students' accounts at one point in time rather than a claim that students' boundaries cannot evolve at all.

This positioning may also explain why students with professional experience appeared more sceptical towards AI-generated output. These students often emphasised accountability, verification, and human judgement, reflecting concerns already discussed in professional human-AI collaboration research [43, 36].

However, our findings sit against a backdrop in which AI-as-teammate is so far mostly a projected future [1] or an individual-level, subordinate relationship [48] rather than an established discourse of equal collaboration, as human–machine teaming itself remains rare in software engineering practice [33]. Yet, our findings might be not applicable for explicitly pair programming, where the developers only have one partner, and thus might be less critical of an AI-partner [44]. As a research community, we should foster discussions on value conflicts and professional identity, contributing to the emerging debate on the role of software engineers in the AI era [3].

Future software engineers require not only technical AI literacy, but also opportunities to critically reflect on responsibility, trust, and acceptable forms of AI participation within collaborative software engineering work.

## 5.2 Valuing Human Collaboration Despite Its Difficulties

Students uphold human responsibility because they value empathy, critical judgment, and contextual understanding: competencies central to professional software engineering [10]. In this respect, the students appear well-prepared for professional practice. They also explicitly value the human character of collaboration and learning, even while acknowledging the difficulties they experience in teamwork.

Importantly, core teamwork problems persisted regardless of AI use. Unequal participation, missed deadlines, weak communication, defensive responses to feedback, and interpersonal tensions remained unchanged. Students neither described AI as helping with these challenges nor expected it to. These findings reinforce prior work suggesting that collaboration challenges

in software engineering are primarily social rather than technical [12, 20]. While AI may reduce organisational friction and support individual productivity, it does not replace the interpersonal competencies required for collaborative software development.

Students therefore appeared to maintain human responsibility not despite teamwork difficulties, but partly because collaboration itself was associated with learning, accountability, and shared ownership. If, as recent work suggests, AI offers productivity gains but cannot address the root causes of collaboration issues, then research, education, and practice must value human collaborative competencies and emerging tools *equally* [1].

Software engineering education and practices should even more emphasise communication, negotiation, constructive feedback, and conflict management.

### 5.3 AI, Inclusion, and Emerging Team Norms

Our findings further suggest that AI can both support and complicate inclusion within software teams. Some students, particularly international students, described AI as helpful for overcoming language barriers and participating more confidently in discussions. In these cases, AI reduced communicative friction and supported participation. This aligns with research on AI-supported task communication [15] and *technology as mediator* [27]. Importantly, students still distinguished this preparatory support from what they considered *real* collaboration.

At the same time, AI introduced new tensions. Prior work shows that unequal access to technology can exclude students [27]. Our findings extend this by showing that differences in beliefs about *appropriate* AI use and learning values may result in low (code) quality, and identity also shapes inclusion [11], and commitment to the team [45]. Our data suggest a possible explanation: students value disagreement and shared struggle. When AI removes these experiences, it may weaken ownership and connection [43].

These findings suggest that AI adoption within teams is not solely a technical issue, but also a sociotechnical negotiation of norms, values, and responsibility. Students actively constructed boundaries around acceptable AI participation while simultaneously negotiating what meaningful collaboration should look like in AI-supported software engineering work.

Within courses, educators could make those boundary-setting explicit, for example through structured team charters (as some of our participating teams already used informally) that specify where AI is and is not used, paired with rubrics that credit visible communication, conflict resolution, and negotiation rather than only technical output.

Future work should explore how cultural and professional context as well as exclusion experiences shape students' human–AI boundaries.

## 6 Conclusions

Our study shows how students draw boundaries around AI when working together in software engineering courses. Building on boundary work theory, we extend its application from individual AI use to teamwork and identify an important distinction between using AI to support collaboration and allowing AI to participate in it. Our findings indicate that students maintain clear boundaries between AI tools and human collaborators in project-based software courses. They mainly use AI for individual work and preparation, which can then support collaboration, for example by helping them communicate ideas more clearly. At the same time, common teamwork challenges persist regardless of AI use, and

students make deliberate decisions about where AI should and should not be involved. These boundaries help preserve what students see as the human core of teamwork, while also limiting AI's role in collaboration. Future research should examine how these boundaries vary across collaboration settings, cultural contexts, domains, tasks, and levels of experience, including professional practice. Longitudinal and multi-cohort studies could further show how accountability-, trust-, and relational boundaries change as AI capabilities and social norms evolve. For software engineering education, our findings suggest that AI literacy should distinguish between boundaries that may reasonably shift as AI improves and those that reflect more fundamental views about what collaboration should involve.

## Data Availability Statement

Due to GDPR and participant confidentiality requirements, the original interview transcripts cannot be made publicly available. The full codebook, including examples, and the complete interview and reflection guides are available at: `https://figshare.com/s/578a68feb95cc8698de1`.

# Large-Scale Evaluation of Android-Related Research Artifacts

**Philipp Holzinger**
Fraunhofer SIT | ATHENE – National Research Center for Applied Cybersecurity, Darmstadt, Germany

**Philipp Rajwa**
Fraunhofer SIT | ATHENE – National Research Center for Applied Cybersecurity, Darmstadt, Germany

## Abstract

**Background.** Many computer science papers rely on software prototypes that implement novel concepts or generate data for empirical evaluation. To support confirmatory research and reuse, more venues now request code and data submissions and conduct artifact evaluations. However, concerns about a reproducibility crisis remain, as studies show that only a small share of published artifacts is actually accessible and working for reuse or reproducing results.

**Aims.** To shed more light on this in the context of Android-related research, we investigate to what extent research artifacts are available, functional, and whether they allow us to reproduce published experimental results. Moreover, we want to understand the reasons why research artifacts might fail to fulfill these objectives.

**Method.** We conducted a large-scale empirical study of Android-related research artifacts that were published between 2011 and 2025. For an initial set of 269 papers, we attempted to locate their associated artifacts, assess whether they can be obtained and executed, and evaluate whether they reproduce the expected output.

**Results.** Starting from 269 papers, only 163 artifacts were still available. Among these, 118 papers published experimental results, yet we were only able to establish 10 experimental setups. Ultimately, only 8 artifacts could fully or partially reproduce the expected output.

**Conclusions.** Our findings provide further evidence for reproducibility challenges in Android-related research. Based on these sobering results, we propose a set of recommendations to strengthen the perceived value of artifacts and to improve their availability, quality, and visibility.

## 1 Introduction

The number of publications in computer science increases steadily. In 2025, more than 400.000 papers have been published at conferences, workshops, and in journals [11]. The need to have scientific output that is independently verifiable has emerged as a critical factor for

© Philipp Holzinger and Philipp Rajwa;

scientific progress. Reusability and reproducibility enable confirmatory research that helps consolidate or falsify scientific findings, and allows researchers to build on top of previously established knowledge [27].

Yet, in the past years, several researchers have declared a *reproducibility crisis* [4, 25, 35, 3], stating that many research publications and their corresponding artifacts cannot be used to reproduce the scientific findings originally presented in the papers.

The research community in the fields of computer science and software engineering has responded to this by establishing independent artifact evaluation processes for many of their conferences. While this is clearly a step forward in terms of scientific rigor, as of today, the reproducibility crisis does not seem to be resolved yet. In a recent survey of 101 software engineering researchers conducted by Azevedo et al. [3], 74% agreed that there is a crisis in software engineering research concerning repeatability, reproducibility, and replicability.

This is supported by an empirical study of Olszewski et al. [28] who evaluated 298 artifacts related to machine learning security published at top-tier security venues. As they show, 56% of artifacts were not runnable, and only 20% were runnable and yielded the expected results.

Further, a recent case study by Muttakin et al. [26] of 100 randomly sampled ICSE artifacts showed that only 40% of them were executable, and only 35% in this subset reproduced the expected results.

Although the generalizability of these studies is limited, they nevertheless raise the question of whether the entire computer science community is inadequately addressing the challenges of reusability and reproducibility.

To shed more light on this important topic, in this study, we perform a large-scale evaluation of Android-related research artifacts, to study their availability, functionality, and reproducibility. The reasons for focusing on Android are threefold: first, there is an extensive body of related research published at various conferences over an extended period of time; second, work in this area is more likely to include software-based artifacts with quantitative results; and third, we possess strong technical expertise in this domain, which makes our manual assessments more substantial and meaningful.

As input to our study, we received a comprehensive dataset of the contents of the ACM Digital Library up to the year 2017, and further considered ICSE publications from 2018 to 2025. Filtered by date, publication type and relevance to Android, we ended up with a final dataset of 269 relevant papers that also reference an artifact. This includes 32 papers that had been awarded at least one badge by an artifact evaluation committee.

Our first finding is that we could only retrieve 163 artifacts by following the instructions provided in the papers, and in some cases even artifacts with an *ACM Artifacts Available* badge were no longer available. Among the available artifacts, only a fraction was functional, and we often had to fix fundamental issues in the code provided, such as hard-coded paths, or flawed dependency management. For reproducibility, we focused on a subset of 118 papers with software-based experiments. Despite our best efforts, we fully reproduced the results for only 3 papers; in most cases, we could not even set up the experiments due to non-functional or incomplete artifacts (among other reasons). While none of the artifacts had a reproducibility badge and many were not designed for that purpose, these results are sobering in light of the perceived reproducibility crisis.

In this paper, we make the following original contributions:

- A large-scale evaluation of Android-related artifacts regarding availability, functionality, and reproducibility
- Recommendations to improve the perceived value of artifacts, their availability, quality, and visibility

This paper is structured as follows. Section 2 introduces relevant background, including terminology, and related work. Section 3 presents our methodology, as well as our research questions. Accordingly, Section 4 gives detailed account of the results of our empirical study. In Section 5 we discuss our findings and in Section 6 we present limitations and threats to validity. Finally, Section 7 provides recommendations based on the lessons we learned during our study, and Section 8 concludes.

## 2 Background and Related Work

In this section, we provide background information on artifacts and evaluation processes, and further present related work.

### 2.1 Research Artifacts

Software implementations are a core component of many scientific contributions in computer science, serving as the basis for experimental studies. Other researchers can independently verify these studies by reproducing or replicating the experiments. To avoid confusing terminology [37], ACM has adopted the following definitions, which we will also use in this paper [12]:

- *Repeatability*: "Same team, same experimental setup"
- *Reproducibility*: "Different team, same experimental setup"
- *Replicability*: "Different team, different experimental setup"

To support confirmatory research and enable other researchers to build upon existing work, authors can supply their experiments – either in part or in full – as artifacts accompanying their papers. ACM defines an artifact as a "digital object that was either created by the authors to be used as part of the study or generated by the experiment itself. For example, artifacts can be software systems, scripts used to run experiments, input datasets, raw data collected in the experiment, or scripts used to analyze results" [12]. Throughout this paper, we use the term *artifact* to describe the entirety of files and supplementary materials linked to a paper, irrespective of their types, contents, or number.

The number of publications that provide an artifact increases over time [22]. Whether papers with artifacts are also cited more often is not clear. While there is previous work that supports this theory [5, 13], a study performed by Winter et al. [42] could not find a statistically significant difference.

While the fundamental development towards more reproducible research results is welcomed, recent studies lament the missing availability [17, 22] or reusability [7] of many software artifacts and even their failure to reproduce experimental results [7, 28].

### 2.2 Artifact Evaluation

Recognizing the need for higher availability and quality of research artifacts, different publication venues have introduced artifact evaluation processes. Authors are encouraged to submit their artifacts, an artifact evaluation committee reviews them and awards badges that confirm, e.g., artifact availability, or functionality. Different badging frameworks have been proposed, but in the context of software engineering, programming languages and security, the ACM badging framework [12] is most prevalent.

It comprises the following three badges commonly awarded by committees:

- *ACM Artifacts Available*: "Author-created artifacts relevant to this paper have been placed on a publically accessible archival repository. A DOI or link to this repository along with a unique identifier for the object is provided." [12]
- *ACM Artifacts Evaluated Functional*: "The artifacts associated with the research are found to be documented, consistent, complete, exercisable, and include appropriate evidence of verification and validation." [12]
- *ACM Artifacts Evaluated Reusable*: "The artifacts associated with the paper are of a quality that significantly exceeds minimal functionality." [12]

In addition to these three badges, the ACM framework further defines an *ACM Artifacts Results Reproduced* and *ACM Artifacts Results Replicated* badge, which require subsequent, independent studies that confirm results presented in previous work.

The ACM badge criteria have found widespread adoption [16, 42], even beyond ACM venues [15]. In 2025, 7 out of 9 CORE2023 A*-ranked conferences in Software Engineering [9] encourage artifact submissions and make explicit references to the ACM badge framework in their call for submissions.

However, even among leading software engineering conferences, there is no consensus on how artifact evaluation should be conducted and what the requirements are.

Out of 25 A-ranked conferences, 23 encourage artifact submission and 16 use a badge framework. However, only 10 award all three ACM artifact evaluation badges, 2 award another subset of the ACM badges, and 4 use their own badge definitions or use another badge framework entirely.

Even fundamental requirements differ between conferences. For example, PLDI 2025 "strongly encourages" submitting artifacts as a Docker container [36], while POPL 2025 does not recommend using Docker due to "cross-platform compatibility issues" [38]. Further, some conferences require authors to publish their artifacts by strictly using one specific artifact archival service [36], while others allow different services [19, 2, 33].

There are even inconsistencies within the same conference when considering back-to-back years. For example, in 2024, ICSE awarded only two badges instead of three, and despite referencing the ACM badging framework, the call used terminology and requirements not in line with the framework [30]. This was fundamentally different in 2025 [31].

In summary, there are efforts to systematize artifact evaluation in the research community, but there is no broad consensus yet.

## 2.3 Related Work

There is previous work that has studied artifact evaluation processes, expectations, and the availability of artifacts. Liu et al. [22] found that the number of papers with artifacts at top-tier software engineering conferences has increased from 2017 to 2022, but also noted that 30% of artifacts from 2017 were no longer available in 2024. Hermann et al. [16] surveyed members of artifact evaluation committees with respect to their expectations. They found that certain expectations are not adequately communicated in calls and further highlight problematic inconsistencies in the use of terminology. Timperley et al. [41] conducted a survey to identify challenges that influence the quality of artifacts, pointing out insufficient reward for authors and reviewers. Heumüller et al. [17] found that out of 604 ICSE papers from 2007 to 2017 claiming to contain artifacts, only 27% contained working links to these artifacts in 2020. In 2022, Frachtenberg [13] surveyed 2439 papers from system conferences and found that 13% of artifacts were no longer available four years after publication.

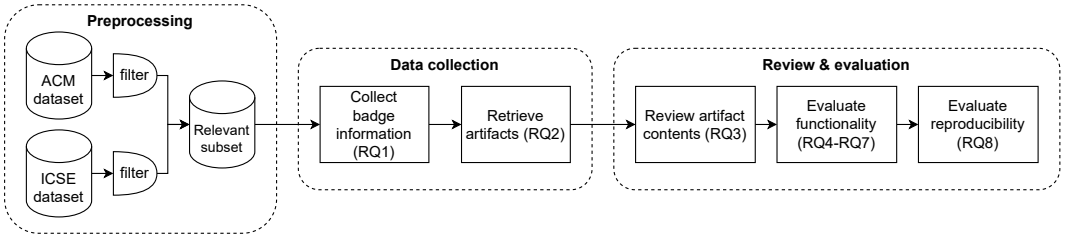

**Figure 1** Overview of the multistep process we used in this study.

There is also prior work that had a focus on reusability and reproducibility. Collberg and Proebsting [7] found that out of 402 computer systems papers with artifacts that were published in ACM conferences and journals around 2012, only 56% were available and only 48% could be built by the authors. In 2016, Reaves et al. [40] performed a systematization of papers on Android security research, and finally evaluated 7 selected application analysis tools with respect to reusability. In 2021, Daoudi et al. [10] could only fully reproduce 1 out of 5 Android malware detector approaches despite putting in significant effort and contacting the original authors. In 2024, Mineau and Lalande [23] evaluated the reusability of 22 Android static analysis tools on a novel input dataset, and found that 12 of them were unusable. Olszewski et al. [28] surveyed 750 machine learning papers from 2013 to 2022 that were published at top-tier security conferences. They could only reproduce 20% of the results and found no statistically significant difference regarding the availability of artifacts after the introduction of artifact evaluation committees. Finally, Muttakin et al. [26] performed a case study of 100 randomly sampled ICSE artifacts and showed that only 40% of them were executable, and, out of these, only 35% reproduced the originally published results.

To the best of our knowledge, in this paper we present the first large-scale evaluation of Android-related research artifacts, considering availability, functionality, and reproducibility.

# 3 Methodology

Figure 1 provides an overview of our approach. In the following, we will define the scope of our study, the datasets we used as input for our evaluation, and present the research questions that we aim to answer.

## 3.1 Scope

We set the focus of our evaluation on papers centered around the Android operating system, including novel approaches to app development, analysis, or testing. For evaluating the reproducibility of papers and their artifacts, we further limit our scope to software-based experiments, because they deliver quantitative results and can be more practically evaluated on a large-scale than, e.g., user and field studies. One reason for choosing Android specifically is that it was released in 2008 [14]. and we can hence look back at a large body of publications in that field. Another reason is that we assume that Android-related papers are more likely to have software-based experiments that they make available as artifacts, as compared to, e.g., papers on formal methods or cryptography. One additional reason is that the Android operating system, as well as app development, is well documented, and there is a large community of developers in this area, which is a benefit in our effort to potentially get a large number of artifacts running.

We further limit the timeframe we consider from 2011 to 2025. The starting year is when the software engineering community introduced artifact evaluation processes, and the end year is the last full calendar year at the time we conducted our study.

## 3.2 Datasets

Identifying papers that fit our scope and have an artifact associated with them requires title, abstract, and full text. Unfortunately, large publication datasets like the dblp (`https://dblp.org`) often contain bibliographic information only, rendering them unsuitable as a data source for our purposes. Instead, we used two alternative datasets as input to our study.

The first dataset is the contents of the ACM Digital Library for the years 1952–2017, that we received as proprietary, structured XML data. A similar dataset with more recent contents was not available to us upon request. Due to its ∼440.000 publication entries, we were required to apply filters. We first removed all publications for the years before 2011, which reduced the set to ∼175.000 entries. We then filtered for entries whose publication type was "regular_article", "orig-research", "", or *none*, by which we removed tutorials, columns, interviews, reviews, introductions, keynotes, and similar contents, which left ∼123.000 entries. Next, we removed entries that had no fulltext content in our dataset, leaving ∼107.000 papers. We then processed titles and fulltext contents to filter for those entries that were likely to be related to Android, using search teams like "Android", "mobile app", and various combinations – the complete rule set is provided in our artifact. The resulting set was a list of ∼3.000 papers. We manually reviewed these publications to select those that refer to an artifact, and filtered out duplicates in our dataset, misclassified data entries, and papers that matched our search criteria, but, based on a group discussion, were not in our scope. This primarily concerns papers that use Android-based devices for data collection, e.g., for human-centric behavioral experiments [24], or transportation studies [43], without a focus on development or testing. The final list from this dataset contains 174 papers.

To include more recent publications, as a second dataset, we considered all ICSE publications from the years 2018-2025. This venue has an A* CORE ranking [8], features an artifact evaluation process, and has been held for several years. Based on manual review and a group discussion, we selected the subset of Android-related papers that fit our scope and reference an artifact, which resulted in 95 papers.

In total, we examined 269 papers for our evaluation.

## 3.3 Research questions

Based on the set of papers that we selected, we aim to answer the following research questions:

**RQ1:** How many artifacts received badges?
**RQ2:** How many artifacts are available?
**RQ3:** How many artifacts contain software?
**RQ4:** How many scripts can be executed?
**RQ5:** How many code artifacts can be built?
**RQ6:** How many binaries can be executed?
**RQ7:** How many artifacts are functional?
**RQ8:** How many artifacts can be used to reproduce paper results?

The first question shall enable us to reason about the potential effects of artifact evaluation on properties of the artifacts that we measure in subsequent questions. RQ2 is dedicated to availability, RQ4-7 are concerned with functionality, while the final research question studies reproducibility. We treat scripts, binaries, and compilable code separately, since they are fundamentally different types of software that may vary in terms of their reusability.

**Table 1** Combinations of badges awarded to papers in our dataset.

| Badge combination | # of papers |
|---|---|
| *ACM Artifacts Available + ACM Artifacts Evaluated Reusable* | 15 |
| *ACM Artifacts Available* | 7 |
| *ACM Artifacts Available + ACM Artifacts Evaluated Functional* | 3 |
| *ACM Artifacts Available + ACM Artifacts Evaluated Functional + ACM Artifacts Evaluated Reusable* | 1 |
| *ACM Artifacts Evaluated Functional* | 1 |
| *ISSTA Artifact Evaluated* | 1 |
| *PLDI Artifact Evaluated* | 1 |
| *ACM Artifacts Evaluated Reusable* | 1 |
| *OOPSLA Artifact Evaluated* | 1 |
| *Artifact evaluated by FSE* | 1 |

When attempting to set up artifacts for evaluation that did not work as is, we set a limit to 3 hours, trying to fix errors. We consider this reasonable, as this exceeds the limits set in prior studies for similar tasks [6, 28]. If within this timeframe we did not succeed, we flagged the respective artifact as "non-functional". Further, we skipped artifacts whose setup would require complex, hard-to-setup distributed system environments in dedicated network infrastructures, and flagged them as "skipped" accordingly.

## 4 Results

In the following subsections, we present the results of our empirical evaluation for each of the research questions stated above.

### 4.1 RQ1: How many artifacts received badges?

In total, 32 out of 269 papers received at least one badge awarded by an artifact evaluation committee. This represents a share of 12%. Table 1 shows the combinations of badges that we found in our dataset. As can be seen, the majority of badges are ACM badges, both in versions 1.0 and 1.1. The most awarded badge in our set is the *ACM Artifacts Available* badge, which was assigned to 26 papers.

Interestingly, although ACM badges were awarded most frequently in our dataset, none of the papers received an *ACM Artifacts Results Reproduced* badge or *ACM Artifacts Results Replicated* badge. We assume that the former was typically not offered by the artifact evaluation committees who reviewed papers in our dataset. The latter badge, as also acknowledged by ACM, may be more suited to awarding it post-publication, which apparently never happened to any of the papers we reviewed.

The share of papers with badges in our dataset is too small to allow for statistical evaluation, however, in the following research questions, we will highlight these papers.

Note that for two papers we found it hard to clearly identify the type of badge that was awarded to the paper, based on the visual indication of the badges on the title pages of the two respective papers. We indicated this in the full list of papers that we provide as an artifact to this publication.

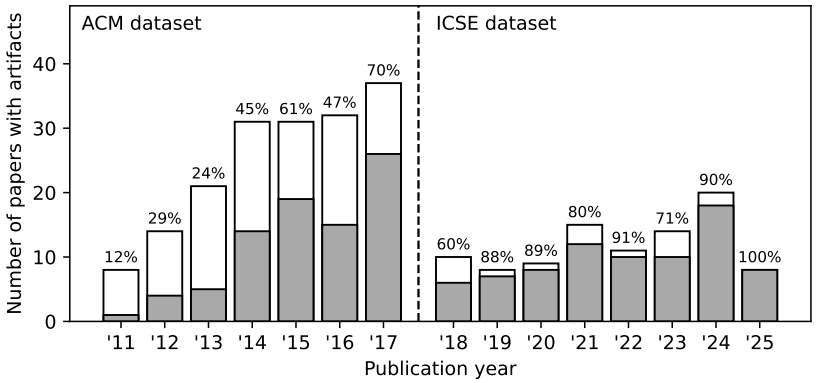

**Figure 2** Number of publications with artifacts from 2011 to 2025. White: total number of publications that reference artifacts. Gray: Share of publications whose artifacts are still available.

## 4.2 RQ2: How many artifacts are available?

For further investigation, we first tried to retrieve the artifacts of the 269 papers in our dataset in the way that is indicated in the respective paper. Typically, papers provided a URL that was supposed to either lead directly to downloadable content, to a repository, or to a project website with further instructions on how to retrieve a copy of the artifact. In 7 cases, artifacts were only available upon request, e.g., by sending an email or submitting an online form.

Figure 2 shows an overview of how many artifacts we were able to retrieve at least partially. Partial availability occurs when only a subset of the specified URLs is accessible and leads to the intended content. As can be seen, in total, we were able to retrieve the artifacts of 163 papers, which represents a share of 61%. As indicated in Figure 2, the share of available artifacts declines over time, i.e., papers published between 2011 and 2013 have a much lower availability rate than papers published more recently. It is still noteworthy, though, that even recent years do not have an availability rate of 100%.

We further found indication that the way artifacts are provided has an impact on availability over time. If we consider only the subset of papers whose artifacts were originally provided via well-known, third-party hosters[1], the availability rate was significantly higher: 92 out of 108 artifacts were available, a share of 85%. This indicates that artifacts hosted on university websites, private blogs, etc. are less likely to remain available.

We found the lowest availability rate for artifacts that were supposed to be available upon request, with no downloadable content whatsoever. All our requests to retrieve the 7 artifacts resulted in no response and hence complete unavailability of these artifacts.

Interestingly, 5 out of the 32 papers with badges were not available anymore, two of which received an *ACM Artifacts Available* badge, one *ISSTA Artifact Evaluated* badge, one *PLDI Artifact Evaluated* badge, and one *Artifact evaluated by FSE* badge.

Note that we have only relied on the instructions presented in the original papers. We have not conducted additional online research to find alternative ways for retrieving any artifacts in cases where we did not succeed.

**Table 2** Artifacts that contain any type of software.

| Combination of types of software | # of papers |
|---|---|
| Code-only | 40 |
| Scripts-only | 40 |
| Scripts + code | 27 |
| Scripts + code + binaries | 15 |
| Code + binaries | 12 |
| Scripts + binaries | 7 |
| Binaries-only | 4 |

**Table 3** Number of script artifacts that we were able to execute. In parentheses: subset of these artifacts that required modifications to make them executable.

| Executable | # of artifacts |
|---|---|
| No | 43 (n/a) |
| Yes | 34 (11 \| 32%) |
| Partially | 10 (7 \| 70%) |
| Skipped* | 2 (n/a) |

*due to time & effort constraints

## 4.3 RQ3: How many artifacts contain software?

We divided the types of software that may be included in an artifact into three categories: scripts, code, and binaries. We classified artifacts from the perspective of a user who wants to reuse the artifact and hence applied the following guidelines.

If an artifact contained substantial logic in any script language that represents a part of the scientific contribution of the original authors, we flagged it as an artifact that contains scripts. This does not include simple make/build scripts, setup shell scripts, etc.

Similarly, we flagged all artifacts to contain code if there is logic implemented in a compiled language, like Java or C++, that needs to be compiled and executed for reusing the artifact. If an artifact provided source code, e.g., as input files to an analysis implemented in a script, this did not qualify.

Lastly, we flagged all artifacts to contain binaries if the artifact contains a pre-compiled executable that needs to be run for reusing the artifact. If, for example, binary executables are provided merely as input to an analysis implemented in a script, we consider them input data, and did not flag this as an artifact that contains binaries.

While this is not a formal classification model, we consider it adequate to roughly describe the contents of artifacts in such a way that it prepares users who want to reuse an artifact for potential challenges.

The results of our classification are shown in Table 2. In total, 145 out of the available 163 artifacts contain software, representing a share of 89%. Code and/or scripts are contained in all artifacts but 4, while 107 artifacts do not contain binaries. A total of 80 artifacts are either code-only or scripts-only artifacts.

## 4.4 RQ4: How many scripts can be executed?

For each of the 89 artifacts that contain scripts we attempted to execute them. In cases where execution of a script as-is did not succeed, we tried to resolve any error messages, syntax errors, etc. with the goal of making it executable in the way originally intended by the authors.

Table 3 shows an overview of the results of this effort. As can be seen, we were able to execute the scripts successfully for only 34 of the 89 artifacts containing scripts, representing 38%. Only 23 of these 34 worked out of the box, the remaining 11 required modifications from us, e.g., due to syntax errors, hard-coded paths, etc. An additional 10 artifacts contained scripts that we were able to execute partially, 7 of which required modifications from our side.

**Table 4** Number of code artifacts that we were able to build. In parentheses: subset of these artifacts that required modifications to build them.

| Buildable | # of artifacts |
|---|---|
| Yes | 47 (28 \| 60%) |
| No | 44 (n/a) |
| Partially | 2 (1 \| 50%) |
| Skipped* | 1 (n/a) |

*due to time & effort constraints

**Table 5** Number of binary artifacts that we were able to execute.

| Executable | # of artifacts |
|---|---|
| Yes | 30 |
| No | 6 |
| Partially | 1 |
| Skipped* | 1 |

*due to time & effort constraints

Full execution of these scripts was not possible, e.g., because they relied on unavailable input data/third-party services, or other software in the respective artifact that did not work.

We restricted our efforts in terms of time and computational/infrastructural resources which resulted in 2 artifacts being skipped for further evaluation.

The remaining 43 artifacts contained scripts that, despite our best efforts, we were unable to execute successfully, representing 48% of the 89 artifacts that contained scripts in our set.

Out of these 43 artifacts, 8 belong to papers that received an *ACM Artifacts Evaluated Reusable* badge, as well as 1 that belongs to a paper that was awarded an *ACM Artifacts Evaluated Functional* badge. Our results do not comply with these badges. An additional 2 papers whose script artifacts we were unable to execute received an *ACM Artifacts Available* badge only, which is in line with our results, as we were able to retrieve the artifacts.

## 4.5 RQ5: How many code artifacts can be built?

In our set of 163 available artifacts, 94 contain code that needs to be compiled for reuse. We attempted this for each one of them and Table 4 shows an overview of our results.

As can be seen, we were able to build 47 code artifacts fully, and 2 additional artifacts partially. More than half of these artifacts required modifications from our side. Reasons for this include minor code errors, various issues concerning project/directory structures, hard-coded paths, dependency version mismatches, etc., as well as changes to make code artifacts compatible with more modern build tool chains.

We again skipped 1 artifact due to effort constraints, which is also one of the two artifacts we skipped in RQ4.

Out of the 44 code artifacts that we were unable to build, 5 received badges, including 3 papers that received *ACM Artifacts Evaluated Reusable* badges, and 2 papers that received an *ACM Artifacts Available* badge only.

## 4.6 RQ6: How many binaries can be executed?

A total of 38 artifacts contain binaries whose execution is required for artifact reuse. This includes native binaries, as well as pre-compiled Java code, etc. The results of our efforts to run them is shown in Table 5.

As can be seen, 30 of these binary artifacts are runnable as intended. We were able to execute 1 binary artifact only partially, because its functionality depends on input data not provided along with the artifact. One artifact that we skipped already in the two previous research questions due to effort constraints is the one artifact that we also skipped here. The

remaining 6 binary artifacts did not run without errors. They either crashed with unhandled errors, included hard-coded paths, or, in one case, relied on a third-party service no longer available.

In contrast to the previous research questions, we have not attempted to reverse engineer them, or patch them, to get them running.

Out of the 6 binary artifacts that we were unable to execute, 3 received badges. This includes 1 artifact with an *ACM Artifacts Evaluated Functional* badge, as well as 1 with an *ACM Artifacts Evaluated Reusable* badge, and 1 that received an *ACM Artifacts Available* badge only.

## 4.7 RQ7: How many artifacts are functional?

In this research question, we will investigate how many of the 145 artifacts that contain software are functional. While, at a first glance, this question may appear straightforward, we generally lack a definition of requirements that would allow us to evaluate the proper functionality of an artifact. Due to the lack of well-defined tests or metrics that we could apply, we will retreat to the most fundamental criteria that define functional software: scripts must be executed by the interpreter without error messages, binaries must be executed by the runtime/operating system without crashes or error messages, and code must be buildable and executable without crashes or error messages. We attempted this for each artifact that contains software, using basic user interactions where required, or example inputs/test cases, where provided in the artifacts. The result of this effort is:

- 41 are functional, either with or without fixes from our side
- 94 are not functional, despite our best efforts to get them running
- for 8 we cannot judge proper functionality, e.g., because they require hardware to which we have no access, or depend on commercial third-party services
- we further skipped 2 due to our effort and resource constraints

Note that an artifact can be functional, but still not be suited for reproduction, e.g., because input data is incomplete or missing. Hence, proper functionality should be considered a prerequisite for reproducibility, rather than a synonym.

## 4.8 RQ8: How many artifacts can be used to reproduce paper results?

We answer this research question in three subsequent steps, as described in the following.

### Step 1: Filter relevant papers

We first reviewed the 163 papers with available artifacts and selected those that contained evaluations with software-based experiments. In contrast, we skipped, e.g., empirical evaluations that reported on user or field studies, or tool/demo papers that presented prototypes without scientific evaluation. If a paper contained multiple evaluations and only a subset matched our criteria, we included it and focused on the relevant subset of experiments. The result of this is a set of 118 papers. Contained in this set are 24 papers with badges, including the following combinations:

- *ACM Artifacts Available* + *ACM Artifacts Evaluated Reusable*: 14 papers
- *ACM Artifacts Available* + *ACM Artifacts Evaluated Functional*: 3 papers
- *ACM Artifacts Available*: 3 papers
- *ACM Artifacts Available* + *ACM Artifacts Evaluated Functional* + *ACM Artifacts Evaluated Reusable*: 1 paper

**Figure 3** Combinations of reasons for why setups for reproducibility failed.

- *ACM Artifacts Evaluated Functional*: 1 paper
- *ACM Artifacts Evaluated Reusable*: 1 paper
- *OOPSLA Artifact Evaluated*: 1 paper

### Step 2: Setup experiments

For each of the 118 papers we proceeded by trying to set them up for evaluation.

For 11 of these 118 artifacts, we found the software required for reproduction to be missing entirely, and flagged them *incomplete* accordingly. None of these papers had received a badge.

In 104 of 118 cases, software was provided with the artifact. We skipped 2 of these artifacts because they required commercial licenses to which we had no (free) access. One of them was assigned an *ACM Artifacts Evaluated Functional* badge, the other one received an *ACM Artifacts Evaluated Reusable* badge. Further, we skipped 1 paper that required specific hardware to which we had no access. It had not been assigned a badge. For 91 of 104 artifacts, our attempt for setup failed because they were either incomplete, non-functional, or both. A total of 18 papers in this set received badges, including 13 papers with an *ACM Artifacts Evaluated Reusable* badge, 2 papers with an *ACM Artifacts Evaluated Functional* badge, and 3 with an *ACM Artifacts Available* badge only. Only the remaining 10 of these 104 artifacts resulted in usable setups, including 7 full setups, and 3 partial setups, that allow for evaluating a subset of the experiments presented by the original authors.

In addition, we also flagged 3 of the 118 artifacts as failed setups that we skipped solely due to effort constraints, none of which received a badge.

Figure 3 provides an overview of the reasons for why setups failed.

### Step 3: Run experiments & compare results

We finally executed the experiments of the 7 full setups and 3 partial setups and compared the output to what was reported in the corresponding papers.

The outcome of this is as follows:

- 3 of the 7 complete setups fully reproduced the results presented in the papers. One had received an *ACM Artifacts Evaluated Functional* badge, one paper received an *OOPSLA Artifact Evaluated* badge, and one received an *ACM Artifacts Evaluated Reusable* badge.

- 2 of the 7 complete setups only partially reproduced the results reported in the paper. One of these papers received both an *ACM Artifacts Evaluated Functional* and *ACM Artifacts Evaluated Reusable* badge. It was a performance comparison that repeatedly yielded a different outcome in our experiments as compared to the results presented in the paper, a type of measurement notoriously hard to reproduce on different hardware. The other paper had not received any badges.
- 2 of the 7 complete setups failed entirely to reproduce the results in the papers. Note, however, that this includes one artifact that contains a proof-of-concept app that is supposed to showcase a critical bug in the Android operating system [1], i.e., a pass-or-fail experiment. The authors indicated, to the best of their knowledge, which versions of Android were affected, and we spent our best effort to retrieve a phone whose outdated Android version we assumed would be suitable for the experiment. Despite this effort, reproduction did not succeed. The Android versions on the phones used by the original authors were different, though, so it is likely that, on another phone, reproduction would have worked. Unfortunately, we were unable to find a phone whose operating system version matched exactly. Both papers were no assigned any badges.
- the 3 partial setups only partially reproduced the expected results, due to their incompleteness. They had not been assigned any badges.

The 8 papers whose artifacts allowed for at least partial reproduction were published between 2014 and 2025, and there is no correlation between age and reproducibility in our dataset.

## 5 Discussion

We acknowledge that we evaluated a set of artifacts with regard to reproducibility that, in many cases, may have never been designed for that purpose. However, we cannot limit ourselves to reproducible artifacts only. In many cases, the original authors do not state what purpose their artifact is supposed to serve. Even artifacts that are referred to as "replication package" by their original authors [21] do not necessarily allow for reproduction.

Further, we flagged artifacts as incomplete from the perspective of researchers attempting to reuse them for reproduction. Authors may see this differently, having deliberately provided artifacts not intended for this purpose.

There may be various reasons for why this was the case. For example, legal reasons, including licensing issues, copyright laws, export restrictions, and so forth may have prevented authors from publishing parts of their code or data [41]. This is a well-known problem and it is unclear how the scientific community wants to deal with this in the long term.

Another important issue is that we also flagged attempts to set up experiments as failed in cases where we skipped the evaluation due to effort constraints, missing hardware, or the requirement to order a commercial license. We deliberately chose this way of presenting our results because these are the same issues that other researchers may encounter in their own efforts to reuse a given artifact. To a certain degree, at least, the authors of artifacts can influence how much effort is required for setup, and what the hardware or license requirements are.

## 6 Limitations and threats to validity

There are various aspects that limit the generalizability of our results. Most importantly, our dataset is limited to the contents of the ACM Digital Library (2011-2017) and ICSE publications (2018-2025). Although this is still a comprehensive set of papers, there are

other publishers and venues that may have a different publication culture, different standards and procedures when it comes to artifact publication, evaluation, and a generally different approach to address the topic of reproducibility.

We further reduced this limited dataset to papers related to Android, which again reduces the generalizability of our results to other areas of research.

Besides, there are various threats to the validity of our results. Foremost, our evaluation involved significant manual labor. Although supported by tools, we ultimately made the decisions about which papers to include or exclude from our evaluation. The entire assessment was a manual undertaking, involving hundreds of hours of researcher time. Our inability to get certain artifacts running could stem from our own lack of expertise, improperly configured test machines, misunderstood instructions, or other human errors. Another team of researchers may hence achieve different results with the same set of artifacts.

To address these factors, we left comments in our set of results that we provide as artifact to this paper. There we state for individual cases, e.g., why our setup attempt failed.

Another threat is the lack of blinding for papers and artifacts, requiring us to address potential conflicts of interest. Wherever possible, we delegated evaluation tasks to staff with no relations to the respective authors. Further, decisions, e.g., which papers to include or exclude, were group decisions. We also did not communicate our evaluation efforts outside our research group, and we have not reached out to any of the artifacts' authors for support. We can thus reasonably assume that we treated each artifact under comparable conditions.

# 7 Recommendations

Our study shows that, despite the introduction of artifact evaluation processes, reproducibility is rare. In this section, we hence provide recommendations that are supposed to increase the perceived value of artifacts, and improve their quality, availability, and visibility.

## 7.1 Artifacts should be archived

Out of our original set of 269 selected papers, we found that only 61% of these papers had their artifacts still available. As we explained, none of the artifacts that were supposed to be available upon request were still retrievable for us. Also, as we showed, artifacts were more likely to remain available when provided via third-party repository hosters. Moreover, there are artifacts that have been revised post-publication, which may make it harder to identify which version was used to generate the research results presented in the original publication to which they belong. For version controlled repositories, this may be possible with extra effort, for artifacts provided without version information, there is uncertainty.

All this makes clear that there is a difference between *availability* and *archiving*. In our view, properly archived artifacts are (a) preserved over time and made available by a time-stable organization, and (b) version-controlled in a way that makes it easy to see which version belongs to the paper.

If an artifact evaluation committee does not account for these aspects when awarding availability badges, the badge largely reduces to confirming the artifact's existence at the time of publication, providing less support for the community than would be desired.

## 7.2 Artifact evaluation should be mandatory

While artifact evaluation processes have been established at many conferences, they typically remain optional for authors [32, 39, 34]. As a result, authors may claim to provide an artifact without mandatory, independent quality control.

Ironically, this contradicts long-standing consensus on software engineering and deployment. One might argue that authors and their institutions are responsible for quality control, but how can a paper be considered *peer-reviewed* if a key part of its contribution has not undergone comparable evaluation? The many fundamental issues in the artifacts we reviewed, including syntax errors, hard-coded paths, improper directory structures, missing configuration files, and so forth reveal a lack of thoroughness in individual cases.

We thus argue that artifact evaluation should be mandatory whenever authors state they provide an artifact. Treating the paper and artifact as one unit – the full contribution – highlights the artifact's value and may be a key step in addressing the reproducibility crisis.

## 7.3 Artifacts should be formally classified

It is difficult to argue about any properties of an artifact when the authors do not clearly state what kind of an artifact they intend to provide, and what its use cases are. Prior work has shown that insufficient documentation hinders reviewers and reuse of artifacts [41]. Ideally, artifacts should be provided with structured metadata that document (a) the type of artifact: measurement data (raw, processed), documentation, software (scripts, code, binaries), machine learning models (weights, checkpoints, ...), questionnaires, ..., (b) URL for download, (c) use case (reuse, reproduction, ...), (d) steps for reuse and reproduction.

Based on this information, artifacts could be evaluated with quality metrics that match their individual types. Further, structured metadata would allow automated processing and search, which could increase the visibility of artifacts in digital libraries.

## 7.4 Artifacts should be self-contained

In several cases, we found artifacts that were not functional, or not usable for reproduction, because they depend on code or data provided by a third party, which is no longer available. In other words, the artifacts were not self-contained, and their usefulness was reduced due to factors outside the control of their authors. We acknowledge that there are cases where this is unavoidable, however, in other cases, such a dependency on external code or data may only be introduced due to a lack of awareness by the original authors. We hence encourage authors to critically evaluate whether their artifact can be made self-contained, and also propose to make this a quality check during artifact evaluation.

## 7.5 Artifacts should not rely on commercial solutions

Several of the 118 artifacts that we attempted to setup for reproduction required a commercial license for a third-party service. Clearly, such a requirement limits the reusability of an artifact and is at odds with the idea of *open research*. While we acknowledge that there are cases where dependence on a commercial third-party service may be unavoidable, we, as a community, should make sure that this only occurs in cases where there is good justification.

One example that we observe more frequently over time is the use of commercial providers of large language models. We encourage authors to evaluate open-source alternatives and provide the results as part of their studies in cases where they decide to use commercial products instead. Artifact evaluators should pay attention to this matter and request justification in cases where the use of commercial services is not properly motivated.

This recommendation is supposed to support the ideal of open research, making research output more accessible, and back up the open-source community.

## 7.6 Reproducibility should be a fully automated process

We spent a significant amount of manual effort into our evaluation of artifacts, and a large share of this effort went into tasks one might consider *overhead*: getting familiar with the contents and structure of the artifact, configuring our test environment, retrieving code and data dependencies, sanity and compatibility checks, fixing issues, and so forth. In a narrower sense, none of this is dealing with the scientific contribution of the original authors, but rather boilerplate tasks that need to be done as a prerequisite for evaluation and reuse.

We acknowledge that overhead can never be fully eliminated and that achievable reductions depend on the specific case. However, our experience was that in too many cases, the effort was unnecessarily high. We argue that artifacts should aim for maximal automation, ideally as one-click solutions that automatically execute all reproduction steps.

Since the beginning of the timeframe we considered, in 2011, technology has advanced, rendering this proposal more realistic today than it was almost 15 years ago. Now it is possible for authors to provide pre-populated containers or virtual machines that are ready for use, thus sparing other researchers and evaluation committees from additional efforts.

In fact, properly automated artifacts would potentially be suited for fully automated evaluation by an AI-based evaluation system, a task that currently fails due to various practical limitations [20].

## 7.7 Establish uniform standards

The fact that ACM has developed a unified framework of badges is an important step for artifact evaluation processes in the research community. However, this framework leaves fundamental aspects of artifact evaluation underspecified, which has the advantage that conference organizers can make individually appropriate decisions, while still being in line with the framework. As stated by ACM, they also consider it "too early to establish more specific guidelines for artifact and replicability review" [12] due to the lack of established consensus regarding artifact submission and evaluation. While we generally agree with this point of view, we think it is possible to take a more differentiated standpoint today than in 2020 when ACM made this last update. For example, this study presents indication that artifacts are more likely to remain available over time if they are deployed via suitable third-party hosters. Therefore, this should be a mandatory requirement across all venues.

Another rule should be that the artifact evaluation committees review artifacts under the same conditions that would apply to any other independent researcher. Specifically, the current badge framework explicitly allows that evaluators interact with artifact authors during evaluation. However, this is often not possible for researchers who, potentially years after the original publication, want to reuse the artifact. The more different the conditions are between evaluators at conferences and researchers in the field, the less meaningful is the badge awarded by the committee. These differences may explain why some of our experimental results were not in line with badges that had been awarded to the respective papers in our dataset. We thus argue that also this should be restricted by the badge framework.

## 7.8 Award comprehensive certificates

Currently, papers that pass artifact evaluation receive one or more badges, represented as icons on the title page of the publication. Unfortunately, due to an underspecified badge framework and the lack of standards, it is hard to judge post-publication as an outsider what the requirements and conditions of artifact evaluation were for any given paper. The original call for artifacts may not be available anymore several years after publication, and even if it

is, it may be sufficiently underspecified as well. In our dataset, we even encountered two papers that had badge icons on their title pages, but due to their visual representation, we were unable to tell with certainty what kind of badges they were.

One way to address this would be to award comprehensive certificates, rather than badges that are only indicated by icons on the title page. These certificates could contain detailed information about the evaluation process, requirements for submission, and which quality metrics were applied. They could also more elaborately state what the outcome of the evaluation was. Such a certificate could, e.g., be attached as a final page to the paper to which it belongs. This general idea can also be found in the current ACM badge framework: "[...] badges included in PDFs and in ACM Digital Library metadata should be linked to a brief explanation of the particular review process which led to the awarding of the badge" [12].

### 7.9 Highlight outstanding work

It is reasonable to assume that positive visibility may increase researchers' motivation to submit high-quality artifacts and participate in evaluation processes. While, over the past years, conference venues have applied changes that certainly improve visibility of artifacts, which includes the entire system of artifact evaluation processes and badges, there may be more that can be done to highlight the importance of artifacts. Ideas may be:

- dedicated artifact tracks with (live) presentations
- hands-on demonstration areas outside of rooms where sessions are held
- public advertising of artifacts, e.g., via social media accounts
- awards for "best artifact" and "best artifact evaluator"
- retrospective evaluations of artifacts and awards for longevity

This is not a comprehensive list, but it should illustrate that the space of opportunities is not yet fully exhausted today when it comes to maximizing the visibility of artifacts. Since this recommendation is not directly based on our data, we hope that future empirical studies will provide more insight into how such efforts may affect artifacts' quality and availability.

### 7.10 Incentivize reproduction and replication work

Although the ACM badge framework includes badges for reproduction and replication, none of the papers in our dataset carried them. Also, outside the context of our study, we do not find it a common practice in computer science research to publish confirmatory research. This is striking when one considers that the majority of researchers assume that we have a reproducibility crisis [3]. We thus argue that it is about time to prominently incentivize confirmatory research that reproduces or replicates previously published results. While having dedicated venues would be an option, as well as dedicated tracks at already established venues, it would already be a starting point to explicitly invite such work in future calls for papers. Examples for ongoing efforts include the dedicated track on Reproducibility and Negative Results at EASE 2026 [29], or the track on Replication and Negative Results at ICSME 2026 [18].

## 8 Conclusion

Prototype implementations underpin many computer science papers by demonstrating novel concepts or generating evaluation data. An increasing number of venues encourage authors to publish code and datasets as supplementary material, and further established artifact evaluation processes. However, prior work suggests that many artifacts may not be suitable for reuse and reproduction, exacerbating an already existing reproducibility crisis.

To shed more light on this, we studied 269 Android-related papers and their artifacts. We found only 163 of these artifacts to be available, and successfully reproduced the expected results for only 8 of them, including partial reproductions. In summary, our study shows that reproducibility remains rare: many papers cannot be independently evaluated, and only a small subset of artifacts are available, functional, and complete. Based on our experience, we provide recommendations for authors and evaluation committees that aim to strengthen the perceived value of artifacts, and to improve their availability, quality, and visibility.

## Data Availability Statement

This study was conducted using both non-public proprietary data and data that is publicly available yet copyrighted. We used metadata about scientific publications, the publications themselves and also data and software artifacts that were referenced in the publications but hosted on third-party websites and repositories.

Metadata and paper contents up until 2017 were obtained from a proprietary dataset from the ACM, which we were allowed to use but not republish in its raw form. Metadata and paper contents for later papers were collected manually from the preceedings of ICSE and downloaded from the websites of the respective publishers via our institutional accounts.

We used the papers' abstracts and full text to classify whether they might be related to Android research. While we cannot share these contents themselves due to copyright, we make available references – including DOIs or URLs – to all included papers in our artifact. Our methodology in Section 3 describes how our work could be replicated using other datasets.

Each of the included papers contains one or more references to research artifacts that we evaluated in our study. The investigated software and data artifacts were published by the authors on a variety of platforms, often lacking license information, deeming them unsuitable for inclusion in our artifact. However, in our artifact, we provide the list of URLs that we used to obtain the respective artifacts.

We make the full set of results of our evaluation efforts available both in PDF and CSV file formats at `https://doi.org/10.6084/m9.figshare.33256998`.

## Abstract

**Background.** Agent systems increasingly invoke heterogeneous third-party services through the Model Context Protocol (MCP), where service licenses, model licenses, and data licenses may be jointly applied during runtime execution. This emerging execution paradigm introduces cross-service compliance conflicts that are difficult to capture with conventional license analysis methods. Existing methods usually assume that the license set under analysis is statically predetermined, making them insufficient for handling novel term semantics in MCP licenses and for analyzing conflict patterns that arise from task-specific selected service subsets.

**Aims.** This paper investigates compositional license conflicts in MCP-based agent workflows. We seek to characterize how license terms interact across compositional MCP services and to provide an automated analysis framework that detects conflicts and identifies license-compatible service replacements.

**Method.** We propose MCP-Licentra, a license conflict analysis framework for MCP-based agent workflows. MCP-Licentra contains four integrated components. First, it extends an existing license term taxonomy with MCP-specific categories and constructs annotated training data for domain adaptation. Second, it fine-tunes License-Llama3-8B with supervised fine-tuning (SFT) and odds ratio preference optimization (ORPO) to recognize license terms and their associated attitudes. Third, it formulates task-specific service selection as a power-set legality verification problem, enabling conflict checking across possible service invocation subsets. Fourth, it recommends license-compatible replacements for conflicting services through semantic embedding retrieval and an iterative compliance checking algorithm under joint functional similarity and license compatibility constraints.

**Results.** We evaluate MCP-Licentra on 3,811 real-world MCP services and 500 compositional service scenarios. MCP-Licentra achieves F1-scores of 88.82% and 86.44% for term identification and license understanding, respectively. For group-level conflict detection, it obtains an FPR of 3.15% and an FNR of 8.77%. For compositional conflict detection, it achieves an overall FPR of 4.90% and an FNR of 3.33%. In addition, MCP-Licentra reaches a resolution success rate of 71.23%, outperforming all baselines.

**Conclusion.** The results show that MCP-based agent workflows introduce compositional compliance risks that are difficult to capture with conventional static license analysis. MCP-Licentra provides an automated framework and empirical evidence for detecting and mitigating such risks in agent systems.

## 1 Introduction

As artificial intelligence technology advances rapidly, agents that invoke multimodal tools and external services to accomplish complex tasks have become a prominent paradigm in large language model (LLM) applications. In this context, the MCP has been proposed as a standardized interaction mechanism for connecting models with external capabilities [16, 37]. MCP provides agents with a standardized interface for accessing external services, enabling them to compose and invoke tool services from diverse providers according to task requirements [12, 37]. These MCP services typically encompass a wide range of functional scenarios, including file processing, database access, and code execution [7, 17]. However, the code components, foundation models, and data resources associated with such services are often governed by distinct licenses or terms of use, exhibiting considerable diversity in licensing origins and heterogeneity in constraint specifications [35]. For instance, a service repository may be released under an open-source license such as MIT or Apache-2.0, the underlying model may carry usage restrictions such as RAIL, and the associated data resources may impose additional constraints regarding commercial use, redistribution, or access conditions. As agents compose and invoke multiple services within a single workflow, incompatibilities among different license terms pertaining to output attribution, derivative work classification, and automated access permissions may give rise to license conflicts, leading to distribution violations and restrictions on commercial deployment.

Prior research has produced a series of approaches to license conflict analysis. Early work focused on automated license identification and extraction. Kapitsaki et al. [18] formalize license terms using SPDX structured information for compatibility checking in package composition scenarios. Liu et al. [22] extend compatibility verification to complex dependency structures by propagating license constraints over dependency graphs. With advances in natural language processing, subsequent studies shifted toward semantic understanding of license terms. Xu et al. [42] propose LiDetector, which applies machine learning to identify key license terms through syntactic parsing and semantic feature extraction, inferring encoded rights and obligations to detect conflicts. Building on this, Xu et al. further propose LiResolver [41], which refines term identification and license extraction while supporting license recommendation and customized generation for compliance resolution. Cui et al. [5] propose DIKE, which automates license term extraction and conflict detection via NLP, revealing widespread license conflicts in popular GitHub projects. Their follow-up work [4] further leverages LLMs to improve detection accuracy in complex real-world scenarios.

Although prior studies advance license conflict detection for static software compositions, their direct application to MCP workflows faces several limitations. First, existing methods largely rely on traditional license datasets such as SPDX, providing limited coverage of

*Corresponding author

emerging AI-specific licensing constraints. As a result, they fail to capture conflicts involving output ownership, automated access, or user profiling inference. Second, they typically assume a static, predetermined license set and determine whether a given composition is conflicting, which is insufficient for analyzing conflicts across different service subsets in MCP workflows. Third, existing mitigation strategies mainly rely on license replacement or relicensing. In MCP settings, however, service licenses are usually predefined by third-party providers and cannot be changed by end users. A more practical direction is to retrieve functionally equivalent alternative services under license compatibility constraints, while this problem remains underexplored.

To address these challenges, we propose MCP-Licentra, a license conflict analysis framework for MCP-based agent workflows. MCP-Licentra fine-tunes License-Llama3-8B for domain adaptation by extending the existing license term taxonomy and constructing annotated training data; formalizes agent service selection as a power set legality verification problem to systematically detect conflicts across all possible service invocation subsets; and recommends license-compatible replacement services through semantic embedding retrieval and an Iterative Compliance Checking (ICC) algorithm. Experiments on 3,811 real-world MCP services and 500 combination scenarios demonstrate that MCP-Licentra consistently outperforms all baseline methods across four tasks, including term identification, license understanding, compositional conflict detection, and conflict resolution. The main contributions of this paper are as follows:
(1) We formalize license conflicts in MCP-based agent workflows as a power set legality verification problem over candidate service subsets, identifying three fundamental challenges absent from conventional static license analysis.
(2) We propose MCP-Licentra, a framework for license term understanding and compositional conflict analysis. It combines a domain-adapted license understanding model with extended term coverage, a power-set-based conflict detection mechanism, and an ICC algorithm for resolving conflicts under functional similarity and license compatibility constraints.
(3) We construct two evaluation datasets, LUD and MCDD, for MCP license conflict analysis. Experiments on 3,811 MCP services and 500 combination scenarios demonstrate that MCP-Licentra achieves F1-scores of 88.82% and 86.44%, FPR of 4.90%, FNR of 3.33%, and RSR of 71.23%, outperforming all baselines.

## 2 Background

### 2.1 MCP Services

The MCP is an open protocol that standardizes interactions between LLMs and external services, enabling unified compositional invocation without custom interfaces [30]. Through standardized service descriptions and invocation mechanisms, MCP allows agents to access registered services for task execution and capability extension [14]. However, the rapid expansion of the MCP ecosystem introduces services from diverse maintainers into shared workflows, inevitably bringing heterogeneous license constraints. Multi-service compositions may yield license incompatibilities regarding distribution, derivative work obligations, or usage restrictions, posing legal risks [13, 24]. Such conflicts typically remain latent at the individual service level and emerge only when multiple services are combined within an agent workflow, leading to more complex compliance analysis.

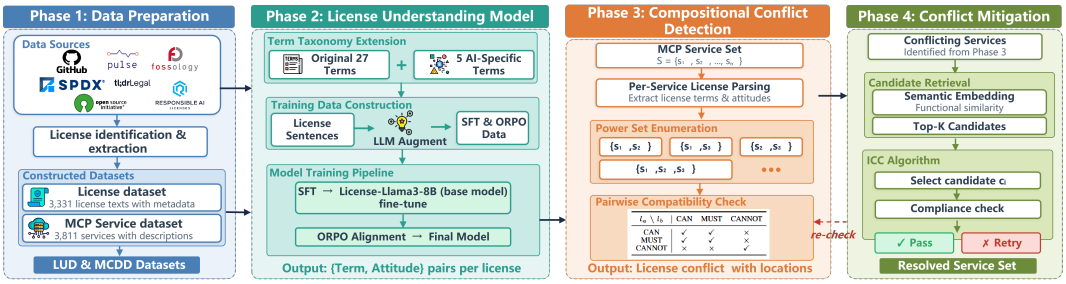

**Figure 1** Overview of the MCP-Licentra framework for compositional license conflict analysis in MCP-based agent workflows.

## 2.2 Open source licenses and license conflicts

Open source licenses are legal instruments that govern the use, reproduction, modification, and distribution of software, defining permissible and prohibited behaviors through specific terms to protect developer rights and promote collaborative development [38]. A license conflict arises when multiple licenses within a project impose mutually contradictory terms, making simultaneous compliance infeasible. For instance, a component license may stipulate "CANNOT sublicense" while the project license requires "CAN sublicense"; similarly, one component may mandate "MUST contact the author" while another specifies "CANNOT contact the author", inevitably violating at least one license [9].

# 3 Methodology

## 3.1 overview

This section presents MCP-Licentra, a compositional license conflict detection framework for MCP-based agent workflows. As shown in Figure 1, the framework includes four components.

## 3.2 Data preparation

This section describes the data collection and preprocessing pipeline for MCP services and license, which provides the foundation for subsequent model training and conflict analysis.

### 3.2.1 Data collection

▶ **MCP service collection.** We collect metadata for 3,821 MCP services from the pulseMCP platform [30], including natural language descriptions, functional summaries, usage examples, and GitHub repository links. After excluding 10 services without valid repository URLs, 3,811 samples are retained. All repositories are cloned locally and preprocessed uniformly, including binary artifact removal, directory encoding standardization, and metadata index construction. The resulting dataset preserves both service descriptions and full source structures, serving as the data foundation for license extraction and conflict analysis.

▶ **License collection.** We collect 3,331 open source licenses from authoritative sources. Among them, 3,324 conventional licenses are drawn from SPDX [39], OSI [25], TLDRLegal [40], and FOSSology [8], while seven AI-specific licenses are obtained from the Responsible AI Licenses (RAIL) project [36]. These AI-specific licenses cover constraints rarely captured

**Table 1** Extended license term taxonomy.

| No. | Term | Explanation |
|---|---|---|
| 1 | User Owns Model Output | User owns model output; licensor claims no rights; user is responsible for its use |
| 2 | User Content Rights | Grant of rights to use, modify, distribute, and display user content |
| 3 | AI Output Attribution | Clear identification of AI-generated content |
| 4 | Automated Access Limitation | Prohibit excessive automated access via bots or crawlers |
| 5 | Predictive User Profiling | Infer characteristics related to insurance risk, health, criminal behavior, identity, or biometrics from personal data |

by conventional license datasets, such as model outputs, data usage, and automated access. Each entry includes a standardized SPDX identifier, license name, version information, and complete legal text. We further build a cross-platform alias mapping to reduce naming inconsistencies, followed by text normalization and deduplication. The resulting dataset provides a structured basis for license identification and conflict analysis.

### 3.2.2 Training data construction

License-Llama3-8B [4] is an instruction-tuned model built on the Llama3 architecture and optimized for license understanding, with strong capabilities in recognizing open source license terminology, term attitudes, and rights obligation structures. However, its term and attitude recognition covers only 27 traditional open source license term categories, providing no support for the novel constraint types introduced by AI-specific licenses. To address this limitation, MCP-Licentra extends the existing term taxonomy with supplementary categories.

We collect the official texts of 7 RAIL-series licenses and apply NLTK [3] sentence segmentation, obtaining 1,169 candidate sentences. Manual filtering retains 689 sentences that express explicit rights or obligation constraints. Semantic analysis of these sentences reveals that a substantial portion encodes constraint types not representable by the existing term taxonomy, including model output ownership, AI-generated content attribution obligations, automated access limitations, and AI-based inference of sensitive personal characteristics.

We further remove two types of unsuitable sentences: ethical recommendations without clear permissive or restrictive attitudes, such as “prevent generating false information to harm others through AI outputs”, and broad statements that cannot be mapped to well-bounded terms, such as “ensure transparency in automated decisions affecting legal rights”. Two researchers experienced in license analysis independently conduct the filtering and achieve high agreement, with a Cohen’s Kappa of 0.95. Disagreements are resolved through discussion or removed. This process retains 365 sentences with clear semantic boundaries, grouped into 5 supplementary term categories and annotated with CAN, MUST, or CANNOT attitudes. Table 1 provides their definitions. To enable License-Llama3-8B to recognize the 5 supplementary term categories and their associated attitudes, we construct supplementary training data by generating semantically equivalent paraphrases from the 365 seed sentences using Qwen3 [44]. For each seed sentence, the corresponding term definition, attitude label, and sentence text are organized into a structured prompt, which is submitted to Qwen3 to generate 10 paraphrases that preserve the original term semantics and attitude while varying in phrasing, sentence structure, and expression angle. The prompt template is shown below.

**### OBJECTIVE**
The following is a dict consisting of license terms, term attitudes, and an official term description. You need the terms and attitude in this dict to write 10 additional term descriptions that are different from the official term descriptions.
**### DICT CONTENT**
{ "terms": {terms_definition}, "attitudes": {attitudes_definition}, "terms_description": "(b) You must give any Third Party recipients of the Model or Derivatives of the Model a copy of this License;" }
**### RESPONSE FORMAT**
Output a JSON list of dicts, each containing keys: terms, attitudes, and terms_description. The generated descriptions must conform to the given terms and attitudes.

The definitions and attitude labels of the 5 supplementary terms are inserted into {terms_definition} and {attitudes_definition} respectively, while one seed sentence is placed in {terms_description}. The prompt is submitted to Qwen3, which returns a JSON list of paraphrased descriptions. The first three entries of an example response are shown below.

**JSON Output Example**
[{"terms": "Provide a copy of this license for the derivative products of the model", "attitudes": "MUST", "terms_description": "A copy of this license must be included with any distribution of the model's derivatives."},
{"terms": "...", "attitudes": "MUST", "terms_description": "You are required to supply this license alongside any derivative works derived from the model."},
{"terms": "...", "attitudes": "MUST", "terms_description": "Whenever distributing a derivative of the model, this license must be provided to all recipients."}, · · · ]

Qwen3 generates 10 paraphrases per seed sentence, producing 3,650 candidate samples. Two researchers experienced in software license analysis independently screen the candidates to ensure that each sentence maps to a specific supplementary term category, preserves the original constraint semantics, introduces no new rights or obligations, and keeps the same attitude label as the seed. Disagreements are resolved through discussion, and unresolved entries are discarded. The filtering retains 3,212 valid sentences, which are combined with the 365 seed sentences to form a 3,577-sample supplementary term dataset. We split the dataset into training, validation, and test datasets at a 7:1:2 ratio, resulting in 2,504, 358, and 715 samples, respectively.

## 3.3 MCP license understanding model

This section presents the domain adaptation training of License-Llama3-8B for term category and attitude recognition across traditional and AI-specific licenses, supporting subsequent conflict detection and mitigation.

### 3.3.1 SFT: term and attitude recognition

Following the construction of the supplementary term taxonomy and the preparation of training data, we apply SFT [21] to adapt License-Llama3-8B for accurate recognition of the extended term categories and their associated attitudes. The 2,504 training samples obtained in Section 3.2.2 are formatted using the following prompt:

**### OBJECTIVE**
Identify the terms and corresponding attitudes contained in the given license text based on the definition of license terms and attitudes.
**### DEFINITIONS**
Terms: {terms_definition}; Attitudes: {attitudes_definition}
**### LICENSE TEXT**
"You may convey modified covered source (...) provided that you: a) retain notices as required in subsection 3.2; and b) add a notice to the modified covered source stating that you have modified it, with the date and brief description of how you have modified it."
**### RESPONSE FORMAT**
Output JSON key-value pairs, where the key is the term name and the value is the corresponding attitude name.

In the prompt, {terms_definition} and {attitudes_definition} are populated with the supplementary term definitions and attitude labels respectively, while the LICENSE TEXT field is filled with the corresponding license description. The expected response is constructed by inserting the ground-truth term-attitude mappings into the response template, forming supervised input-output pairs for fine-tuning.

**JSON Output Example**
After analyzing the license text, I've identified the following terms and attitudes:
{"Modify": "CAN", "State Changes": "MUST", "Include Notice": "MUST"}

To reduce catastrophic forgetting of the original 27 term categories, SFT jointly uses the 2,504 supplementary training samples and the original License-Llama3-8B dataset. The original 19,883 samples are split at a 7:1:2 ratio, with 12,726 samples used for training. Following Li et al. [20], we adopt re-balanced sampling, where 80% of each mini-batch comes from the supplementary dataset and 20% from the original dataset. This increases exposure to new term semantics while preserving traditional term recognition. The SFT objective maximizes the conditional log-likelihood of the reference response.

$$\log P_\theta(y \mid x) = \frac{1}{M} \sum_{t=1}^{M} \log P_\theta(y_t \mid x, y_{<t}) \tag{1}$$

Here, $x$ is the tokenized input prompt, $y = (y_1, \ldots, y_M)$ is the tokenized output sequence, $y_t$ is the $t$-th output token, $y_{<t}$ denotes the preceding tokens, $P_\theta(y_t \mid x, y_{<t})$ is the probability of $y_t$ under model $\theta$, and $M$ is the output length. Through SFT training, the model establishes a stable mapping from license text to term-attitude pairs within a unified term space, preserving recognition performance on the original 27 term categories while substantially improving generalization to the 5 supplementary term categories.

### 3.3.2 ORPO: output consistency and hallucination reduction

Although SFT equips the model with term-to-attitude mapping capabilities, likelihood maximization alone may lead to output instability, attitude prediction bias, and hallucinations in complex license contexts. To address this issue, we apply ORPO-based preference alignment after SFT to strengthen the model's preference toward correct term-attitude combinations and suppress hallucination tendencies [15]. For each supplementary term training sample, we construct a preference pair consisting of a chosen response $y_w$ and a rejected response $y_l$. The chosen response corresponds to the accurate term-attitude combination determined by human annotation or rule-based verification, while the rejected response is obtained by randomly perturbing attitude labels or mismatching term names. The SFT-trained License-Llama3-8B is then further fine-tuned with the ORPO objective $L_{\text{ORPO}} = L_{\text{SFT}} + \lambda L_{\text{OR}}$, where $L_{\text{SFT}} = -\frac{1}{M}\sum_{t=1}^{M} \log P_\theta(y_t \mid x, y_{<t})$ denotes the negative log-likelihood loss, consistent with the SFT objective, and $\lambda$ is a weighting factor. The odds ratio loss is defined as $L_{\text{OR}} = -\log \sigma\left(\log \frac{\text{odds}_\theta(y_w|x)}{\text{odds}_\theta(y_l|x)}\right)$, where $\text{odds}_\theta(y \mid x) = \frac{P_\theta(y|x)}{1-P_\theta(y|x)}$ and $P_\theta(y \mid x)$ denotes the sequence-level generation likelihood. By increasing the relative preference for $y_w$ over $y_l$, $L_{\text{ORPO}}$ improves the model's sensitivity to term attitude polarity and reduces misclassification risk in conflict detection.

Here, $L_{\text{SFT}}$ denotes the negative log-likelihood loss, which is consistent with the objective used in the SFT stage, and $\lambda$ is a weighting factor. $L_{\text{OR}}$ denotes the odds ratio loss, where the odds function is defined as $\text{odds}_\theta(y \mid x) = \frac{P_\theta(y|x)}{1-P_\theta(y|x)}$, and $P_\theta(y \mid x)$ denotes the sequence-level generation likelihood. $L_{\text{ORPO}}$ encourages a higher probability for $y_w$ and a lower probability for $y_l$, improving the model's sensitivity to term attitude polarity and reducing misclassification risk in conflict detection.

## 3.4 Compositional license conflict detection

### 3.4.1 License extraction

MCP-Licentra builds on ScanCode's [1] rule-matching framework and extends its rule set to support AI-specific license detection. ScanCode's matching mechanism relies on token subsequence matching, which requires exact matches between key tokens in license texts and standard sentences in the rule base. However, AI-specific license terms often appear in project documentation as paraphrased expressions or non-standard license statements, causing the native matching mechanism to miss licenses such as those in the RAIL series. To address this limitation, MCP-Licentra preserves the original rule base and introduces a fuzzy matching strategy based on semantic similarity, using the 365 seed term descriptions from Section 3.2.2 as supplementary rules. Each rule text $\text{rule}_i$ is first normalized and then tokenized into $R_i = \text{tokenize}(\text{normalize}(\text{rule}_i)) = [r_{i1}, r_{i2}, \ldots, r_{ik_i}]$, where $R_i$ denotes the token sequence of the $i$-th rule, $r_{ij}$ denotes its $j$-th token, and $k_i$ denotes the sequence length. These sequences form an extended rule base $\mathcal{R} = \{R_1, R_2, \ldots, R_m\}$, where $m = 365$.

The target document text is processed identically to obtain token sequence $T = [t_1, t_2, \ldots, t_n]$. A sliding window of length $|R_i|$ is applied over $T$, and for each subsequence $W$ the weighted similarity with rule $R_i$ is computed as:

$$\text{Sim}(R_i, W) = \alpha_0 \cdot \text{Sim}_{\text{Jaccard}}(R_i, W) + \alpha_1 \cdot \text{Sim}_{\text{Cosine}}(R_i, W) \tag{2}$$

where $\text{Sim}_{\text{Jaccard}}(R_i, W) = \frac{|R_i \cap W|}{|R_i \cup W|}$, $\text{Sim}_{\text{Cosine}}(R_i, W) = \frac{\sum_j f_{R_i}(r_j) \cdot f_W(r_j)}{\|f_{R_i}\| \cdot \|f_W\|}$, $f_{R_i}(r_j)$ and $f_W(r_j)$ denote the term frequencies of token $r_j$ in $R_i$ and $W$ respectively, and $\alpha_0$, $\alpha_1$ are weighting coefficients satisfying $\alpha_0 + \alpha_1 = 1$. A rule $R_i$ is considered matched in the document if $\max_W \text{Sim}(R_i, W) \geq \gamma$, where $\gamma$ is the similarity threshold. The extended rules are integrated into the ScanCode detection pipeline alongside the rule base, preserving coverage of traditional open-source licenses while closing the detection gap for AI-specific license declarations.

### 3.4.2 Compositional license conflict detection

Existing license conflict detection methods typically rely on pairwise compatibility checks over predefined licenses. MCP-based agent workflows, however, involve multiple selected services whose joint license constraints may introduce conflicts beyond individual pairs. Pairwise analysis therefore provides limited coverage for multi-service interactions. MCP-Licentra instead formulates conflict detection as legality verification over service subsets. Because invocation order does not affect the resulting license combination, each workflow configuration is represented as a subset of selected MCP services and verified independently, enabling systematic coverage of all license combinations.

In an MCP-based agent workflow, a user selects a base language model and a set of MCP services. The licenses associated with the base model form the Model License set $ML = [ML_1, ML_2, \ldots, ML_k]$, and the licenses associated with the $i$-th MCP service form the Server License set $SL_i = [SL_{i1}, SL_{i2}, \ldots, SL_{ik_i}]$. The selected MCP service set is denoted as $S = \{S_1, S_2, \ldots, S_m\}$, where $m$ denotes the number of services included in the workflow configuration. The non-empty power set of $S$ contains $2^m - 1$ subsets. This design restricts detection to the selected services and avoids checking unrelated services in the MCP registry.

Since service invocation order does not affect license combinations, all activated service subsets within the selected MCP service set can be represented as the non-empty subsets of $S$, denoted as $C = \mathcal{P}(S) \setminus \{\emptyset\}$. For any service combination $S' = \{S_{i_1}, S_{i_2}, \ldots, S_{i_n}\} \subseteq S$, the combined license set is defined as $\text{CLS}(S') = ML \cup \bigcup_{j=1}^{n} SL_{i_j}$.

**Table 2** Conflict detection between $l_a$ and $l_b$.

| $l_a \setminus l_b$ | CAN | MUST | CANNOT |
|---|---|---|---|
| CAN | ✓ | ✓ | × |
| MUST | ✓ | ✓ | × |
| CANNOT | × | × | ✓ |

To determine pairwise license compatibility within a combination, we define a compatibility relation over the three term attitudes CAN, MUST, and CANNOT. A conflict arises when one license expresses CAN or MUST on a term while another expresses CANNOT on the same term; all other attitude pairs are considered compatible, as summarized in Table 2. The conflict detection function is defined as:

$$\text{Conflict}(\text{CLS}(S')) = \begin{cases} 1 & \text{if } \exists\,(l_a, l_b) \in \text{CLS}(S') \times \text{CLS}(S'),\ l_a \not\sim l_b \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

where $l_a \not\sim l_b$ denotes a term-level conflict between licenses $l_a$ and $l_b$. MCP-Licentra enumerates all subsets in $C$ and partitions them into a compliant set and a conflict set:

$$C_{\text{legal}} = \{S' \in C \mid \text{Conflict}(\text{CLS}(S')) = 0\}, \quad C_{\text{conflict}} = C \setminus C_{\text{legal}} \tag{4}$$

In practice, MCP-Licentra first scans service repositories to extract license texts, then identifies the specific license terms and their attitudes, and finally performs compatibility checking across all service combinations to produce $C_{\text{legal}}$ and $C_{\text{conflict}}$ along with the corresponding conflicting terms.

## 3.5 Conflict mitigation

Existing license conflict mitigation methods rely on license substitution or relicensing, which is infeasible in MCP scenarios because service licenses are controlled by third-party providers. MCP-Licentra instead treats mitigation as compliant alternative service retrieval, identifying functionally similar and license-compatible replacements for conflicting services and resolving compositional conflicts through iterative compliance checking.

### 3.5.1 Alternative service retrieval

MCP-Licentra encodes all MCP services in the service catalog into dense vectors using Qwen3-Embedding-8B [45] to support efficient retrieval of functionally similar services. For each service, the name, description, and classification fields are extracted and concatenated into a standardized information string following the format below.

The standardized strings of all catalog services are encoded into dense vectors and stored in a vector index. For a conflicting service, its information string is encoded into a query vector $\mathbf{m} \in \mathbb{R}^d$ and compared with each candidate vector $\mathbf{n}_i \in \mathbb{R}^d$ in the index using cosine similarity, where the retrieval score is computed as $\text{score}_i = \frac{\mathbf{m} \cdot \mathbf{n}_i}{\|\mathbf{m}\| \cdot \|\mathbf{n}_i\|}$. where $\cdot$ denotes the dot product, $\|\mathbf{m}\|$ and $\|\mathbf{n}_i\|$ are the norms of the query and candidate vectors respectively, and $d$ is the embedding dimension. All candidates are ranked in descending order of $\text{score}_i$, and those with $\text{score}_i \geq \tau$ are retained. The top-$k$ services among the filtered candidates form the alternative service list:

$$\text{Recommended}(\mathbf{m}) = \{S_i \mid \text{score}_i \geq \tau \wedge \text{argmax}_k(\text{score}_i)\} \tag{5}$$

where $\tau$ is the similarity threshold, $k$ is the maximum candidate list size, and $S_i$ denotes the $i$-th candidate alternative service.

### 3.5.2 Iterative compliance checking

In MCP compositional conflict scenarios, conflicts do not always manifest as a single service being incompatible with both $ML$ and the remaining services. More complex cases involve multiple conflict points across different service subsets simultaneously, where replacing a single service is insufficient to restore overall compliance. To handle such multi-point conflicts, MCP-Licentra introduces an ICC mechanism that replaces conflicting services and continuously updates the current compliant service set until a compliant configuration is obtained or no feasible replacement exists.

Given the conflict detection results $C_{\text{legal}}$ and $C_{\text{conflict}}$, MCP-Licentra replaces conflicting services one by one using the license constraints of the current compliant combinations as the reference. The replacement order follows two priority principles. The replacement order follows two priority principles. Under the ML-first principle, services conflicting with $ML$ are handled first, as such conflicts directly affect the compatibility of the entire combination with the underlying model. Under the minimal modification principle, when conflicts occur among MCP services, the service with the highest number of conflicts is prioritized, minimizing the total number of replacements required to restore compliance. The replacement priority of each conflicting service $S_{ij}$ within conflict group $S_i$ is quantified as:

$$\text{Priority}(S_{ij}) = \beta \cdot \mathbf{1}[\text{IsConflictWith}(S_{ij}, ML)] \quad +(1-\beta) \cdot \frac{\text{ConflictNum}(S_{ij})}{\text{ConflictNum}_{\max}} \tag{6}$$

where $\mathbf{1}[\cdot]$ is the indicator function, $\text{ConflictNum}(S_{ij})$ denotes the number of conflicts between $S_{ij}$ and other services in $S_i$, and $\beta \in [0, 1]$ balances the two principles.

For each conflict group $S_i \in C_{\text{conflict}}$, MCP-Licentra sorts the conflicting services by $\text{Priority}(S_{ij})$ in descending order and generates a candidate replacement set for each $S_{ij}$ using the retrieval method described above. A candidate $S'_{ij}$ is accepted if:

$$\text{IsCompatible}\left(S'_{ij},\ ML \cup \text{Licenses}(C_{\text{legal}})\right) = \text{True} \tag{7}$$

Upon acceptance, the conflict group is updated and the compliant set is revised as:

$$S_i \leftarrow (S_i \setminus \{S_{ij}\}) \cup \{S'_{ij}\}, C_{\text{legal}} \quad \leftarrow C_{\text{legal}} \cup \{S_i\}, \quad C_{\text{conflict}} \leftarrow C_{\text{conflict}} \setminus \{S_i\} \tag{8}$$

If no compatible replacement exists for a conflicting service, the corresponding conflict group is added to IrreplaceableList and removed from $C_{\text{conflict}}$. The process repeats until $C_{\text{conflict}} = \emptyset$, at which point the algorithm outputs the updated $C_{\text{legal}}$, the replacement record RecommendedList, and IrreplaceableList. Since $C_{\text{legal}}$ is updated immediately after each replacement, all subsequent compatibility checks are performed against the latest state, ensuring that newly introduced replacements do not generate new license conflicts with existing compliant combinations.

## 4 Experimental setup

### 4.1 Datasets

**License understanding dataset (LUD).** LUD evaluates the model's ability to recognize license terms and infer their associated attitudes. The dataset combines 3,577 supplementary term samples from Section 3.2.2 and 19,883 samples from the original License-Llama3-8B [4] training dataset. Both subsets are partitioned at a 7:1:2 ratio, producing test splits of 715 and 3,977 samples respectively, which are merged to form a LUD test dataset of 4,692 samples covering both traditional open source licenses and AI-specific supplementary licenses.

**MCP Conflict detection dataset (MCDD).** MCDD is used to evaluate license conflict detection in MCP service combination scenarios. We randomly sample from the 3,811 MCP services described in Section 3.2.1 to construct service combinations of sizes 1 to 5, generating 100 groups per size for a total of 500 groups. Each group is assigned one of three base models, Llama3-8B, Qwen3-32B, or DeepSeek-V4-Pro, to simulate real-world agent workflow scenarios. Three domain experts independently annotate all 500 groups for license conflicts. Inter-annotator agreement is measured by Fleiss' Kappa, resulting in a coefficient of 0.86. Disagreements are first resolved by majority voting, and remaining contested cases are adjudicated through expert discussion, producing the final ground-truth annotations.

## 4.2 Baselines

We compare MCP-Licentra with 7 license analysis baselines and 5 LLM baselines.

**License analysis baselines.** Text Similarity [11] is a heuristic method that matches license sentences to term categories by computing cosine similarity against term representative vectors. FOSS-LTE [19] applies LDA topic modeling to match license text topic distributions against manually defined term topics. DIKE [5] frames term identification as a multi-label classification task using a Label-specific attention network to predict multiple term labels simultaneously. LiDetector [42] employs a Bi-LSTM sequence labeling model to identify term entities token by token. LiResolver [41] extends LiDetector with fine-grained entity modeling, recognizing action, object, attitude, and condition entities to infer term attitudes. L$^3$icNexus [4] combines regex-based term extraction with a language model for context-aware attitude inference. SPDX-VT [18] constructs a directed license compatibility graph based on SPDX rules for conflict detection.

**LLM Baselines.** DeepSeek-V4-Pro [6], Qwen3-32B [34], Llama-4-Scout-17B [23], GPT-4.5 [26], and Claude 3.5 Sonnet [2] perform term identification and attitude inference under zero-shot settings using the same prompt template as Section 3.3, with temperature set to 0.

## 4.3 Metrics

Accurate conflict detection requires correctly recognizing license terms and inferring their attitudes. Following prior work, we adopt Precision $= TP/(TP + FP)$, Recall $= TP/(TP + FN)$, and their harmonic mean F1 $= 2 \cdot \text{Precision} \cdot \text{Recall}/(\text{Precision} + \text{Recall})$ as metrics, where $TP$, $FP$, and $FN$ denote true positives, false positives, and false negatives, respectively.

Two evaluation metrics are designed to assess resolution effectiveness and replacement efficiency respectively. The Resolution Success Rate, defined as RSR $= N_{\text{resolved}}/N_{\text{conflict}}$, measures the proportion of conflict groups successfully restored to a compliant state, where $N_{\text{conflict}}$ is the total number of conflict groups and $N_{\text{resolved}}$ is the number of groups successfully incorporated into $C_{\text{legal}}$ by the ICC algorithm. The Average Replacement Number, defined as ARN $= \frac{1}{N_{\text{resolved}}} \sum_{i=1}^{N_{\text{resolved}}} R_i$, measures the average number of replacement operations per successfully resolved group, where $R_i$ denotes the number of replacements for the $i$-th resolved group. Note that $R_i$ does not equal the number of conflicting services, as replacing a single service may simultaneously eliminate multiple conflicts. ARN therefore reflects the actual replacement efficiency under the minimal modification principle.

**Table 3** Comparison on term identification.

| Method | Precision(%) | Recall(%) | F1-score(%) |
|---|---|---|---|
| Text Similarity | 18.39 | 49.25 | 26.78 |
| FOSS-LTE | 16.58 | 67.12 | 26.59 |
| DIKE | 84.39 | 59.69 | 69.92 |
| LiDetector | 85.32 | 65.89 | 74.36 |
| LiResolver | 76.58 | 71.92 | 74.18 |
| $L^3$icNexus | 90.31 | 78.33 | 83.89 |
| DeepSeek-V4-Pro | 49.82 | 76.71 | 60.41 |
| Qwen3-32B | 22.96 | 64.32 | 33.84 |
| Llama-4-Scout | 34.79 | 65.34 | 45.40 |
| GPT-5.4 | 51.63 | 76.89 | 61.78 |
| Claude 3.5 Sonnet | 38.88 | 69.62 | 49.90 |
| **MCP-Licentra** | **92.83** | **85.15** | **88.82** |

### 4.4 Experimental settings

All experiments run on a server with 2×NVIDIA H100 GPUs (80GB HBM3), an Intel Xeon Platinum 8463B CPU, and 50GB memory, using Python 3.10.13 and PyTorch 2.2.0. During SFT, we train for 5 epochs with a learning rate of $2 \times 10^{-5}$ and a batch size of 8, applying the re-balanced sampling strategy described in Section 3.3.1. During ORPO, we fine-tune for 3 epochs with a loss weight of $\lambda = 0.1$. Both stages use the AdamW optimizer with a cosine warmup schedule and a warmup ratio of 0.03.

## 5 Evaluation and discussion

### 5.1 Research questions

In this section, we evaluate MCP-Licentra on real-world datasets and answer the following research questions:
**RQ1:** How effective is MCP-Licentra in license term and attitude analysis?
**RQ2:** How do license extension, SFT, and ORPO contribute to MCP-Licentra?
**RQ3:** How effectively does MCP-Licentra detect and mitigate conflicts in MCP service combinations?

### 5.2 Evaluation on license understanding

We evaluate MCP-Licentra on the LUD test dataset for license term identification and attitude inference, comparing it with 6 applicable baselines and 5 LLM-based methods using precision, recall, and F1-score. SPDX-VT is excluded because it directly checks predefined license relationships without a standalone term or attitude analysis. Results are reported in Table 3.

As shown in Table 3, MCP-Licentra achieves the best performance across all metrics, with 92.83% precision, 85.15% recall, and an 88.82% F1-score. Compared with the strongest baseline, $L^3$icNexus, MCP-Licentra improves precision, recall, and F1-score by 2.52%, 6.82%, and 4.93%, respectively. This gain mainly comes from targeted fine-tuning on supplementary term data, which improves the recognition of AI-specific license terms beyond zero-shot generalization. Text Similarity and FOSS-LTE perform worst, with F1-scores of 26.78% and 26.59%, respectively, because they assign only one term per sentence and cannot handle multi-term license statements. FOSS-LTE also shows severe over-prediction, as indicated by its low precision of 16.58% despite a recall of 67.12%. DIKE, LiDetector, and LiResolver

**Table 4** Comparison on license understanding.

| Method | Precision(%) | Recall(%) | F1-score(%) |
|---|---|---|---|
| Text Similarity | 14.93 | 38.75 | 21.56 |
| FOSS-LTE | 14.63 | 59.87 | 23.51 |
| DIKE | 71.37 | 50.97 | 59.47 |
| LiDetector | 72.65 | 57.02 | 63.89 |
| LiResolver | 64.01 | 64.23 | 64.12 |
| $L^3$icNexus | 88.36 | 76.27 | 81.87 |
| DeepSeek-V4-Pro | 47.57 | 74.76 | 58.14 |
| Qwen3-32B | 20.91 | 60.31 | 31.05 |
| Llama-4-Scout | 31.76 | 60.67 | 41.69 |
| GPT-5.4 | 50.12 | 69.92 | 58.39 |
| Claude 3.5 Sonnet | 36.96 | 65.43 | 47.24 |
| **MCP-Licentra** | **90.51** | **82.72** | **86.44** |

perform better, with LiDetector achieving the highest F1-score among them at 74.36%, but they remain behind $L^3$icNexus and MCP-Licentra due to their limited ability to capture complex license language. Among zero-shot LLM baselines, GPT-5.4 and DeepSeek-V4-Pro achieve F1-scores of 61.78% and 60.41%, respectively, while the remaining LLMs perform notably worse, further confirming the need for domain-specific fine-tuning.

Based on the license term identification results, each identified term is further classified into one of three attitudes: CAN, CANNOT, or MUST. Compared with term identification, attitude inference requires deeper semantic reasoning because the model must infer normative intent from context, especially under negation, ambiguity, or complex syntax. We evaluate each method by predicting attitudes for the identified terms and report precision, recall, and F1-score. Since this task depends on the preceding term identification stage, missed terms cannot be evaluated. The results therefore reflect the end-to-end performance of the two-stage pipeline.

As shown in Table 4, MCP-Licentra achieves the best performance across all metrics, with Precision 90.51%, Recall 82.72%, and F1 86.44%, improving F1 by 4.57% over the strongest baseline $L^3$icNexus (81.87%), primarily through better attitude inference on supplementary term categories. Text Similarity and FOSS-LTE perform worst (F1 21.56% and 23.51%), as static matching and topic modeling lack capacity for syntactic and contextual reasoning. DIKE, LiDetector, and LiResolver show limited attitude inference due to architectural constraints in handling domain-specific license language, compounded by error propagation from term identification. LLM baselines, despite strong general language modeling, all underperform fine-tuned methods due to insufficient domain-specific understanding of license semantics and compliance logic.

**Answer to RQ1:** MCP-Licentra achieves F1-scores of 88.82% and 86.44% on term identification and license understanding, consistently outperforming all baselines. These results validate that the extended term taxonomy and task-oriented training strategy effectively enhance license analysis in MCP scenarios.

## 5.3 Effect of license extension, SFT, and ORPO

To assess the contribution of each component in the license understanding module, we conduct ablation experiments using the same dataset and metrics as Section 5.2, constructing three variants. The first variant, w/o license extension, removes the supplementary term taxonomy and restricts training and inference to the original 27 terms, which is equivalent

**Table 5** Performance comparison of ablation variants.

| Method | Term Ident. | | | License Und. | | |
|---|---|---|---|---|---|---|
| | P | R | F1 | P | R | F1 |
| Llama3-8B | 8.97 | 71.79 | 15.95 | 8.32 | 67.26 | 14.81 |
| w/o License Ext. | 90.31 | 78.33 | 83.89 | 88.36 | 76.27 | 81.87 |
| w/o SFT | 91.08 | 81.22 | 85.87 | 88.97 | 78.16 | 83.22 |
| w/o ORPO | 92.53 | 84.21 | 88.17 | 89.92 | 80.86 | 85.15 |
| **MCP-Licentra** | **92.83** | **85.15** | **88.82** | **90.51** | **82.72** | **86.44** |

to using the L$^3$icNexus License-Llama3-8B model directly. The second variant, w/o SFT, retains the supplementary term taxonomy in the prompt but removes the additional SFT on supplementary term data, using the original L$^3$icNexus fine-tuned model instead. The third variant, w/o ORPO, retains both license extension and SFT but removes the preference alignment stage. All variants use the same temperature setting as Section 5.2 during inference.

Table 5 presents the ablation results. All variants substantially outperform the unadapted Llama3-8B baseline, as they inherit the fine-tuning foundation of L$^3$icNexus and maintain stable recognition of the original 27 term categories. Performance differences therefore primarily reflect each variant's capability in handling AI-specific supplementary terms. Removing License Extension causes F1-score to drop by 4.93% on Term Identification and 4.57% on license understanding, with Recall declining more sharply than precision, confirming that License Extension primarily enhances term coverage rather than prediction precision. Removing SFT while retaining License Extension leads to an F1-score decline of approximately 2.95%. The observation that w/o SFT outperforms w/o License Extension suggests that injecting supplementary term definitions into the prompt provides limited zero-shot generalization, yet this cannot substitute for parameter-level adaptation. SFT remains essential for converting extended term knowledge into stable recognition capability. Removing ORPO produces marginal degradation, with F1-score declining by 0.65% and 1.29% on the two tasks respectively. The larger impact on license understanding indicates that ORPO improves the consistency and reliability of attitude inference, reducing inconsistent outputs that may persist after SFT. Overall, the three components address distinct performance bottlenecks. License Extension broadens term coverage, SFT internalizes extended knowledge into model parameters, and ORPO enhances attitude inference reliability. Their complementary contributions collectively support the superior performance of the MCP-Licentra.

**Answer to RQ2:** License extension and SFT are the primary drivers of performance improvement. License Extension broadens term coverage, SFT internalizes extended term semantics and attitude classification rules into model parameters, and ORPO further improves output consistency and reliability, with all three components collectively enabling the MCP-Licentra to achieve optimal performance on both tasks.

## 5.4 MCP license conflict detection and mitigation

This section evaluates MCP-Licentra's conflict detection on the MCDD dataset (Section 4.1) at two levels. Group-level detection treats each base-model and MCP-service combination as a composite project and compares MCP-Licentra with SPDX-VT [18], DIKE [5], LiDetector [42], LiResolver [41], and L$^3$icNexus [4]. Since these baselines target static single-project analysis, we adapt their inputs by treating the base model and each service as independent components

**Table 6** Group-level license conflict detection results.

| Method | #Report | FPR(%) | FNR(%) |
|---|---|---|---|
| SPDX-VT | 2310 | 4.14 | 72.89 |
| DIKE | 3516 | 4.49 | 49.45 |
| LiDetector | 3946 | 3.44 | 35.06 |
| LiResolver | 4152 | 3.23 | 29.86 |
| L$^3$icNexus | 4962 | 3.31 | 13.13 |
| **MCP-Licentra** | **5132** | **3.15** | **8.77** |

in a unified detection target. Compositional detection further checks possible service subsets of different sizes, reflecting task-specific activation in agent workflows. Both settings use False Positive Rate (FPR) and False Negative Rate (FNR), computed as FPR $= FP/(FP + TN)$ and FNR $= FN/(FN + TP)$, where $FP$, $TN$, $FN$, and $TP$ denote false positives, true negatives, false negatives, and true positives, respectively.

### 5.4.1 Group-level license conflict detection

For each sample group, all licenses associated with the base model and MCP service set are extracted and submitted as a unified detection target. The MCDD dataset contains 4,777 positive and 24,539 negative samples across the 500 annotated combination groups. Results are presented in Table 6.

MCP-Licentra achieves the best performance with FPR 3.15% and FNR 8.77%. SPDX-VT's reliance on a predefined compatibility graph covering only a limited license set results in an FNR of 72.89%. DIKE, LiDetector, and LiResolver adopt LSAN-based multi-label classification, Bi-LSTM sequence labeling, and RoBERTa-based entity modeling respectively, with FNR decreasing progressively, yet all three remain substantially behind L$^3$icNexus and MCP-Licentra due to limited semantic representation capacity. MCP-Licentra and L$^3$icNexus achieve comparable FPR values of 3.15% and 3.31%, while MCP-Licentra reduces FNR by 4.36%, indicating that the detection gap between the two methods is primarily attributable to false negatives. This FNR reduction is attributed to supplementary term fine-tuning, which enhances the model's sensitivity to conflicts involving AI-specific license terms and compensates for the missed detections of L$^3$icNexus on such cases.

### 5.4.2 Compositional license conflict detection

In real-world agent workflows, a task typically activates only a subset of registered MCP services, requiring conflict detection at both combination and subset levels. We therefore apply MCP-Licentra to all non-empty service subsets in the MCDD ground-truth dataset. For a combination of $m$ services, exact verification requires checking $2^m - 1$ subsets. Our cost analysis shows that $m \leq 5$ remains tractable: each group contains at most 31 subsets and requires 5.60 seconds on average, supporting expert annotation, conflict verification, and error analysis. By contrast, $m = 6$ yields 63 subsets with an average detection time of 10.37 seconds, while $m = 10$ yields 1,023 subsets per group, or 102,300 subsets for 100 groups, about 33 times the scale of $m = 5$. Based on this analysis, we use $m \leq 5$ for MCDD construction and exact-verification experiments, balancing verification cost, annotation reliability, and experimental controllability. This setting is a practical evaluation choice rather than a theoretical limit of MCP-Licentra. Here, $m$ denotes the number of MCP services involved in a task or verification instance, not the total number configured in the agent environment.

**Table 7** Compositional license conflict detection results.

| Combination | 1-MCP | | 2-MCP | | 3-MCP | | 4-MCP | | 5-MCP | | Total | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | FPR | FNR | FPR | FNR | FPR | FNR | FPR | FNR | FPR | FNR | FPR | FNR |
| 1-MCP | 5.71 | 3.08 | – | – | – | – | – | – | – | – | 5.71 | 3.08 |
| 2-MCP | 4.29 | 3.85 | 6.45 | 2.90 | – | – | – | – | – | – | 4.95 | 3.52 |
| 3-MCP | 4.67 | 3.11 | 4.55 | 2.83 | 7.41 | 2.74 | – | – | – | – | 4.95 | 2.93 |
| 4-MCP | 4.41 | 3.41 | 4.17 | 3.19 | 5.21 | 3.62 | 7.69 | 2.70 | – | – | 4.67 | 3.33 |
| 5-MCP | 4.73 | 3.63 | 4.35 | 3.54 | 5.15 | 3.39 | 5.83 | 3.16 | 8.70 | 2.60 | 4.96 | 3.40 |
| **Total** | **4.64** | **3.46** | **4.42** | **3.29** | **5.34** | **3.41** | **6.16** | **3.08** | **8.70** | **2.60** | **4.90** | **3.33** |

**Table 8** License conflict resolution results.

| Method | #Resolved | RSR(%) | ARN |
|---|---|---|---|
| LexicalMatch | 193 | 53.91 | 1.67 |
| StaticOrder | 243 | 67.88 | 1.54 |
| SinglePass | 162 | 45.25 | 1.39 |
| **MCP-Licentra** | **255** | **71.23** | **1.42** |

Table 7 reports detection results by combination size and subset size, with 100 combinations evaluated for each setting. A 5-MCP combination contains 31 non-empty subsets and requires 5.6 seconds on average for detection. To evaluate MCP-Licentra in a realistic workflow, a project-management and document-synchronization agent is constructed with DeepSeek-V4-Pro, GitHub Projects [29], Filesystem [28], Todoist [32], and Notion [31]. When only GitHub Projects and Filesystem are activated, MCP-Licentra correctly identifies the GPL-2.0 and Apache-2.0 incompatibility, demonstrating its ability to detect conflicts within task-activated service subsets. As subset size increases, FPR rises while FNR decreases, reflecting more conservative conflict judgments under increasingly complex license interactions. For 5-MCP combinations, FPR increases from 4.73% for 1-MCP subsets to 8.70% for 5-MCP subsets, while FNR decreases from 3.63% to 2.60%. Overall, MCP-Licentra achieves an FPR of 4.90% and an FNR of 3.33%, indicating stable detection performance across subset sizes.

## 5.5 License conflict mitigation evaluation

This section evaluates MCP-Licentra's conflict mitigation capability on 358 conflict groups randomly sampled from the detection results in Section 5.4. We set the candidate pool size to $k = 10$ and use $\tau = 0.75$ as the similarity threshold based on sensitivity analysis. This setting filters low-relevance candidates while preserving stable RSR and ARN; higher thresholds, such as 0.80 and 0.90, reduce candidate coverage and lower RSR.

To assess the contribution of each design in the conflict resolution module, we construct three ablation variants targeting semantic retrieval, priority ordering, and iterative compliance checking. LexicalMatch replaces Qwen3-Embedding-8B retrieval with Jaccard similarity to evaluate the role of semantic retrieval in candidate quality. StaticOrder follows the service order instead of priority scoring to assess the effect of ML-first and minimal-modification principles on resolution efficiency. SinglePass performs only one replacement attempt for each service in $C_{\text{conflict}}$, without iterative rechecking, to evaluate the benefit of iterative compliance verification for multi-point conflicts. All other components remain unchanged.

Table 8 presents the experimental results. MCP-Licentra achieves the best performance, resolving 255 out of 358 conflict groups with an RSR of 71.23% and an ARN of 1.42. A conflict group is counted as resolved when a replacement service satisfies functional similarity, license compatibility, and post-replacement compliance verification. Thus, the remaining

unresolved cases indicate that at least one of these conditions cannot be satisfied within the top-$k$ candidate pool, due to insufficient candidate coverage, low functional similarity, or residual license conflicts after replacement. StaticOrder performs closest to the full method, with an RSR of 67.88% and an ARN of 1.54, indicating that removing priority ordering reduces resolution effectiveness and increases replacement cost. LexicalMatch further drops to an RSR of 53.91% and an ARN of 1.67, confirming that lexical similarity alone cannot reliably retrieve high-quality replacement candidates. SinglePass achieves the lowest RSR of 45.25%, showing that iterative compliance checking is necessary for resolving complex multi-point conflicts. Its ARN of 1.39, slightly lower than that of the full method, suggests that SinglePass mainly succeeds on simpler conflict groups requiring fewer replacements.

**Answer to RQ3:** MCP-Licentra achieves FPR of 3.15% and 4.90% and FNR of 8.77% and 3.33% on group-level and compositional conflict detection, respectively, and attains an RSR of 71.23% and ARN of 1.42 on conflict resolution, outperforming all ablation baselines and validating the three core design components.

# 6 Related work

## 6.1 License identification

License identification is fundamental to open source compliance. FOSSology [8] identifies licenses by aligning source text against templates using the binary Symbolic Alignment Matrix. Ninka [10] performs sentence-level matching in source code files. ScanCode [1] compiles a large-scale index of license texts and detection rules. SPDX [39] provides standardized license identifiers, TLDRLegal [40] summarizes terms in plain language, and OSI [25] maintains a curated list of certified licenses. These tools are designed for source code and package scenarios, leaving MCP services uncovered. MCP-Licentra addresses this gap by leveraging LLMs to identify and standardize license information for MCP services.

## 6.2 License compliance analysis

Ensuring compliance with all dependent license terms is central to open source research. Kapitsaki et al. [27] develop a graphical tool for visualizing license compatibility. Cui et al. [5] propose DIKE for automated conflict detection via NLP, with follow-up work [4] leveraging LLMs to improve accuracy. Other studies examine incompatibility in ecosystems such as NPM [33] and PyPI [43]. However, these approaches target conflicts in source code and package dependencies, relying on predefined rules or expert knowledge within traditional supply chains. In MCP settings, third-party services are combined within workflow configurations under distinct license terms, posing challenges that existing methods do not address. MCP-Licentra employs LLMs for license compatibility analysis across MCP services and recommends compatible alternatives via semantic retrieval.

# 7 Threats to Validity

**Internal validity.** The primary threat to internal validity lies in the annotation quality of training data. To mitigate this, we employ multiple annotators with cross-validation and resolve disagreements through discussion. Additionally, the fine-tuning process may introduce bias toward specific license styles; we address this by incorporating diverse license texts during training.

**External validity.** Our evaluation is based on 3,811 MCP services and 500 dynamic combination scenarios, which may not fully represent all real-world deployments. The generalizability of our findings to other service ecosystems or emerging license types requires further investigation.

## 8 Conclusion

This paper formalizes license conflict analysis in MCP-based agent workflows as a powerset legality verification problem. We propose MCP-Licentra, which integrates domain-adapted license understanding, compositional conflict detection over service subsets, and iterative conflict resolution. We further extend the license-term taxonomy and construct two datasets, LUD and MCDD, for license understanding and multi-service conflict evaluation. Experiments show that MCP-Licentra consistently outperforms existing baselines across license understanding, conflict detection, and resolution. Future work will focus on scaling to larger service ecosystems and adapting to evolving license and compliance requirements.

# Bigger Is Not Always Better: Performance and Sustainability Trade-Offs in LLMs for Python Bug-Fixing Tasks

**Syed Fakhar Abbas Naqvi**
University of Tartu, Estonia

**Hina Anwar**
University of Tartu, Estonia

## Abstract

**Background.** Large Language Models (LLMs) are increasingly used in software engineering tasks such as code generation, bug detection, and program repair. However, their use introduces inference-time costs that are rarely considered together with functional performance, especially in debugging and repair workflows where models may be invoked repeatedly.

**Aim.** This study evaluates the correctness-energy trade-offs of LLMs across model scales in Python bug-fixing tasks. We examine how model size relates to code correctness, inference time, and GPU energy consumption.

**Method.** We conduct a controlled empirical evaluation of six open-source code-oriented LLMs, ranging from 1.5B to 15B parameters, on 40 real-world Python bugs from the BugsInPy benchmark. Each model is executed multiple times per task under a consistent hardware and prompting setup. Repair performance is measured using Pass@k and test-suite outcomes, while computational cost is measured using inference time and GPU energy consumption. We also analyze generated outputs to identify recurring failure patterns.

**Results.** Increasing model size substantially raised computational cost without consistently improving correctness. The smallest model, Qwen 1.5B, achieved the best overall performance, with a Pass@1 score of 43% and an average runtime of 38.7 seconds. In contrast, StarCoder 15B achieved a Pass@1 score of 23%, required 96.7 seconds, and consumed approximately 7 times more energy per inference while solving fewer tasks. Higher success rates were also observed in web-related projects, suggesting that structurally localized bugs are more effectively handled by current models.

**Conclusion.** On the evaluated localized Python bug-fixing tasks, smaller LLMs offered a more favorable trade-off between correctness, inference time, and energy consumption. These results suggest that scaling model size does not automatically lead to more efficient LLM-based repair, and that inference cost should be considered alongside functional correctness when comparing models.

## 1 Introduction

Large Language Models (LLMs) are increasingly used in software engineering tasks, including code generation, bug detection, automated debugging, and program repair [12]. Code-oriented LLMs can generate patches, complete missing code, and assist developers in reasoning about faulty program behavior. As these models become more accessible through local deployment and integrated development tools, they are likely to be invoked repeatedly during software development workflows.

This growing use of LLMs raises an important sustainability concern. AI models consume substantial energy during training and continue to consume energy during inference after deployment [2], [8], [9], [22]. For example, the energy consumed during LLaMA 3.1 training has been compared to the emissions from 83 years of electricity use by a single household in the United States [2]. Prior work has also reported that training a large neural network can produce emissions comparable to those of multiple cars over their lifetimes [9]. With the increasing demand for large-scale AI systems, data centers are projected to consume a growing share of global electricity, reaching approximately 20% by 2030 [9].

However, in software engineering workflows, sustainability concerns extend beyond model training. Once deployed, LLMs consume energy during inference, the process by which trained models generate outputs [8], [9], [22]. Inference is particularly relevant in debugging and repair because these tasks are often iterative: developers may request multiple fixes, regenerate patches, or apply models across many defects. As a result, even moderate per-inference costs can accumulate when LLMs are used frequently.

This concern aligns with Green AI, which argues that AI research should consider computational cost alongside model performance [6]. For LLM-based software engineering, this means evaluating not only whether a model produces correct outputs, but also the inference cost required to produce them. Prior studies have examined the environmental impact of large-scale AI systems, the energy efficiency of LLM-generated code, and differences between smaller and larger models in programming tasks [2], [9], [16], [20]. These studies provide useful evidence, but energy measurements are highly dependent on hardware, task configuration, implementation choices, and measurement boundaries [1]. Therefore, results from one type of programming task do not necessarily generalize to other software engineering activities.

Bug fixing is a particularly relevant setting for studying correctness-energy trade-offs. Developers spend substantial time locating, understanding, and repairing defects [25], [21], [23]. Debugging includes several subtasks, such as bug localization, classification, and repair, and different bug types may require different levels of reasoning and contextual understanding [24]. Python bug fixing is also a practical and challenging target. Python is widely used in domains such as data science, machine learning, automation, web development, and backend systems. At the same time, Python bugs can be difficult to repair because of dynamic typing, heterogeneous data structures, and domain-specific library usage [24].

Despite growing interest in Green AI and LLM-based software engineering, limited empirical evidence is available on the inference-time cost of using open-source code LLMs for real-world bug fixing. Much prior work evaluates the efficiency of generated code after it is produced, for example, by measuring the runtime or energy consumption of the generated program. In contrast, this study focuses on the energy consumed by the model during repair generation. This distinction matters because, in LLM-based debugging, sustainability concerns arise from both the code eventually produced and the repeated inference required to obtain it.

In this paper, we investigate the correctness–energy trade-offs of LLM-based Python bug fixing, with particular emphasis on how model size influences both repair effectiveness and inference cost. We evaluate six open-source code-oriented LLMs, ranging from 1.5B to 15B parameters, on 40 real-world bugs from the BugsInPy benchmark under a consistent hardware and prompting setup. Our goal is to determine whether increasing model size improves correctness–cost behavior, or whether smaller models can offer more favorable trade-offs under the evaluated conditions.

The study is scoped to localized bug repair, where the faulty code can be isolated to a single function or class and replaced as a complete block. Repair scenarios that require repository-level reasoning, coordinated edits across multiple files, or a broader architectural understanding are outside the scope of this work. Accordingly, the findings and conclusions should be interpreted in the context of this class of localized repair tasks.

This paper makes the following contributions:

- We provide a controlled empirical comparison of six open-source code-oriented LLMs on real-world Python bug-fixing tasks from BugsInPy.
- We measure repair correctness, inference time, and GPU energy consumption under a consistent experimental setup, making inference cost visible alongside functional correctness.
- We analyze correctness-energy trade-offs across model scales and show that larger models do not necessarily provide more efficient LLM-based repair in the evaluated setting.
- We characterize recurring failure patterns in generated repairs to help explain differences in model behavior.

The rest of the paper is organized as follows. Section 2 discusses related work on Green AI, energy-aware LLM evaluation, and LLM-based software repair. Section 3 presents the research questions and describes the methodology and experimental setup. Section 4 presents the results. Section 5 discusses implications, and Section 6 presents threats to validity. Section 7 concludes the paper.

## 2 Related Work

Energy-aware software engineering has increasingly examined how software systems, programming practices, and AI-assisted development affect energy consumption. In the context of LLM-assisted programming, recent work has studied both the energy behavior of generated code and the computational cost of using the models themselves. This section summarizes representative studies that motivate our focus on inference-time energy in LLM-based bug fixing.

Rani et al. [17] studied whether LLMs can improve the energy efficiency of existing code. They optimized 400 MATLAB scripts using GPT-3, GPT-4, Llama, and Mixtral, and compared the results with optimizations produced by a senior MATLAB developer. Their evaluation considered energy consumption, memory usage, and other performance metrics. The results showed no clear energy benefit from LLM-based optimization and indicated negative effects on memory usage. Their findings suggest that LLM-assisted code optimization does not automatically lead to more sustainable software and that energy effects must be evaluated empirically.

A prerequisite for such evaluations is reliable energy measurement. Sallou et al. [18] addressed this challenge by introducing EnergiBridge, a cross-platform tool for measuring software energy consumption on Linux, Windows, and macOS. This is relevant because many earlier energy measurement tools were platform-specific, making comparisons difficult

across environments. However, even with improved tooling, energy measurements remain sensitive to hardware, operating system behavior, workload characteristics, and experimental configuration.

Several studies have evaluated the energy efficiency of code generated by LLMs. Islam et al. [9] compared code generated by 20 LLMs with human-written code using energy consumption, runtime, memory usage, and correctness. Their results showed that human-written code was approximately 1.17 times more energy-efficient than DeepSeek-v3 and more efficient than other evaluated LLM outputs. They also found that increasing problem complexity was associated with greater inefficiency in LLM-generated code. These findings show that functional correctness alone is insufficient for evaluating AI-generated code.

Ashraf et al. [2] studied energy-aware code generation across model scales. They compared three small open-source models, StableCode-3B, StarCoderBase-3B, and Qwen2.5-Coder-3B-Instruct, against two large proprietary models, GPT-4.0 and DeepSeek-Reasoner, using 150 Python programming tasks from LeetCode. Their evaluation measured correctness, runtime, memory usage, and energy consumption during execution of the generated code. The results showed that large models achieved stronger correctness and runtime performance, while small models were more energy-efficient in more than half of the cases where their outputs were correct. Their study is closely related to ours because it compares models of different sizes under a sustainability lens. However, their measurement target is the execution cost of generated code, whereas our study measures the inference cost of generating repairs.

This distinction is important because energy consumption in AI-assisted software engineering arises at different points in the workflow. Early Green AI work emphasized the need to account for computational costs across the AI life cycle [6, 22]. More recent work shows that inference can substantially increase the overall energy footprint of deployed AI systems, as models may be executed repeatedly at scale [9]. Fernandez et al. [7] similarly emphasize that inference can represent a major share of energy consumption in deployed AI systems. In LLM-based debugging, this repeated-use concern is especially relevant: developers or tools may request multiple patches, regenerate outputs, or apply models across many defects before arriving at a correct fix.

Overall, prior work provides important evidence on software energy measurement, LLM-generated code efficiency, and model-scale comparisons. However, most related studies focus on the energy behavior of generated code after execution or on general programming problems. Less is known about the inference-time energy cost of using open-source code-oriented LLMs for real-world bug-fixing tasks. This study addresses that gap by evaluating six open-source code LLMs of different sizes on Python bugs from BugsInPy, measuring repair correctness, inference time, and GPU energy consumption during patch generation under a consistent experimental setup.

# 3 Methodology

We conduct a controlled experiment to evaluate open-source code-oriented LLMs of different sizes on Python bug-fixing tasks. The goal is to examine how model size relates to repair correctness, inference time, and GPU energy consumption during repair generation.

## 3.1 Research Questions and Hypotheses

The study is guided by three research questions:

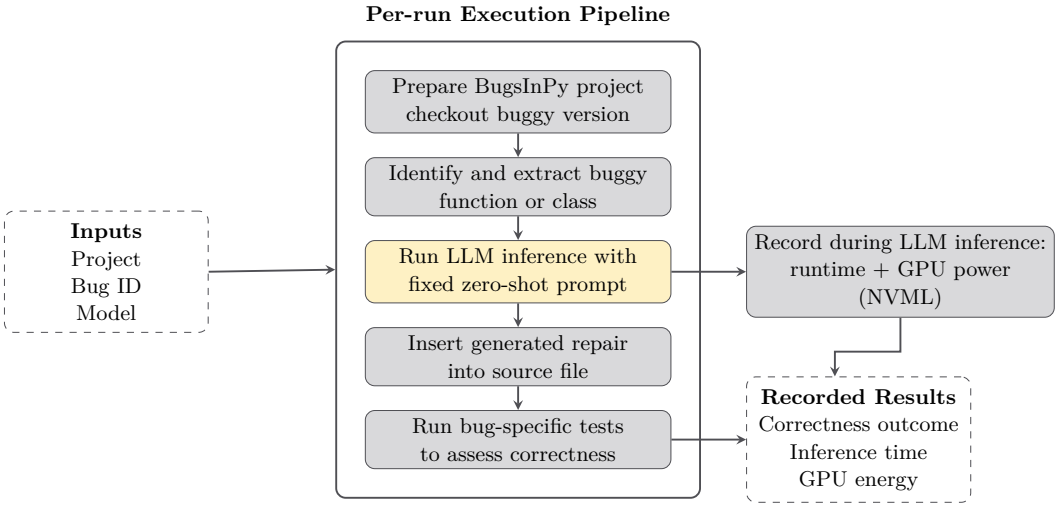

**Figure 1** Per-run experimental workflow. Runtime and GPU power are recorded only during LLM inference; tests are used to determine repair correctness.

**RQ1.** How do LLMs of varying sizes differ in their ability to fix Python bugs in terms of repair correctness and inference time?

**RQ2.** What is the inference-time energy cost associated with running these models on Python bug-fixing tasks?

**RQ3.** Which model provides the most favorable trade-off between correctness, inference time, and energy consumption?

We investigate two hypotheses:

***H1.*** Smaller models can achieve comparable repair correctness to larger models while requiring less inference time and energy consumption.

***H2.*** Larger models require greater energy resources during inference than smaller models, regardless of whether the generated fix is correct.

## 3.2 Experimental Design

For each experimental run, the pipeline takes a selected model and a selected bug as input. It prepares the buggy project state, extracts the buggy function or class, prompts the model to generate a repair, inserts the generated repair into the source file, and executes the associated tests to determine correctness. Figure 1 summarizes this per-run pipeline.

The study evaluates block-level repair: each generated output replaces the extracted buggy function or class. This supports automated insertion and testing, but does not evaluate repository-wide or multi-location repairs.

Runtime and GPU power are recorded only during LLM inference, from immediately before repair generation until the model output is returned. Repository setup, extraction, prompt construction, patch insertion, and test execution are excluded. Because power is measured using NVML, reported energy values represent GPU-side inference energy, not full-system energy.

**Table 1** Overview of selected models.

| Identifier | Model Name | Parameters | Size |
|---|---|---|---|
| Qwen1.5 | Qwen2.5-Coder-1.5B | 1.5B | Small |
| StableCode3 | StableCode-3B | 3B | Small |
| DeepSeek6 | DeepSeek-Coder-6.7B-Instruct | 6.7B | Small |
| StarCoder7 | StarCoder2-7B | 7B | Medium |
| CodeLlama13 | CodeLlama-13B-Instruct | 13B | Medium |
| StarCoder15 | StarCoder2-15B | 15B | Medium |

## 3.3 Benchmark and Models

Python was selected because of its widespread use in AI, data science, automation, web development, and backend systems [19]. We use BugsInPy [24], a benchmark of real-world Python bugs from open-source GitHub projects. We selected 40 bugs from BugsInPy projects, including Ansible, Black, Cookiecutter, FastAPI, Luigi, Sanic, Scrapy, TQDM, and Youtube-dl. The selected bugs cover several software domains, including web frameworks, automation, developer tools, utilities, and data-processing projects. The selection was constrained by the block-level repair setting used in this study: a bug was included only if the buggy code could be localized to a function or class, the relevant block could be extracted for prompting, and the associated test suite could be executed in our environment. Bugs requiring multi-file repairs, repository-level changes, unavailable dependencies, or non-reproducible test environments were excluded.

We evaluate six open-source code-oriented LLMs ranging from 1.5B to 15B parameters. Models were selected based on open-source availability, Python support, and prior use or performance in code-related benchmarks such as HumanEval [5] and CodeXGLUE [13]. Following prior work [2], we categorize models up to approximately 6–7B parameters as small and models from 7B to 15B parameters as medium-sized. Table 1 summarizes the selected models and their parameter sizes. All selected models are publicly available on the Hugging Face[1] model repository. All models were executed locally on the same hardware. Proprietary API-based models were not included because their inference energy cannot be measured directly under the same hardware and measurement conditions.

## 3.4 Prompting and Execution

A fixed zero-shot prompt was used for all models and tasks to ensure a consistent evaluation setting. We deliberately used a single standardized prompt rather than model-specific prompting or alternative prompting strategies, such as few-shot prompting. This design reduces prompt engineering as a source of variation and enables the models to be compared under identical prompting conditions [4] [3]. The prompt instructs the model to generate a complete Python function or class and to output only executable code.

[1] `https://huggingface.co/`

```
You are a Python expert.
Fix the following {block_type} named '{block_name}'.
STRICT RULES:
- Output ONLY valid Python code
- DO NOT explain anything
- DO NOT include markdown
- DO NOT include text before or after code
- The output MUST start with: def {block_name} OR class {block_name}
- The code MUST be complete and executable
BUGGY CODE:
{buggy_block}
```

Generated outputs were evaluated without manual intervention. Outputs containing non-code text, Markdown formatting, incomplete blocks, syntax errors, unexpected function or class structures, or missing return statements were counted as unsuccessful repairs (counted as failures in Pass@k). We intentionally did not edit, clean, or reformat generated outputs because adherence to the fixed output constraints is part of the evaluated zero-shot repair setting. For executable repairs, correctness was determined solely by whether the generated repair passed the associated bug-specific test suite.

All models used the same prompt template and were executed without task-specific or model-specific decoding tuning. Generation followed the defaults of the inference library/model configuration used in our scripts. The batch size was 1. Model loading time was excluded from inference-time and energy measurements. Random seeds were not fixed; instead, each bug-model pair was executed 10 times to capture output and measurement variability.

For each bug-model pair, we perform 10 independent runs, resulting in 2,400 intended model executions. Each run takes a project identifier, bug identifier, and model identifier as input; prepares the BugsInPy workspace; extracts the buggy block; runs LLM inference; inserts the generated repair; executes the bug-specific tests using `pytest`; and records correctness, inference time, and GPU energy.

A run is successful if the generated repair passes all bug-specific tests. A bug is considered fixed by a model if at least one of the model's 10 generated repairs passes the tests. Runs failing due to syntax errors, runtime errors, failed tests, invalid output format, or timeout are counted as unsuccessful. The timeout policy was governed by the overall SLURM job time limit.

All experiments are conducted on a dedicated GPU node equipped with an NVIDIA Tesla V100 GPU with 32 GB memory, 4 CPU cores, and 128 GB RAM. Each experiment is executed as an independent job with an identical configuration, and a fixed delay is introduced between repeated runs to reduce thermal effects.

All runs used the same software environment, model execution scripts, and measurement scripts. The models were loaded before each measured run. Model-loading energy and time are excluded from the reported inference cost.

## 3.5 Measurements and Analysis

Repair correctness is evaluated using execution-based testing. A generated repair is correct if it passes the bug-specific test cases. Since each bug-model pair is evaluated over 10 runs, we use Pass@k to summarize repair success [11, 5]. Pass@1 is computed as:

$$\text{Pass@1} = \frac{\text{Total Successful Attempts}}{\text{Total Attempts}} \tag{1}$$

Pass@1 is computed as the observed proportion of successful repairs across repeated independent runs. For Pass@10, a bug is considered solved for a given model when at least one out of the 10 generated repairs successfully passes the bug-specific test suite.

Inference time is measured using `time.perf_counter`. GPU energy is measured during inference using NVML, with GPU power sampled every 100 ms and integrated over time:

$$E_{\text{measured}} = \sum P(t) \times \Delta t \tag{2}$$

where $P(t)$ is instantaneous GPU power and $\Delta t$ is the sampling interval. Baseline idle energy is subtracted from measured energy:

$$E_{\text{final}} = E_{\text{measured}} - E_{\text{baseline}} \tag{3}$$

Because NVML reports GPU-side power, the reported values represent GPU inference energy rather than full-system energy. Baseline idle GPU energy was measured under the same job configuration and sampling interval, and subtracted from measured inference energy to estimate the additional GPU energy associated with repair generation.

For each run, we record the model identifier, bug identifier, execution status, number of tests passed, total number of tests, correctness outcome, inference time in seconds, and GPU energy in Joules.

The collected data are aggregated across repeated runs. For RQ1, we analyze Pass@1, the number of bugs fixed, and inference time. For RQ2, we analyze GPU energy consumption. For RQ3, we jointly compare repair correctness, inference time, and GPU energy consumption to identify correctness-energy trade-offs across models.

To compare energy differences between models, we aggregate inference-energy measurements per bug-model pair across the 10 runs and use the per-bug average as the unit of analysis. This gives one paired energy value per bug for each model. We use the Wilcoxon signed-rank test [14] for pairwise comparisons and report Vargha–Delaney $A_{12}$ effect sizes [10] to quantify the magnitude of differences. Because multiple comparisons are performed, p-values are interpreted together with effect sizes and descriptive trends rather than as the sole basis for conclusions.

Finally, we conduct an exploratory inspection of generated repairs that failed to fix the observed failure to identify recurring failure patterns, such as invalid syntax, incomplete repairs, incorrect function or class structure, incorrect repair logic, or outputs that do not address the observed failure. This inspection supports the interpretation of the quantitative results rather than producing a validated taxonomy.

## 4 Results

This section presents the results organized by the three research questions. We analyze repair correctness, inference time, GPU energy consumption, and the resulting correctness-energy trade-offs across the evaluated models. Only bug-model pairs with 10 completed runs were included in the analysis. Of the 40 selected bugs, 35 had complete and consistent 10-run coverage across all six models and were retained for analysis. Bugs with incomplete runs due to execution timeouts or missing run logs were excluded to ensure a balanced comparison. The final dataset, therefore, contains 35 bugs (2,100 runs). The complete experimental results are available in the replication repository as a CSV file.

## 4.1 RQ1: Repair Correctness and Inference Time

*How do LLMs of varying sizes differ in their ability to fix Python bugs in terms of repair correctness and inference time?*

This RQ evaluates H1 by examining whether smaller models can achieve repair correctness comparable to larger models while requiring less inference time. Table 2 summarizes repair correctness and inference time for each evaluated model. Pass@10 is reported as the number of bugs, out of the 35 bugs retained for aggregate analysis, for which a model generated at least one test-passing repair across its 10 runs, while Pass@1 represents the observed proportion of successful repair attempts across all runs. The difference between these measures reflects the repeated-run setting, in which some bugs are solved consistently across multiple runs, while many others are not solved at all.

**Table 2** Repair correctness and inference time across models.

| Model | Size | Pass@10 | Pass@1 | Avg Time (s) |
|---|---|---|---|---|
| Qwen1.5 | Small | 15 | 0.43 | 38.7 |
| StableCode3 | Small | 7 | 0.20 | 45.7 |
| DeepSeek6 | Small | 5 | 0.14 | 54.3 |
| StarCoder7 | Medium | 8 | 0.23 | 48.2 |
| CodeLlama13 | Medium | 14 | 0.40 | 68.5 |
| StarCoder15 | Medium | 8 | 0.23 | 96.7 |

As shown in Table 2 and Figure 2, Qwen1.5 achieves the strongest repair performance among the evaluated models, fixing 15 unique bugs and reaching a Pass@1 of 0.43 while maintaining the lowest average inference time (38.7s). CodeLlama13 performs competitively in terms of correctness, fixing 14 bugs with a Pass@1 of 0.40, but requires substantially longer average execution time (68.5s). The remaining models fix fewer tasks and exhibit lower overall Pass@1 values.

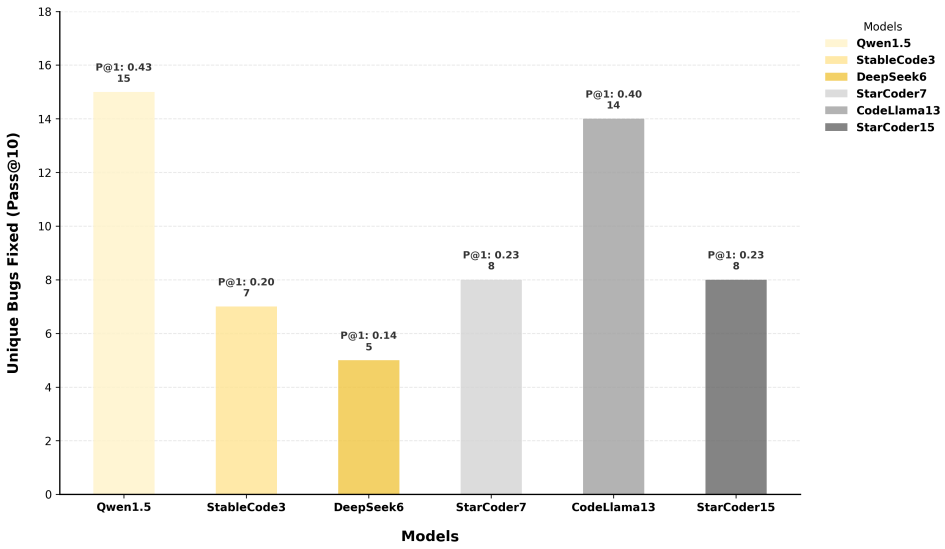

**Figure 2** Repair correctness across models.

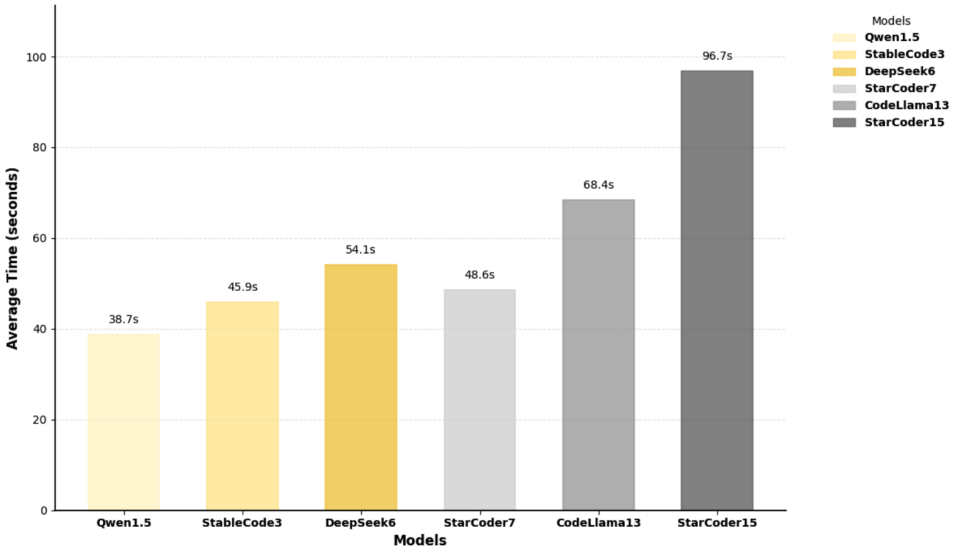

**Figure 3** Average inference time across models.

These results indicate that increasing model size does not consistently lead to higher repair correctness or lower inference time in this setting. For example, StarCoder15, the largest evaluated model, fixes only 8 bugs, achieves a Pass@1 of 0.23, and requires the highest average inference time (96.7s). As illustrated in Figure 3, overall inference runtime increases with model scale, although the trend is not strictly monotonic across model families.

**Summary:** Qwen1.5 achieved the highest Pass@10 and Pass@1 while also requiring the lowest average inference time. This supports H1 in the evaluated setting, although CodeLlama13 was competitive.

### 4.1.1 Exploratory Failure Analysis

Although Qwen1.5 achieves the highest Pass@1, its score remains below 0.50, indicating that even the best-performing model does not reliably generate a test-passing repair in a single attempt. We conducted a targeted manual inspection of repairs generated for 20 bugs across all six models, covering 1,200 outputs (20 bugs $\times$ 6 models $\times$ 10 runs). The analysis was exploratory and aimed at identifying recurring failure patterns rather than constructing a validated failure taxonomy. Figure 4 presents five illustrative cases selected from this inspection to show recurring success and failure behavior across repeated runs.

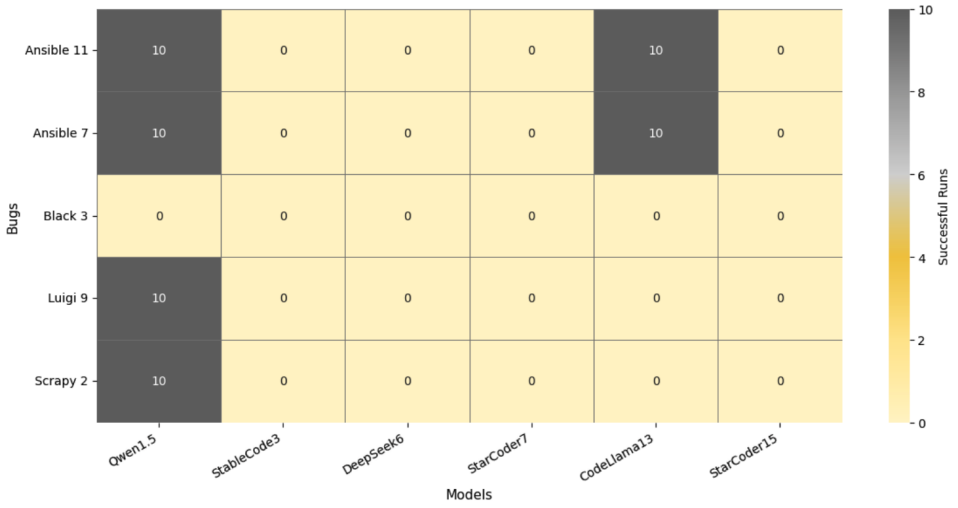

**Figure 4** Number of successful runs for selected bugs across models (out of 10 independent attempts).

As shown in Figure 4, repair outcomes exhibit a pronounced 0-or-10 pattern: a model either succeeds in all 10 runs or fails in all 10 runs.For Ansible 7 and Ansible 11, Qwen1.5 and CodeLlama13 produce test-passing repairs in all 10 runs, whereas the remaining models fail in every run. Qwen1.5 similarly achieves 10/10 successful runs for Luigi 9 and Scrapy 2, while no evaluated model successfully repairs Black 3.

Ansible 11 provides an illustrative example of how output structure can affect repair success. The bug requires updating the `map_obj_to_commands` function to construct CLI command strings for networking banners based on state conditions (`absent` vs. `present`). Specifically, when the state is `present`, the function must determine whether the target banner text differs from the existing text and format the string using specific delimiter tags (`@\n...\n@`).

As illustrated by the following generated repair, Qwen1.5 produces a concise, self-contained function that satisfies the required structure and passes the associated tests. Qwen1.5 and CodeLlama13 both achieve 10/10 successful runs for this bug.

```
def map_obj_to_commands(updates, module):
    commands = list()
    want, have = updates
    state = module.params['state']

    if state == 'absent' and 'text' in have.keys() and have['text']:
        commands.append('no␣banner␣%s' % module.params['banner'])

    elif state == 'present':
        if want['text'] and (want['text'] != have.get('text')):
            banner_cmd = 'banner␣%s' % module.params['banner']
            banner_cmd += '␣@\n'
            banner_cmd += want['text'].strip()
            banner_cmd += '\n@'
            commands.append(banner_cmd)

    return commands
```

Manual inspection revealed that models like StarCoder7 and DeepSeek6 generated the correct `banner_cmd` logic but failed to execute because they wrapped the code in triple-backtick Markdown blocks (`"‘python ... "‘`) or redeclared the parent module import after the return statement. Since our execution pipeline treats syntax/insertion errors as immediate failures, these minor formatting deviations caused complete test suite failures.

**Taxonomy of Recurring Failures.** Across all 20 manually inspected bugs, failures fall into three main categories:

1. **Structural & Format Violations (∼50% of failures in medium models):** Inclusion of Markdown tags, explanatory text, duplicated function signatures, or code outside the target block.
2. **Incomplete Repairs (∼30% of failures):** Correct handling of primary branches but omission of required initializations, return statements, or edge-case null checks.
3. **Incorrect Logic (∼20% of failures, predominant in Qwen1.5):** Flawed API usage, invalid state checks, or incorrect enumeration (enum) indexing (e.g., in *Black 3*).

**Unexpected Findings.** The manual inspection showed that structural and formatting violations were more common than complex algorithmic misunderstandings (such as incorrect recursion or invalid mathematical operations). In several cases, generated outputs partially captured the intended repair logic but failed because they violated the required block structure or output format. This suggests that within the evaluated zero-shot block-repair setting, output compliance can be as important as the quality of semantic repair.

### 4.1.2 Project and Category-Level Performance

We also examine repair success across projects and broader project categories to understand whether model behavior varies by software domain. Table 3 reports the number of bugs fixed by each model for each project included in the selected benchmark subset.

**Table 3** Project-wise number of bugs successfully fixed by each model.

| Project | Qwen1.5 | StableCode3 | DeepSeek6 | StarCoder7 | CodeLlama13 | StarCoder15 |
|---|---|---|---|---|---|---|
| Ansible | 2 | 0 | 0 | 0 | 2 | 0 |
| Black | 0 | 0 | 0 | 0 | 0 | 0 |
| CookieCutter | 0 | 0 | 0 | 0 | 0 | 0 |
| FastAPI | 4 | 4 | 3 | 4 | 4 | 4 |
| Luigi | 1 | 0 | 0 | 0 | 1 | 0 |
| Sanic | 1 | 1 | 1 | 1 | 1 | 1 |
| Scrapy | 3 | 0 | 0 | 0 | 3 | 1 |
| TQDM | 4 | 2 | 1 | 3 | 3 | 2 |
| Youtube-dl | 0 | 0 | 0 | 0 | 0 | 0 |

The results show that *FastAPI*, *Sanic*, and *TQDM* are solved more consistently across models, while *Ansible*, *Luigi*, and *Scrapy* are more selective. Qwen1.5 performs strongly across several projects, particularly *FastAPI*, *Scrapy*, and *TQDM*. CodeLlama13 also performs competitively, while StableCode3 and DeepSeek6 show more limited success across projects. In contrast, none of the evaluated models successfully solved bugs from the *Black*, *CookieCutter*, and *Youtube-dl* projects.

Figure 5 aggregates the project-level results into broader categories. The heatmap shows the percentage of bugs fixed by each model within each category.

The evaluated *Web* category is solved consistently across all models. This may indicate that the evaluated web-related bugs are more localized or structurally regular, although confirming this would require a more detailed bug-characteristic analysis. Performance is

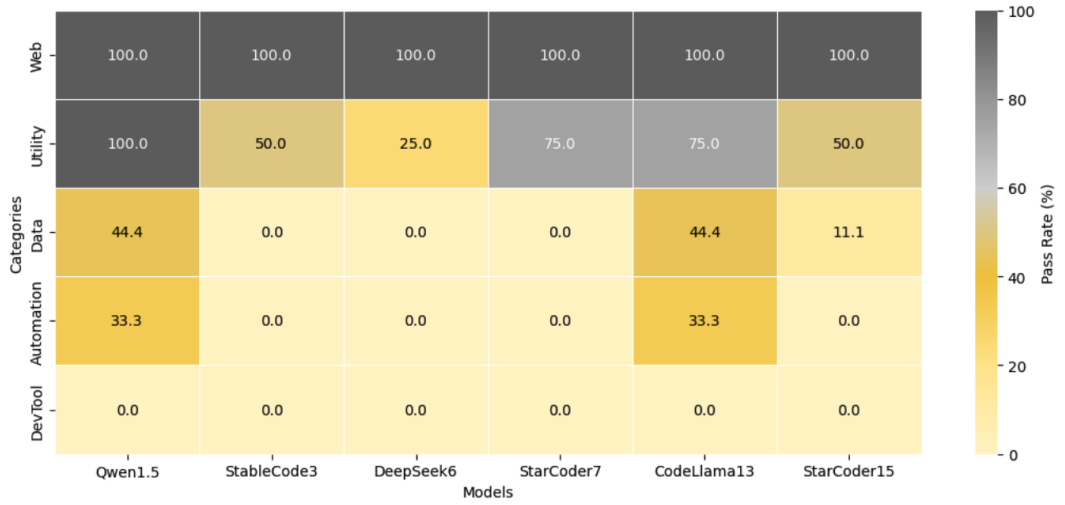

**Figure 5** Model performance across project categories.

more moderate in the *Utility* category and lower in the *Data*, *Automation*, and *DevTool* categories. No model solves the evaluated *DevTool* bugs, suggesting that this category was particularly challenging in the selected benchmark subset. These observations indicate that repair success depends not only on model size but also on the characteristics of the underlying bugs.

## 4.2 RQ2: Inference-Time GPU Energy Cost

*What is the inference-time energy cost associated with running these models on Python bug-fixing tasks?*

This RQ evaluates H2 by comparing GPU energy consumption during inference between larger and smaller models. Inference-time GPU energy consumption is one factor in the sustainability of deployed LLM-based software engineering systems, especially when models are invoked repeatedly. Figure 6 shows the average GPU energy consumption per inference after subtracting baseline idle energy.

Average GPU energy consumption increases with model size in the evaluated set. Qwen1.5 consumes approximately 526 J per inference, followed by StableCode3 with 905 J and DeepSeek6 with 1,050 J. Among the medium-sized models, StarCoder7 consumes approximately 1,651 J, CodeLlama13 requires around 2,784 J, and StarCoder15 consumes over 3,200 J per inference. These results show that medium-sized models incur substantially higher GPU inference energy costs than smaller models.

Figure 7 shows the distribution of GPU energy consumption across tasks for each model. Smaller models consume less GPU energy overall, but their energy values vary more across tasks. Manual inspection suggests that this variation may be related to differences in generated output length and structure, although output length was not analyzed as a separate quantitative variable. In contrast, CodeLlama13 and StarCoder15 show consistently higher but relatively less variable energy consumption, indicating more stable but more expensive inference behavior.

We further analyze GPU energy differences using Vargha–Delaney $A_{12}$ effect sizes. Figure 8 presents pairwise comparisons, where each cell represents the probability that the model on the vertical axis consumes more GPU energy than the model on the horizontal axis.

Values close to 1.0 indicate that the row model usually consumes more GPU energy than the column model, while values close to 0.5 indicate similar distributions. The heatmap reports lower-triangular pairwise comparisons to avoid duplicate symmetric entries.

The $A_{12}$ results show clear differences between small and medium-sized models. Comparisons involving StarCoder7, CodeLlama13, and StarCoder15 produce values close to 1.0 against smaller models, indicating a high probability that these models consume more GPU energy across tasks. Differences among smaller models are less pronounced, although Qwen1.5 remains the lowest-energy model overall.

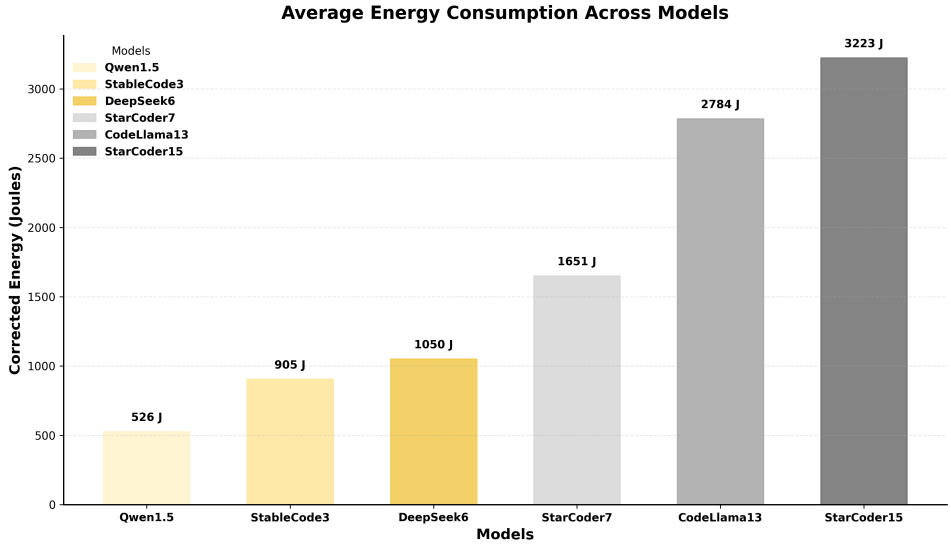

**Figure 6** Average GPU energy consumption per inference across models.

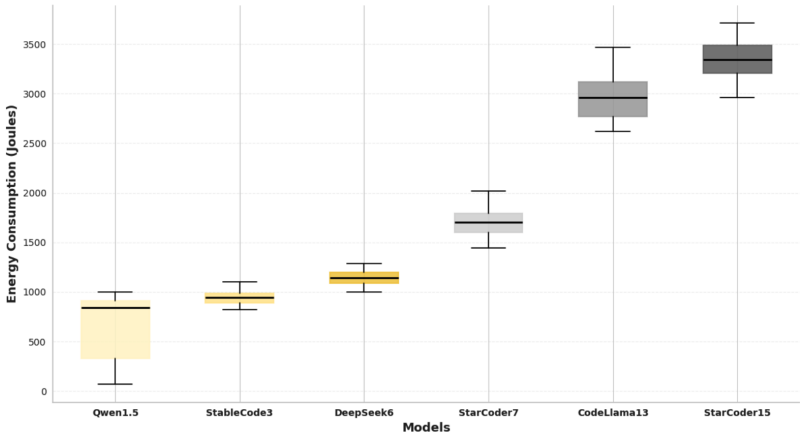

**Figure 7** Distribution of GPU energy consumption across models.

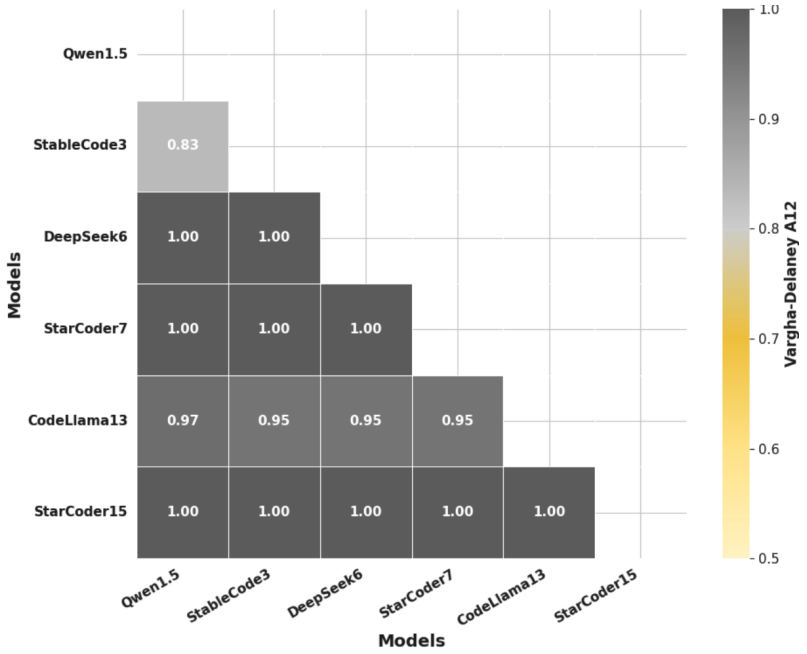

**Figure 8** Pairwise comparison of GPU energy consumption using Vargha–Delaney $A_{12}$ effect size.

**Table 4** Pairwise Wilcoxon signed-rank test results comparing Qwen1.5 with other models.

| Comparison | p-value | Significant |
|---|---|---|
| Qwen1.5 vs StableCode3 | $< 0.001$ | Yes |
| Qwen1.5 vs DeepSeek6 | $< 0.001$ | Yes |
| Qwen1.5 vs StarCoder7 | $< 0.001$ | Yes |
| Qwen1.5 vs CodeLlama13 | $< 0.001$ | Yes |
| Qwen1.5 vs StarCoder15 | $< 0.001$ | Yes |

Because Qwen1.5 has the lowest average GPU energy consumption, we use it as the reference model for pairwise Wilcoxon signed-rank tests. Using per-bug average GPU energy values, the tests show statistically significant differences between Qwen1.5 and all other evaluated models.

**Summary:** GPU energy consumption increases substantially with model size in the evaluated set. Qwen1.5 consumes the least GPU energy, and pairwise statistical tests show significant differences between Qwen1.5 and all other models. This supports H2 in the evaluated setting.

## 4.3 RQ3: Correctness–Energy Trade-offs

*Which model provides the most favorable trade-off between correctness, inference time, and energy consumption for Python bug-fixing tasks?*

RQ3 compares repair correctness, inference time, and GPU energy consumption jointly. Figure 9 presents normalized values for the three dimensions across models. Energy and runtime are cost dimensions, so lower normalized values are preferable for those lines. Repair correctness is a benefit dimension, so higher normalized values are preferable for the correctness line.

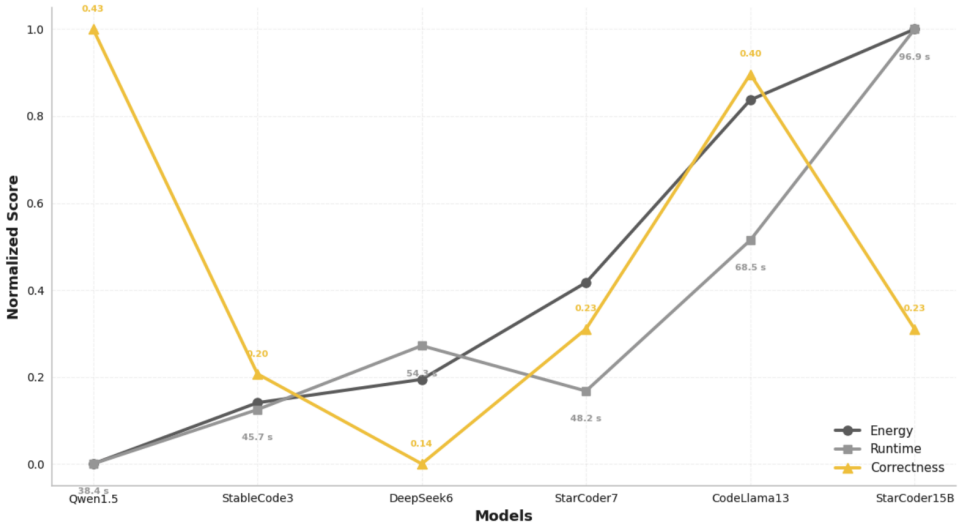

**Figure 9** Normalized trade-off comparison of GPU energy consumption, inference time, and repair correctness across models. All metrics are Min-Max scaled to $[0, 1]$, Lower values are preferable for energy and runtime, whereas higher values are preferable for repair correctness. Data labels display raw, unnormalized values for direct reference.

Qwen1.5 provides the strongest overall trade-off between correctness and energy. It is the only model that is best on all four reported dimensions: Pass@10, Pass@1, average inference time, and average GPU energy consumption. CodeLlama13 achieves competitive repair correctness, but at substantially higher inference time and GPU energy cost. StarCoder15 consumes the most energy and takes the longest inference time, yet achieves lower repair correctness than both Qwen1.5 and CodeLlama13.

These results show that higher model size and higher GPU energy consumption do not necessarily translate into better repair performance. In the evaluated setting, repair correctness does not increase consistently with model size, whereas inference time and GPU energy consumption generally do. Therefore, correctness-only comparisons would miss an important part of the model-selection trade-off for LLM-based repair.

**Summary:** Qwen1.5 provides the most favorable trade-off between correctness and energy among the evaluated models, while also achieving the lowest average inference time. Larger models generally incur higher runtime and GPU energy costs without consistent improvements in correctness in this benchmark.

## 5 Discussion

The results show that model size alone is not a reliable indicator of repair effectiveness in the evaluated Python bug-fixing setting. Qwen1.5, the smallest model in the study, achieved the strongest repair correctness while also requiring the lowest inference time and GPU energy consumption. In contrast, larger models, such as StarCoder15, incurred substantially higher runtime and energy costs without corresponding gains in correctness. This suggests that scaling model size does not automatically improve correctness; there are energy trade-offs in LLM-based repair.

One explanation is the block-level and format-constrained nature of the repair task. Each model was asked to generate a complete replacement for a function or class and to output only executable Python code. The exploratory failure analysis suggests that several failures were caused not only by incorrect repair logic, but also by output-structure problems such as extra text, duplicated code, incomplete blocks, or code outside the expected structure. In such a setting, concise, structurally compliant outputs may be more useful than longer or more complex outputs.

The project and category-level results further indicate that repair success depends on the characteristics of the underlying bugs. The evaluated web-related bugs were solved more consistently across models, whereas DevTool, Data, and Automation tasks were more challenging. This suggests that future studies should examine bug characteristics more explicitly, including locality, dependency structure, and whether the repair requires a broader repository context.

For researchers, these findings reinforce the need to report inference time and GPU energy alongside repair correctness. For practitioners, the results suggest that smaller open-source code LLMs should not be dismissed solely because of their size, especially in local or repeated debugging workflows. However, these implications are limited to the evaluated models, prompt, benchmark, and hardware setup, and should not be interpreted as a general claim that smaller models are always preferable.

## 6 Threats to Validity

**Construct validity.** Repair correctness is measured using execution-based testing: a generated repair is considered correct if it passes the bug-specific test suite. This is common in automated program repair, but passing the available tests does not guarantee semantic equivalence to the developer patch or correctness for all inputs. In addition, this study measures GPU energy during model inference using NVML. The reported values therefore represent GPU-side repair-generation energy, not full-system or end-to-end pipeline energy; CPU, memory, disk, cooling, repository setup, patch insertion, and test execution are excluded. The repair task is also limited to function- or class-level replacement, so bugs requiring multi-location edits, new imports outside the extracted block, configuration changes, or broader repository-level reasoning are not captured.

**Internal validity.** Energy and runtime measurements can be affected by GPU state, thermal behavior, background processes, caching, and scheduling effects. To reduce these threats, all experiments were executed on the same dedicated GPU node with an identical configuration, a fixed delay between repeated runs, and baseline idle energy subtraction. Full-system energy could not be measured because CPU and host-level energy profiling were restricted in the HPC environment. Model-output variability is another threat. We did not apply task-specific or model-specific decoding tuning and relied on the default generation behavior of the inference library/model configuration. Random seeds were not fixed; instead, each bug-model pair was executed 10 times, and results were aggregated across attempts. Invalid or non-compliant outputs, such as Markdown, explanations, incomplete code, syntax errors, or outputs with an unexpected structure, were counted as unsuccessful repairs and were not manually edited.

**External validity.** The study initially selected 40 Python bugs from BugsInPy, of which 35 were retained for the balanced aggregate comparison across all six models due to complete and consistent run coverage. The six evaluated open-source code-oriented LLMs range

from 1.5B to 15B parameters and were executed on a single hardware configuration: an NVIDIA Tesla V100 GPU with 32 GB of memory, 4 CPU cores, and 128 GB of RAM. Results may not generalize to proprietary models, larger or newer models, quantized variants, tool-augmented repair systems, other programming languages, other benchmarks, or different hardware. Results may also differ under alternative prompt designs, decoding configurations, or model-specific tuning. Therefore, the findings should be interpreted as evidence for the evaluated models, tasks, prompts, and hardware setup. In particular, our conclusions should not be generalized to automated program repair scenarios requiring repository-level reasoning, cross-file modifications, or broader contextual understanding.

**Conclusion validity.** Repeated runs, statistical tests, and effect sizes are used to support comparisons across models. However, the benchmark size is limited, and multiple pairwise comparisons may increase the risk of false positives; therefore, statistical results are interpreted together with descriptive trends and effect sizes. The qualitative failure analysis is exploratory and is used to support the interpretation of quantitative results rather than to provide a validated taxonomy of LLM repair failures.

## 7 Conclusion

This study presents an empirical evaluation of open-source LLMs for localized Python bug-fixing tasks, where each repair replaces a single extracted function or class. Using the BugsInPy benchmark, models ranging from 1.5B to 15B parameters were evaluated under controlled conditions. The results show that increasing model size does not consistently improve performance for the localized repair scenarios investigated in this study. In particular, the smallest model (Qwen 1.5B) achieved the highest overall performance while consuming significantly less energy. In contrast, larger models incurred substantially higher computational costs without delivering proportional gains in correctness, indicating diminishing returns from scaling. The qualitative analysis further suggests that output characteristics, such as conciseness and structural correctness, can affect repair success in the evaluated block-level setting. In the inspected cases, some medium-sized models produced longer or more structurally complex outputs, which were more susceptible to formatting or structural failures. These findings highlight an important trade-off between performance and sustainability in AI-assisted software engineering. Rather than defaulting to larger models, practitioners should select models based on task requirements, reliability constraints, and resource efficiency.

### Future Work

This study can be extended in several directions. First, to include a broader range of models, including larger-scale and proprietary systems, to better understand how model size and architectural differences influence both performance and energy consumption. In addition, exploring alternative prompting strategies, such as few-shot and instruction-based prompting, may provide further insight into how input design affects both correctness and computational efficiency. Second, the evaluation can be expanded to cover additional programming languages and more diverse software systems, enabling analysis of whether the observed trends generalize beyond Python-based bug-fixing tasks. Incorporating a larger set of bugs, including those currently excluded due to dependency or execution constraints, would further improve the representativeness of the results. Finally, future studies can extend energy measurement beyond GPU inference to capture full-system consumption, including CPU, memory, and the complete execution pipeline.

## Abstract

**Background.** Evaluating automated Software Requirements Specification (SRS) generation is challenging because few datasets provide fine-grained traceability between source requirements, intermediate elicitation artifacts, and generated specifications.

**Aims.** We study whether legacy SRS documents can serve as controlled reference evidence for constructing traceable synthetic pre-SRS artifacts that enable fine-grained evaluation of LLM-based requirements transformations.

**Method.** We conduct an empirical study using *ReqGenX*, a controlled pipeline that decomposes SRS sections into atomic statements grounded in the SRS content, routes atoms to standards-inspired artifact types through multi-LLM plurality voting, and generates artifacts using constrained prompts with iterative judge-guided refinement. We evaluate *ReqGenX* on seven PURE SRS documents using grounding, quality, information retention, and downstream reconstruction analyses.

**Results.** *ReqGenX* produces highly grounded, well-formed atoms that score strongly on our atomicity and downstream-utility criteria, with median AlignScore values typically between 0.96 and 0.99 and Prometheus scores ranging from 4.34 to 4.85. Generated artifacts remain strongly grounded in their source atoms, with AlignScore values typically between 0.80 and 0.94 and judge pass rates near 100%; stricter Prometheus evaluation yields pass rates ranging from 54.8% to 97.1%. In a downstream SRS reconstruction case study, artifact-backed atoms remain recoverable from generated SRSs, with SBERT means between 0.69 and 0.75 and AlignScore medians between 0.76 and 0.84.

**Conclusions.** Traceable synthetic pre-SRS artifacts can support fine-grained evaluation of LLM-based SRS generation, while exposing tradeoffs among faithfulness, information retention, and artifact completeness. These artifacts are intended as controlled evaluation resources rather than substitutes for primary elicitation evidence.

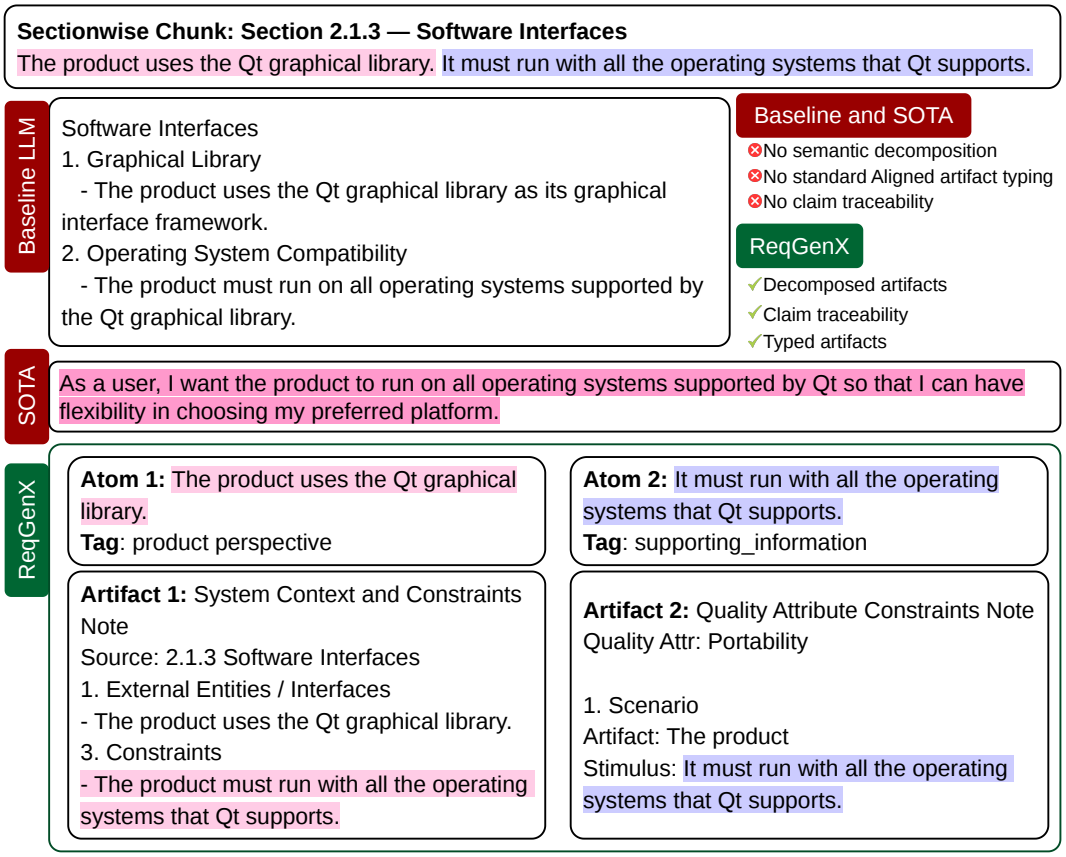

**Figure 1** Example of section-to-atom decomposition and artifact routing. The illustrative direct-generation branch merges claims, whereas *ReqGenX* decomposes and routes them to typed, traceable artifacts. This branch illustrates the traceability problem and is not an experimentally evaluated baseline or SOTA comparison. Colored highlights ( : requirement content, : supporting information content) map source statements to artifact content.

## 1 Introduction

Large language models (LLMs) are increasingly used in requirements engineering (RE) for SRS generation, requirement extraction and validation, and intermediate artifacts such as user stories and acceptance criteria [25, 40, 34]. Related work has also sought to make software behavior and assumptions explicit through behavioral contracts and inferred data preconditions [5, 4], while recent LLM-based approaches extend this direction to formal and executable specification generation, intent-aware development workflows, and structured representations of functional requirements derived from developer discussions [7, 9]. At the SRS level, however, an LLM-generated document may omit source information, merge distinct concerns, or introduce unsupported requirements. Evaluating LLM-based SRS compilation, therefore, requires more than document-level quality: it requires evidence about which source claims support generated content and where information is preserved or lost. Prior NLP4RE work addresses requirements classification, extraction, quality analysis, and traceability [39]; PURE provides public requirements documents [18], and traceability research links information across lifecycle artifacts [19]. However, existing public resources do not jointly provide source requirements, intermediate RE artifacts, generated specifications,

and their provenance links. This limits researchers' ability to localize failures across multi-stage LLM-supported requirements transformations. We therefore study where information is preserved, transformed, or lost when legacy SRSs are used as controlled source evidence.

In this study, *pre-SRS artifacts* are typed intermediate representations of requirements that can precede or support SRS authoring, including use-case briefs, quality-attribute constraints, context notes, acceptance criteria, terminology/reference artifacts, and assumption/dependency records. *ReqGenX* generates synthetic proxy artifacts from legacy SRS content; it does not recover the historical elicitation materials behind the original SRSs or address greenfield elicitation from interviews, stakeholder discussions, issue reports, regulations, or other primary evidence. Our primary audience is researchers evaluating LLM-supported RE transformations.

Figure 1 illustrates the traceability problem using a *QHeadache* section from PURE [18]. The section contains a Qt library dependency and an operating system compatibility constraint. An illustrative direct-generation branch merges these claims into one generic artifact, whereas *ReqGenX* decomposes them into separate atoms and routes them to typed artifacts while preserving claim-level provenance. To study this problem, *ReqGenX* uses each SRS as controlled evidence and operates in three stages: (1) normalization and decomposition into atomic statements grounded in the observed SRS chunk; (2) semantic routing through multi-LLM plurality voting with human review; and (3) artifact-specific generation with iterative quality checks. Stable identifiers preserve provenance from SRS sections through atoms, semantic tags, and generated artifacts. We evaluate grounding, atomicity, downstream utility, information retention, decision reliability, artifact quality, and downstream reconstruction across seven PURE SRSs.

Our results show that atoms are strongly grounded, with median AlignScore values typically between 0.96 and 0.99, although source coverage varies substantially across datasets and models. Generated artifacts also remain strongly grounded in their source atoms, with AlignScore values typically between 0.80 and 0.94, while stricter Prometheus evaluation reveals wider variation in artifact quality. In the downstream reconstruction case study, artifact-backed atoms remain partially recoverable, with SBERT means of 0.690–0.753 and AlignScore medians of 0.760–0.842. These results show that strong grounding at one stage of transformation does not imply complete information preservation downstream. We do not position *ReqGenX* as a production SRS-generation system; rather, we use it as a traceable experimental setting for studying information preservation, evidence granularity, artifact quality, and LLM-based intermediate decisions. This setting exposes intermediate failure modes that final-document evaluation alone cannot localize.

Our contributions are:

- We characterize LLM-based atomization across seven PURE SRSs, showing that strong atom-level faithfulness can coexist with substantial variation in source coverage.
- We evaluate typed artifact generation and show that strong source grounding does not necessarily imply artifact completeness or structural quality.
- We analyze stage-wise information loss across SRS→Atoms→Artifacts and evaluate downstream reconstruction separately as a controlled recoverability case study.
- We evaluate semantic routing and LLM-based quality judgment against human-reviewed labels, including a human-calibrated judge-selection procedure.
- We release a traceable replication package containing processed SRSs, generated atoms and artifacts, prompts, codebooks, provenance metadata, and evaluation outputs [8].

Sections 2–4 present the pipeline, experimental design, and results; Sections 5–8 discuss lessons learned, related work, threats to validity, and conclusions.

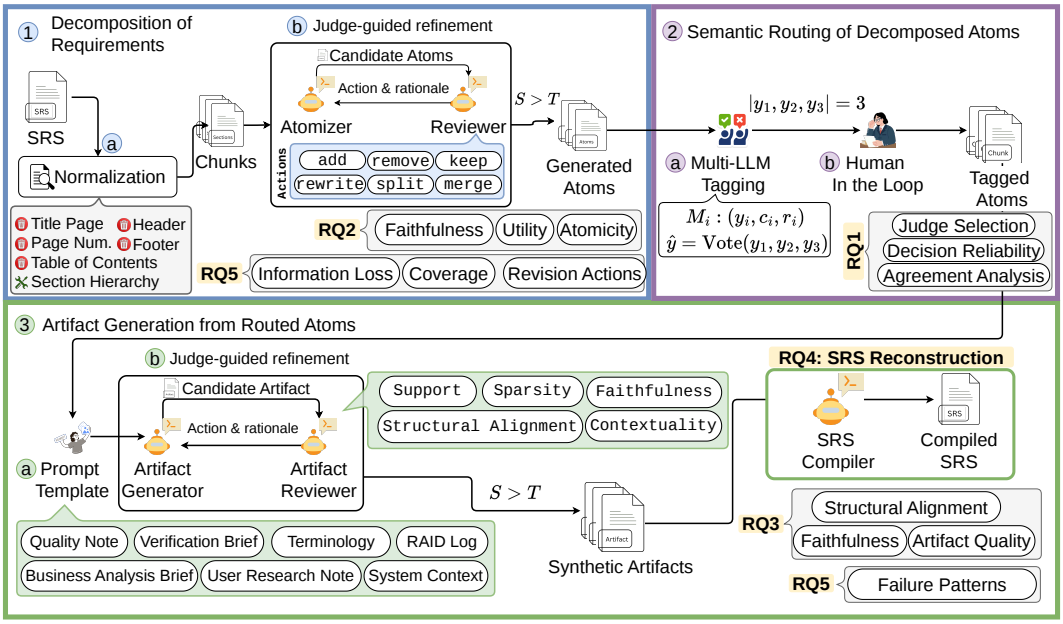

**Figure 2** End-to-end *ReqGenX* study pipeline for deriving and evaluating traceable synthetic pre-SRS artifacts from legacy SRS documents.

## 2 Study Pipeline

**Terminology.** We use *section* for a logical SRS unit after normalization, *chunk* for the text associated with that section, and *atom* for a minimal proposition extracted from and supported by a chunk. Throughout this paper, *source* refers to the observed legacy SRS content used as evidence, not to the unknown historical elicitation materials from which the SRS may have been created. An atom should express one coherent statement and remain interpretable in isolation, consistent with the requirements-quality notion of atomicity [20].

*ReqGenX* is intentionally a multi-stage experimental pipeline rather than a lightweight or deployment-ready RE tool. We assess its stages through manual normalization checks, human-reviewed routing labels, candidate-model screening, reconciled human annotations for judge selection, grounding metrics, and external Prometheus evaluation. Figure 2 summarizes three stages: (1) decomposition into atoms grounded in the observed SRS content; (2) semantic routing of atoms to artifact types; and (3) generation and refinement of typed pre-SRS artifacts.

### 2.1 Decomposition of Requirements

The pipeline begins with an SRS document, typically provided as a PDF. We convert each document into a text representation that preserves headings, lists, and basic structure, then normalize it by removing presentation-oriented material and repairing common PDF-conversion errors [10, 28]. The normalized text is manually checked against the original SRS to ensure that requirements content is preserved and parsing artifacts are not introduced. Although PURE also provides parsed XML representations, our implemented pipeline operates on the original SRS documents and includes PDF-to-text normalization as preprocessing; using PURE's XML could reduce this effort in future replications.

**Table 1** Routing of atom tags to pre-SRS artifact types.

| IEEE 29148 Artifact | Atom Tags |
|---|---|
| Business Analysis Brief | Purpose, Scope, Product Functions |
| User Research | User Characteristics |
| System Context and Constraints | Product Perspective, Limitations, Supporting Information, Other |
| Use Case Brief | Functional |
| Quality Attribute Constraints | Availability, Fault Tolerance, Operability, Performance, Portability, Scalability, Security, Legal, Usability, Look and Feel, Maintainability |
| Acceptance Criteria Sheet | Verification |
| Terminology and References | Definitions, References, Acronyms and Abbreviations |
| RAID Log Entry | Assumptions and Dependencies |

The normalized SRS is segmented into section-wise chunks that retain section and source-document metadata. An LLM-based atomizer then separates independent propositions while preserving qualifiers, conditions, bounds, and scope. In the running example of Figure 1, the software-interface section is decomposed into separate atoms for the Qt dependency and operating-system compatibility.

Each atom is evaluated for three criteria: *faithfulness*, requiring every claim to be supported by the source chunk; *atomicity*, requiring one self-contained proposition rather than bundled ideas or structural fragments; and *downstream utility*, which we operationalize as whether the atom contains sufficient requirements-relevant information to instantiate at least one artifact type in Table 1. Because LLM-generated atoms may still be ambiguous, infeasible, or unsupported [33], a separate judge scores these criteria and returns `keep`, `rewrite`, `split`, `merge`, `remove`, or `add` actions. Failed atom sets are revised before routing.

## 2.2 Semantic Routing of Decomposed Atoms

After decomposition, *ReqGenX* assigns each atom an IEEE 29148-inspired semantic tag [2, 39, 21]. Table 1 maps these tags to pre-SRS artifact families. In the running example, the Qt-library atom is routed to a System Context and Constraints artifact, whereas the operating-system compatibility atom supports a portability-related Quality Attribute Constraint. Routing follows an independent proposal-then-aggregate strategy. The atomizer proposes an initial tag, three LLM agents independently label the atom without observing peer outputs, and plurality voting selects the final tag [35, 41]. Unresolved cases receive human-in-the-loop (HITL) review before artifact generation. Atoms tagged as `requirements` undergo a second classification as *functional*, *quality*, or *other*. Functional atoms are routed to Use Case Briefs, whereas quality atoms are routed to Quality Attribute Constraints and further assigned a PROMISE-NFR subtype, such as availability, performance, portability, security, or usability [27]. These subtypes guide artifact expression rather than changing the artifact family. The same plurality-voting and human-review process is used for this second classification.

## 2.3 Artifact Generation and Review

After routing, *ReqGenX* transforms each validated atom into an artifact using a type-specific template. In the running example, the two routed atoms are expressed using their corresponding artifact structures while preserving their source identifiers. The `atom_text` is

the primary source of truth: substantive artifact content must be supported by the atom, while semantic tags, section metadata, and chunk context are used only for structure or minor disambiguation. Generated artifacts retain an identifier linking them to their source atoms, and post-processing removes residual formatting or rationale text. Templates are deliberately conservative: they prohibit unsupported enrichment, omit unsupported fields, and permit empty outputs when the available evidence cannot support a valid artifact. A rubric-based judge evaluates artifacts for *faithfulness*, *support*, *contextuality*, *structural alignment*, and *sparsity*. Failed artifacts are revised using judge feedback until they satisfy the acceptance threshold or the refinement budget is exhausted. The eight artifact families in Table 1 cover the principal information roles considered in this study and draw on established requirements and architecture documentation practices [13, 2, 11, 1].

### 2.4 Traceability and Provenance Model

*ReqGenX* maintains provenance across transformations so that generated outputs can be audited against their SRS evidence. Chunks retain document and section metadata, while each generated artifact receives a stable trace identifier linked to its source atom, semantic label, and relevant source context. The resulting chain connects the SRS document and section to the chunk, atom, semantic tag, generated artifact, and, for the reconstruction case study, matched SRS sentence windows. In the running example, this chain links the original QHeadache section to each atom, semantic label, and generated artifact. We use these links for grounding checks, information retention analysis, and downstream recoverability evaluation. This metadata is not intended as a complete industrial traceability solution; it provides the provenance required for the controlled analyses in this study.

## 3 Experimental Design

We evaluate *ReqGenX* as a controlled empirical pipeline for studying information change across transformations from legacy SRS content to synthetic pre-SRS artifacts and downstream reconstruction. We examine five complementary aspects: 1 the reliability of routing and quality decisions that determine how atoms proceed through the pipeline; 2 atomization quality and information preservation; 3 artifact grounding and structural quality; 4 downstream recoverability in an SRS reconstruction case study; and 5 stage-wise information loss and associated failure patterns. Together, these dimensions expose behavior that final-document evaluation alone cannot localize. In RQ1, *RE-specific intermediate decisions* refer to semantic routing, which determines which artifact family an atom can support, and quality judgment, which determines whether generated outputs proceed downstream.

- **RQ1:** How reliable are the RE-specific intermediate decisions made by LLMs within *ReqGenX* for semantic routing and quality judgment, and how does reliability vary across models and decision types?
- **RQ2:** How does atomization quality vary across LLMs and SRS documents in terms of faithfulness, atomicity, downstream utility, and source-information coverage?
- **RQ3:** How does the quality of generated pre-SRS artifacts vary across LLMs and SRS documents in terms of grounding, sparsity, structural alignment, and rubric-based quality?
- **RQ4:** To what extent are artifact-backed source atoms recoverable after downstream SRS reconstruction in a controlled case study?
- **RQ5:** At which transformation stages is source information lost, and which revision and failure patterns explain the observed losses?

RQ1 uses PROMISE-NFR candidate-model screening, Cohen's $\kappa$ agreement with human-reviewed routing labels, and human-calibrated judge selection using F1, false-positive rate (FPR), and false-negative rate (FNR). RQ2 compares seven SRSs and three atomizer models using AlignScore, atomicity, downstream utility, Prometheus, and source coverage. RQ3 evaluates artifacts using source-atom AlignScore, internal-judge acceptance, Prometheus, and artifact-specific quality criteria. RQ4 uses a four-dataset reconstruction case study with Claude-generated artifacts, GPT-4o compilation, and SBERT/AlignScore recoverability. RQ5 combines stage-wise retention, revision-action frequencies, and artifact-generation failure traces.

## 3.1 Dataset

We construct the benchmark from PURE [18] following the document-selection protocol of Okamoto et al. [28]. Because *ReqGenX* operates on ordered text, we retain documents explicitly identified as SRSs whose requirements can be represented as textual sections, paragraphs, and lists. We exclude other specification types and SRSs containing substantive figures or non-revision-history tables that lack a stable linear reading order; revision-history tables are retained because they can be normalized without changing their meaning. The resulting benchmark contains seven SRSs: Get Real, Library, Puget Sound, QHeadache, VUB, Libra, and Home, comprising 31,454 words, 1,408 sentences, and 369 sections. This selection favors text-oriented SRSs and may underrepresent failures arising in figure-heavy, table-heavy, or multimodal specifications.

## 3.2 Implementation and Large Language Models

We implemented *ReqGenX* in Python 3.11 with LLM interactions orchestrated through LangChain. Experiments ran on a 28-core Intel® Xeon® W-3465X CPU (2.50 GHz), 256 GB RAM, and an NVIDIA RTX 6000 Ada Generation GPU under Ubuntu 24.04.2 LTS. We use a temperature of 1.0 to encourage output diversity. The evaluated model set spans closed- and open-source families and includes Claude Sonnet 4.6, GPT-4o, GPT-OSS (20.9B), Gemma 3 (27.4B), Phi-4 (14.7B), Mistral (7.2B), Llama 3.1 (8.0B), Qwen3 (30.5B and 8.2B), and LLaMA 3 (8.0B), used across atom generation, semantic routing, artifact generation, and review.

## 3.3 Evaluation Procedure

### 3.3.1 Judge Calibration and Selection

For quality judgment, we sample 291 triples from 1,195 Claude Sonnet 4.6-generated artifact instances. Two annotators independently score atom and artifact quality using the shared 1–5 rubric, with disagreements adjudicated into reconciled reference labels. Candidate judges are compared against these labels using F1, FPR, and FNR. Because false acceptance can propagate low-quality outputs downstream, judge selection prioritizes low FPR.

### 3.3.2 Reconstruction Case-Study Procedure

RQ4 is evaluated on four datasets using an additional pipeline for generation, quality assurance, and traceability matching. We use Claude Sonnet 4.6-generated artifacts for their strong upstream performance, and GPT-4o as a separate compiler model. GPT-4o compiles the artifacts into SRS drafts under ISO/IEC/IEEE 29148-inspired constraints while

preserving artifact-level traceability, then refines them for ambiguity, singularity, verifiability, and syntactic correctness. Each reconstructed SRS is then matched to its accepted artifact-backed source atoms using the reconstruction metrics defined below.

## 3.4 Evaluation Metrics

We use grounding and rubric-based quality measures as the primary indicators of output quality, while coverage, agreement, revision actions, and reconstruction metrics serve as complementary diagnostics for localizing information loss, model disagreement, and downstream recoverability.

**AlignScore.** We use AlignScore [37] to measure semantic support. For atoms, the source chunk is the context and the atom is the claim; for artifacts, the source atom is the context and the artifact is the claim. We use 0.80 as the support threshold for unsupported-rate analyses.

**Judge LLM and Prometheus Evaluation.** A rubric-based judge scores atom and artifact quality on a 1–5 scale, with scores $\geq 4$ treated as passing. Atoms are assessed for faithfulness, atomicity, and downstream utility; artifacts for faithfulness, support, contextual use, structural alignment, and sparsity. Prometheus [24] provides an external complementary rubric-based assessment.

**Embedding-Based Information Retention.** We estimate source retention using cosine similarity over `text-embedding-3-large`. Source SRS text is divided into overlapping two-sentence units and matched to final atoms; a unit is covered when its best-match similarity is at least 0.75. We use this measure for atomization coverage and stage-wise SRS→Atoms→Artifacts retention.

**Downstream SRS Reconstruction Metrics.** We measure the recoverability of accepted artifact-backed atoms from reconstructed SRSs. Each SRS is segmented into overlapping sentence windows, and source atoms are matched to their closest windows using SBERT cosine similarity [31]. AlignScore is then applied with the matched SRS window as context and the source atom as the claim. SBERT captures semantic similarity, whereas AlignScore estimates factual support.

# 4 Results and Evaluation

## 4.1 RQ1: Reliability of LLM-Based RE Decisions

**Finding 1:** Reliability of LLM-based RE-specific intermediate decisions varies across models and decision types. Semantic tagging is more stable than fine-grained requirement classification, while judge performance also differs across models. These results indicate that intermediate LLM decisions in RE pipelines should be validated independently rather than treated as uniformly reliable, particularly when their errors can propagate to downstream artifacts.

**Table 2** Performance of candidate LLMs on the PROMISE dataset for plurality voting selection. Metrics are reported as support-weighted per-class precision, recall, and F1; weighted F1 is averaged from per-class F1 values.

| Model | Precision | Recall | F1 |
|---|---|---|---|
| Claude Sonnet 4.6 | 0.80 | 0.84 | **0.81** |
| GPT-4o | 0.78 | **0.86** | **0.81** |
| GPT-OSS | 0.84 | 0.68 | 0.70 |
| Phi-4 | 0.84 | 0.55 | 0.59 |
| Qwen3 (30B) | **0.92** | 0.43 | 0.50 |
| Qwen3 (8B) | 0.80 | 0.46 | 0.50 |
| LLaMA 3 (8B) | 0.44 | 0.37 | 0.36 |

**Note:** Bold values indicate the best value in each metric column; underlined values indicate the second-best value. Ties are marked for all tied values.

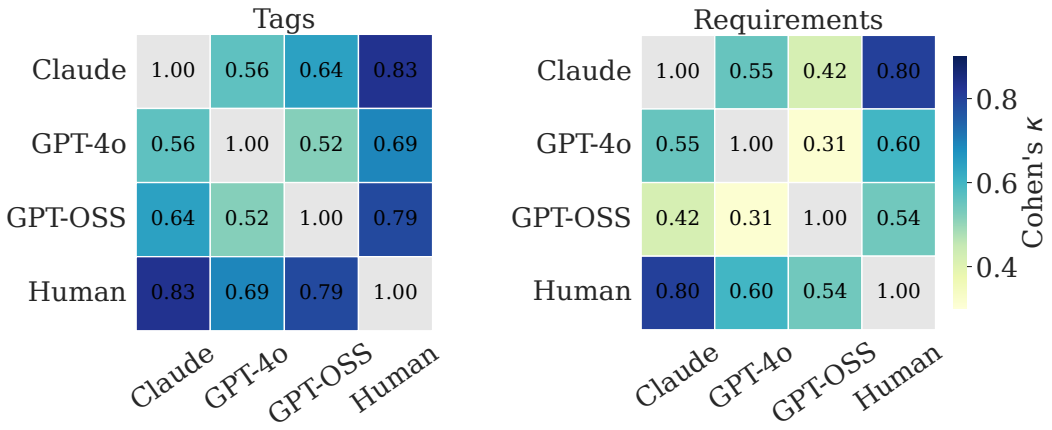

**Figure 3** Pairwise Cohen's $\kappa$ agreement among LLM-generated and human-reviewed labels for semantic tag assignment and requirement classification. Diagonal cells denote self-agreement, while off-diagonal cells show agreement between annotator/model pairs.

RQ1 shows that reliability varies across models and decision types. On the re-labeled PROMISE-NFR dataset[1], Claude Sonnet 4.6 and GPT-4o achieve the strongest weighted F1 among closed-source models, while GPT-OSS is the strongest open-source model. Because PROMISE-NFR does not cover the full *ReqGenX* routing schema, Table 2 should be interpreted as evidence of general requirement-classification ability rather than direct routing accuracy. Based on this screening, we use Claude Sonnet 4.6, GPT-4o, and GPT-OSS 20B as complementary voters for plurality-based routing. On the actual *ReqGenX* routing schema, agreement with human-reviewed labels is consistently higher for semantic tags than for fine-grained requirement classification. The analysis includes 2,054 semantic-tag instances and 1,177 requirement-label instances; human review corrected 353 semantic tags (17.2%) and 58 requirement labels (4.9%). Figure 3 shows that Claude has the strongest agreement with human-reviewed labels, reaching $\kappa = 0.83$ for tags and $\kappa = 0.80$ for requirements, while model-to-model agreement is weakest for requirement classification, where GPT-4o

[1] `https://zenodo.org/records/14330485`

**Table 3** Comparison of candidate judge LLMs for atom- and artifact-level assessment against reconciled human labels. F1 is higher-is-better. FPR and FNR are lower-is-better.

| | Atoms | | | Artifacts | | |
|---|---|---|---|---|---|---|
| **LLM** | **F1 ↑** | **FPR ↓** | **FNR ↓** | **F1 ↑** | **FPR ↓** | **FNR ↓** |
| Gemma 3 | <u>0.80</u> | 0.33 | 0.20 | **0.88** | **0.29** | 0.13 |
| GPT-4o | 0.77 | <u>0.28</u> | 0.27 | **0.88** | 0.63 | <u>0.03</u> |
| Phi-4 | 0.79 | 0.46 | <u>0.16</u> | <u>0.87</u> | <u>0.47</u> | 0.09 |
| Mistral | 0.74 | 0.89 | **0.12** | 0.84 | 1.00 | **0.01** |
| Llama 3.1 | 0.66 | **0.23** | 0.44 | 0.83 | 0.90 | 0.04 |
| GPT-OSS | **0.81** | 0.49 | **0.12** | 0.76 | 0.77 | 0.21 |

**Note:** Bold values indicate the best value in each metric column; underlined values indicate the second-best value. Ties are marked for all tied values.

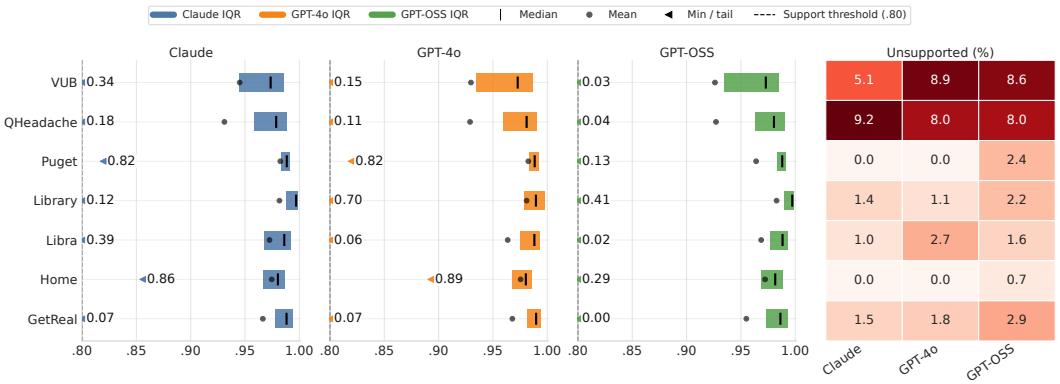

**Figure 4** Chunk-level atom faithfulness across datasets and atomizer models. Most atomized outputs achieve high central AlignScore values, with medians generally above 0.95, but several dataset-model pairs exhibit low-scoring tail cases. Unsupported rates are computed using the AlignScore support threshold of 0.80 and show that high typical faithfulness can still coexist with occasional unsupported atoms.

and GPT-OSS fall to $\kappa = 0.31$. For quality judgment, the 291 human-annotated triples yield strong inter-annotator agreement, with Cohen's $\kappa = 0.84$ for atoms and $\kappa = 0.97$ for artifacts. Table 3 shows that Gemma 3 provides the best overall tradeoff under the judge-selection criteria defined in Section 3, with F1 scores of 0.80 for atoms and 0.88 for artifacts while avoiding the substantially higher false-positive rates of GPT-OSS for atoms and GPT-4o for artifacts. We therefore use Gemma 3 as the automated judge for large-scale evaluation.

## 4.2 RQ2: Quality of Generated Atoms

RQ2 evaluates whether LLMs can decompose legacy SRS sections into atoms that are faithful, atomic, and useful for downstream artifact generation. Overall, the results show that LLM-generated atoms are usually well grounded, but atomization is not equivalent to lossless extraction: usable decomposition requires balancing faithfulness, source coverage, atomicity, and downstream utility.

Figure 4 shows that generated atoms are generally faithful to their source chunks. Across datasets and models, median AlignScore values typically range from 0.96 to 0.99, while unsupported rates remain below 3% for most dataset-model pairs. The strongest cases

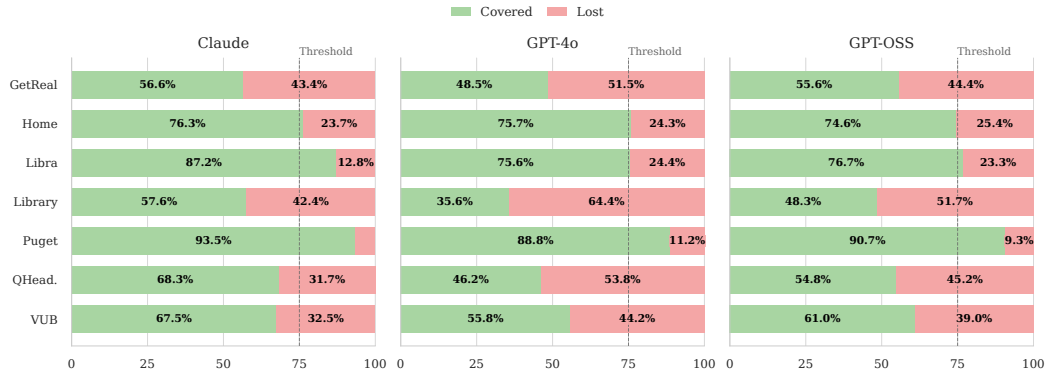

**Figure 5** Information coverage and loss across datasets using overlapping window-2 source units with a similarity threshold of 0.75. Each horizontal stacked bar shows the percentage of covered and lost source information units for a given model and dataset.

**Table 4** Final atom quality across SRSs and atomizer models. Atomicity and usability pass rates report the percentage of final atoms receiving judge scores $\geq 4$; average Judge (Gemma 3) and Prometheus scores are reported on a 1–5 scale.

| SRS | Atomicity Pass % | | | Usability Pass % | | | Avg. Judge Score | | | Avg. Prometheus Score | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Claude | GPT-4o | GPT-OSS | Claude | GPT-4o | GPT-OSS | Claude | GPT-4o | GPT-OSS | Claude | GPT-4o | GPT-OSS |
| VUB | **98.1** | 92.5 | 96.4 | **96.2** | 85.6 | 89.8 | **4.84** | 4.70 | 4.75 | **4.72** | 4.69 | 4.67 |
| QHeadache | **98.0** | 76.0 | 87.5 | **93.9** | 70.7 | 75.0 | **4.84** | 4.65 | 4.66 | 4.77 | 4.77 | **4.80** |
| Puget Sound | 96.2 | **96.3** | 94.5 | 82.6 | 84.6 | **87.4** | 4.67 | **4.69** | **4.69** | 4.34 | **4.44** | 4.37 |
| Library | **90.0** | 85.6 | 87.6 | **87.9** | 82.2 | 80.3 | **4.87** | 4.76 | 4.75 | 4.81 | 4.77 | **4.85** |
| Libra | 93.0 | 94.1 | **95.3** | 91.0 | 89.8 | **92.2** | 4.78 | **4.80** | **4.80** | 4.72 | **4.75** | 4.72 |
| Home | 98.5 | **100** | 99.3 | **97.0** | 90.3 | 94.6 | **4.90** | 4.86 | 4.85 | 4.70 | 4.69 | **4.72** |
| Get Real | 95.4 | 93.0 | **95.7** | 81.5 | 82.5 | **85.7** | 4.64 | 4.62 | **4.73** | 4.46 | **4.60** | 4.59 |

*Note.* **Bold** values indicate the best-performing model for each dataset and metric group; underlined values indicate the second-best model. Ties are marked for all tied models.

occur in Puget Sound and Home, where unsupported rates are 0.0% for Claude Sonnet 4.6 and GPT-4o, and remain low for GPT-OSS. The highest unsupported rates appear for QHeadache with Claude-generated atoms (9.2%) and for VUB with GPT-4o and GPT-OSS atoms (8.9% and 8.6%, respectively). These low-scoring tails show that median faithfulness alone is insufficient: occasional unsupported atoms can still appear and may propagate into routing and artifact generation. Model-level differences are small and should be interpreted cautiously. A paired bootstrap over the seven SRSs shows that Claude and GPT-4o are not clearly separated on mean AlignScore, while Claude is only slightly higher than GPT-OSS; for unsupported rate, Claude is lower than GPT-OSS by 1.13 percentage points, but not clearly separated from GPT-4o. We therefore treat model rankings as descriptive rather than conclusive.

**Finding 2:** LLM atomization is generally faithful in the information it retains, but high faithfulness does not imply high source coverage. This distinction matters for RE evaluation pipelines: grounding and information retention should be assessed separately, since an atom can be well supported by its source while still omitting relevant source content.

Figure 5 shows a sharper tradeoff for source coverage. Puget Sound is consistently best preserved, with 88.8–93.5% coverage, followed by Libra with 75.6–87.2%. In contrast, GPT-4o covers only 35.6% of Library and 46.2% of QHeadache. This suggests that atomization is

**Figure 6** Artifact quality over generated artifacts. Mean AlignScore, Prometheus pass ratio, and judge pass ratio are reported on a 0–1 scale. All models show high atom-level grounding and high judge acceptance, while Prometheus reveals stricter variation in artifact completeness and quality.

often faithful in what it retains, but may omit or transform source information depending on the dataset and model. Some loss is expected: judge-guided revision can remove redundant, structural, vague, or low-utility content to produce cleaner atoms for downstream use. Thus, coverage should be interpreted alongside faithfulness rather than as a standalone failure signal. Table 4 shows that final atoms are generally well-formed after revision. Atomicity pass rates range from 76.0% to 100.0%, with most dataset-model pairs above 90%, while usability pass rates range from 70.7% to 97.0%. Average Gemma 3 judge scores remain high, ranging from 4.62 to 4.90, and Prometheus scores range from 4.34 to 4.85. These results indicate that LLMs can produce strong atomic decompositions, but downstream utility is harder to achieve than atomicity and benefits from explicit judge-guided refinement.

## 4.3 RQ3: Quality of the Generated Artifacts

**Finding 3:** Generated pre-SRS artifacts can remain strongly grounded in their source atoms while still varying substantially in completeness, sparsity, and structural alignment. For RE evaluation pipelines, grounding alone is therefore insufficient; artifact-specific quality checks are necessary to assess whether generated artifacts are structurally adequate for downstream use.

Across datasets and models, generated artifacts remain strongly grounded in their source atoms, but stricter quality assessment reveals substantially greater variation than the internal judge. Figure 6 summarizes these results. Mean AlignScore values typically range between 0.80 and 0.94, indicating that generated artifacts are largely supported by their source atoms. Claude Sonnet 4.6 shows the strongest and most stable grounding performance, reaching 0.94 on Library, while GPT-OSS exhibits larger variation, dropping to 0.61 on the same dataset. Judge pass ratios are nearly saturated after iterative refinement, remaining close to 1.00 across almost all dataset-model pairs. This suggests that the review-and-repair loop reliably produces artifacts that satisfy the pipeline's acceptance criteria. However, Prometheus reveals substantially greater variation, with pass ratios ranging from 0.55 to 0.97. The strongest

**Table 5** Downstream reconstruction retention scores. SBERT measures semantic similarity between source atoms and generated SRS, while AlignScore estimates factual support.

| Dataset | SBERT | | | AlignScore | | |

Prometheus result appears on QHeadache using GPT-4o (0.97), while lower scores occur for VUB and Home, particularly for GPT-OSS and GPT-4o. This gap indicates that atom-level grounding alone does not guarantee artifact completeness, sparsity, or structural quality. Taken together, these results show that generated artifacts can remain strongly grounded in their source atoms while still varying substantially under stricter artifact-quality assessment.

## 4.4 RQ4: Downstream SRS Reconstruction

RQ4 evaluates downstream recoverability as a controlled four-dataset case study rather than practitioner-ready SRS generation. Table 5 reports retention across 473 accepted artifact-backed atoms. SBERT means range from 0.690 to 0.753, indicating moderate-to-high semantic recoverability. AlignScore medians range from 0.760 to 0.842, while lower means and wider IQRs show that factual support is more variable than semantic similarity. These low-support cases may reflect abstraction, rephrasing, or additional content introduced during SRS compilation rather than direct omission alone.

**Finding 4:** LLM-generated pre-SRS artifacts can support partial downstream SRS reconstruction, but semantic similarity does not guarantee factual recoverability. For RE evaluation, reconstructed SRSs should therefore be treated as traceable drafts whose retained source support must be checked explicitly, rather than as complete or practitioner-ready specifications.

## 4.5 RQ5: Information Loss and Failure Patterns

Information loss is distributed across both SRS→Atoms and Atoms→Artifacts transformations rather than concentrated in a single step. Claude retains the most source information end-to-end, preserving 52.7–84.2% of source content, while GPT-4o shows the largest cumulative loss, dropping to 23.5% retention on QHeadache; GPT-OSS falls between these ranges, retaining 39.3–63.1%. Loss also varies by dataset: QHeadache and Get Real lose substantial information during SRS→Atoms conversion, suggesting that implicit or weakly structured statements are difficult to stabilize as atoms, whereas Library and Puget Sound lose more information during Atoms→Artifacts conversion, indicating that valid atoms may still be too narrow to instantiate constrained artifact templates.

Revision and artifact diagnostics help explain these patterns. Most atom-level revisions involve granularity, context, or downstream usefulness rather than unsupported hallucination. The most frequent buckets are bundled or non-atomic claims (30.4%), context-dependent wording (20.4%), and weak or non-actionable wording (8.5%) [8]. Rewrite and remove actions

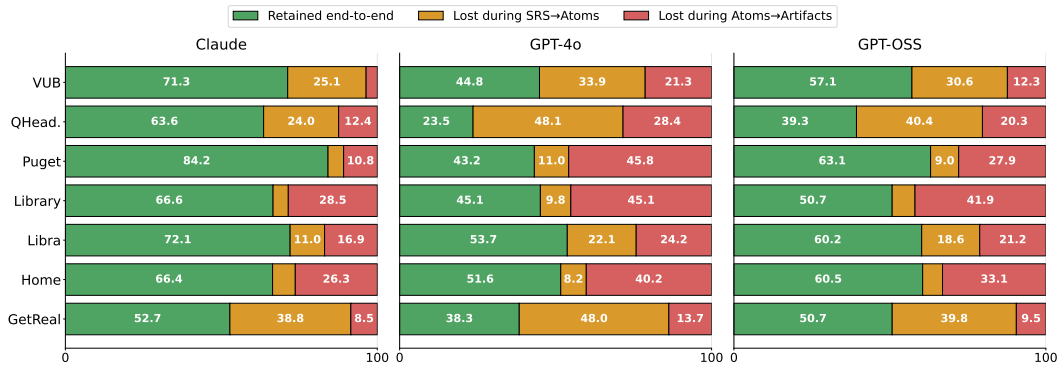

**Figure 7** Stage-wise information retention across the *ReqGenX* pipeline. Green indicates information retained end-to-end, while yellow and red indicate estimated information loss during atomization and artifact generation, respectively.

dominate, while split actions remain visible for dense SRS sections; merge and add actions are rare. This suggests that the atomizer more often over-produces weak or underspecified atoms than under-produces missing ones.

**Finding 5:** Information loss is stage-specific and often reflects evidence granularity rather than generation failure. Decomposition can discard implicit, redundant, or weakly actionable source content, while artifact generation can fail when a valid atom is too narrow to instantiate a complete typed artifact. For RE evaluation pipelines, information retention should therefore be assessed at multiple transformation stages rather than only at the final output.

Artifact-level failures show a related evidence-granularity problem: missing or incomplete artifacts are rarely due to parsing or generation crashes, but usually occur because the selected atom lacks enough evidence to fill the target artifact structure. For Claude, sparse artifacts are often associated with *chunk-only information*, while for GPT-4o and GPT-OSS the dominant issue is *template fields omitted*.

## 5 Lessons Learned

1 *LLM-based RE decisions need uncertainty-aware evaluation.* RQ1 shows that LLMs can support semantic routing and quality judgment, but reliability varies across decision types. Because routing determines artifact assignment and judging controls downstream acceptance, disagreement can reveal ambiguous requirements, weak artifact boundaries, and cases needing human review. LLM4RE researchers should therefore evaluate routing confidence and disagreement patterns, and assess false-acceptance risk, while practitioners should review low-confidence and automatically accepted outputs.

2 *Not every SRS statement is immediately artifact-ready.* RQ2 shows that LLM-generated atoms can be faithful and well-formed, while source coverage still varies across datasets and models. Legacy SRSs mix concrete requirements with context, vague notes, structural fragments, and partially specified ideas. Some statements can directly seed pre-SRS artifacts, while others require additional context or aggregation. Researchers should therefore study artifact readiness, while practitioners should avoid forcing every SRS statement into an artifact template.

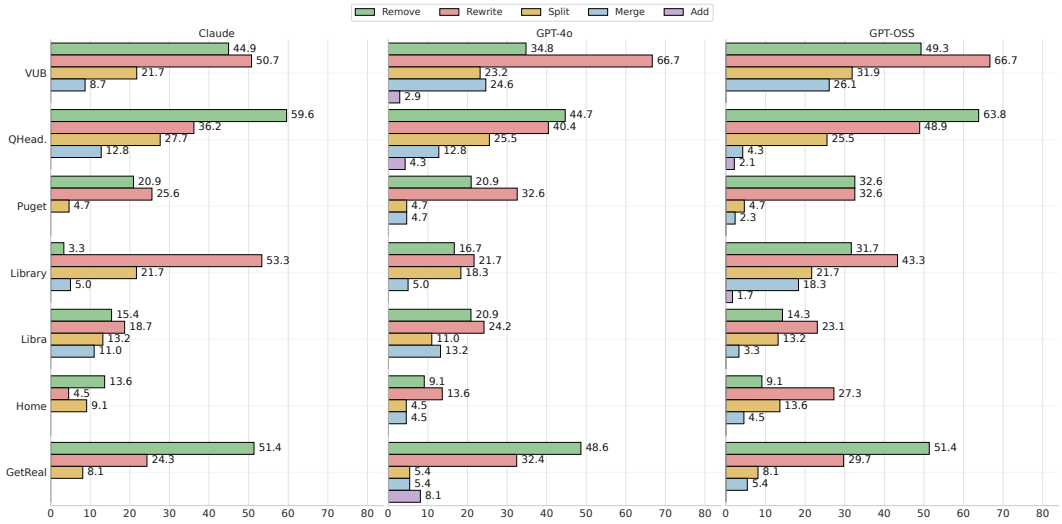

**Figure 8** Revision action rates across datasets and atomizer models. Rewrite and remove actions dominate across most dataset-model pairs, while split actions remain visible for structurally dense SRS sections.

3 *Artifact generation requires balancing completeness and evidence control.* RQ3 shows that artifacts can remain grounded in their source atoms, but grounding alone does not guarantee completeness or usefulness. Adding synthetic details may improve completeness but risks unsupported content, while strict atom-grounding can produce sparse artifacts. Evidence-aware generation should therefore support full, partial, or deferred artifacts depending on available evidence, with missing fields treated as signals of insufficient source support.

4 *SRS reconstruction is feasible, but factuality must be checked across artifact chains.* RQ4 shows that LLM-generated pre-SRS artifacts can support SRS reconstruction with partial source recoverability. However, synthetic details may propagate into fluent, structurally valid text that remains only partially supported by the original atoms. Future work should therefore evaluate factuality across the full source SRS→Atoms→Artifacts→reconstructed SRS chain and review generated drafts through their trace links.

5 *The main bottleneck is evidence granularity.* RQ5 shows that information loss often occurs because evidence is too implicit, bundled, or too narrow for the next stage of transformation. Context-dependent statements may be difficult to express as standalone atoms, while valid atoms may still be too narrow to instantiate complete artifacts. Future LLM4RE systems should preserve context at appropriate granularity through related-atom grouping, context-only evidence, and partially specified artifacts.

## 6 Related Work

Recent work shows that LLMs can support requirements engineering (RE) activities such as elicitation, user-story generation, acceptance-criteria generation, functional design specification, and SRS drafting [33, 30, 34, 29, 26, 25, 36, 40]. Broader Large Language Models for Software Engineering (LLM4SE) surveys also report increasing use of LLMs across software engineering tasks [16, 22, 38]. These studies demonstrate that LLMs can generate useful requirements artifacts, whereas our work studies a different problem: how legacy SRS content can be decomposed into traceable atomic evidence, routed to typed pre-SRS artifacts, and evaluated for downstream reconstruction.

NLP4RE has long studied requirements classification, extraction, ambiguity analysis, traceability, and quality assessment [39, 3, 21, 14, 12, 20]. Recent work also explores extracting models or requirements from agile backlogs, app reviews, and other textual sources [6, 15], as well as using NLI for RE classification and defect or conflict analysis [17]. Closest to our setting, Okamoto et al. [28] study LLM-based restructuring of organically written SRSs into ISO/IEC/IEEE 29148-compliant documents. Our work shares the goal of making legacy SRSs more structured and analyzable, but operates at a finer granularity by decomposing sections into atomic propositions before routing them to pre-SRS artifact types.

Public datasets such as PURE [18] support reproducible NLP4RE research, while recent work calls for reusable benchmarks, clearer reporting, and stronger traceability resources [3, 23]. Traceability recovery research further emphasizes linking information across heterogeneous lifecycle artifacts [19]. *ReqGenX* contributes to this direction by using public SRSs as seed evidence for constructing traceable synthetic pre-SRS artifacts.

Taken together, these strands intersect with *ReqGenX* along several dimensions but address different transformation goals. LLM-based requirements and SRS-generation studies [25, 36, 40] primarily generate or assess requirements artifacts or documents, whereas *ReqGenX* studies provenance-preserving transformations across intermediate representations. SRS-restructuring work, such as Okamoto et al. [28], transforms existing specifications toward standardized document structures, while *ReqGenX* first decomposes legacy SRS content into claim-level atoms and routes those atoms into typed synthetic pre-SRS artifacts. Traceability-recovery research [19] links information across existing lifecycle artifacts, whereas *ReqGenX* constructs an explicit SRS-to-atom-to-artifact provenance chain so that information preservation and loss can be measured during generation. We therefore position *ReqGenX* as a controlled empirical evaluation pipeline rather than a general-purpose SRS-generation method.

## 7 Threats to Validity

**Construct validity.** Our metrics assess the quality of traceability-grounded proxies rather than the completeness of requirements. AlignScore measures factual support, SBERT semantic recoverability, and judge/Prometheus scores rubric-based quality; none establishes full SRS coherence, ISO conformance, or practitioner usefulness. Likewise, *downstream utility* indicates whether an atom can instantiate an artifact type, not whether practitioners would find it useful. Human assessment primarily supports routing review and judge calibration; the 291-triple Claude Sonnet 4.6 sample is not a broad human evaluation across models and datasets. Public PURE and PROMISE-NFR data may also introduce benchmark-exposure effects [32]. We mitigate these threats through human-reconciled labels, external Prometheus assessment, and complementary coverage, agreement, and retention analyses.

**Internal validity.** Multiple LLM-based stages introduce sensitivity to prompts, model updates, decoding, and nondeterminism, while using LLMs for both generation and evaluation may introduce correlated bias. We mitigate these risks through plurality voting, human-calibrated judge selection, external Prometheus evaluation, multiple model families, model-independent grounding measures, fixed prompts and codebooks, traceability metadata, and manual input checks. Nevertheless, automated judgments remain calibrated proxies rather than human ground truth. Moreover, at temperature 1.0 and with one generation run per configuration, our results do not demonstrate stability across repeated runs.

**External validity.** Our evaluation covers seven selected text-oriented PURE SRSs and a fixed set of synthetic artifact types; results may differ for proprietary, safety-critical, multimodal, table-heavy, or actively maintained industrial requirements. PURE also does not capture the evolving and negotiation-heavy evidence of active projects. Because our study begins with authored SRSs, it does not evaluate elicitation from interviews, stakeholder discussions, issue reports, app reviews, regulations, or other primary evidence. The generated pre-SRS artifacts are therefore synthetic proxies, not recovered practitioner-authored artifacts, and reconstruction should not be interpreted as end-to-end SRS generation from raw stakeholder information. Future work should evaluate industrial and primary elicitation data with broader practitioner assessment.

**Conclusion validity.** Our analyses involve a few SRS documents, nested evaluation units, fixed thresholds, and one generation run per model. We use dataset-level aggregation, distributional summaries, paired bootstrap comparisons where applicable, and cautious interpretation of model differences. We do not conduct component-level ablations or a full baseline comparison, so we cannot isolate the effects of plurality voting, judge-guided refinement, or artifact-specific templates. Existing end-to-end baselines also lack the intermediate provenance required for several analyses. Future work should compare single-model versus plurality routing, refinement versus no refinement, and generic versus artifact-specific generation. Accordingly, our conclusions concern feasibility, tradeoffs, and failure modes rather than statistical superiority, practitioner readiness, or deployment effectiveness.

## 8 Conclusion

We conducted a controlled empirical study of how information changes when legacy SRS content is decomposed into atomic evidence, routed to synthetic pre-SRS artifacts, and used for downstream reconstruction, using *ReqGenX* as a traceable evaluation pipeline. Across seven selected text-only PURE SRSs, the results show that LLMs can produce well-formed, strongly grounded atomic statements and typed artifacts, but these transformations are not lossless. Semantic routing and quality judgment require human-grounded model selection, strong artifact grounding does not guarantee structural completeness, and downstream reconstruction preserves source information only partially. These findings show that traceable synthetic artifacts can support fine-grained evaluation of LLM-based requirements transformations while exposing tradeoffs among faithfulness, coverage, sparsity, and recoverability. Future work should extend the study to primary elicitation sources, industrial and multimodal requirements, broader practitioner evaluation, simpler component-level baselines and ablations, and loss-aware decomposition or more flexible artifact schemas for partially specified evidence. Overall, the results support *ReqGenX* primarily as traceable experimental infrastructure for studying LLM-based requirements transformations, rather than as evidence of an end-to-end or deployment-ready SRS-generation solution.

## Data Availability Statement

To support reproducibility, we provide a stable repository [8] containing processed inputs, generated artifacts, traceability metadata, evaluation outputs, scripts, prompts, templates, configurations, and documentation.

# Is Self-Admitted Technical Debt Tested? An Empirical Study of Coverage, Co-Change, and Impact

## Abstract

**Background.** When developers write a `TODO` or `FIXME` comment, they are explicitly admitting that the code is suboptimal: a built-in warning that this logic deserves extra scrutiny. Yet it is an open question whether Self-Admitted Technical Debt (SATD) actually receives that scrutiny in the form of software testing.

**Aim.** We aim to characterize the relationship between SATD and testing across three dimensions: the extent to which SATD-affected code is covered by existing tests, whether developers synchronize test additions with debt resolution, and whether such testing affects the long-term observability of resulting defects.

**Method.** For that, we conducted an empirical study on eight open-source Java projects, analyzing test coverage of 784 SATD instances identified in the latest releases and performing a longitudinal examination of 5,175 SATD removal events.

**Results.** Our results show that while 60.7% of SATD-affected code is covered by existing test suites, developers rarely synchronize test modifications with debt resolution; manual inspection confirms that only 3.4% of SATD removal commits include new tests specifically targeting the resolved debt (vs. 12.5% that co-add tests in the same commit). Longitudinal analysis further suggests that SATD resolutions exhibit nearly identical localized bug induction rates within short-to-medium-term windows regardless of test modifications. However, over a longer, unrestricted observation window, a slight divergence emerges where the test-added group reaches a higher cumulative defect alignment probability (6.32% vs. 4.37%), a counterintuitive trend potentially driven by the selective testing of inherently complex components.

**Conclusion.** Developers treat SATD repayment as an ordinary code change rather than as a high-risk maintenance activity: most debt removals proceed without targeted verification, despite the developer's own prior flag that the code is suboptimal.

**2012 ACM Subject Classification** Software and its engineering; Software and its engineering → Risk management

## 1 Introduction

Technical debt is an inherent byproduct of software development: facing deadlines or incomplete specifications, developers sometimes implement solutions they know are suboptimal [24]. Rather than leaving that knowledge implicit, they often record it directly in the source code through comments such as `TODO`, `FIXME`, and `HACK`. This practice, known as Self-Admitted Technical Debt (SATD) [29], is surprisingly widespread: between 2.4% and 31% of source files in open-source projects contain such comments [29], and the flagged code tends to persist for tens to hundreds of days before being resolved [30, 9], during which time it continues to be more change-prone and defect-prone than surrounding code [36].

What makes SATD distinctive is that the developer's own comment serves as an explicit warning: this code is known to be fragile, incomplete, or incorrect. Unlike latent defects that remain hidden until discovered, SATD represents a conscious acknowledgment that the implementation may not behave as intended. Such code should therefore be subject to verification, and software testing is the primary mechanism through which developers confirm that code behaves correctly and does not regress under future changes.

Software testing serves as a primary mechanism for early defect detection and regression prevention. A rich body of literature has examined the relationship between test coverage and defect detection capability [19], revealing, for example, that higher statement or branch coverage correlates with greater fault-detection effectiveness, though the strength of this relationship varies across projects and coverage metrics [21]. Researchers have also studied how test modifications affect code quality, finding that commits accompanied by test changes tend to introduce fewer regressions than those without [35]. More broadly, tests act as a safety net during refactoring and code modifications, and the presence or absence of adequate tests can influence the success of such changes [39].

Despite these parallel lines of research, SATD studies and testing studies have progressed largely in isolation. These findings are naturally complementary, yet the relationship between SATD and testing remains largely unexplored. First, it is unknown to what extent code containing SATD is protected by test suites. Second, there is a lack of empirical evidence on how often commits that remove SATD are accompanied by changes to test code, that is, the extent to which developers are conscious of testing during the SATD lifecycle. Third, whether adding tests at the time of SATD removal actually reduces the rate of subsequent bug occurrences has not been verified.

To address these gaps, we conducted an empirical study on eight open-source Java projects hosted on GitHub, examining the relationship between SATD and testing across two temporal scales. First, we identified 784 SATD instances in the latest releases to evaluate their current test coverage. Second, we performed a longitudinal analysis of 5,175 SATD removal events to investigate the co-occurrence of test modifications and the long-term observability of resulting defects. Based on this extensive dataset, we pose the following three research questions and summarize our key findings:

***RQ*$_1$: To what extent is SATD covered by tests compared to the overall codebase?** We found that 60.7% of SATD-affected code is covered by test cases. Furthermore, when categorizing SATD into technical types (e.g., Design, Requirement, and Defect debt), median coverage remained similar across types (41.7%–50.0%), indicating that the specific type of

debt does not significantly influence whether it gets tested. These results indicate that a majority of admitted debt is within the reach of existing verification frameworks. Notably, in several projects, SATD-affected code exhibited higher test coverage compared to the overall codebase, indicating that developers do not necessarily neglect brittle areas.

***RQ*$_2$: To what extent do developers add targeted tests when removing SATD?** Despite the high baseline coverage, our analysis of 5,175 removed SATD revealed a disconnect during the debt lifecycle; only 3.4% of SATD removals included concurrent modifications to test code. This suggests that while developers may rely on a pre-existing safety net, they rarely update or tailor tests specifically in response to the resolution of known debt.

***RQ*$_3$: What is the impact of removing SATD without adequate testing on software quality?** To understand the impact of these rare testing efforts, we analyzed the relationship between bug induction and SATD removals that included concurrent test additions. Our results indicate that the presence of test modifications yields no immediate reduction in localized bug induction rates within short-to-medium-term windows (*e.g.,* 30, 90, and 180 days). Interestingly, over an unrestricted time window, a slight divergence becomes visible, with the test-added group exhibiting a higher cumulative probability of subsequent defect alignment than the no-test group. This counterintuitive pattern suggests that general test modifications within a commit do not inherently prevent regressions, potentially because they lack sufficient coverage for the resolved logic. Alternatively, this may reflect a selection bias where developers selectively implement tests for particularly complex or critical SATD instances that remain inherently prone to defects.

## 2 Motivating Example

Software maintenance requires a continuous, synchronized effort between the evolution of production code and its corresponding test suite. Prior studies on code co-evolution, such as the work by *Levin and Yehudai* [23], have observed that this synchronization is often neglected in practice; developers frequently perform code fixes without correspondingly updating or adding tests within the same commit. While such findings highlight a general disconnect in maintenance activities, a critical question remains: *Does this trend persist even when developers have explicitly flagged the code as fragile or suboptimal?*

When developers write an SATD comment like `TODO` or `FIXME`, they are explicitly admitting that the logic is suboptimal – a built-in warning that the code deserves extra scrutiny. In an ideal development workflow, the resolution of such debt should be a controlled, verified process. For instance, in the Dubbo project (Listing 1), a developer identified a limitation where the system only checked a single registry. When this debt was eventually repaid (Listing 2), the developer not only refactored the logic but also provided a corresponding test case (Listing 3) to verify the new implementation. This scenario illustrates a rigorous approach where the removal of admitted debt is immediately fortified by quality assurance.

However, the presence of a `TODO` or `FIXME` does not always act as a trigger for such caution. Another scenario is illustrated by the Hibernate project. In Listing 4, a developer acknowledged a "wierd implementation" caused by "hacky behavior." While the SATD comment was later removed in an attempt to clean up the logic (Listing 5), this change was not accompanied by any new tests. Without a safety net, this testless debt removal introduced a regression that was later identified as a bug-inducing change.

This discrepancy reveals a blind spot in technical debt management. While prior research has focused heavily on the identification and classification of SATD, there is a lack of systematic understanding regarding the testing. Even if general code changes often lack

**Listing 1** Original code with SATD (Dubbo, `ServiceCheckUtils.java`)

```java
public static boolean isRegistered(ProviderModel providerModel) {
    // TODO, only check the status of one registry and no protocol now.
    Collection<Registry> registries = registryManager.getRegistries(); // setup
     omitted
    if (CollectionUtils.isNotEmpty(registries)) {
        AbstractRegistry abstractRegistry = (AbstractRegistry) registries.
         iterator().next();
        // ... omitted for brevity ...
    }
}
```

**Listing 2** Refactored code after SATD removal (Dubbo, `ServiceCheckUtils.java`)

```java
public static boolean isRegistered(ProviderModel providerModel) {
    // check all registries status
    for (ProviderModel.RegisterStatedURL registerStatedURL :
     providerModel.getStatedUrl()) {
        if (registerStatedURL.isRegistered()) {
            return true;
        }
    }
}
```

**Listing 3** Newly added test code accompanying the SATD removal (Dubbo, `ServiceCheckUtilsTest.java`)

```java
@Test
public void testIsRegistered() {
    // ... test setup omitted for brevity ...
    boolean registered = ServiceCheckUtils.isRegistered(providerModel);
    assertFalse(registered);
}
```

**Listing 4** Original code with SATD (Hibernate, `DenormalizedTable.java`)

```java
@Override
public Iterator getUniqueKeyIterator() {
    //wierd implementation because of hacky behavior
    //of Table.sqlCreateString() which modifies the
    //list of unique keys by side-effect on some
    //dialects
    Map uks = new HashMap();
    uks.putAll( getUniqueKeys() );
    uks.putAll( includedTable.getUniqueKeys() );
    return uks.values().iterator();
}
```

tests, the failure to verify code that has been explicitly admitted as problematic represents a higher-risk category of neglect. This study aims to bridge this gap by quantifying the relationship between testing practices and the SATD lifecycle, providing the empirical link between these two previously disconnected domains of software engineering research.

**Listing 5** Bug-inducing code: SATD removed without accompanying test additions (HIBERNATE, `DenormalizedTable.java`)

```
@Override
public Iterator getUniqueKeyIterator() {
    Iterator iter = includedTable.getUniqueKeyIterator();
    while ( iter.hasNext() ) {
        UniqueKey uk = (UniqueKey) iter.next();
        createUniqueKey( uk.getColumns() );
    }
    return getUniqueKeys().values().iterator();
}
```

# 3 Study Design

## 3.1 Research Questions

The following research questions and their motivations guide our empirical investigation.

**$RQ_1$: To what extent is SATD covered by tests compared to the overall codebase?**

SATD represents a developer's own acknowledgment that a piece of code is suboptimal or incomplete. Prior work has shown that such debt-ridden code tends to be more change-prone and defect-prone than surrounding code [36], and that SATD comments persist for tens to hundreds of days before being resolved [30, 9]. Given these known risks, one might expect developers to compensate with more thorough testing. Yet it is equally plausible that writing tests for SATD-affected code, much like the resolution of the debt itself, is also postponed under time pressure. While prior studies have examined the relationship between test coverage and defect detection [19, 21], no study has directly investigated whether SATD-affected code receives adequate test coverage. We therefore aim to determine the extent to which SATD is covered by test suites and how this coverage varies across different types of debt.

**$RQ_2$: To what extent do developers add targeted tests when removing SATD?**

Static coverage alone cannot tell us whether developers are consciously investing in test quality during the SATD lifecycle, or whether any existing coverage is merely incidental. Prior studies on developer behavior during refactoring have found that test updates are often neglected even when production code changes substantially [39]. Whether this pattern extends to SATD-related commits, where the code is already known to be suboptimal, remains an open question. Understanding this reveals whether quality assurance is treated as an integral part of debt management or whether it is systematically overlooked during these high-risk changes.

**$RQ_3$: What is the impact of removing SATD without adequate testing on software quality?**

Prior work has shown that SATD-related changes tend to be more complex and harder to perform than typical modifications [36], indicating that debt resolution carries inherent risks. However, no study has directly quantified how concurrent test additions during SATD removal influence the observability of subsequent defects. Therefore, we aim to evaluate the effect of concurrent test additions on linked bug-inducing rates during debt resolution, investigating whether such tests serve as an effective diagnostic mechanism for capturing regressions that would otherwise persist as undetected failures.

**Table 1** Overview of SATD found within method bodies in analyzed projects.

| Repository | Release | Module(s) | #Comments | #SATD | % SATD |
|---|---|---|---|---|---|
| *Group 1: Projects with preconfigured Jacoco plugin* | | | | | |
| Commons Lang [4] | commons-lang-3.18.0 | src | 1,042 | 28 | 2.7 |
| Commons IO [3] | commons-io-2.20.0 | src | 568 | 23 | 4.0 |
| Hibernate [15] | 6.6.28 | hibernate-core | 11,808 | 530 | 4.5 |
| Dubbo [5] | dubbo-3.3.5 | dubbo-common | 924 | 21 | 2.3 |
| *Group 2: Projects where Jacoco plugin was manually added* | | | | | |
| JFreeChart [20] | v1.5.6 | src | 2,865 | 60 | 2.1 |
| Spoon [17] | v11.2.1 | src | 2,207 | 25 | 1.1 |
| Maven [6] | maven-3.9.11 | maven-core, maven-compat | 862 | 69 | 8.0 |
| Storm [7] | v2.8.2 | storm-server, storm-client | 3,563 | 43 | 1.2 |
| **Total** | | | 23,839 | **799** | 3.4 |

## 3.2 Subject Projects

For our study, we selected a diverse set of eight open-source Java projects, as detailed in Table 1. While purely static SATD studies analyze larger corpora [28, 27], our design prioritizes dynamic test execution and manual inspection, requiring stable build environments and a deliberate trade-off in corpus size. The chosen projects vary in domain and scale, covering utility libraries, application frameworks, specialized tools, and build infrastructure. This allows us to generalize our findings across different software development contexts. For each project, we analyzed a specific, recent release to ensure the relevance of our findings. The projects are divided into two categories based on their pre-existing test coverage infrastructure, which is central to our analysis.

Jacoco-preconfigured projects comprises four projects that already had the Jacoco test coverage plugin configured. This group includes foundational core utility libraries (Commons Lang and Commons IO) and large-scale application frameworks (Hibernate, an Object-Relational Mapping framework, and Dubbo, a microservice framework).

Manually configured projects comprises four projects for which we manually added the Jacoco plugin to perform our analysis. This group includes specialized libraries (JFreeChart, a charting library, and Spoon, a metaprogramming library) and development infrastructure tools (Maven, a build automation tool, and Storm, a real-time stream processing system).

## 3.3 Data Collection and Processing Pipeline

Our methodology involves a multi-stage pipeline to detect SATD, measure its test coverage, and trace its lifecycle and impact on defects.

**1) SATD Detection and Classification.** We employed DebtHunter [31], a state-of-the-art, ML-based SATD detection tool. The study introducing the tool demonstrated its high performance, with a precision of 97.2%, a recall of 96.7%, and an F1-score of 96.5%, outperforming other detection tools. In addition to SATD detection, we use DebtHunter to classify SATD by type. Since our study focuses on technical debt within executable logic, we modified the tool for two purposes: (1) to restrict detection to comments within method bodies, and (2) to extract the location of each SATD instance, including file name, method name, and line number.

**Table 2** Classification of all 799 SATD instances.

| Type | # | % |
|---|---|---|
| Design | 518 | 64.8 |
| Requirement | 256 | 32.0 |
| Defect | 22 | 2.8 |
| Test | 3 | 0.4 |
| Documentation | 0 | 0.0 |

To independently verify the reliability of DebtHunter, we manually validated its detection results on the three projects not included in its original training: Dubbo, Spoon, and Storm. We inspected all 129 comments flagged as SATD by the tool across these three projects (prior to applying the method body restriction). Our review confirmed that the classifications for Spoon and Storm were highly accurate, identifying zero false positives. For Dubbo, however, we found 10 false positives, which were non-SATD comments related to configuration (*e.g.,* `load dubbo.applications.xxx`). We excluded these 10 false positives from our dataset before proceeding with the analysis.

Using DebtHunter, we categorized the instances into five types: Design, Requirement, Defect, Test, and Documentation. As shown in Table 2, our dataset is dominated by Design (logical structure) and Requirement (requirement specifications) debt.

**2) Measuring Test Coverage via Tracer Lines.** To measure test coverage, we transform the passive SATD comment into an active, executable tracer line. For each identified SATD, we attempt to replace the comment line with an executable statement (i.e., `System.out.println("SATD: IMPLEMENTATION");`). We then run the project's entire test suite and analyze the generated jacoco.xml reports. An SATD is considered covered if an inserted tracer line is reported as executed by Jacoco. However, this direct replacement fails in two scenarios, for which we manually analyze the SATD and map it to an appropriate executable line within the relevant debt-ridden code block.
*(i) Inappropriate Location:* The comment is not located within the actual debt-ridden code block it refers to. For example, in Listing 6, the `FIXME` comment is placed above the `if` block, but it refers to the logic within the `for` loop. Replacing the comment line directly would test the area outside the relevant logic.

**Listing 6** Example of an SATD comment in an inappropriate location (Hibernate, `MapBinder.java`).

```
1 //FIXME pass the Index Entity JoinColumns
2 if ( !collection.isOneToMany() ) {
3     //index column should not be null
4     for ( AnnotatedJoinColumn column : mapKeyManyToManyColumns.getJoinColumns()
       ) {
5         column.forceNotNull();
6     }
7 }
```

*(ii) Syntax Error: The replacement violates Java syntax.* In Listing 7, the `TODO` comment is located within a variable declaration statement. Inserting an executable statement at the comment's location would break the assignment logic, causing a compilation error.

**Listing 7** Example of an SATD comment causing a syntax error if replaced (HIBERNATE, `SqmSelectionQueryImpl.java`).

```
protected List<R> doList() {
    final boolean containsCollectionFetches =
            //TODO: why is this different from QuerySqmImpl.doList()?
            statement.containsCollectionFetches();
    // ... omitted for brevity ...
}
```

**3) Mining SATD Lifecycle and Test Additions.** To detect SATD-removing events, we utilized a customized version of SATDBailiff [1], a specialized framework for mining SATD history. We replaced its original SATD detecting engine with DebtHunter to ensure methodological consistency. By applying this modified version of SATDBailiff to the commit history of our target projects, we were able to systematically identify commits where SATD was removed. We then analyzed these commits to determine if they included any modifications to the test suite.

**4) Linking SATD Removal to Defects.** To investigate the impact of SATD removal on software quality, we analyzed the relationship between SATD removal events and subsequent bug introductions. We first identified bug-fixing commits across the eight Java projects and employed LLM4SZZ [33], an advanced SZZ variant, to identify the specific commits and methods that introduced the bugs.

Unlike commit-level analysis, we performed a method-level matching to ensure high precision. Specifically, we identified instances where a bug was introduced within the same method from which the SATD had been removed. This allowed us to correlate the act of debt resolution directly with the emergence of subsequent defects. Finally, we compared the linked bug-inducing rates between SATD removals accompanied by test additions and those that were not. Because SZZ can only identify bugs that were eventually detected and fixed, this rate captures defects that were observable enough to surface in the project's bug-fixing history. This comparison examines whether adding tests helps surface latent issues in these fragile areas rather than leaving them as undetected regressions.

## 3.4 Data Analysis Methodology

Our analysis follows a two-fold approach. First, we perform a cross-sectional analysis of the latest releases to measure test coverage of SATD (RQ1). We compare SATD coverage against project-level branch coverage baselines. We then perform a longitudinal analysis of the projects' history (RQ2 and RQ3). We investigate the frequency of test additions during SATD removals (RQ2), and compare the bug introduction rates between SATD removals accompanied by tests against those that were not (RQ3), quantifying the risks associated with testless debt repayment.

# 4 Results

## $RQ_1$: To what extent is SATD covered by tests compared to the overall codebase?

We applied our tracer-line instrumentation approach to all 799 SATD instances. Table 3 presents the detailed breakdown of instrumentation process and the final test coverage results. First, we attempted to automatically replace the comment with an executable tracer.

Instances that compiled successfully and were deemed to be in a suitable location were categorized as Automatic (B). The remaining instances either failed the automatic step (e.g., Syntax Error) or were manually identified as being in an Inappropriate Location. We attempted to manually map these instances to a suitable executable line. The instances that were successfully mapped constitute the Manual (C) category. Instances that could not be mapped were Excluded (D), primarily because the SATD comment was located within a code block that was already commented out. Consequently, the summation of the successfully instrumented instances from the Automatic and Manual categories constitutes the final set of Analyzed SATD (E) (i.e., $E = B + C$).

**Table 3** SATD Instrumentation Feasibility and Test Coverage Results per Project, Compared to Overall Project Branch Coverage.

| Project | Filtering Process | | | | | Coverage Result (%) | |
|---|---|---|---|---|---|---|---|
| | All SATD (A) | Auto. (B) | Man. (C) | Excl. (D) | Anal. (E) | SATD Cov. (%) | Overall Branch Cov. (%) |
| *Group 1: Projects with pre-configured Jacoco plugin* | | | | | | | |
| Commons Lang | 28 | 6 | 20 | 2 | 26 | 26.9* | 92.9 |
| Commons IO | 23 | 22 | 0 | 1 | 22 | 95.5 | 85.7 |
| Hibernate | 530 | 463 | 65 | 2 | 528 | 70.8 | 58.5 |
| Dubbo | 21 | 11 | 0 | 10 | 11 | 45.5 | 53.7 |
| *Group 2: Projects where Jacoco plugin was manually added* | | | | | | | |
| JFreeChart | 60 | 58 | 2 | 0 | 60 | 40.0 | 46.9 |
| Spoon | 25 | 21 | 4 | 0 | 25 | 52.0 | 55.8 |
| Maven | 69 | 55 | 14 | 0 | 69 | 30.4 | 32.0 |
| Storm | 43 | 39 | 4 | 0 | 43 | 25.6 | 11.9 |
| **Total** | 799 | 675 | 109 | 15 | 784 | **60.7** | – |

* This low coverage is an outlier caused by a cluster of 18 identical, untested Design SATD in Validate.java.

The coverage results in Table 3 provide the first answer to our research question. Overall, we found that 60.7% (476 out of 784) of the analyzable SATD instances are covered by tests. A deeper analysis reveals that the projects are not uniform and instead follow three distinct testing patterns.

*1. Extra Care:* In three projects – Commons IO, Hibernate (both Group 1), and Storm (Group 2) – we observed SATD coverage that is higher than the project's overall branch coverage baseline (*e.g.,*Commons IO: 95.5% vs. 85.7% baseline; Storm: 25.6% vs. 11.9% baseline). This suggests that in these projects, developers pay at least equal, if not more, attention to known debt.

*2. General Postponement:* In four projects – Dubbo (from Group 1), and JFreeChart, Spoon, and Maven (from Group 2) – the SATD coverage was roughly proportional to, or slightly lower than, their project baselines (*e.g.,*Dubbo: 45.5% vs. 53.7% baseline; Maven: 30.4% vs. 32.0% baseline). The Dubbo case is particularly revealing: despite being in the Jacoco-configured group, its SATD is not prioritized, indicating that a pre-existing testing culture does not, by itself, guarantee extra care for SATD.

*3. Targeted Postponement:* Commons Lang (from Group 1) presents a notable contrast. Despite maintaining a strict CI threshold that yields a high observed branch coverage of 92.9%, its SATD coverage is remarkably low at 26.9%.

We investigated this outlier and found it is caused by a single cluster of 18 identical Design SATD comments in the Validate.java file (see Listing 8). The comment refers to a potential future enhancement changing a `void` method to return a `value` on the success path.

**Table 4** Distribution of Test Coverage rates per SATD Type and Pattern.

| Classification | 1. Extra Care (Tested / Total) | 2. General Post. (Tested / Total) | 3. Targeted Post. (Tested / Total) |
|---|---|---|---|
| Design | 243/ 365 ( 66.6%) | 48/ 116 ( 41.4%) | 6/ 24 ( 25.0%) |
| Requirement | 144/ 204 ( 70.6%) | 15/ 48 ( 31.3%) | 1/ 2 ( 50.0%) |
| Defect | 16/ 21 ( 76.2%) | 0/ 1 ( 0.0%) | – |
| Test | 3/ 3 ( 100.0%) | – | – |
| **Total** | 406 / 593 **(68.5%)** | 63 / 165 **(38.2%)** | 7 / 26 **(26.9%)** |

Our instrumentation (Listing 9) confirmed that this success path is entirely untested. The project's high 92.9% branch coverage is achieved by thoroughly testing only the failure path (the `IllegalArgumentException`). This demonstrates that even strictly-enforced project-metric thresholds can be insufficient, as developers may focus tests on satisfying CI while leaving known technical debt on other paths untested.

**Listing 8** Example of 18 identical SATD comments in their original, inappropriate location (Commons Lang, Validate.java).

```
1 public static void exclusiveBetween(final double start, final double end, final
   double value) {
2     // TODO when breaking BC, consider returning value
3     if (value <= start || value >= end) {
4         throw new IllegalArgumentException(String.format(
           DEFAULT_EXCLUSIVE_BETWEEN_EX_MESSAGE, value, start, end));
5     }
6 }
```

**Listing 9** The code from Listing 8 after manual instrumentation with the tracer line.

```
1 public static void exclusiveBetween(final double start, final double end, final
   double value) {
2     if (value <= start || value >= end) {
3         throw new IllegalArgumentException(String.format(
           DEFAULT_EXCLUSIVE_BETWEEN_EX_MESSAGE, value, start, end));
4     }
5     System.out.println("SATD:␣DESIGN");
6 }
```

**Coverage by SATD Type.** Beyond project-level patterns, we investigated whether the type of technical debt influences its likelihood of being tested. Table 4 summarizes the coverage rates for each SATD type across the three project patterns. Within each pattern, the differences among SATD types are modest compared to the differences between patterns: in the Extra Care group, Design (66.6%), Requirement (70.6%), and Defect (76.2%) all attain coverage above 66%, while in the General Postponement group, coverage drops to 41.4% for Design and 31.3% for Requirement with the single Defect instance left uncovered. The Targeted Postponement group records the lowest values (Design: 25.0%, Requirement: 50.0%).

Aggregating across projects yields the same picture. The median coverages for Design (50.0%), Requirement (41.7%), and Defect (50.0%) cluster closely together with widely overlapping interquartile ranges. Contrary to the intuitive expectation that high-risk defect debt would be prioritized for testing, the technical type of SATD does not appear to influence whether it gets tested.

Test debt is a special case: all 3 instances come from HIBERNATE and yield a median of 100%. These comments flag inadequacies in the existing tests themselves, and the surrounding code was fully exercised even though the developer considered the test logic incomplete.

**Answer to RQ1**

We found that 60.7% (476 out of 784) of the analyzable SATD instances are covered by tests, and there are three distinct patterns of care: (1) Extra Care in three projects, (2) General Postponement in four projects, and (3) Targeted Postponement in Commons Lang where debt-ridden paths were selectively ignored.
Furthermore, all three major SATD types (Design, Requirement, and Defect) show similar median coverages (clustered between 41.7% – 50.0%) and widely overlapping distributions, suggesting that the technical type of SATD does not significantly influence whether it gets tested.

## $RQ_2$: To what extent do developers add targeted tests when removing SATD?

Findings from RQ1 revealed that over 60% of SATD instances are covered by existing tests in latest release revision. This suggests that code containing technical debt is generally within the reach of the project's testing infrastructure. However, from a software maintenance perspective, a critical juncture is the resolution of this debt. When an SATD comment is removed, it often signifies that the suboptimal logic has been refactored or replaced. It is therefore vital to understand whether such SATD removals trigger the creation of new tests to verify the updated implementation.

To identify commits involving SATD removals, we applied a modified version of SATDBailiff [1] to the main branch of each project. While the original tool relies on SATD Detector, we integrated DebtHunter as the underlying engine to maintain consistency with our identification criteria in RQ1 (see Table 5 for per-project counts).

Our methodology for detecting test additions involves a logical diff of test method names between consecutive commits. First, we perform AST analysis (using `javalang`[1]) on each file in the main branch to extract sets of method names marked with the `@Test` annotation. By comparing these sets across revisions, we identify newly added test methods. To prevent false positives caused by simple refactorings, such as method renaming, we cross-reference Git patch information to verify the similarity between added and deleted lines. Test methods identified as renames are excluded, ensuring that we only count genuine functional additions to the test suite.

In this analysis, we focus on simultaneous co-evolution within a single commit. This is supported by *Wang et al.* [35], who found that production and test code co-evolution primarily happens in the same commit (median $\approx$ 47.0%) and that the number of co-evolutions decreases over time. Thus, same-commit analysis serves as a reliable proxy for determining

[1] `https://github.com/c2nes/javalang`

**Table 5** Test Addition Rates for SATD Removal Instances.

| Project | Total SATD | w/ Co-added Tests (%) | w/ Verified Tests (%) |
|---|---|---|---|
| *Extra Care (RQ1 pattern)* | | | |
| Hibernate | 3125 | 439(14.0%) | 123(3.9%) |
| Storm | 200 | 7(3.5%) | 1(0.5%) |

*Note:* **Co-added Tests**: Tests introduced in the same commit as the SATD removal instance. **Verified Tests**: A subset of co-added tests manually confirmed to specifically target the logic of the removed SATD.

whether developers add targeted tests as part of the SATD removal process. To ensure the validity of our findings, we complemented the automated identification with a rigorous manual inspection. While we first identified 649 SATD instances where test addition and SATD removal occurred within the same commit, these automated results do not necessarily imply a causal or logical relationship between the two.

To bridge this gap, two of the authors independently inspected each of the 649 instances to determine whether the added test methods were specifically intended to exercise or verify the logic related to the removed SATD. For each instance, both inspectors examined the code changes in the commit and the content of the newly added test methods to assess their relevance to the resolved debt. The two inspectors initially agreed on the classification for 78.3% of the instances, yielding a Cohen's $\kappa$ of 0.55, which indicates moderate agreement according to the interpretation by Landis and Koch [22]. Additionally, during this initial screening, the inspectors identified and filtered out 127 false positives produced by DebtHunter (e.g., non-SATD comments incorrectly flagged as SATD) to ensure data purity. Disagreements were subsequently resolved through adjudication by a third author, who independently reviewed the conflicting cases and made the final determination. This dual-inspection protocol with third-party adjudication allows for a more precise and reproducible assessment of how often developers explicitly address technical debt through testing. The inspectors have over 5-15 years of programming experience and prior familiarity with the SATD and testing literature.

As shown in Table 5, our instance-level analysis reveals a trend distinct from the static snapshots in RQ1. Initially, we identified 649 instances where SATD removal and test addition co-occurred within the same commit. However, our rigorous manual inspection revealed that some of these were not genuine SATD removals, such as file renamings, misidentified comments, or instances where the SATD was unresolved.

After excluding these cases, we confirmed 517 valid co-occurring instances. Among all 5,175 SATD removals, only 174 instances (3.4%) were verified as having new tests specifically targeting the removed SATD logic. The gap between the overall co-addition rate (12.5%)

**Table 6** Statistics of Bug-Inducing Commit Identification via LLM4SZZ.

| Project | Bug-Fixing Commits | With Bug-Inducing | Rate |
|---|---|---|---|
| Commons Lang | 424 | 263 | 62.0% |
| Commons IO | 232 | 108 | 46.6% |
| Hibernate | 3,199 | 2,300 | 71.9% |

| JFreeChart | 74 | 46 | 62.2% |
| **Total** | 8,331 | 6,178 | **74.2**% |

and the verified rate (3.4%) indicates that even when tests appear in the same commit as an SATD removal, most are not directed at the resolved logic. Such co-occurring tests are typically peripheral changes (touching unrelated test fixtures, fixing pre-existing test failures, or covering other features modified in the same commit) rather than targeted verification of the debt resolution.

This gap varies considerably across projects. Spoon and Dubbo show the largest drops, with Spoon falling from 50.7% co-added to 19.4% verified and Dubbo from 39.3% to 8.0%. In these two projects, developers frequently bundle test changes with SATD removal commits, but most of those tests target unrelated logic. Hibernate, despite contributing the largest absolute number of verified instances (123), shows a low per-removal verified rate of 3.9%, suggesting that even projects with extensive testing infrastructure rarely add targeted verification at the moment of debt resolution.

**Answer to RQ2**

While SATD instances are generally covered by existing tests (RQ1), our manual verification reveals that only 3.4% of SATD removals are accompanied by new tests specifically tailored to the debt resolution. This suggests that SATD removal is predominantly performed without targeted verification, relying instead on a pre-existing safety net that may not be specifically optimized for the updated implementation.

## $RQ_3$: What is the impact of removing SATD without adequate testing on software quality?

To establish a foundation for identifying defects potentially introduced by SATD removal, we first characterized the bug dataset collected using LLM4SZZ. As shown in Table 6, we analyzed a total of 8,331 bug-fixing commits across eight open-source Java projects. From these, our pipeline successfully identified at least one bug-inducing commit for 6,178 bug-fixes, yielding an overall identification rate of 74.2%. This high success rate provides a sufficient corpus for tracing defects back to their origins and examining their proximity to SATD removal events.

The identification process utilized two complementary strategies: direct Large Language Model (LLM) analysis of patch content and a combination of traditional SZZ with LLM-based validation. The direct analysis (S1) succeeded in 58.5% of the files, while the SZZ+LLM

approach (S2) succeeded in 59.4%. Both strategies converged on the same result in 46.4% of the cases, demonstrating the consistency of our methodology. In total, we identified 10,933 unique bug-inducing commits, linked to 132,572 individual buggy statements.

Our analysis in RQ2 established that only 3.4% of all SATD removals (174 instances) are manually validated as being targeted by dedicated test modifications. To assess whether this scarcity influences subsequent defects, we compared bug induction rates between the test-added and no-test groups across multiple observation windows, excluding the 127 false positives filtered out during the RQ2 manual validation. Table 7 summarizes the results. Across short-to-medium-term intervals (30, 90, and 180 days), the bug induction rates are nearly identical between the two groups (1.72% vs. 1.89%, 2.30% vs. 2.36%, and 2.87% vs. 2.89%, respectively). A slight divergence becomes visible over longer windows, with the test-added group reaching 6.32% versus 4.37% when no time limit is imposed.

These results are counterintuitive: one might expect tests added during debt resolution to suppress subsequent defects. The bugs counted here, however, are those eventually identified and fixed in the same method as the SATD removal, not necessarily defects caused by the resolution itself, which complicates causal interpretation. Several factors may contribute to the observed pattern. The accompanying tests may not have been sufficient to verify the resolved logic. Developers may also add tests selectively to SATDs that are particularly critical or complex, whose inherent difficulty produces defects despite the presence of tests. Disentangling these mechanisms is beyond the scope of this study and warrants future investigation, possibly motivating the development of SATD-aware test prioritization techniques.

**Table 7** Bug-Inducing Commits Linked to SATD Removals across Observation Windows.

| Metric | Tests Added | No Tests |
|---|---|---|
| Within 30 days | 3 (1.72%) | 92 (1.89%) |
| Within 90 days | 4 (2.30%) | 115 (2.36%) |
| Within 180 days | 5 (2.87%) | 141 (2.89%) |
| No time limit | 11 (6.32%) | 213 (4.37%) |

**Answer to RQ3**

SATD resolutions accompanied by test modifications show no immediate reduction in linked bug induction rates within short-to-medium-term windows (1.72% vs. 1.89% within 30 days), and a slight long-term gap (6.32% vs. 4.37% with no time limit) is difficult to attribute to a single cause. The observed pattern may reflect insufficient test targeting, selection effects toward particularly complex SATDs, or tests surfacing latent defects that would otherwise go unrecorded.

## 5 Discussion and Implications

This section reflects on the three results presented above and considers what they imply for SATD management and software testing practice. We first interpret the patterns observed in test coverage, co-evolution, and defect alignment, and then derive implications for researchers and practitioners.

**Interpretation of Results.** The results suggest that the relationship between technical debt and testing is not straightforward. While one might expect developers to be more careful with code they know is suboptimal, our analysis in RQ1 indicates that this only happens in a minority of cases. Most projects follow a pattern of General Postponement, where technical debt is tested no more (and sometimes less) than the rest of the codebase. This suggests that the same factors leading to the introduction of technical debt, such as time pressure, likely also lead to insufficient testing of that code.

A particularly interesting observation is the Targeted Postponement pattern, exemplified by the Commons Lang project. In this case, the project maintains very high branch coverage, yet the specific execution paths containing technical debt are completely untested. This happens because tests are focused on "failure paths" (e.g., verifying that exceptions are thrown) to satisfy coverage metrics, while the "success paths" where the technical debt resides are ignored. This finding suggests that high-level coverage metrics can provide a false sense of security, as they do not necessarily reflect the testing quality of the most risk-prone parts of the system.

The longitudinal analysis in RQ2 and RQ3 reveals a disconnect in how testing accompanies the SATD lifecycle. Developers rarely synchronize test modifications with debt resolution, and the long-term differences in linked bug rates between the test-added and no-test groups admit multiple non-exclusive interpretations: tests may be insufficient to verify the resolved logic, developers may add tests selectively to particularly complex SATDs, or tests may surface latent defects that would otherwise go unrecorded. While we cannot adjudicate among these interpretations within the present data, they converge on a common implication: SATD repayment is currently treated as an ordinary code change rather than a high-risk maintenance activity warranting dedicated verification.

**Implications.** Our results converge on the implication that SATD repayment requires more deliberate verification than it currently receives. This finding has several implications for both researchers and practitioners.

For researchers, our study suggests several directions for future work. Since tests accompanying SATD removal may be insufficient to exercise the resolved logic, researchers should develop SATD-aware test generation techniques that produce tests targeting the specific code paths involved in the debt. Because developers also appear to add tests selectively, often to particularly complex SATDs, SATD prioritization techniques that identify which debt items most warrant verification effort would help focus testing resources. Furthermore, the impact of CI/CD coverage thresholds on test quality warrants further investigation: our findings suggest that high global coverage does not necessarily translate to a robust safety net, and strict thresholds may incentivize developers to create tests merely to satisfy numerical requirements rather than to verify complex debt-ridden areas.

For practitioners, these findings offer practical guidance for debt management. Project managers should not rely solely on project-wide coverage percentages, which can mask the lack of validation in critical, debt-heavy areas. Instead, they should supplement these with local coverage analysis of code marked with `TODO` or `FIXME` tags. Furthermore, organizations should treat SATD resolution as a high-risk maintenance activity warranting dedicated verification, rather than relying on existing safety nets that may not be adequate for the resolved logic.

# 6 Related Work

## 6.1 Empirical Studies of Testing

Large-scale empirical studies have consistently found a weak positive correlation between test volume and defect counts across open-source projects. *Kochhar et al.* [21] examined over 20,000 open-source projects, finding that projects with more code and more developers tend to have more test cases, and identifying a weak positive correlation between test volume and defect counts. *Islam et al.* [18] revisited these findings in a decade-long longitudinal study of Java projects, confirming that while testing grows alongside the codebase, this weak correlation remained stable through 2021. Beyond static metrics, *Beller et al.* [8] used IDE instrumentation to show that testing is frequently treated as an afterthought rather than a proactive activity.

The timing of test changes relative to production code has also been studied: while *Marsavina et al.* [25] established fundamental co-evolution patterns, *Wang et al.* [35] found that co-evolutions predominantly occur in the same commit (median $\approx 47\%$) and that their frequency decreases over time. Comparative studies on TDD vs. test-last development [13, 34] further show that different methodologies yield distinct coverage profiles: TDD tends to encourage higher branch coverage through refined test cases, while test-last development results in broader method-level coverage. Despite these insights, existing literature rarely addresses whether these practices apply specifically to code explicitly marked as technical debt, which is the gap our work fills.

## 6.2 Self-Admitted Technical Debt

Since *Potdar and Shihab* [29] formally introduced SATD, showing it appears in 2.4%–31% of source files with 26–64% eventually removed, substantial work has accumulated on identification and classification. Task tags (`TODO`, `FIXME`, `XXX`) have been established as reliable SATD signals [14]; complementary efforts include ontologies standardizing debt vocabulary [2], ML-based methods for distinguishing design from requirement debt [11], and LLM-based approaches for fine-grained classification [32]. Regarding lifecycle and impact, *Wehaibi et al.* [36] showed that while SATD-related changes do not always induce more immediate defects, they are more complex and difficult to perform, thereby hindering future modifications; *Mensah et al.* [26] further identified inadequate testing (21.2%) as one of the leading drivers of SATD, directly motivating our study.

*Maldonado et al.* [10] found that the majority of SATD is eventually resolved, frequently by the same developer who introduced it, persisting between 82–613 days on average before removal. To manage the resulting volume, *Lima et al.* [12] proposed a hybrid prioritization approach combining SATD descriptions with static analysis findings, achieving greater precision than comment-text-only methods. Despite these advances, while *Mensah et al.* identified inadequate testing as a *cause* of SATD, there remains a lack of empirical evidence on how testing practices are employed to safeguard the repayment process, which is the focus of this research.

# 7 Threats to Validity

**Construct validity.** concerns whether our metrics and procedures accurately capture the phenomena we intended to study. One potential threat to construct validity involves our use of tracer-line instrumentation as a proxy for measuring the test coverage of SATD instances.

While inserting an executable statement directly into the debt-ridden code block provides a precise way to verify execution, it does not guarantee that the tests fully exercised the specific logic described in the technical debt comment. For example, a tracer line confirms that a code block was reached, but not necessarily that all execution sub-paths within that block were covered. We mitigated this by manually mapping tracers to the most relevant lines within the debt-ridden block when automatic insertion was not possible.

Another threat related to construct validity is our method for linking SATD removal to subsequent defects. Our primary analysis imposes no time limit, treating any bug introduced in the same method as potentially related to the SATD removal. We report results at 30, 90, and 180-day windows as sensitivity analyses. While the no-limit approach is most conservative about excluding relevant bugs, it may also include bugs introduced by unrelated changes to the same method. Additionally, we cannot fully rule out that the higher bug-detection rate in the test-added group is partially explained by greater change complexity; a controlled analysis matching commits by churn size would be needed to isolate the effect of test addition from the effect of commit scale.

**Internal validity.** refers to the extent to which the observed results are due to the factors under study rather than confounding variables. The accuracy of the automated tools used in our study, such as DebtHunter, SATDBailiff, and LLM4SZZ, represents a potential threat to internal validity. To mitigate errors in SATD detection, we manually validated the results on a subset of our projects and excluded identified false positives. For the identification of bug-inducing commits, we used LLM4SZZ, which employs large language models that can exhibit stochastic behavior. We addressed this by using its dual-strategy approach and confirming the consistency between independent identification strategies.

There is also a risk of human error during the manual mapping of tracer lines for complex cases, such as inappropriate comment locations or syntax errors. To minimize this risk, we followed a protocol where instrumentation was carefully reviewed to ensure that the tracer line accurately reflected the execution of the logic referred to by the SATD comment, rather than just the literal position of the original comment.

**External validity.** concerns the generalizability of our findings to other contexts. We analyzed eight open-source Java projects from different domains and of varying scales. However, our findings may not generalize to commercial software, projects written in other programming languages, or systems with different testing cultures. We tried to broaden the scope of our observations by including projects with both pre-existing and manually integrated testing infrastructures.

The scope of the SATD instances we analyzed also presents a threat to generalizability. Our study was strictly limited to technical debt found within method bodies, which was necessary to measure executable coverage precisely. This means we excluded technical debt documented at the class or package level, such as architectural debt. Consequently, our conclusions primarily apply to technical debt related to implementation and local design rather than high-level system architecture.

To ensure the reliability and replicability of our study, we relied on established open-source tools including Jacoco, DebtHunter, and SATDBailiff. We have also provided a comprehensive replication package that contains our datasets, instrumentation scripts, and analysis results to allow other researchers to verify and build upon our work.

## 8 Conclusion

We empirically investigated the relationship between SATDs and software testing in eight open-source Java projects, examining 784 SATD instances for cross-sectional test coverage and 5,175 SATD removal events for longitudinal co-evolution and defect alignment.

Our central finding is a co-evolution gap between debt resolution and test maintenance. Although 60.7% of SATD-affected code is covered by existing tests, only 3.4% of SATD removals are accompanied by tests specifically targeting the resolved debt (vs. 12.5% that co-add any tests). Developers, therefore, treat SATD repayment as an ordinary code change rather than as a high-risk maintenance activity, despite their own prior flag.

Moreover, these rare test additions show no evidence of preventing short- to medium-term regressions: bug induction rates within 30, 90, and 180 days are nearly identical across the test-added and no-test groups (*e.g.,* 1.72% vs. 1.89% within 30 days). This null effect need not mean tests are ineffective in general; developers may selectively add tests to particularly difficult SATDs, whose complexity dominates the outcome. Separating test effectiveness from the difficulty of the underlying debt, and designing SATD-aware verification that prioritizes the hardest cases, are promising future directions.

## Data Availability Statement

To support the reproducibility of our study, we have made our collection pipelines publicly available as replication packages. Throughout this research, we comprehensively utilized two repositories to build our foundational pipeline: the customized version of DebtHunter used for method-level SATD detection and precise metadata extraction [37], and the history mining framework that integrates our customized DebtHunter engine into SATDBailiff to trace SATD-removing events throughout the project lifecycle [38]. For the long-term defect analysis in RQ3, the replication package containing our execution scripts and environment for defect tracking and LLM4SZZ [33] analysis is provided at [16].

## Abstract

**Background.** LLM-based multi-agent systems (LLM-MAS) are increasingly applied to software engineering (SE) tasks. However, most systems are evaluated end-to-end, entangling architectural choices with model selection, prompting, and task-specific tooling. As a consequence, the effects of individual architectural factors remain empirically underexplored.

**Aims.** We investigate how Communication Structure (Hierarchical vs. Centralized) and Coordination Strategy (Dynamic vs. Static) influence three outcome dimensions in LLM-MAS for Python refactoring: output generation and validity; operational cost and execution efficiency; and structural transformation. We also examine whether the two factors interact.

**Method.** We conduct a controlled $2 \times 2$ factorial experiment under identical model, dataset, orchestration, prompting, and tool configurations, evaluated on 2,000 real-world Python refactoring instances drawn from open-source machine learning (ML) repositories. We measure output generation and validity through file generation, syntactic validity, and similarity-based acceptance; operational cost and execution efficiency through execution time, LLM calls, and token usage; and structural transformation through static code metrics.

**Results.** Coordination Strategy is the dominant architectural factor: Static configurations achieve substantially higher output validity and lower operational cost across all token-based and call-based measures. Communication Structure exhibits a heterogeneous effect, strongly influencing call-based behavior but having limited impact on token consumption. The two factors interact significantly on all cost measures, with the strongest interaction observed on LLM calls. Among the evaluated configurations, Hierarchical+Static consistently provides the best tradeoff between validity and cost, whereas Centralized+Dynamic fails to produce acceptable output for a substantial fraction of instances.

**Conclusions.** Coordination Strategy exerts more consistent effects than Communication Structure on both output validity and operational cost, while the interaction between the two factors is central to explaining architectural behavior. The study demonstrates how controlled factorial designs can isolate architectural effects in LLM-MAS research, and it provides empirical guidance for designing cost-efficient architectures with strong output validity for SE tasks.

## 1 Introduction

LLM-MAS are increasingly adopted for SE tasks via role specialization, structured coordination, and tool grounding [9, 18]. Recent code-oriented systems vary substantially in internal organization: hierarchical arrangements of specialized agents [14, 19, 44], centralized coordination by a manager agent [2], and static or dynamic tool invocation [13, 28, 34, 43]. Yet the literature has advanced faster in proposing such systems than in understanding them: architectures are typically evaluated end-to-end, entangling architectural choices with model selection, prompting, and task-specific tooling [9, 18]. Such evaluations reveal whether a system succeeds or fails, but not which architectural decisions drive that outcome.

Isolating architectural effects requires a domain where (i) the task decomposes into subtasks suited to role specialization, (ii) outputs admit structured evaluation, and (iii) real-world instances are available at scale. Automated refactoring meets all three: it decomposes into analysis, localization, and transformation subtasks that map onto specialized agent roles [14, 44]; its outputs can be assessed via syntactic, structural, and similarity-based criteria; and labeled instances abound in open-source repositories [25]. Refactoring improves the internal structure of code without altering its observable behavior [5, 22], providing a repeatable workload for controlled comparison. LLM-MAS have begun to tackle this problem, yet existing systems cover only a narrow slice of the architectural design space [14, 34, 43, 44].

A controlled architectural comparison requires factors that are both taxonomically grounded and experimentally manipulable. Recent surveys describe a broad LLM-MAS design space [7, 9, 17, 18, 39, 45], and within the refactoring literature the most clearly instantiated architectural distinctions concern how agents communicate and how execution is coordinated [14, 34, 43, 44]. We therefore focus on *Communication Structure* – how control and information flow are distributed among agents – and *Coordination Strategy* – whether task execution and tool invocation are prescribed in advance or determined adaptively at runtime. No prior refactoring study isolates their effects in a crossed design, leaving their individual and interaction effects empirically uncharacterized.

We address this gap with a controlled $2 \times 2$ factorial experiment manipulating *Communication Structure* [Hierarchical (H) vs. Centralized (C)] and *Coordination Strategy* [Dynamic (Dyn) vs. Static (Sta)], yielding four configurations: MAS-1 (H+Dyn), MAS-2 (H+Sta), MAS-3 (C+Dyn), and MAS-4 (C+Sta). All share identical model, dataset, orchestration, prompting, and tools, with each architecture processing every input instance, enabling estimation of main effects and their interaction while controlling for input-level variability.

The experiment uses $N = 2{,}000$ real-world file-level refactoring instances drawn from open-source Python ML repositories [25], each with aligned pre- and post-refactoring snapshots. Outcomes are analyzed across three planes: *output generation and validity* (file generation, syntactic validity, similarity-based acceptance), *operational cost and execution efficiency* (execution time, LLM calls, token consumption), and *structural transformation* (static code metrics). Given non-normal distributions, we use non-parametric procedures throughout: Pearson's $\chi^2$ and Fisher's exact tests for generation and validity; ART-ANOVA for operational cost; and Friedman, Wilcoxon signed-rank, Kruskal–Wallis, and Dunn tests for structural transformation and efficiency; all with Holm–Bonferroni correction and effect sizes reported.

This experimental setting gives rise to three research questions.

**RQ1** *How do the four architectural configurations differ in file generation success, syntactic validity, and similarity-based output acceptance?*

**RQ2** *What are the main effects of Communication Structure and Coordination Strategy on operational cost, and do these two architectural factors interact?*

**RQ3** *How do the four architectural configurations differ in (a) the structural transformations they apply to the input code and (b) their execution efficiency?*

Taken together, this design yields four main contributions. **Experimentally**, it provides a controlled $2 \times 2$ factorial study isolating Communication Structure and Coordination Strategy as architectural factors in LLM-MAS for automated Python refactoring under common model, prompting, orchestration, tool, and dataset conditions. **Empirically**, it produces evidence on the main and interaction effects of these factors on output generation and validity, operational cost, and structural transformation. **Methodologically**, it demonstrates how controlled factorial designs can isolate architectural effects in LLM-MAS research, exposing interaction effects that end-to-end benchmarking conflates. **As an artifact**, it releases a replication package comprising 2,000 refactoring instances, four implemented LLM-MAS, execution logs, and analysis scripts.

# 2 System Architectures

## 2.1 Architectural Design Factors

We characterize the architectures along two manipulated factors governing execution control in LLM-MAS: *Communication Structure* and *Coordination Strategy*. Both are grounded in recent LLM-MAS surveys [7, 9, 17, 18, 39, 45] and were selected because they admit direct operationalization in automated refactoring under identical experimental conditions.

**Communication Structure.** Communication Structure concerns how control and information flow are organized among agents, commonly distinguished as decentralized, hierarchical, or centralized [7, 9, 17, 18, 39, 45]. We focus on the hierarchical and centralized structures, since both admit a clean crossing with Coordination Strategy under a fixed agent set, whereas decentralized communication would also require modifying agent count and autonomy, and is thus outside the scope of this experiment.

- **Hierarchical:** agents are organized into sequential functional tiers, and control emerges from tier-to-tier sequencing rather than a dedicated coordinator. Outputs from one tier are passed directly to the next. We operationalize this through three tiers: *analysis* (file reading and static code inspection), *localization* (refactoring suggestion and evaluation), and *resolution* (code transformation and output generation).
- **Centralized:** a dedicated coordinator orchestrates the remaining agents through explicit control artifact specifying execution order. We operationalize this through a *Planning Agent* that decomposes the request into an ordered step list and dispatches work.

**Coordination Strategy.** Coordination Strategy concerns whether execution and tool use are fixed in advance or determined adaptively at runtime [39]. We operationalize it as follows:

- **Dynamic:** tool invocation is delegated to *ReAct*-style agents [46], which interleave reasoning and acting and decide at run time whether and how to invoke their tools.
- **Static:** tool invocation is prescribed by the workflow or planning artifact. Tools are called when and where the architecture specifies, independently of intermediate observations.

## 2.2 Controlled Invariants and Shared Setup

To isolate architectural effects, all four configurations share the same model, orchestration substrate, tool set, agent responsibilities, and retry bounds. Only Communication Structure and Coordination Strategy vary across architectures.

**Model and Orchestration.** All agents use the *open-mixtral-8x22b*[1] model through the same public API, with default inference parameters and no fine-tuning beyond role-specific instructions. All workflows are implemented in *LangGraph*[2], which represents execution as explicit stateful graphs. Holding both the model and orchestration framework constant prevents architectural comparisons from being confounded by model or framework variation.

**External Tools.** Each architecture has access to the same three tools over source-code and file artifacts: (i) Analyze Code, implemented with *Radon*[3] and *Lizard*[4]; (ii) Read File; and (iii) Write File. The difference across architectures is therefore not *which* tools are available, but *where* tool invocation is controlled: by ReAct agents in Dynamic configurations, and by the workflow/plan in Static configurations.

**Execution Types and Agent Roles.** Two execution types are used throughout the study. *Prompt-based agents* produce outputs through a single LLM inference and do not invoke tools directly. *ReAct agents* [46] interleave reasoning and tool use, selecting actions from intermediate observations. Architectures are constructed from a fixed set of roles with stable responsibilities across configurations. The *Suggestion Agent*, *Evaluation Agent*, *Refactoring Agent*, and *Planning Agent* are prompt-based: the Suggestion Agent generates candidate refactoring suggestions from the input code and analysis results; the Evaluation Agent assesses those candidates and provides feedback for iterative refinement; the Refactoring Agent applies validated decisions to produce the modified source file; and the Planning Agent, present only in centralized configurations (MAS-3, MAS-4), decomposes the refactoring request into an ordered step list specifying execution order and responsibility assignment. The *File System Agent* and *Code Analysis Agent*, exclusive to Dynamic configurations (MAS-1, MAS-3), are ReAct agents encapsulating file I/O operations (Read File, Write File) and static source code analysis (Analyze Code), respectively.

**Shared Iterative Mechanisms.** All architectures include two bounded loops applied identically across configurations. In the *Suggestion–Evaluation loop*, the Suggestion Agent is re-invoked with corrective feedback when a proposed refactoring is rejected. In the *syntactic-validity loop*, the Refactoring Agent is re-invoked with AST parser errors when the generated file fails to parse. Both loops are capped at three iterations; once the budget is exhausted, the last generated result is forwarded.

## 2.3 MAS-1: Hierarchical + Dynamic

MAS-1 instantiates the *Hierarchical* communication structure with *Dynamic* coordination. As shown in Figure 1, execution is organized into three functional tiers. The *analysis* tier consists of the File System Agent, which reads the input file through Read File, and the Code Analysis Agent, which invokes Analyze Code. The *localization* tier contains the Suggestion and Evaluation agents, which iteratively refine candidate refactorings through the shared Suggestion–Evaluation loop. The *resolution* tier contains the Refactoring Agent, which applies the accepted transformation under the shared syntactic-validity loop, after which the File System Agent writes the final output through Write File. MAS-1 therefore separates functionality by tier while leaving tool use to agent-level decisions at run time.

[4] https://github.com/terryyin/lizard

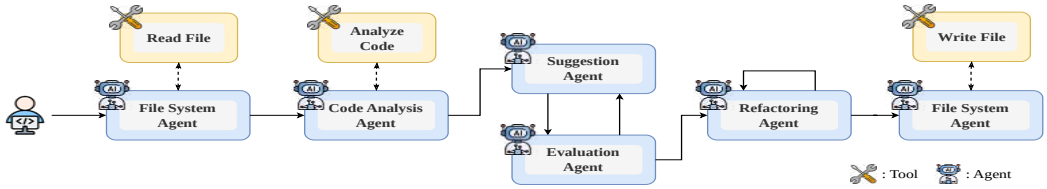

**Figure 1** MAS-1 (H+Dyn). A tier-based workflow is combined with ReAct tool invocation. The File System and Code Analysis agents decide at run time when and how to invoke their tools.

## 2.4 MAS-2: Hierarchical + Static

MAS-2 preserves the same *Hierarchical* tier structure as MAS-1 but switches from *Dynamic* to *Static* coordination. As shown in Figure 2, the analysis tier is still followed by localization and resolution, but READ FILE, ANALYZE CODE, and WRITE FILE are invoked directly by the workflow rather than by ReAct agents. The Suggestion–Evaluation loop and the syntactic-validity loop remain unchanged. MAS-2 is thus architecturally matched to MAS-1 on communication structure and functional decomposition, differing only in the locus of tool orchestration, making the MAS-1/MAS-2 pair the cleanest comparison for the effect of Coordination Strategy under hierarchical control.

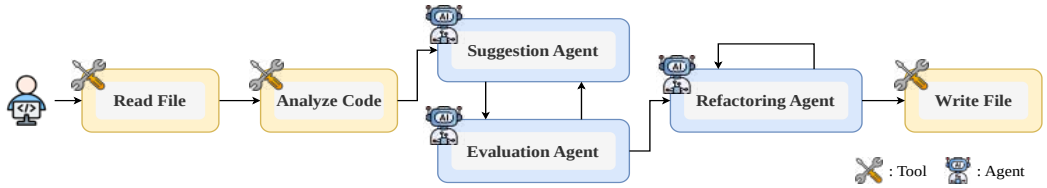

**Figure 2** MAS-2 (H+Sta). The tier-based organization is unchanged, but tool calls are embedded directly in the workflow rather than delegated to ReAct agents.

## 2.5 MAS-3: Centralized + Dynamic

MAS-3 replaces the tier-based control structure with *Centralized* coordination while retaining *Dynamic* tool use. As shown in Figure 3, execution begins with a Planning Agent that decomposes the refactoring request into an explicit ordered step list identifying which agent should perform each step. File System and Code Analysis agents remain ReAct-based and retain autonomy over when and how to invoke their tools. Suggestion and Evaluation agents perform iterative refinement, and Refactoring Agent applies the validated transformation under the shared retry bounds. MAS-3 therefore centralizes global control without eliminating adaptive local tool use: relative to MAS-1, the key change is the explicit planner.

## 2.6 MAS-4: Centralized + Static

MAS-4 combines *Centralized* communication structure with *Static* coordination. As shown in Figure 4, the Planning Agent generates a step list that specifies both agent dispatch and tool calls. Execution follows that plan directly: file access and static analysis are performed through workflow-level tool invocation, after which the Suggestion, Evaluation, and Refactoring agents proceed under the same bounded refinement and syntactic retry mechanisms used in the other architectures. MAS-4 thus removes agent-level autonomy over tool use while preserving explicit planning as the locus of coordination.

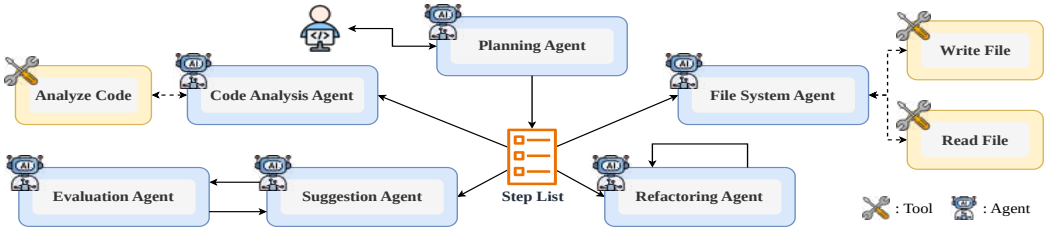

**Figure 3** MAS-3 (C+Dyn). A Planning Agent specifies the global step sequence, while ReAct agents retain local autonomy over tool invocation.

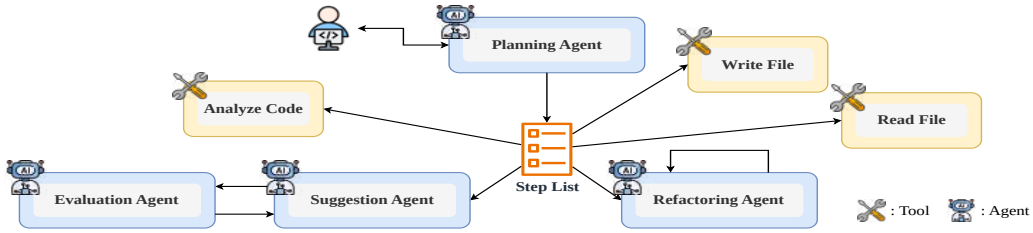

**Figure 4** MAS-4 (C+Sta). Planning Agent controls both agent sequencing and tool invocation.

# 3 Experimental Design

## 3.1 Research Questions and Rationale

The experiment addresses three research questions organized around the three outcome dimensions, spanning the full evaluation scope of the study: from the capacity of each architecture to produce accepted outputs, through the cost incurred in doing so, to the structural character of those outputs and the efficiency with which they are generated.

RQ1-Rationale: LLM-MAS are non-deterministic and can fail to produce output, parseable code, or structurally plausible refactorings. Characterizing where each architecture breaks down is essential for assessing its practical usability and for interpreting any downstream comparison on cost or structural outcomes.

RQ2-Rationale: The cost of LLM-MAS directly constrains their deployment at scale, yet prior work bundles cost with full-system design. Isolating each factor's effect, and detecting whether they interact, is therefore essential for principled architectural guidance under realistic budgets.

RQ3-Rationale: Accepted output does not imply equivalent transformation behavior: architectures may differ in how aggressively they restructure the input code. Characterizing these structural differences, together with architecture-level efficiency, is essential for selecting a configuration aligned with a desired refactoring style and runtime profile.

## 3.2 Study Design and Experimental Units

The experimental object of the study is an LLM-MAS architecture for automated Python refactoring. The experimental unit is a single file-level refactoring instance. Treatments correspond to the four architectures obtained by crossing *Communication Structure* (Hierarchical vs. Centralized) with *Coordination Strategy* (Dynamic vs. Static): MAS-1 through MAS-4. The design is paired by construction: every instance is exposed to all four treatments under identical model, prompting, orchestration, and tool conditions. This repeated-measures setup

controls for input-level heterogeneity and allows observed differences to be attributed more directly to the manipulated architectural factors. All non-architectural elements are held constant across configurations, as detailed in Section 2.2.

## 3.3 Dataset Description

Isolating architectural effects requires labeled, real-world refactoring instances at scale. We therefore use a dataset [29] derived from *MLRefScanner* [25], a collection of refactoring-labeled commits mined from open-source Python ML repositories – a coherent ecosystem, since Python is the dominant language of the ML domain and its mature static analysis tooling directly supports our validation and measurement pipeline. Following the sampling procedure adopted in prior work [28], we use a sample of $N = 2{,}000$ file-level refactoring instances drawn from 167 repositories. The dataset spans eight refactoring types: Add Parameter, Rename Method, Remove Parameter, Change/Rename Parameter, Extract Method, Rename Class, Change Return Type, and Inline Method. Each instance contains two aligned file versions: the pre-refactoring snapshot (`original.py`), which serves as input to all four architectures, and the developer-produced post-refactoring snapshot (`human_ref.py`), used exclusively as a reference for calibrating the plausibility filter in downstream structural analyses and not as an oracle that generated outputs must reproduce.

## 3.4 Experimental Pipeline and Data Collection

For each input instance $i$, `original.py` is processed independently by each architecture $a \in \{1, 2, 3, 4\}$, producing two outputs: a candidate refactored file ($\texttt{mas\_ref}_{a,i}\texttt{.py}$) when one is produced, and a system-level log ($\texttt{sys\_statistics}_{a,i}\texttt{.json}$) recording execution status, execution time, LLM calls, and input, output, and total token counts regardless of outcome. Generated files undergo a three-stage validation pipeline: (i) *file generation* – whether any output file was produced; (ii) *syntactic validity* – whether the file parses via Python's abstract syntax tree (AST) parser; (iii) *similarity-based acceptance* – whether the file exceeds the plausibility threshold defined in Section 3.5. Structural metrics are computed only for accepted outputs, and per-instance metric deltas $\Delta M_{a,i} = M(\texttt{mas\_ref}_{a,i}\texttt{.py}) - M(\texttt{original}_i\texttt{.py})$ quantify how strongly each architecture changes the structural properties of the input file, forming the basis of the structural comparisons reported for RQ3(a). Each $\texttt{sys\_statistics}_{a,i}\texttt{.json}$ is retained regardless of execution outcome: it operationalizes output generation success at the file generation stage (RQ1) and provides the cost and efficiency measures analyzed for RQ2 and RQ3(b).

## 3.5 Output Validation and Similarity-Based Filtering

Syntactic validity is necessary but not sufficient to treat a generated file as a plausible refactoring of the input. An architecture may produce Python code that parses successfully while being structurally unrelated to the original file. To reduce contamination in downstream structural analyses, we therefore apply a similarity-based plausibility filter that retains only outputs with strong correspondence to the input.

**Composite Similarity Score.** For each pair (`original.py`, candidate file), we compute a normalized similarity score $S \in [0, 1]$ as a weighted sum of six token-based similarity measures, capturing token overlap (Jaccard [24], $w = 0.111$; Dice [38], $w = 0.114$), global edit sensitivity and ordering (Levenshtein distance [23], $w = 0.241$; Levenshtein ratio [33], $w = 0.227$), and tolerance to limited reordering (Jaro [6], $w = 0.134$; Jaro–Winkler [40], $w = 0.172$). The weights are adopted from prior work on token-based code similarity [4].

**Threshold Selection.** We analyze the empirical distribution of $S$ separately for each source: MAS-1 through MAS-4 and the human refactoring files. Shapiro-Wilk tests reject normality ($p < 0.05$) and D'Agostino's test indicates left-skewed distributions consistent with the presence of low-similarity outliers. We fit a two-component Gaussian Mixture Model (GMM) to each source-specific distribution and define the source-specific threshold as the score at which the posterior probability of belonging to the high-similarity component equals 0.5, i.e., the Bayes decision boundary under symmetric misclassification costs. The resulting thresholds are 0.7698 for MAS-1, 0.7797 for MAS-2, 0.6226 for MAS-3, 0.7231 for MAS-4, and 0.8521 for the human refactoring distribution.

**Reference Threshold and Filtering Policy.** To enforce a single acceptance criterion across architectures, we adopt the threshold derived from the human refactoring distribution, *0.8521*, as the common filtering threshold for all automated outputs. This choice anchors plausibility to developer-produced refactorings while avoiding architecture-specific calibration, which would otherwise risk confounding the cross-architecture comparison. The policy is deliberately conservative: some outputs may be structurally plausible yet excluded because they diverge from typical human refactoring patterns. This trade-off is revisited in Section 6 as a threat to construct validity. The filter is used only to support conditional structural analysis. It does not establish semantic equivalence, behavioral preservation, or functional correctness. Its purpose is to exclude structurally implausible outputs before computing metrics intended to characterize architectural transformation behavior.

## 3.6 Evaluation Measures

**Output Generation and Validity.** Output generation and validity are evaluated at three successive stages over the full set of $N = 2{,}000$ instances per architecture. The *file generation rate* is the proportion of inputs for which the architecture produces any output file. The *syntactic validity rate* is the proportion for which the produced file parses successfully as Python. The *similarity acceptance rate* is the proportion that additionally exceeds the common plausibility threshold defined in Section 3.5. Together, these three measures distinguish failures to produce output, failures to produce syntactically valid output, and failures to produce structurally plausible output. Throughout the study, *validity* thus refers to syntactic parseability and similarity-based plausibility; it does not imply behavior preservation or successful application of the intended refactoring type (see Section 6).

**Operational Cost and Execution Efficiency.** From the system-level logs, we extract execution time, number of LLM calls, and token counts. These measures are collected for every execution regardless of output validity, since unsuccessful runs still consume time, calls, and tokens. In the analysis, they serve two roles. First, they operationalize *operational cost* for RQ2, where we estimate the main and interaction effects of the two architectural factors. Second, they support architecture-level comparison of *execution efficiency* for RQ3.

**Structural Transformation.** We compute eight static metrics commonly used in maintainability and complexity studies [10, 16, 35]: (i) average cyclomatic complexity (Avg_CC) [21]; (ii–iv) Halstead volume, effort, and difficulty (Hal_Vol, Hal_Eff, Hal_Diff) [8]; (v) lines of code (LoC) [27]; (vi) number of functions (Func_Count) [5]; (vii) comment density (Comm_Den) [26]; and (viii) average function length (Avg_Func_Len) [5]. Metrics are computed statically using *Radon* and *Lizard*; no code execution is required. Structural analyses are conducted on the metric deltas defined in Section 3.4 and only for outputs that pass both AST validation and similarity-based filtering.

## 3.7 Statistical Analysis

The statistical analysis is organized around the data structure and the three research questions. Three properties of the design guide our choice of procedures. First, Shapiro–Wilk tests reject normality ($p < 0.05$) for all paired differences, motivating non-parametric analyses throughout. Second, every input is processed by all four architectures, yielding a paired repeated-measures design whenever alignment is preserved. Third, all pairwise comparisons within a measure family are adjusted using Holm–Bonferroni [11] to control the family-wise error rate at $\alpha = 0.05$, retaining greater power than classical Bonferroni correction.

**RQ1 Analysis.** RQ1 examines how the four architectures differ in file generation success, syntactic validity, and similarity-based acceptance. Each outcome is binary at the instance level and summarized as a proportion over $N = 2{,}000$ executions per architecture. We use Pearson's $\chi^2$ test for the four-architecture comparison, and Fisher's exact test for the six pairwise contrasts. Fisher's exact is preferred for pairwise contrasts because expected counts may be small for the weakest configurations. Effect sizes are reported as Cohen's $h$ [3], with thresholds: negligible ($< 0.2$), small (0.2 to 0.5), medium (0.5 to 0.8), and large ($\geq 0.8$).

**RQ2 Analysis.** RQ2 examines the main effects of *Communication Structure* and *Coordination Strategy* on operational cost, and whether they interact. Because cost measures are recorded for every execution, the complete set of architecture-instance observations is available (4 architectures $\times$ 2,000 instances = 8,000 obs.). To obtain factor-level estimates under non-normality, we use the Aligned Rank Transform (ART) followed by standard two-way ANOVA [41], which aligns the data separately for each main effect and the interaction before ranking, thereby preserving factorial interpretability. Effect sizes are reported as partial $\eta^2$: negligible ($< 0.01$), small (0.01 to 0.06), medium (0.06 to 0.14), and large ($\geq 0.14$).

**RQ3 Analysis.** RQ3 examines how the architectures differ in the structural transformations they apply and in their execution efficiency.

a) **Structural transformation.** Structural metrics are continuous, non-normal, and only available for outputs that survive both validation stages. Because this filtering yields different accepted subsets per architecture, we report two complementary analyses:
   - *Paired analysis:* We restrict the sample to instances accepted by all four architectures, preserving the paired structure and controlling for input-specific variability. We apply Friedman tests followed by pairwise Wilcoxon signed-rank tests with Holm–Bonferroni correction. Effect sizes are reported as matched-pairs rank-biserial correlation $r_{rb}$: negligible ($< 0.1$), small (0.1 to 0.3), medium (0.3 to 0.5), and large ($\geq 0.5$).
   - *Marginal analysis:* To avoid bias toward easier instances in the paired subset, we complement it with a marginal analysis using each architecture's full accepted set as independent, unbalanced samples. We apply Kruskal–Wallis tests followed by Dunn's test with Holm–Bonferroni correction. Effect sizes are reported as Cliff's $\delta$ [32]: negligible ($< 0.147$), small (0.147 to 0.33), medium (0.33 to 0.474), and large ($\geq 0.474$).

   We do not apply factorial ART to the structural metrics, as the paired intersection contains only $N = 146$ instances, providing insufficient power for reliable interaction testing across eight metrics. This limitation is revisited in Section 6.

b) **Execution efficiency.** To complement the factorial cost analysis of RQ2 with a direct architecture-level view, execution-efficiency measures are analyzed under the full paired design over $N_{\text{paired}} = 2{,}000$ instances. This sample is preserved because these measures

are available for every execution regardless of output validity. We apply Friedman tests followed by pairwise Wilcoxon signed-rank tests with Holm–Bonferroni correction, reporting $r_{rb}$ as effect size. Because each architecture is executed once per input, these measures characterize observed execution behavior under a single execution per input; the consequences for stochastic variability are discussed in Section 6.

# 4 Results and Discussion

## 4.1 RQ1: Output Generation and Validity

Table 1 reports execution outcomes per architecture across the three stages defined in Section 3.6. Three architectures (MAS-1, MAS-2, MAS-4) reach near-complete levels ($\geq 94\%$) at both *file generation* and *syntactic validity*. MAS-3 is the only configuration that breaks down at these early stages, generating output for only 49.9% of inputs and a syntactically valid file in 37.7%. At *similarity acceptance*, the three non-MAS-3 architectures separate into a clear ordering: MAS-2 (75.5%) > MAS-4 (62.6%) > MAS-1 (53.0%). The bottom row of Table 1 (SA/SV) reports retention among syntactically valid outputs, where the contrast is cleaner: Static configurations retain a substantially larger fraction than Dynamic ones under both communication structures (76.4% and 66.5% vs. 54.7% and 52.3%).

**Table 1** Output generation and validity per architecture. The first three rows show successful instances out of $N = 2{,}000$.

| Outcome | MAS-1 (H+Dyn) | MAS-2 (H+Sta) | MAS-3 (C+Dyn) | MAS-4 (C+Sta) |
|---|---|---|---|---|
| File generation (FG) | 1993 (99.7%) | **2000 (100.0%)** | 997 (49.9%) | **2000 (100.0%)** |
| Syntactic validity (SV) | 1935 (96.8%) | **1976 (98.8%)** | 753 (37.7%) | 1884 (94.2%) |
| Similarity acceptance (SA) | 1059 (53.0%) | **1509 (75.5%)** | 394 (19.7%) | 1252 (62.6%) |
| SA / SV | 54.7% | **76.4%** | 52.3% | 66.5% |

Factorial labels: H/C = Hierarchical / Centralized; Dyn/Sta = Dynamic / Static.

Pearson's $\chi^2$ rejects equality of rates across architectures at every stage (Table 2), so we use pairwise Fisher exact tests to localize differences. At *file generation*, MAS-3 differs from every other architecture with large effects, while MAS-1, MAS-2, and MAS-4 remain indistinguishable. The same pattern holds at *syntactic validity*, except for a small but significant advantage of MAS-2 over MAS-4. At *similarity acceptance*, MAS-3 again differs from all others with medium-to-large effects; in addition, MAS-2 accepts more outputs than MAS-1 and MAS-4, while MAS-1 and MAS-4 are indistinguishable.

**Table 2** Pairwise comparisons for output generation and validity.

| Pair | File gen. | | | | Syntactic | | | | Similarity | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Sig | Dir | $h$ | Mag | Sig | Dir | $h$ | Mag | Sig | Dir | $h$ | Mag |
| $MAS_{1vs2}$ | ✗ | – | – | – | ✗ | – | – | – | ✓ | ↓ | -0.47 | * |
| $MAS_{1vs3}$ | ✓ | ↑ | 1.46 | *** | ✓ | ↑ | 1.46 | *** | ✓ | ↑ | 0.71 | ** |
| $MAS_{1vs4}$ | ✗ | – | – | – | ✗ | – | – | – | ✗ | – | – | – |
| $MAS_{2vs3}$ | ✓ | ↑ | 1.57 | *** | ✓ | ↑ | 1.60 | *** | ✓ | ↑ | 1.19 | *** |
| $MAS_{2vs4}$ | ✗ | – | – | – | ✓ | ↑ | 0.27 | * | ✓ | ↑ | 0.28 | * |
| $MAS_{3vs4}$ | ✓ | ↓ | -1.57 | *** | ✓ | ↓ | -1.33 | *** | ✓ | ↓ | -0.91 | *** |

**Sig** (Significance): ✓ rejects equality after Holm–Bonferroni ($p_{adj} < 0.05$); ✗ otherwise. **Dir** (Direction): sign of $h$; ↑ indicates that $MAS_X$ exhibits a higher rate than $MAS_Y$ in the comparison $MAS_{X\text{vs}Y}$; ↓ the opposite. $h$: Cohen's $h$ effect size. **Mag** (Magnitude): $|h|$ classified as negligible (–), small (*), medium (**), or large (***).

The results reveal two distinct phenomena. Early in the pipeline, failures concentrate in a single configuration, MAS-3 (Centralized+Dynamic), rather than in all Dynamic or all Centralized architectures. A plausible explanation is the combination of global planning with local tool autonomy: the plan presumes actions such as writing the output file, but the ReAct agents retain discretion over tool invocation and may terminate without executing them, so a run can complete its steps without materializing an output; root-cause analysis of these failures is left to future work. Later, once outputs are syntactically valid, the dominant separation shifts to Coordination Strategy: Static configurations preserve a substantially larger share of plausible outputs under the common similarity filter, regardless of communication structure.

***Answer to RQ1.*** At file generation and syntactic validity, only MAS-3 (C+Dyn) fails substantially, while MAS-1, MAS-2, and MAS-4 perform similarly. At similarity acceptance, the dominant separation is by Coordination Strategy: Static configurations retain a substantially larger fraction of syntactically valid outputs than Dynamic ones under both communication structures, with MAS-2 (H+Sta) achieving the highest final acceptance rate.

## 4.2 RQ2: Factorial Analysis of Operational Cost

Table 3 shows a strong descriptive pattern across cost measures. Within both communication structures, Dynamic coordination consumes more than Static on every measure. However, the size of this penalty differs sharply: moving from Static to Dynamic raises total tokens by approximately +138% under Hierarchical communication (from 15,104 to 35,844) but by only +31% under Centralized (from 20,156 to 26,338). MAS-2 (H+Sta) is the global cost minimum on every measure.

**Table 3** Median values per architecture for cost measures analyzed by ART-ANOVA.

| Measure | Hierarchical | | Centralized | |
|---|---|---|---|---|
| | MAS-1 (Dyn) | MAS-2 (Sta) | MAS-3 (Dyn) | MAS-4 (Sta) |
| Execution time (s) | 82.2 | **60.9** | 124.7 | 70.9 |
| LLM calls | 12 | **3** | 11 | 8 |
| Input tokens | 26,247 | **11,697** | 19,838 | 15,986 |
| Output tokens | 9,606 | **3,362** | 6,843 | 3,793 |
| Total tokens | 35,844 | **15,104** | 26,338 | 20,156 |

ART-ANOVA (Table 4) confirms this pattern across measures. Coordination Strategy is the dominant main effect: large on LLM calls and on input, output, and total tokens, and medium on execution time. Communication Structure is more heterogeneous: large on LLM calls, medium on execution time, small on output tokens, and negligible on input and total tokens. The interaction is significant on all measures, but its magnitude varies from small on execution time to large on LLM calls. In all cases, the interaction shows that the cost impact of Dynamic coordination depends on the communication structure with which it is paired.

The interaction deserves emphasis because it changes the substantive reading of the main effects. Considering only main effects, Communication Structure would appear nearly irrelevant for token-based cost. Once the interaction is included, however, the Hierarchical structure emerges as the setting where Dynamic coordination becomes especially expensive. This explains why MAS-1 is the most token-intensive configuration even though the isolated main effect of structure on total tokens is negligible.

**Table 4** ART-ANOVA effects and interaction on cost measures.

| Measure | Structure (C & H) | | Coordination (Dyn & Sta) | | Interaction | |
|---|---|---|---|---|---|---|
| | $\eta_p^2$ | Mag | $\eta_p^2$ | Mag | $\eta_p^2$ | Mag |
| Execution time | 0.092 | ** | 0.137 | ** | 0.037 | * |
| LLM calls | 0.343 | *** | 0.774 | *** | 0.504 | *** |
| Input tokens | 0.002 | – | 0.238 | *** | 0.084 | ** |
| Output tokens | 0.034 | * | 0.377 | *** | 0.063 | ** |
| Total tokens | 0.007 | – | 0.278 | *** | 0.080 | ** |

$\eta_p^2$: partial eta-squared effect size. **Mag** (Magnitude): $\eta_p^2$ classified as negligible (–), small (*), medium (**), or large (***).

***Answer to RQ2.*** Coordination Strategy is the dominant factor, with large effects on LLM calls and token consumption, and a medium effect on execution time. Communication Structure has a heterogeneous profile: large on LLM calls, medium on execution time, small on output tokens, and negligible on input and total tokens. The two factors interact on every cost measure, with the strongest interaction on LLM calls (large) and the weakest on execution time (small). Across all interactions, Dynamic coordination is substantially more expensive under Hierarchical than Centralized communication, making MAS-1 (H+Dyn) the most costly configuration and MAS-2 (H+Sta) the least costly.

## 4.3 RQ3: Structural Transformations and Execution Efficiency

### 4.3.1 Structural Transformations

Structural metrics are analyzed at two levels. The *paired* analysis uses the intersection of instances accepted by all four architectures ($N_{\text{paired}} = 146$), preserving input alignment and controlling for input-level variability. The *marginal* analysis uses each architecture's full accepted set ($N = 1059, 1509, 394, 1252$ for MAS-1 through MAS-4), providing higher power at the cost of comparing unbalanced, non-aligned samples.

**Paired analysis.** Friedman tests reject equality on four of the eight metrics (Avg_CC, Hal_Diff, LoC, Func_Count). Pairwise Wilcoxon comparisons (Table 5) reveal a single dominant pattern: MAS-1 (H+Dyn) separates from each of the other three architectures on Avg_CC, LoC, and Func_Count, with medium-to-large effects. Relative to the others, MAS-1 generates more functions, longer files, and lower average cyclomatic complexity per function. Hal_Diff differentiates only $\text{MAS}_{1vs4}$. All comparisons among MAS-2, MAS-3, and MAS-4 are non-significant.

**Marginal analysis.** Kruskal–Wallis rejects equality on all eight metrics. The paired result is largely reproduced: MAS-1 remains the main structural outlier, again generating more functions, longer files, and lower Avg_CC relative to the others (Table 6). These effects are smaller than in the paired analysis, as expected given the added input heterogeneity. The marginal analysis also detects differences among MAS-2, MAS-3, and MAS-4 not visible in the paired analysis, but these are uniformly small or negligible. Marginal comparisons should be read with caution, particularly those involving MAS-3, since its accepted subset contains only 394 of 2,000 instances and is thus biased toward inputs on which MAS-3 produces plausible outputs; this post-treatment selection bias is discussed in Section 6.

**Table 5** Paired pairwise comparisons (Wilcoxon signed-rank + Holm–Bonferroni) for significant structural metrics where $N_{\text{paired}} = 146$.

**Sig** (Significance): ✓ rejects equality after Holm–Bonferroni ($p_{adj} < 0.05$); ✗ otherwise. **Dir** (Direction): sign of $\delta$; ↑ indicates that $MAS_X$ exhibits a higher value than $MAS_Y$ in the comparison $MAS_{XvsY}$; ↓ the opposite. $\delta$: Cliff's delta effect size. **Mag** (Magnitude): $|\delta|$ classified as negligible (–), small (*), medium (**), or large (***).

Both analyses converge on the same interpretation: architectural separation in structural transformation is concentrated in MAS-1 (H+Dyn), which applies the most decomposition-heavy transformation profile, generating more functions and longer files while lowering average per-function complexity. MAS-2, MAS-3, and MAS-4 remain structurally close.

***Answer to RQ3(a).*** MAS-1 (H+Dyn) is the main structural outlier, generating more functions, longer files, and lower average cyclomatic complexity per function than the other architectures. MAS-2, MAS-3, and MAS-4 are structurally close, with mostly small or negligible differences across both paired and marginal analyses.

### 4.3.2 Execution Efficiency

Friedman tests reject equality on every efficiency measure across all $N_{\text{paired}} = 2{,}000$ executions. Pairwise Wilcoxon comparisons (Table 7) reveal a highly regular structure: for LLM calls, input, output, and total tokens, the four architectures follow a strict ordering, MAS-2 (H+Sta)

< MAS-4 (C+Sta) < MAS-3 (C+Dyn) < MAS-1 (H+Dyn), with every pairwise contrast significant and nearly all effects large, consistent with RQ2. Execution time follows a different ordering: MAS-2 < MAS-4 < MAS-1 < MAS-3, inverting the positions of MAS-1 and MAS-3. This inversion is substantively important: despite being the most token-expensive, MAS-1 is faster than MAS-3, whose elapsed-time penalty reflects inefficient execution driven by its severe early-stage output generation failures rather than by token volume alone.

**Table 7** Pairwise comparisons on execution efficiency (Wilcoxon signed-rank + Holm–Bonferroni, $N_{\text{paired}} = 2{,}000$). All comparisons are significant after Holm–Bonferroni ($p_{adj} < 0.05$).

| Pair | Exec. time | | | LLM calls | | | In. tokens | | | Out. tokens | | | Total tok. | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Dir | $r_{rb}$ | Mag | Dir | $r_{rb}$ | Mag | Dir | $r_{rb}$ | Mag | Dir | $r_{rb}$ | Mag | Dir | $r_{rb}$ | Mag |
| $\text{MAS}_{1vs2}$ | ↑ | 0.45 | ** | ↑ | 0.99 | *** | ↑ | 0.92 | *** | ↑ | 0.98 | *** | ↑ | 0.97 | *** |
| $\text{MAS}_{1vs3}$ | ↓ | -0.47 | ** | ↑ | 0.67 | *** | ↑ | 0.52 | *** | ↑ | 0.47 | ** | ↑ | 0.58 | *** |
| $\text{MAS}_{1vs4}$ | ↑ | 0.25 | * | ↑ | 0.96 | *** | ↑ | 0.72 | *** | ↑ | 0.94 | *** | ↑ | 0.85 | *** |
| $\text{MAS}_{2vs3}$ | ↓ | -0.88 | *** | ↓ | -0.99 | *** | ↓ | -0.43 | ** | ↓ | -0.99 | *** | ↓ | -0.65 | *** |
| $\text{MAS}_{2vs4}$ | ↓ | -0.33 | ** | ↓ | -0.99 | *** | ↓ | -0.57 | *** | ↓ | -0.61 | *** | ↓ | -0.66 | *** |
| $\text{MAS}_{3vs4}$ | ↑ | 0.78 | *** | ↑ | 0.98 | *** | ↑ | 0.38 | ** | ↑ | 0.89 | *** | ↑ | 0.56 | *** |

**Dir** (Direction): sign of $r_{rb}$; ↑ indicates that $\text{MAS}_X$ exhibits a higher value than $\text{MAS}_Y$ in the comparison $\text{MAS}_{X\text{vs}Y}$; ↓ the opposite. $r_{rb}$: matched-pairs rank-biserial correlation. **Mag** (Magnitude): $|r_{rb}|$ classified as negligible (–), small (*), medium (**), or large (***).

***Answer to RQ3(b).*** Token-based and call-based measures follow a stable ordering (MAS-2 < MAS-4 < MAS-3 < MAS-1), whereas elapsed time follows a different ordering in which MAS-3 (C+Dyn) becomes the slowest. Static configurations are the most efficient and stable, while Dynamic configurations diverge into two behaviors: high-cost decomposition-heavy transformation (MAS-1, H+Dyn) and severe output generation failures with poor runtime efficiency (MAS-3, C+Dyn).

## 4.4 Discussion

**Coordination Strategy is the dominant execution-control dimension.** Across the three research questions, the clearest and most reproducible pattern is the advantage of Static over Dynamic coordination, visible in the retention of plausible outputs after syntactic validation, in the dominant main effects on nearly all cost measures, and in the stable architecture ordering for token- and call-based efficiency. This empirically supports the broader LLM-MAS literature, which treats coordination and tool orchestration as core architectural variables rather than secondary implementation details [7, 9, 18], and shows that whether tool use is prescribed in advance or delegated adaptively at runtime matters more than how control is organized among agents.

**Architectural effects are interaction-sensitive rather than purely additive.** The strongest methodological result is not the main effect of Coordination Strategy alone, but its interaction with Communication Structure on all cost measures. Hierarchical communication does not uniformly increase or decrease cost; instead, it specifically amplifies the penalty of Dynamic coordination. As shown in Table 3, moving from Static to Dynamic raises total tokens by +138% under Hierarchical communication, but only +31% under Centralized. MAS-1 is thus the worst token-consuming architecture not because Hierarchical structure is generally costly, but because it is costly when paired with Dynamic tool orchestration. These interactions arise even under a fixed model, task, and tooling context, complementing recent comparative work that found limited differences across other agent-configuration axes [15].

**Dynamic coordination does not fail in one way; it fails in two.** The two Dynamic architectures do not form a coherent family in the way the two Static ones do. MAS-1 succeeds at file generation and syntactic validity but is expensive and structurally aggressive, whereas MAS-3 is comparatively less token-expensive yet fails to produce usable outputs for a large fraction of instances and exhibits the worst runtime behavior. This divergence suggests that Dynamic coordination increases sensitivity to the surrounding control structure rather than exerting a uniform effect, widening the behavioral envelope toward either expensive productive transformation or unstable execution depending on how control is organized.

**Structural improvement is not one-dimensional.** MAS-1 lowers average cyclomatic complexity per function while simultaneously increasing lines of code and number of functions, indicating a decomposition-heavy transformation style consistent with the broader refactoring literature, which has long shown that improvements in one structural dimension may coexist with increases in others [16, 22]. MAS-1 thus tends toward a specific structural strategy, breaking code into more, simpler units at the price of larger files and higher fragmentation, rather than performing uniformly better refactoring overall.

**Implications for empirical evaluation of LLM-MAS.** The results also speak to evaluation methodology. Recent surveys note that most existing LLM-MAS studies evaluate complete systems end-to-end, making architectural attribution difficult [9,18]. This study shows that a controlled factorial design can expose interaction effects that partial comparisons would miss: comparing only MAS-2 against MAS-3 might suggest centralized control is problematic, while comparing only MAS-1 against MAS-2 might suggest Dynamic coordination is universally harmful, yet the full crossed design shows that what matters is the combination of both dimensions, not either in isolation.

**Practical reading of the four configurations.** For automated Python refactoring under the conditions studied here, MAS-2 (Hierarchical+Static) is the most attractive default, combining the best similarity acceptance rate with the lowest operational cost while avoiding the structural extremity of MAS-1 and the output generation failures of MAS-3. MAS-4 (Centralized+Static) is a credible alternative when explicit planning is desired, but consistently weaker than MAS-2 on validity and cost. The two Dynamic configurations are harder to justify as defaults: one is operationally expensive, the other operationally unstable. While this does not mean Dynamic coordination is never useful, in the present refactoring setting its benefits are not evident enough to offset its cost and output generation liabilities.

## 5 Related Work

**LLM-MAS Design Space in Software Engineering.** Prior work explores a wide range of LLM-MAS designs for automating SE activities that exceed the scope of single-prompt assistance, including development workflows [12, 30], issue resolution and bug fixing [1, 2, 19, 20, 37], and code review and generation [36, 47]. Across these tasks, systems differ in how responsibilities are distributed, how agents communicate, how execution is planned, and how tools are incorporated: ChatDev [30] and MetaGPT [12] decompose work into specialized roles with structured interaction protocols; Coder [2], MASAI [1], MARSCode [19], Alibaba Lingma [20], and MAGIS [37] combine task decomposition, repository exploration, and tool-supported interaction in different ways; and CodeAgent [36] and AdaCoder [47] vary in supervisory control, with CodeAgent centralizing oversight through a dedicated QA-Checker

agent and AdaCoder deferring planning adaptively. However, most of these systems are evaluated as complete systems under task-specific configurations, which makes architectural effects difficult to separate from model choice, prompt design, or tooling, a limitation that recent surveys identify with respect to SE-specific applications [9, 18] and general multi-agent collaboration mechanisms [7, 17, 39, 45], and that our results confirm: the interaction between Communication Structure and Coordination Strategy would remain undetectable under end-to-end evaluation.

**Multi-Agent Approaches to Automated Refactoring.** Within automated refactoring, the literature is smaller and more fragmented: MANTRA [44] combines retrieval-augmented generation with multi-agent collaboration for method-level Java refactoring; Siddeeq et al. [34] propose a multi-agent Haskell refactoring pipeline; RefactorGPT [14] structures refactoring as a sequence of specialized ChatGPT agents; MUARF [43] introduces a developer-reviewer workflow as a notable example of runtime-adaptive coordination; Rajendran et al. [31] describe a centralized conceptual framework without empirical evaluation; and prior empirical work on Python refactoring demonstrates feasibility but evaluates systems end to end [28]. The most salient architectural variation concerns two questions: how control and information flow are organized among agents (*Communication Structure*), and whether tool invocation and execution order are fixed in advance or resolved at runtime (*Coordination Strategy*). Yet existing evaluations bundle these choices with model selection, prompt design, and task-specific tooling [14, 28, 34, 43, 44], making attribution to either factor impossible. Our results show that this attribution matters: Coordination Strategy emerged as the dominant factor across all outcome dimensions, and its interaction with Communication Structure would not have been isolable without a controlled crossed design.

**Empirical Comparison of Agent Architectures.** The gap is not the absence of LLM-MAS for refactoring, but the absence of controlled empirical evidence isolating architectural effects from confounding factors, a limitation explicitly identified in prior surveys [7, 9, 18]. Closest to our work, Kim [15] compares agent configurations varying in specialization granularity across nine SE tasks, finding small performance differences and attributing most behavior to the underlying model. Our findings complement and extend that result: while Kim finds limited architectural signal across granularity configurations, we find strong signal when Communication Structure and Coordination Strategy are crossed. This suggests that the relevant axis of variation matters and that factorial designs crossing multiple dimensions may reveal effects that single-axis comparisons miss.

## 6 Threats to Validity

We structure this section following Wohlin et al. [42], addressing conclusion, internal, construct, and external validity.

**Conclusion validity.** *Low statistical power* arises most clearly in the structural analysis: after AST validation and similarity-based filtering, the jointly accepted intersection contains only $N = 146$ instances, insufficient for reliable interaction testing across eight structural metrics; we thus restrict factorial inference to cost measures and analyze structural outcomes through complementary paired and marginal non-parametric comparisons. *Random variation in treatment execution* is a concern because each architecture runs only once per input – given the stochastic nature of LLM inference, repeated executions could yield different

outputs, costs, or failure rates. *Violated assumptions in factor-level analysis* remain a risk for RQ2, as ART-ANOVA does not explicitly model the instance-level dependence induced by the repeated-measures design; we partially mitigate this by complementing the factorial analysis with paired Friedman/Wilcoxon comparisons and reporting effect sizes throughout. Finally, to reduce *multiplicity*, all pairwise comparisons are adjusted with Holm–Bonferroni correction.

**Internal validity.** The main threat concerns *confounding in treatment implementation*: Communication Structure and Coordination Strategy are manipulated through specific instantiations involving fixed agent roles, prompts, planning artifacts, and LangGraph workflows, so the observed effects should be read as properties of these operationalizations rather than of all possible hierarchical, centralized, static, or dynamic architectures. A second threat is *post-treatment selection*: structural metrics are available only for outputs passing both validation stages, yielding unequal accepted subsets. We mitigate this by reporting both a paired analysis on the jointly accepted subset and a marginal analysis on each architecture's full accepted set.

**Construct validity.** The principal threat is *incomplete operationalization of refactoring quality*: the eight static metrics capture complexity, size, modularity, and documentation-related properties but do not establish semantic correctness or behavior preservation, and the similarity-based filter excludes structurally implausible outputs without guaranteeing that retained ones are behavior-preserving or that the intended refactoring type was applied. A second subthreat is *operationalization bias* in the use of `human_ref.py`: while this choice avoids architecture-specific calibration, the resulting human-anchored threshold (0.8521) is conservative and may disproportionately exclude outputs from architectures whose similarity distributions are shifted downward, most notably MAS-3 (source-specific threshold 0.6226). A third threat concerns *cost measurement*: execution time, token usage, and call counts do not directly model monetary cost, energy consumption, or deployment-time latency.

**External validity.** Several subthreats limit generalizability. Under *interaction of treatment and subjects*, the dataset is restricted to file-level Python refactoring instances drawn from ML repositories in *MLRefScanner*. Findings may not generalize to other languages, domains, or refactoring granularities; tasks with broader repository context or longer action horizons, such as issue resolution, may reward adaptive coordination more than the file-level setting studied here. Under *interaction of treatment and setting*, all configurations use a single foundation model (`open-mixtral-8x22b`) and orchestration substrate (LangGraph). Other model families or frameworks may interact differently with hierarchical versus centralized communication or static versus dynamic coordination: models with stronger native tool-calling could narrow the observed Static–Dynamic gap, although the interaction between the two factors, being structural rather than model-specific, is less tied to this experimental setting. Finally, under *interaction of treatment and construct operationalization*, the study examines only cooperative architectures spanning two manipulated dimensions and four configurations. Other regions of the LLM-MAS design space – decentralized communication, non-cooperative interaction, alternative planning mechanisms, and different tools – remain outside this paper's scope.

## 7 Conclusion

This paper presented a controlled $2 \times 2$ factorial comparison of four LLM-MAS for automated Python refactoring, crossing *Communication Structure* (Hierarchical vs. Centralized) with *Coordination Strategy* (Dynamic vs. Static) across 2,000 real-world instances under identical model, dataset, orchestration, prompting, and tool conditions.

*Coordination Strategy* emerged as the dominant architectural factor: Static configurations consistently retained a larger fraction of syntactically valid outputs under the plausibility filter and incurred substantially lower token-based and call-based costs than Dynamic configurations. *Communication Structure* showed a heterogeneous profile, strongly affecting call behavior, with a medium effect on execution time, a small effect on output tokens, and a negligible effect on input/total token consumption. At the architecture level, MAS-2 (H+Sta) provided the best tradeoff between validity and cost, MAS-1 (H+Dyn) was the most expensive configuration and the main structural outlier, and MAS-3 (C+Dyn) was the only configuration to fail on a substantial fraction of inputs.

Static coordination is the preferable default when output validity and operational cost are primary concerns, and the controlled factorial design exposes interaction effects that remain hidden in standard end-to-end benchmarking. Future work should incorporate behavioral correctness checks, root-cause analysis of architecture-specific failures, repeated executions under controlled randomness, additional LLM families, alternative orchestration frameworks, other languages and repository domains, and broader regions of the LLM-MAS design space, including decentralized and non-cooperative architectures.

## Data Availability Statement

The replication package accompanying this study is openly available on Zenodo under a CC-BY 4.0 license (source code additionally under MIT) at: `https://doi.org/10.5281/zenodo.20042886`. The package includes: **(i)** the source code of the four LLM-MAS architectures (MAS-1 through MAS-4), implemented with LangGraph, with documentation and scripts to execute each architecture individually or all four in sequence; **(ii)** the experimental dataset of $N = 2{,}000$ Python refactoring instances collected during the experiment, comprising the original, human-refactored, and four agent-refactored versions of each file, together with the per-execution system logs; **(iii)** the analysis scripts covering the full statistical pipeline (output validity tests, structural comparisons, and cost analysis) used to produce all results reported for RQ1, RQ2, and RQ3.

## Abstract

**Background.** Compilers are actively developed programs, with newer versions implicitly promising better performance.

**Aim.** In this paper, we evaluate whether the cost of the expected improvements in optimisations in newer versions of the GCC C compiler pays off, both in terms of execution time and energy consumption.

**Method.** To do so, we select 10 major versions of GCC (spanning GCC-4 to GCC-13), and four different optimization flags (*-Og*, *-O2*, *-O3*, and *-Os*) to compile and run benchmarks written in C from the SPEC CPU 2017 benchmarking suite, measuring both the energy and time of compilation and running of the benchmarks. A linear mixed-effects model mapping the GCC major version number to a numerical variable is then fitted to the data.

**Result.** We find a statistically significant trend of decreasing running costs when optimized with *-O2* and *-O3*, with an overall decrease in costs (for both energy and time) amounting to 13% for *-O2* and 9% for *-O3* overall (from GCC-4 to GCC-13). However, this is not without a cost, as there is also a statistically significant trend of increasing compilation cost for the optimization levels tested except *-Og*, with an increase amounting to 17% in energy and 15% in time with *-O3* enabled, and 18% in energy and 16% in time with *-O2* enabled. Some benchmarks benefit more than others, which we hypothesize is due to more advanced vectorization in newer compiler versions.

**Conclusion.** GCC is producing lower-cost programs, at the expense of higher compilation cost. Still, the trade-off is well worth it as a single additional execution of the compiled program offsets the increased cost of compilation for both the run-time and energy cost.

**2012 ACM Subject Classification** Software and its engineering → Compilers; Software and its engineering → Runtime environments

## 1 Introduction

One of the most important types of program is the optimising compiler. The job of a compiler is to translate text to a runnable program, while performing optimisations that can improve running time, possibly on specific machines or architectures. For final production code, we generally want the fastest program possible, thus compilers often receive updates with new promising optimizations, resulting in hopefully better performing programs. With these improvements of optimizations, we expect to see the cost of running the compiled programs decrease, though, at the possible cost of increased compile time as we perform more advanced optimizations.

However, does this expected reduction in running costs actually occur, and is it really worth it? The types of programs that are written every day differ greatly, and not every optimization will optimize every program equally. Indeed, some may harm the performance. If the cost of every single compilation increases, surely, this added cost will compensate for itself by the cost of the compiled program decreasing as well. Programs are only compiled a few times, and hopefully run many times. Stated somewhat cheekily "Compiler optimizations should pay for themselves" [4]. But do they?

It is possible to interpret how compiler optimizations may pay for themselves in several different ways. The most common metric to consider is the execution time, which often gives a good overall assessment of the programs. There also exist more machine-specific metrics: memory consumption, cache behaviour, etc. A more recent metric is energy consumption; either measured externally as wall-plug power or on the machine with, for example, RAPL [9] or an integrated power management circuit. In this work, we have chosen to use the time and energy cost as metrics. Execution time gives the classical cost as a basis for comparison, while energy cost (measured with RAPL) gives an alternative contemporary metric that is receiving increased focus.

There is an inherent trade-off between more compiler optimizations and faster programs produced. The more optimization the compiler does, the faster the compiled program will generally become. Because of this trade-off, compilers will usually have a hierarchy of coarse-grained flags that you can quickly apply to get a faster program, at the cost of higher compilation costs. For GCC, this hierarchy is *-O0* *-O1*, *-O2*, and *-O3*, with other flags (*-Og*, *-Os*, and *-Oz*) also being available.

To test this, we need a set of benchmarks that we can compile and measure performance. As a representative selection of programs, we use all the benchmarks of the SPEC CPU 2017 suite [21] written in C. The SPEC CPU 2017 benchmark suite is an industry standard consisting of several real-world programs with carefully selected input aiming at stress testing the system's processor, memory, and compiler.

In this paper, we address the research question: "Is there a downward trend in compilation costs between increasing versions of the GNU C Compiler (GCC) and the performance of the compiled programs?" We consider both time and energy costs of compilation and execution, and examine how coarse-grained optimization flags evolve across GCC versions. Our main experimental factors are GCC major version, optimization flag ($-Os$, $-Og$, $-O2$, $-O3$), and SPEC CPU 2017 C benchmarks. As dependent variables, we measure compilation time and energy, execution time and energy, and the size of the produced benchmark binaries.

The SPEC CPU 2017 C benchmarks serve as our experimental objects. We analyze data with linear mixed effects models in the form of ANOVA and ANCOVA to quantify trends in GCC versions and assess the statistical significance of the observed effects.

## 2 Related Work

Prior work has studied software energy consumption across programming languages, compilers, compiler versions, and optimization configurations. We organize this work from broader language-level comparisons toward studies most closely related to our focus on GCC version evolution and optimization flag groups.

Several studies have compared the energy consumption of programs written in different programming languages. Pereira et al. [19] compare the energy consumption of a range of programming languages using RAPL-based energy measurements, while Gordillo et al. [6] later conduct a similar comparison using physical energy measurements. Both give similar results and, notably, show that C is always at the top of energy efficiency for the studied benchmarks.

Kempen et al. [12] extend this line of work by further examining the relationship between the programming language and the with implementation of the language. Using RAPL, they show that, when factors such as the number of available cores and the CPU clock frequency are held constant, all language implementations exhibit a constant power draw. Furthermore, they show that different implementations of a language can play a role for their energy usage, which they demonstrate for CPython and PyPy, and LuaJit and Lua.

Concerning C compilers, a study by Hebbar et al. [8] uses SPEC and an Intel machine to determine that the Intel C compiler produces (significantly) faster programs than the GCC compiler due to better utilization of Intel's specialized vector instructions. Another study compares the GCC and the Intel C compiler and determines that the GCC compiler is more energy efficient, although for a different set of benchmarks [10]. However, when measuring execution time, they get more varying results. At some clock frequencies, the GCC outperforms the Intel compiler, and at others, the Intel compiler outperforms the GCC compiler.

There has been some recent work on how a compiler evolves over time. Most similar to our work is Jiménez et al. [11] studying the impact of choosing a newer versions of the compiler/interpreter on energy and time for programs in C, Python, and Java, using a benchmark suite of algorithms taken from the Computer Language Benchmarks Game (CLGB). Their result shows no clear trend; that a newer version means less energy. Ournani et al. [17] study the energy usage of different versions over a variety of Java Virtual Machine (JVM) distributions. They concluded that newer versions generally use less energy than older ones and that the different distributions form clusters of similar energy consumption. They also note that C has the highest correlation between execution time and energy consumption, and Java has the weakest one. In addition, two master's theses [2,16] both look at what effect the compiler/interpreter version has for energy usage. They both use RAPL to measure energy, and both use the CGLB as benchmarks. Olvera compares different versions of Python, C++ (using GNU g++), Java, and JavaScript, and comes to the conclusion that a newer version greatly impacts energy usage for Python and JavaScript. But for Java and especially C++, the version number has little impact. Azevedo compares different versions of C (LLVM's clang), C++ (LLVM's clang), Java, and Python, arriving at a similar conclusion that selecting a newer version generally will slightly improve energy consumption, but that the newest version need not be the optimal. The author notes that this tendency is the weakest, or non-existent, for C (LLVM) depending on the benchmark.

**Script 1** GCC benchmarking.

```
foreach GCC in GCC versions do download and build GCC with -O2;
create configurations: (GCC version, optimization flag, benchmark, repetitionn);
randomize configuration order;
compile once to warm up;
foreach configuration in configurations do
    wait until 45°C; measure as we compile the configuration;
foreach configuration in configurations do
    wait until 45°C; measure as we run the configuration;
```

The effect of different optimization flags on the energy usage of a C or C++ program has been studied by Absdulsalam et al. [1], where they find using *-O2* and *-O3* over *-O1* will reduce the energy usage, and also finding that C, C++, and Java consistently outperform Python energy-wise.

The standard optimization flags: *-O1*, *-O2*, and *-O3*, are convenient, however they are not always optimal. It is possible to select specific, fine-grained optimization flags that outperform them for specific benchmarks and specific machines. Pallister et al. [18] find specific GCC flags for embedded hardware that reduce the energy consumption, and give some evidence that there is no universally good set of flags for any benchmark and any hardware. Similarly, Georgiouo et al. [5] find specific (ordered) subsets of the standard flags giving more energy efficient programs for embedded hardware using LLVM. There has also been work on other language optimization flags. For example Kirkeby et al. [14], look at Haskell + GHC's different optimizations at a granular level. The authors come to the conclusion that the optimization flags do statistically affect the energy usage and execution time, and in general show that for 24% of the tested combinations, the energy usage went down enabling optimizations.

Taken together, prior work has investigated either the effect of compiler versions on energy consumption or the effect of compiler optimization configurations. Our study combines these perspectives in a longitudinal analysis focused specifically on GCC. We examine 10 systematically selected GCC versions using four standard optimization levels and SPEC CPU 2017, and measure both compilation and execution costs in terms of time and energy. The most similar work will be further compared to our work in Section 5.

## 3 Methodology

To test how compilation costs and compiled program's running cost change throughout the evolution of GCCs we design Script 1. We wait until a fixed temperature of $45^oC$ is reached to reduce any impact temperature-variation has on the energy usage.[1] This temperature has been experimentally shown to yield the smallest energy consumption using a similar setup [14]. The experiment was conducted in a temperature-controlled room, on a laptop always connected to the power. The laptop is running no other user programs, and we kept the background processes to a minimum.

[1] Temperature is managed by reading from `/sys/class/thermal/thermal_zone3/temp`.

## 3.1 The Machine

In order to compile the wide array of GCC versions, we use a "chroot"-environment with Debian Jessie. This should not meaningfully affect performance, the only difference is the usage of different libraries (such as LibC – the C standard library). But we are aiming to measure the impact of the *compiler*, not libraries.

We have the following hardware + OS configuration:

| | |
|---|---|
| **Laptop** | LENOVO_MT_20F6_BU_Think_FM_ThinkPad X260 |
| **CPU** | Intel(R) Core(TM) i5-6200U CPU @ 2.30GHz, *Skylake* |
| **Host OS** | 5.15.0-171-generic, Ubuntu 22.04.5 LTS |
| **Chroot LibC** | Debian GLIBC 2.19-18+deb8u10 |

We use `-march=native`, allowing for specific architecture instruction adaptations. Skylake was first supported in GCC version 6; before that (for us version 4 and 5) GCC defaults to using Broadwell instructions.

## 3.2 On RAPL

Intel's Running Average Power Limit is used as a tool for measuring energy usage. Its accuracy has been demonstrated in several studies [7, 13, 20]. In particular, Khan et al. [13] note that the accuracy of RAPL has been improved in Haswell, and even further in Skylake, which is the microprocessor of our computer. Moreover, RAPL has been widely used to compare energy usage [2, 14, 16, 17, 19].

RAPL gives us 4 different readings: PP0, PP1, DRAM, and PKG. PP0 is included into PKG, and PP1 is "Uncore" devices such as the GPU and is not included in our computer. To obtain an overall energy usage, we take the sum of PKG and DRAM; this is in alignment with previous studies (for example in the works of Pereira et al. [19]).

The RAPL registers can occasionally overflow. This manifests itself in huge negative numbers, and these results are then filtered out. In total, 294 rows were filtered, of which 28 were for compilation and 266 for running. However, for each benchmark run, at most 3 (out of 30) for each group were filtered out.

## 3.3 Which GCC Versions To Pick?

GCC is an actively developed and widely used program. With this comes many mainline releases, but also changes to previous mainline releases. Changes to previous mainline releases can also happen after a new mainline release. In order to pick the versions to compare against each other, we follow three maxims. Firstly, (1) we choose versions of GCC with strictly increasing release dates. Moreover, (2) the major version number must be different for each version. And finally, (3) we want our versions to be more or less equally spaced in terms of the amount of development done to them – which we measure by their release date.

The strategy of always picking the 3rd iteration of the major release for each version aligns well with our maxims. Figure 1 shows all releases of GCC from version 5 to version 15 with the 3rd iteration of each version highlighted. Each version's release date is more-or-less evenly spaced by one year. As we would like to benchmark a total of 10 versions of GCC, we obtain the following versions: 4.9.3, 5.3.0, 6.3.0, 7.3.0, 8.3.0, 9.3.0, 10.3.0, 11.3.0, 12.2.0, and 13.2.0. In the remainder of this work, we will refer to the different versions by their major version, i.e., the first number in the version triplet (4 for 4.9.3).

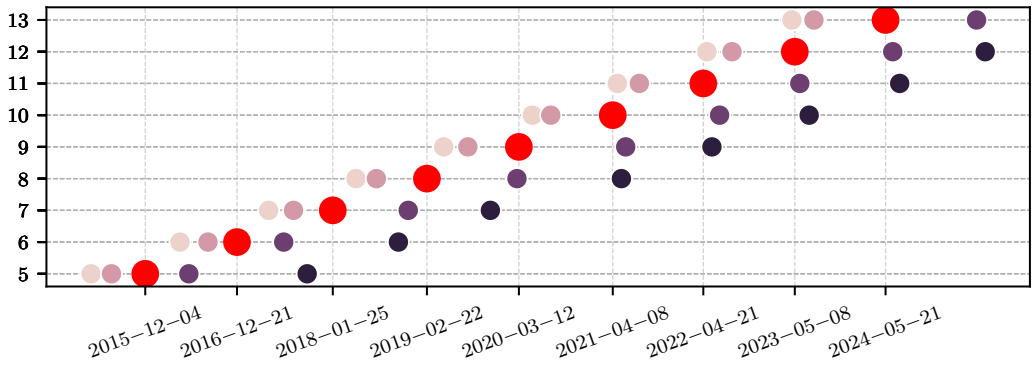

**Figure 1** GCC versions release timeline. GCC major versions from 5 to 13 over release dates. Each 3rd minor version is highlighted in red, with its release date marked by the ticks.

## 3.4 Which Optimization Flags to Pick?

While it would be ideal to include all the optimization flags of GCC, this is not feasible. Instead we pick the following four flags: *-Og*, *-O2*, *-O3*, and *-Os*, aiming to get a good mix of the different types of optimizations. *-Og* optimizes for the best debugging experience. It performs a few optimizations and, thus, creates a good baseline as the first optimization flag a developer would use. *-Os* is used for optimizing for the lowest space of the binaries compiled. *-O2* and *-O3* are the primary optimisation flags for production code. These two are expected to take longer to compile, but they generate the fastest code with *-O3* aiming to produce the fastest programs. Taken together, these four flags strike a good balance between having a variety of different optimization targets, and also keeping the time for the experiments to run manageable.

## 3.5 Which Benchmarks to Pick?

We decided to use the "SPEC CPU® 2017" benchmark suite for this study [21], henceforth referred to as SPEC. SPEC is designed to be an industry-standardized, CPU-intensive suite for measuring and comparing compute intensive performance and striking a good balance of being both compilation-intensive and execution-intensive. As we are measuring the evolution of the GCC C compiler specifically, we choose the subset of the SPEC benchmarks that are only written in C.

SPEC distinguishes between *speed* and *rate* benchmarks, where *speed* measures the score for a single copy and *rate* measures the score for multiple (a user-defined amount) concurrent copies. *speed* is compiled with OpenMP support, and *rate* is not. Hence, each concurrent copy in *rate* runs in a "single-threaded" manner. To best measure how the compiler evolves, we have chosen to disable OpenMP support[2] by using *rate* with only a single concurrent copy. The scoring metric *rate* uses is not relevant as we are measuring our costs (energy and time) independent of SPEC.

We are then left with the following eight benchmarks: *500.perlbench_r*, *502.gcc_r*, *505.mcf_r*, *519.lbm_r*, *525.x264_r*, *538.imagick_r*, *544.nab_r*, and *557.xz_r*. Table 1 provides a brief overview of what each benchmark does.

[2] Disabling OpenMP does not disable instruction-level parallelism, such as vectorization, which GCC attempts to optimise for – possibly to great effect, as we will see later.

**Table 1** Overview of benchmarks used, adapted from SPEC documentation [21], which classifies benchmarks by predominantly integer or floating-point operations.

| Benchmark | Based on | Type |
|---|---|---|
| *500.perlbench_r* | Perl (v5.22.1), interpreter for a popular scripting language. | Integer |
| *502.gcc_r* | GCC (4.5.0) with many optimization flags, IA32 as target. | Integer |
| *505.mcf_r* | MCF, a single-depot vehicle scheduling. | Integer |
| *519.lbm_r* | 3D incompressible fluids simulation. | Floating Point |
| *525.x264_r* | H.264/AVC video encoder. | Integer |
| *538.imagick_r* | ImageMagick, an image manipulation tool. | Floating Point |
| *544.nab_r* | Nucleic Acid Builder, a molecular modelling application. | Floating Point |
| *557.xz_r* | XZ Utils (5.0.5), in-memory file (de)compression. | Integer |

We note that *502.gcc_r* and *525.x264_r* have some compatibility issues, that were fixed by following the recommended solutions described in the benchmark. Namely using *-fcommon* for *525.x264_r* and using *-fgnu89-inline* for *502.gcc_r*. *500.perlbench_r* also had an issue which we were not able to remedy for GCC version 4; therefore, that benchmark is not included and has no data points for this version.

Finally, note that SPEC CPU 2026 has been released, with SPEC CPU 2017 therefore set for retirement. However, SPEC CPU 2017 remains appropriate for our study, as our compilers span from 2014 to 2024.

## 4 Results and Statistical Evaluation

The dataset is stratified into measurements of ENERGY and TIME within COMPILE ($N = 9452$) and RUN ($N = 9216$). Each strata consists of a full factorial design with approximately 30 repetitions for each combination of GCC_VERSION (10 levels: *gcc-04.09.03*, ..., *gcc-13.03.00*), OPTIMIZATION (4 levels: *-Os*, *-Og*, *-O2*, *-O3*) and BENCHMARK (8 levels); except the benchmark *500.perlbench_r* that could not run with GCC-4.

The four strata are analysed in separate linear mixed effects models with fixed effects of BENCHMARK, OPTIMIZATION and GCC_VERSION, and the interactions OPTIMIZATION:BENCHMARK and OPTIMIZATION:GCC_VERSION, and random effects of OPTIMIZATION within combinations of BENCHMARK and GCC_VERSION. This was done for a model (below referred to as ANOVA) where GCC_VERSION in the fixed effects part was used as a categorical variable, and a model (below referred to as ANCOVA) where it was used as a numerical variable GCC_MAJOR giving the major version from 4 to 13. In the models, ENERGY and TIME were log-transformed and GCC_MAJOR was also log-transformed in the ANCOVA model. Thus, after back-transformation by the exponential function, the ANCOVA model corresponds to a power relation between the response and GCC major, and contrasts may be interpreted as relative changes.

In brief, we fitted eight statistical models (ANOVA and ANCOVA for the four strata) with response either $Y = \text{ENERGY}$ or $Y = \text{TIME}$, and where $(A_{\text{-}Os}, A_{\text{-}Og}, A_{\text{-}O2}, A_{\text{-}O3}) \sim \mathcal{N}_4(0, \Sigma)$ are independent across BENCHMARK and GCC_VERSION, and $\epsilon_i \sim \mathcal{N}(0, \sigma^2)$ are independent across observation index $i$:

$$\begin{aligned}\text{ANOVA:}\quad \log(Y_i) = {} & \alpha(\text{OPTIMIZATION}_i, \text{BENCHMARK}_i) \\ & + \beta(\text{OPTIMIZATION}_i, \text{GCC\_VERSION}) \\ & + A_{\text{OPTIMIZATION}_i}(\text{BENCHMARK}_i, \text{GCC\_VERSION}_i) + \epsilon_i\end{aligned}$$

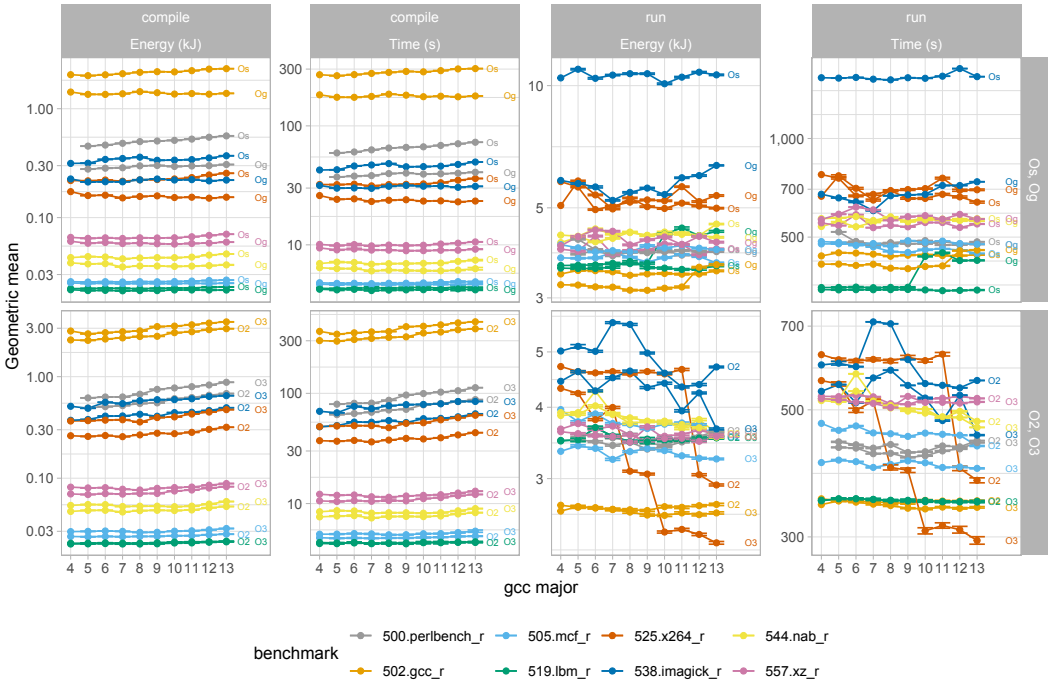

**Figure 2** Raw geometric means (points) with associated 95% confidence intervals (error bars) of the approximately 30 repetitions for each combination of BENCHMARK, OPTIMIZATION, and GCC_VERSION within the 4 strata. The individual combinations of benchmark and optimization are connected by lines across the GCC version. Note that the y-axes are logarithmic and different in the eight panels.

$$\begin{aligned}\text{ANCOVA:}\quad \log(Y_i) = {} & \alpha(\text{OPTIMIZATION}_i, \text{BENCHMARK}_i) \\ & + \gamma(\text{OPTIMIZATION}_i) \cdot \log(\text{GCC\_MAJOR}) \\ & + A_{\text{OPTIMIZATION}_i}(\text{BENCHMARK}_i, \text{GCC\_VERSION}_i) + \epsilon_i\end{aligned}$$

The models were fitted in the statistical software R using the package `lme4` (v. 2.0-1), and estimates are given as estimated marginal means using the package `emmeans` (v. 2.0.2).

## 4.1 Changes Over GCC Version

Figure 2 shows the raw geometric means (i.e., back-transformed raw means in the logarithmic scale) for the 4 strata within combinations of BENCHMARK, OPTIMIZATION, and GCC_VERSION. The benchmarks are connected by lines across the GCC versions. We can see that there is a large difference in the scale of time and energy consumption for the benchmarks, and that some benchmarks experience dramatic reductions in the running cost for energy and time, in particular for *-O2* and *-O3*. This justifies the modelling on the logarithmic scale (otherwise the estimates would be dominated by the benchmarks with the largest consumptions) as well as the addition of the random effects (to model particular behaviour of the benchmarks across optimization and GCC version).

Figure 3 shows the estimated development in energy and time consumption for the four optimizations across the population of benchmarks as a function of the GCC version. The dots with error bars show that estimates and associated 95% confidence intervals from the ANOVA models, and the smooth curves and regions show the same for the ANCOVA

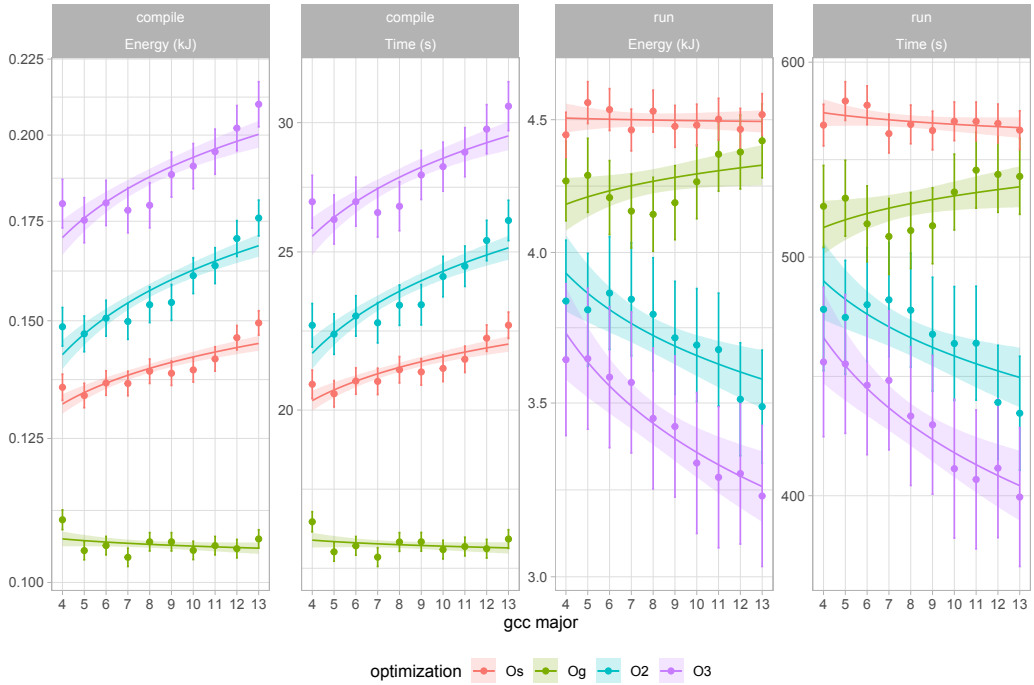

**Figure 3** Estimates (points for ANOVA, lines for ANCOVA) and associated 95% confidence intervals (error bars for ANOVA, regions for ANCOVA) for energy and time consumption. Note that the y-axes are logarithmic and different in the four panels.

models. Since the ANOVA models can be understood as the fully non-linear models, whereas the ANCOVA models stipulate a particular functional form (namely a power relation after the back-transformation), we see that the ANCOVA models do not capture the non-linear behaviour. In particular, the ANCOVA model does not capture the dip for the optimization flag *-Og* in Run Energy and Run Time around GCC-8. However, in all cases the ANCOVA models may be used to describe the overall trends from GCC-4 to GCC-13.

Table 2 shows the estimated slopes on the logarithmic scale for the ANCOVA models. After back-transformation, the slopes correspond to the exponents in the power relation between the response and the GCC major version. For the optimization flags *-O2* and *-O3*, we see statistically highly significant changes across major with a decrease in run energy and time, and an increase in compile energy and time. For the optimization flag *-Os* we see a highly significant increase in compilation energy and time. For the other six slopes with optimization flags *-Os* and *-Og* we have either non-significant or borderline significant changes. However, the ANCOVA models do not capture the dip for GCC-8 for energy and time consumption for *-Og*. Furthermore, the ANOVA models show a clear decrease until around GCC-8 followed by a clear increase afterwards.

Table 3 shows the estimated ratios (using the ANOVA models) between consecutive GCC major versions within energy and time in combinations with the four optimization flags. After back-transformation the contrasts are interpreted as ratios giving the relative change. In total there are 144 such ratios: 9 consecutive comparisons for each of the 16 combinations of measuring (Run, Compile), response (Energy, Time) and the different optimization flags. Hence, we will only show the ratios that are statistically significantly different from 1.

**Table 2** Estimated slopes in ANCOVA models with 95% confidence intervals. P-values are for the null hypotheses of no trend, i.e. slope equal to 0. Note that the slopes are on the log vs log scale, and hence correspond to the power exponents after back-transformation. Note also that P-values and confidence intervals are not adjusted for multiple testing.

| Measuring | Response | Optimization | Estimate | P-value |
|---|---|---|---|---|
| Run | Energy | Os | -0.003 (-0.019 ; 0.014) | 0.7607 |
| Run | Energy | Og | 0.029 (-0.000 ; 0.059) | 0.0523 |
| Run | Energy | O2 | -0.080 (-0.123 ; -0.037) | 0.0003 |
| Run | Energy | O3 | -0.115 (-0.168 ; -0.063) | 0.0001 |
| Run | Time | Os | -0.012 (-0.028 ; 0.004) | 0.1444 |
| Run | Time | Og | 0.032 ( 0.001 ; 0.064) | 0.0461 |
| Run | Time | O2 | -0.077 (-0.123 ; -0.030) | 0.0012 |
| Run | Time | O3 | -0.117 (-0.172 ; -0.063) | 0.0001 |
| Compile | Energy | Os | 0.080 ( 0.061 ; 0.099) | 0.0001 |
| Compile | Energy | Og | -0.012 (-0.027 ; 0.002) | 0.1015 |
| Compile | Energy | O2 | 0.143 ( 0.115 ; 0.172) | 0.0001 |
| Compile | Energy | O3 | 0.136 ( 0.101 ; 0.170) | 0.0001 |
| Compile | Time | Os | 0.068 ( 0.050 ; 0.086) | 0.0001 |
| Compile | Time | Og | -0.009 (-0.023 ; 0.004) | 0.1710 |
| Compile | Time | O2 | 0.126 ( 0.098 ; 0.154) | 0.0001 |
| Compile | Time | O3 | 0.120 ( 0.087 ; 0.154) | 0.0001 |

## 4.2 Effect of Optimization

Table 4 shows the estimated ratios between the four optimization flags within the four combinations of Compile and Run, and energy and time consumption. We see that all these ratios are highly significantly different from 1. The contrasts are chosen to give estimated ratios above 1. Thus, for run energy we have shown the ratio *-O2*/*-O3* instead of the ratio *-O3*/*-O2*, and we see that optimization *-O2* is estimated to use 8.1% more run energy than *-O3*. Overall *-O3* has the highest consumption for Compile and the lowest consumption for Run. This is also evident from Figure 3. Table 4 gives the estimated ratios: for each optimization flags it shows how much more efficient one optimization flag is over another.

## 4.3 Changes for Individual Benchmark Programs

As seen in Figure 2 the individual programs have different developments across GCC versions. In particular for Run Energy and Run Time, where programs like *538.imagick_r* have almost constant consumption from GCC-4 to GCC-13, whereas programs like *525.x264_r* experience huge efficiency gains.

In this section, we examine how the individual programs deviate from the overall changes captured by the ANOVA models. This may be done by inspecting the predicted random effects. Figure 4 shows the exponential function of the difference of the predicted random effects between two consecutive GCC versions within benchmark and optimization. The interpretation of these values is the relative change in consumption in relation to the overall changes in consumption. Note that the y-axes are on a logarithmic scale and different in the 32 panels. For instance, as visualized by the red dot at `gcc-12` in panel in the 5'th row and 3'rd column of Figure 4, we see that the Run Energy for *525.x264_r* in optimization *-O2* decreased more than 30% more than the general change from GCC-11 to GCC-12. This example is particularly pronounced as Run Energy for *525.x264_r* in optimization *-O2* otherwise follows the general pattern in consumption across the GCC versions (i.e. the other ratios are close to 1).

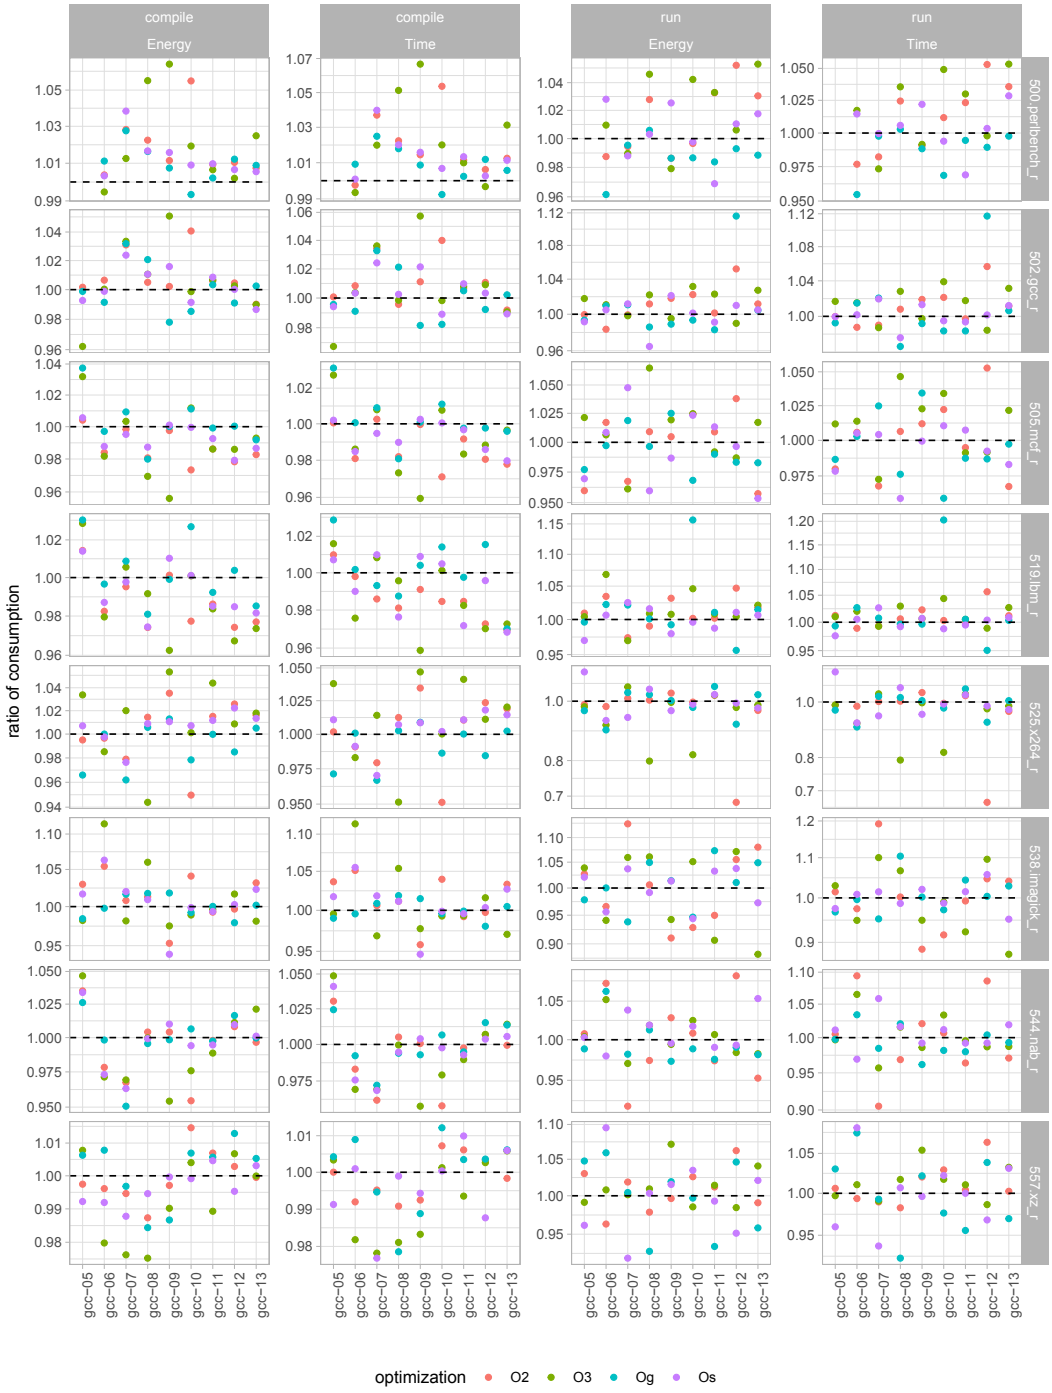

**Figure 4** Predicted ratios of relative changes between GCC versions in comparison to the overall behaviour. Note that the y-axes are on a logarithmic scale and different in the 32 panels.

**Table 3** Changes of estimated marginal means between GCC version within ANOVA models. Only changes significant on the 5% level are shown. Note that P-values and confidence intervals are not adjusted for multiple testing.

| Measuring | Response | Optimization | GCC | Estimated ratio | P-value |
|---|---|---|---|---|---|
| Run | Energy | Os | 4 to 5 | 1.029 (1.001 ; 1.057) | 0.0402 |
| Run | Time | Os | 6 to 7 | 0.974 (0.949 ; 0.999) | 0.0422 |
| Compile | Energy | O2 | 9 to 10 | 1.042 (1.002 ; 1.084) | 0.0383 |
| Compile | Energy | O2 | 11 to 12 | 1.043 (1.003 ; 1.085) | 0.0361 |
| Compile | Energy | Og | 4 to 5 | 0.953 (0.934 ; 0.974) | 0.0001 |
| Compile | Energy | Og | 7 to 8 | 1.024 (1.004 ; 1.045) | 0.0198 |
| Compile | Energy | Os | 11 to 12 | 1.033 (1.006 ; 1.062) | 0.0160 |
| Compile | Time | Og | 4 to 5 | 0.958 (0.940 ; 0.977) | 0.0001 |
| Compile | Time | Og | 7 to 8 | 1.022 (1.003 ; 1.041) | 0.0246 |
| Compile | Time | Os | 11 to 12 | 1.030 (1.003 ; 1.058) | 0.0268 |

**Table 4** Estimated ratios and associated 95% confidence intervals between select optimizations within the ANOVA models. Note that P-values and confidence intervals are not adjusted for multiple testing.

| Measuring | Response | Contrast | Estimated ratio | P-value |
|---|---|---|---|---|
| Run | Energy | O2 / O3 | 1.081 (1.061 ; 1.101) | 0.0001 |
| Run | Energy | Og / O2 | 1.147 (1.127 ; 1.167) | 0.0001 |
| Run | Energy | Og / O3 | 1.240 (1.214 ; 1.266) | 0.0001 |
| Run | Energy | Os / O2 | 1.210 (1.191 ; 1.230) | 0.0001 |
| Run | Time | O2 / O3 | 1.085 (1.065 ; 1.105) | 0.0001 |
| Run | Time | Og / O2 | 1.134 (1.113 ; 1.156) | 0.0001 |
| Run | Time | Og / O3 | 1.230 (1.203 ; 1.257) | 0.0001 |
| Run | Time | Os / O2 | 1.224 (1.203 ; 1.246) | 0.0001 |
| Compile | Energy | O2 / Og | 1.481 (1.468 ; 1.494) | <0.0001 |
| Compile | Energy | O2 / Os | 1.128 (1.123 ; 1.134) | <0.0001 |
| Compile | Energy | O3 / Og | 1.767 (1.748 ; 1.786) | <0.0001 |
| Compile | Energy | O3 / O2 | 1.193 (1.186 ; 1.200) | <0.0001 |
| Compile | Time | O2 / Og | 1.429 (1.417 ; 1.442) | <0.0001 |
| Compile | Time | O2 / Os | 1.113 (1.108 ; 1.119) | <0.0001 |
| Compile | Time | O3 / Og | 1.679 (1.661 ; 1.697) | <0.0001 |
| Compile | Time | O3 / O2 | 1.175 (1.168 ; 1.181) | <0.0001 |

Table 5 shows the most pronounced relative changes. These are ranked according to the absolute value of the relative log ratio, which is an ad hoc measure defined by

$$\frac{\text{log ratio}}{\sqrt{\text{mean}\big[(\text{log ratio within measuring, response, optimization, benchmark})^2\big]}}$$

Thus, the relative log ratio targets changes that stick out the most in Figure 4.

## 4.4 Variance Parameters

Table 6 shows an example of the estimated variance parameters, specifically in the ANOVA model for Run Energy. Based on this we can make estimates for the standard deviation of parameter estimates in future studies. Thus, suppose that we make a new study with $n$ benchmarks and $m$ replications within each optimization. Then the estimated standard deviation of the estimate for the difference $\beta(\text{-}O3, k) - \beta(\text{-}O3, j)$ for GCC versions $k \neq j$, say,

**Table 5** Most pronounces changes between consecutive GCC versions in comparison to the overall consumptions as ranked by the absolute value of the relative log ratio measure. Only changes with $|log(\text{ratio})| > 0.1$ and |relative log ratio| > 2.5 are shown.

| Measuring | Response | Optimization | Benchmark | GCC version | Ratio | Relative log ratio |
|---|---|---|---|---|---|---|
| Run | Energy | O2 | 525.x264_r | 11 to 12 | 0.684 | -18.65 |
| Run | Time | O2 | 525.x264_r | 11 to 12 | 0.668 | -18.01 |
| Run | Energy | Og | 502.gcc_r | 11 to 12 | 1.116 | 10.15 |
| Run | Time | Og | 519.lbm_r | 9 to 10 | 1.203 | 8.90 |
| Run | Energy | Og | 519.lbm_r | 9 to 10 | 1.157 | 7.11 |
| Run | Time | Og | 502.gcc_r | 11 to 12 | 1.117 | 6.38 |
| Compile | Energy | O3 | 538.imagick_r | 5 to 6 | 1.115 | 4.14 |
| Compile | Time | O3 | 538.imagick_r | 5 to 6 | 1.114 | 4.10 |
| Run | Time | O2 | 538.imagick_r | 6 to 7 | 1.192 | 3.02 |
| Run | Time | O3 | 525.x264_r | 7 to 8 | 0.792 | -2.91 |
| Run | Energy | O3 | 525.x264_r | 7 to 8 | 0.799 | -2.76 |
| Run | Energy | Os | 525.x264_r | 4 to 5 | 1.116 | 2.65 |
| Run | Time | Og | 525.x264_r | 5 to 6 | 0.904 | -2.60 |
| Run | Time | Os | 525.x264_r | 4 to 5 | 1.129 | 2.55 |
| Run | Energy | Og | 525.x264_r | 5 to 6 | 0.898 | -2.53 |

**Table 6** Estimated standard deviations and correlations for random terms in ANOVA model for run energy.

| Random effect | Std. Dev. | Correlation | | |
|---|---|---|---|---|
| $A_{O2}$ | 0.0723 | | | |
| $A_{O3}$ | 0.0903 | 0.50 | | |
| $A_{Og}$ | 0.0473 | 0.16 | 0.13 | |
| $A_{Os}$ | 0.0267 | 0.13 | 0.30 | 0.06 |
| Residual $\epsilon_i$ | 0.0112 | | | |

is given by

$$\widehat{\text{sd}}\big(\hat{\beta}(\text{-}O3, k) - \hat{\beta}(\text{-}O3, j)\big) = \sqrt{\frac{2 \cdot \widehat{\text{sd}}(A_{O3})^2}{n} + \frac{2 \cdot \widehat{\text{sd}}(\epsilon_i)^2}{n \cdot m}} \approx \frac{\sqrt{2} \cdot 0.0903}{\sqrt{n}}$$

We see that this estimated standard deviation is mostly dependent on the number of benchmark programs.

## 4.5 Size of Compiled Benchmarks

As we can see in Figure 5, *-Os* consistently produces the smallest – in terms of binary size – resulting program, and *-O3* consistently produces the largest. *-O2* and *-Og* have similar sizes, with *-O2* starting as the smaller of the two, but ending up as the bigger of the two. Moreover, we can see that there is no clear trend towards increasing binary sizes nor decreasing binary sizes with newer GCC versions. *-Og* ends up smaller, *-O2* ends up bigger, *-O3* ends up roughly where it started, and *-Os* ends up smaller, but all of them with bumps.

## 4.6 Summary of Results

There is a statistically significant trend ($P = 0.0001$) of compilation getting more expensive in both time and energy, when compiling with the optimization flags *-O2*, *-O3*, and *-Os*. The trend of compilation becoming more expensive over time is coupled with *-O2* and *-O3*

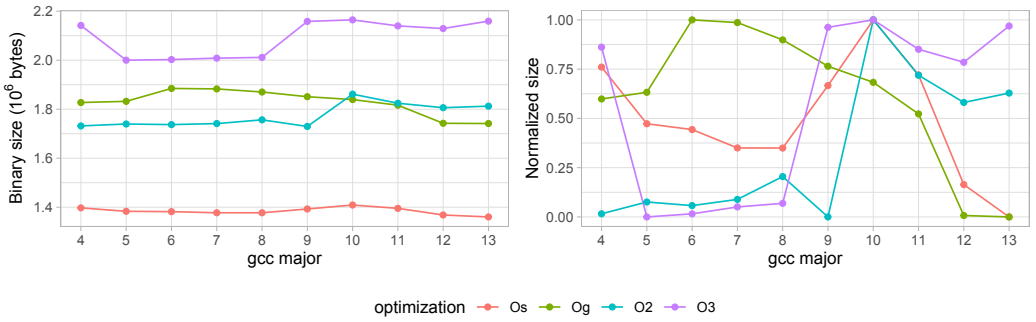

**Figure 5** Sum of the binary sizes produced by compiling the benchmarks. Left panel shows the absolute values. Right panel shows each optimization flag normalized to a $0-1$ range.

producing programs that use less energy and less time, with a statistically significant trend ($P \leq 0.0012$ for *-O2* and $P = 0.0001$ for *-O3*) of running costs becoming cheaper; the effect being more drastic for *-O3*.

We can calculate the predicted relative change between two GCC versions $v_1$ and $v_2$ by taking $e^{s \cdot \log(\frac{v_2}{v_1})} - 1$, inserting the desired $s$ from Table 2. As an example, the relative change of energy costs between version 4 and 13 for *-O3* is $e^{-0.115 \cdot \log(\frac{13}{4})} - 1 \approx -12.68\%$, or in other words a 12.68% decrease in energy consumption.

Using this calculation, throughout all the GCC versions, comparing the version GCC-4 to the version GCC-13, and integrating values from Table 2 we obtain the following results:

| Metric | Flag | Estimate | 95% C.I. |
|---|---|---|---|
| Run Energy | *-O3* | -12.68% | (-17.96% , -7.16%) |
| Run Time | *-O3* | -12.88% | (-18.35% , -7.16%) |
| Compile Energy | *-O3* | 17.39% | (12.64% , 22.19%) |
| Compile Time | *-O3* | 15.19% | (10.80% , 19.90%) |
| Run Energy | *-O2* | -9.00% | (-13.50% , -4.27%) |
| Run Time | *-O2* | -8.68% | (-13.50% , -3.47%) |
| Compile Energy | *-O2* | 18.36% | (14.52% , 22.47%) |
| Compile Time | *-O2* | 16.01% | (12.24% , 19.90%) |

In summary, using the newest version made the benchmarks improve by ≈13% for *-O3* and by ≈9% for *-O2*. This was at the cost of making the compilation around ≈16% more expensive for *-O3* and around ≈17% more expensive for *-O2*.

## 5 Discussion

For the optimization flags *-O2* and *-O3* the energy and time costs are decreasing with newer versions of GCC, and the compilation costs are increasing. To assess whether compiler development "pays for itself", we must compare how much the reduced running costs are in comparison to the increased compilation costs. This is rather straightforward: for every benchmark and optimization flag, compiling is cheaper (in both time and energy) than a single run of the corresponding benchmark. Even the most expensive compilation (*502.gcc_r* with *-O3*, around 3.5kJ and 45s) is comparable to the cheapest run (*525.x264_r* with *-O3*, around 2.2kJ and 27s). Consequently, the extra compilation cost of newer GCC versions is "paid off" by the second execution. This supports the advice of using the newest GCC version, as long as *-O2* or *-O3* is employed.

By contrast, *-Os* and *-Og* do not exhibit clear trends towards lower execution costs, which is unsurprising given that they prioritize, respectively, binary size and debugging experience. As shown in Figure 5, newer GCC versions do not necessarily produce smaller binaries overall, but *-Os* consistently yields the smallest binaries among the optimization levels.

## 5.1 Benchmarks Differ – No Silver Bullet for Optimization

Certain benchmarks seem to benefit more from newer versions of GCC than others. In particular *525.x264_r* starts out being one of the benchmarks with the highest running cost, to one of the ones with the lowest running costs when optimized with *-O2* or *-O3*. A lot of these improvements happen in sudden jumps towards lower running costs between consecutive versions, implying a certain version of GCC made an optimization that improved a particular benchmark.

From Table 5 we see that *525.x264_r* has two large additional drops in running cost compared to other benchmarks, between GCC-11 and GCC-12 for *-O2*, and between GCC-7 and GCC-8 for *-O3*. Both of these releases coincide with changes to GCC's vectorization, including reworked cost metrics in GCC-8, and auto-vectorization being enabled for *-O2* in GCC-12. [3] A further jump for *525.x264_r* between GCC-9 and GCC-10 for *-O3* is visible in Figure 2. We suspect this is related to several reported missing optimizations (bug IDs: 64745, 89653, 88915, 57169, and 89386) that were flagged as fixed in GCC-10 relating to vectorization (one of them even explicitly mentions *525.x264_r*).

We therefore hypothesise that the sudden improvements observed for *525.x264_r* are largely due to enhanced vectorization in newer GCC versions. This could be tested by repeating our experiments with vectorization disabled.

There are other benchmarks behaving differently than the mean, but all of them less significantly than *525.x264_r*. In principle all programs can benefit from improved vectorization; *525.x264_r* stands out as it is particularly amiable to it. Since SPEC is designed to include a series of representative benchmarks, we do not expect the improvements we see to be restricted to any single workload, such as *525.x264_r*.

There are some consecutive versions where compilation became statistically significantly more expensive for the compilation of all benchmarks. Between GCC-9 and GCC-10, and between GCC-11 and GCC-12, the *-O2* compilations became $\approx 4\%$ more expensive, energy-wise. These versions coincide with function inlining and vectorization becoming enabled for *-O2*, so we hypothesize the increased costs is at least partially due to this.

## 5.2 Result Comparison with Prior Findings

Previous studies have investigated how compiler or interpreter versions affect energy consumption across different programming languages [2, 11, 16, 17]. Among these, the works of Jiménez et al. [11] and Azevedo [2] are most directly comparable to our work because they include C and study the effect of compiler version on energy consumption. In contrast to our study, neither of them identifies a general downward trend in energy usage for GCC [11] nor Clang [2].

Their experimental designs differ considerably from ours. Both studies use the Computer Language Benchmarks Game (CLBG) and adopt benchmark-specific compiler configurations prescribed by CLBG. While Azevedo does not report the exact flags, the replication package provided by Jiménez et al. shows that, across GCC versions 7–11, all nine C benchmarks are compiled with *-O3*, and eight of the nine use OpenMP.

[3] See `https://gcc.gnu.org/gcc-8/changes.html` and `https://gcc.gnu.org/gcc-12/changes.html`.

These differences in experimental design provide several possible explanations for the different trends observed. One possible explanation for the difference in observed trends concerns the experimental coverage. Jiménez et al. characterize GCC evolution over a narrower range of versions (7–11) and under a single highly optimized configuration, whereas we study GCC 4–13 and systematically evaluate several optimization levels. Our results show that the longitudinal trend depends on the optimization level, suggesting that broader version coverage and multiple optimization configurations may reveal effects that are less apparent over a shorter interval or under a single configuration.

Benchmark selection may also contribute to the difference. Both Azevedo and Jiménez et al. use CLBG, whereas we use SPEC CPU 2017. Our results show substantial variation across SPEC CPU 2017 benchmarks in how they benefit from newer GCC versions, suggesting that benchmark selection may influence whether a general version-dependent trend is observed. We hypothesize that the CLBG benchmarks may already be sufficiently hand-optimized that they leave less opportunity for newer compiler optimizations. The presence of manually written vectorization code, including uses of `immintrin.h`, `emmintrin.h`, and `v2dt`, in Jiménez et al.'s replication package [11] supports this interpretation. This is particularly relevant because our results suggest that improvements in auto-vectorization account for a substantial part of the performance gains observed for SPEC CPU 2017. If the code is already manually vectorized, there is less opportunity for the compiler's auto-vectorization to provide additional performance gains [15]. In contrast to CLBG benchmarks, SPEC CPU 2017 was designed with portability across architectures as an explicit goal, the benchmarks were carefully selected to have the ability to have their platform or architecture-dependent code disabled [3].

A further difference concerns parallelism. Most C benchmarks used by Jiménez et al. [11] employ OpenMP-based parallelism, whereas we deliberately disable OpenMP-level parallelism to reduce variation unrelated to compiler evolution, while retaining instruction-level parallelism (such as vectorization), which *is* affected by compiler evolution. Parallel execution introduces additional sources of variation, including thread scheduling, synchronization overhead, and workload distribution, which may increase benchmark-specific variability and make an underlying compiler-version trend less apparent.

Beyond the overall version trend, prior work also helps interpret some benchmark-specific changes observed in our results. In Hebbar et al. [8], GCC version 5.5.0 was outperformed by Intel's compilers on the SPEC 2017 benchmarks. The authors attribute this difference in part to more effective use of advanced vectorization. In particular, for *525.x264_r* the authors find that Intel outperforms GCC by 155%, and for our specific selection of benchmarks, Intel generally outperforms GCC by more than 40%, except for *500.perlbench_r* and *502.gcc_r* where GCC performs slightly better. Together with our hypothesis for the drastic *525.x264_r* improvement, this suggests that newer GCC versions may be reducing the performance gap previously observed between GCC and Intel's compilers in this area – at least for *525.x264_r*.

## 5.3 Threats to Validity, Limitations, and Future Work

Our results come from a single computer with an `x86-64` Skylake microprocessor, and how other architecture evolves is not clear. Since many of the improvements we see might be linked to improved vectorization, other architectures, particularly ones without vectorization support, might benefit less from newer versions. We would expect either no link between newer versions or a weaker one. Other machines with same architecture and setup may also slightly different results, but the trend is expected to be unchanged.

Given that we see so much variation in how the different benchmarks behave, we cannot necessarily rule out the possibility that different benchmarks would give different results. However, as SPEC is a trusted industry-standard benchmark measuring the performance of real-world programs and the chosen subset covers a wide range of different program profiles, we would hypothesise that our results hold for similar real-world programs written in C.

GCC is a collection of multiple compilers and SPEC is a suite of benchmarks written in several programming languages. A natural future work would be to compare our results to the other two languages SPEC and GCC have in common, namely Fortran and C++. However, since they share a back-end the difference would probably not be drastic.

The selection of the different versions of GCC was done with the expectation that performance between minor versions within the same major version of GCC would have few changes. Whether this is true or not is left for future work.

We choose to disable OpenMP in our benchmarks, effectively disabling multi-threading. Parallelism of all sorts is especially interesting for energy consumption. However, we believe that it was correct to disable it, as it better isolates the impact of the change in version on performance. It does leave the question of whether we get the same results, for time but especially energy, if OpenMP was enabled.

## 6 Conclusion

Does GCC C compiler development pay for itself? That is, do newer versions of GCC reduce the time and energy costs of running compiled programs, at a low-enough increased costs of compiling the programs? Using SPEC CPU 2017 on a `x86-64` Skylake machine, with 10 different GCC versions spanning from *gcc-04.09.03* to *gcc-13.03.00*, we find that it does for the optimisations levels *-O2* and *-O3*.

There is a statistically significant trend for both energy and time costs decreasing when compiled with *-O2* and *-O3*, at the costs of a statistically significant increasing trend of compilation costs (energy and time) for the same optimizations flags, all with $P \leq 0.0012$. Throughout all the versions tested, benchmarks improve by ≈13% when compiled with *-O3*, and ≈9% when compiled with *-O2*. This is at the additional cost of compilation costs increasing by ≈16% and ≈17% for *-O3* and *-O2* respectively.

In practice, a program is compiled only a few times, but runs many times. We note that the cost of compiling a benchmark was always lower than the cost of running the corresponding benchmark. Therefore, the additional costs of using a newer version of GCC are paid off by the second running of the benchmark.

No statistically significant trend of improvement was found for the benchmarks compiled with *-Os* and *-Og*. This is not surprising, as neither of them has a goal of optimization. Rather, they optimize for the debugging experience and for space usage.

Certain benchmarks benefit more than others from newer versions of GCC, notably *525.x264_r*, which starts as one of the most expensive to run and becomes one of the cheapest when optimized with *-O2* or *-O3*. We hypothesize this substantial improvement is in large part due to improvements in auto-vectorization; the GCC versions where we observe the largest performance gains coincide with changes in GCC's auto-vectorization feature. This suggests adapting performance-critical code to better match patterns targeted by auto-vectorization, or explicitly writing vectorization code oneself, can yield large performance benefits. More broadly, it highlights that how much a compiler can optimize any given program is dependent on the type of program being compiled.

Although SPEC benchmarks are indeed just benchmarks, they consist of many real-world programs and are designed to measure the performance of a compiler (together with the processor and the memory subsystem). Therefore, we believe that the results carry over to other C programs. Continuing, we cannot say for sure whether versions after GCC-13 continue reducing costs, but given newer CPUs with newer instructions for GCC to support, we suspect it would.

## Data Availability Statement

All the data together with analysis scripts and scripts to replicate the experiment is available on: `https://doi.org/10.6084/m9.figshare.32316525`. The link has documentation for the data-set, and there is a `README.md` file for how to read, and do the experiment together with the analysis.

## Abstract

**Background.** Infrastructure-as-Code (IaC) has become a standard in software deployment, with Dockerfiles among its most prevalent formats. However, Dockerfiles often exhibit *Dockerfile smells*, violations of best practices that can harm reproducibility, build time, image size, and security. Although prior work has proposed detectors, fixes, and refactoring catalogs, existing knowledge remains mostly descriptive or illustrative, lacking explicit transformation rules with source and target structures, and applicability conditions intended to support behavior-preserving application.

**Aims.** This work aims to provide a catalog of formalized transformation rules for removing Dockerfile smells and to evaluate how practitioners perceive the resulting Dockerfile.

**Method.** We formalized rules for a set of ten Dockerfile transformations and conducted a mixed-method empirical study with 59 participants: 39 survey respondents and 20 interviewees from industry and academia with varied levels of Docker experience.

**Results.** Participants generally preferred the resulting Dockerfiles, which achieved an overall mean acceptance rate of 76%. Nine rules were accepted by a majority of participants, with the highest acceptance rate reaching 95%. Participants favored transformations that improved stability, security, and build time, but were less favorable toward transformations that reduced readability or made debugging harder.

**Conclusions.** Our findings suggest that formalized Dockerfile transformations are a promising basis for refactoring support, but their adoption depends on balancing technical quality improvements with developers' practical expectations.

**2012 ACM Subject Classification** Software and its engineering → Empirical software validation; Software and its engineering → Maintaining software; Software and its engineering → Software defect analysis; Software and its engineering → Software evolution

## 1 Introduction

In today's software development, applications are expected to be portable, scalable, and reproducible across execution environments [4]. At the same time, development processes increasingly rely on short and continuous release cycles [13, 7]. Containerization supports these requirements by packaging an application with its dependencies and execution environment into an isolated, reproducible unit. Among containerization technologies, Docker has become one of the most widely adopted solutions [19], relying on Dockerfiles to specify how container images are built [5].

Although Dockerfiles make execution environments explicit, writing them correctly is not trivial. Developers must define base images, dependencies, environment variables, files, and commands while following best practices related to maintainability, reproducibility, performance, and security [9, 26, 35, 36]. When these practices are violated, Dockerfiles may contain recurring quality problems, known as *Dockerfile smells* [34]. Such smells can negatively affect image size, build time, reproducibility, and security. For example, if a Dockerfile does not specify a non-root user, the application runs as root inside the container, increasing the impact of any exploit, especially when access is granted to mounted volumes, sensitive files, or permissive capabilities. Likewise, using unpinned or outdated base images can introduce vulnerable dependencies or cause builds to resolve to inconsistent versions.

Prior research has substantially advanced our understanding of Dockerfile quality. Existing studies have investigated the prevalence of Dockerfile smells, their evolution, and the extent to which developers fix them [5, 34, 26]. Other studies have proposed taxonomies of Docker-specific technical debt categories and refactorings [17, 16]. However, these refactorings are still mostly proposed at a descriptive or illustrative level. As a result, it remains unclear how such refactorings can be systematically applied as concrete transformation rules, and whether developers perceive the resulting Dockerfiles as useful, readable, and acceptable in practice.

In this paper, we address this gap by presenting a catalog of formalized transformation rules that remove ten common Dockerfile smells. The transformations were derived from prior studies on Dockerfile smells and Docker-specific refactorings [17, 16, 25]. We selected transformations that address different quality concerns, including readability, maintainability, build efficiency, image size, reproducibility, and security. Each transformation is specified using source and target patterns, preconditions, and meta-variables, making the rules more actionable than high-level refactoring descriptions.

To evaluate practitioners' perceptions of the resulting Dockerfiles, we conducted a mixed-method empirical study involving 59 participants: 39 survey respondents and 20 interviewees. Our results show that participants preferred the transformed Dockerfiles in 76% of the cases, with acceptance ranging from 95% for the most favored transformation to 25% for the only one rejected by most participants, *Extract RUN Instructions*. Participants strongly favored transformations that enhanced stability, security, and built caching efficiency, but we also observed a tension between technical optimization and human readability: developers sometimes rejected transformations when they increased cognitive load, reduced readability, or made debugging more difficult.

In summary, this paper makes the following contributions: (i) A catalog of formalized transformation rules for ten Dockerfile smells; (ii) An empirical evaluation of practitioners' perceptions of these transformations resulting Dockerfiles; and (iii) A qualitative analysis of the reasons why practitioners accept or reject Dockerfile transformations.

## 2 Related Work

The study of Infrastructure-as-Code (IaC) quality has gained significant attention in recent years. Sharma et al. [29] analyzed thousands of Puppet repositories to detect configuration smells, establishing a basis for understanding quality issues in configuration code. In the specific context of containerization, Cito et al. [5] conducted a large-scale study of the Docker ecosystem on GitHub, finding missing version pinning and heavyweight base images among the most common issues. Subsequent work further characterized the prevalence of Dockerfile smells: Wu et al. [34] defined them as instructions violating Dockerfile-specific (DL) or shell-script (SC) best practices, showing in a large-scale GitHub study that such smells are highly prevalent.

Beyond smell detection, researchers have investigated whether Dockerfile smells are relevant to developers and whether they are willing to accept fixes. Rosa et al. [25] evaluated Hadolint smells from the perspective of expert Dockerfile developers, showing that experts prioritize only a subset of the evaluated smells, and proposed an expanded, community-informed catalog. In a complementary study, Rosa et al. [26] analyzed smell-removing commits and submitted pull requests with smell fixes to developers, finding that developers pay more attention to performance-related fixes (e.g., image size, build time) and are generally willing to accept fixes for common smells.

Researchers have also investigated Docker-specific refactoring practices. Ksontini et al. [17] proposed a taxonomy of generic and Docker-specific refactorings based on an analysis of Docker projects, which was later expanded to include additional refactoring mechanisms and technical debt categories [16]. Tool support has also begun to emerge: Ksontini et al. [15] introduced DRMiner, a tool that identifies and analyzes Dockerfile refactoring candidates, and, more recently [18], explored automating Dockerfile refactoring using Large Language Models via In-Context Learning, reporting improvements in image size and build duration.

Although prior studies provide substantial evidence on Dockerfile smells and refactoring practices, the knowledge remains largely descriptive, typically expressed through names, definitions, or examples rather than explicit operational rules. This limitation is particularly relevant as recent studies have shown that quality issues in specialized software artifacts evolve throughout the software lifecycle and require more systematic support for quality management and remediation [24].

Our work addresses this gap by formalizing selected fixes as transformation rules and empirically evaluating their perceived quality. Besides making the transformations explicit and actionable, these rules may provide structured demonstrations, constraints, or explanations for LLM-based refactoring approaches such as that proposed by Ksontini et al. [18], and may help assess whether a generated change conforms to an intended transformation. We additionally evaluate practitioners' perceptions of concrete instances derived from these rules. This empirical step is crucial, as even transformations with expected technical benefits may not be adopted if developers perceive them as less readable, harder to debug, or misaligned with their practices.

## 3 Catalog of Formalized Transformations

This section presents our catalog of formalized transformations for Dockerfile smells. Each transformation is defined as an explicit rule that maps an original Dockerfile structure to a revised one, along with the metavariables used and the preconditions under which the transformation is intended to preserve behavior.

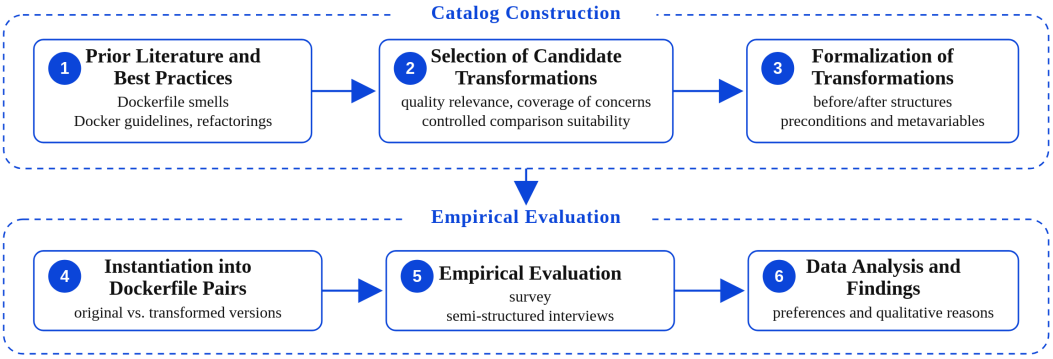

**Figure 1** Overview of the research design, from the construction of the transformation catalog to its empirical evaluation.

Figure 1 summarizes our workflow. The first phase concerns the construction of the catalog: starting from Dockerfile smells, refactorings, and best practices reported in prior work, we selected transformations based on relevance, coverage of quality concerns, and suitability for controlled comparison. Each transformation was then formalized as an abstract rule comprising a source structure, a target structure, preconditions, and metavariables, as described in Section 3.2. The second phase concerns the empirical evaluation: we instantiated each rule into concrete before-and-after Dockerfile snippets and assessed them with practitioners through a survey and semi-structured interviews.

## 3.1 Derivation and Selection of Transformations

We derived the transformation set from prior studies on Dockerfile smells, smell fixes, and Docker-specific refactorings [16, 17, 25, 26, 34]. We first reviewed the problems and refactoring operations reported in these studies and extracted candidates directly applicable to Dockerfiles. When different studies described equivalent or closely related problems, we consolidated them into a single transformation; for example, recommendations concerning missing image tags and the use of the `latest` tag were merged into the *Explicit Version Pinning* transformation. Conversely, when a broader refactoring could address distinct problems through different concrete changes, we kept separate variants: the *Update Base Image* refactoring, for instance, was instantiated as separate transformations targeting heavyweight base images and manually installed dependencies.

We then selected ten transformations according to the following criteria. First, each transformation had to address a Dockerfile smell or refactoring explicitly documented in prior literature. Second, we prioritized transformations targeting smells reported as prevalent in prior empirical studies. For example, *Replace ADD with COPY* (T9) targets the incorrect use of `ADD` for operations that only require local file copying, a smell accounting for 9.04% of the violations reported by Lin et al. [19]; similarly, *Explicit Version Pinning* (T7) addresses untagged base images and the use of the `latest` tag, accounting for 3.30% and 1.90% of the violations reported by the same study. Third, we sought to cover different Dockerfile quality concerns, including readability, maintainability, build efficiency, image size, reproducibility, and security. Fourth, each candidate had to be expressible as a transformation rule with identifiable source and target structures, metavariables, and applicability conditions. Finally, the transformation had to admit a compact before-and-after representation suitable for the controlled pairwise comparisons used in our survey and interviews.

We excluded candidates that were specific to Docker Compose or other orchestration artifacts, required substantial knowledge of the surrounding project, could not be represented through sufficiently explicit applicability conditions, or would require examples too extensive for the empirical instruments. The final set was limited to ten transformations to balance coverage of different quality concerns against the time and cognitive effort required from survey and interview participants.

The resulting catalog is literature-derived and prevalence-informed, but neither exhaustive nor intended as a ranking of the most frequent or severe problems in the Docker ecosystem. Prevalence was one of several selection criteria rather than a uniform requirement, since the source studies differ in datasets, smell definitions, detection tools, and units of analysis. Our goal was a diverse and empirically manageable set of transformations for formalization and controlled evaluation. The findings should therefore be read as characterizing practitioners' perceptions of the ten transformations included in this study, not as evidence that these represent all Dockerfile smells or the ten most important Dockerfile quality problems.

## 3.2 Formalization Procedure

Once the transformations were selected, we formalized them using the template-based representation proposed by Soares et al. [31]. In their approach, refactorings are represented by a left-hand side (LHS), describing the original structure, and a right-hand side (RHS), describing the refactored structure, complemented when necessary by applicability conditions and expected quality improvements.

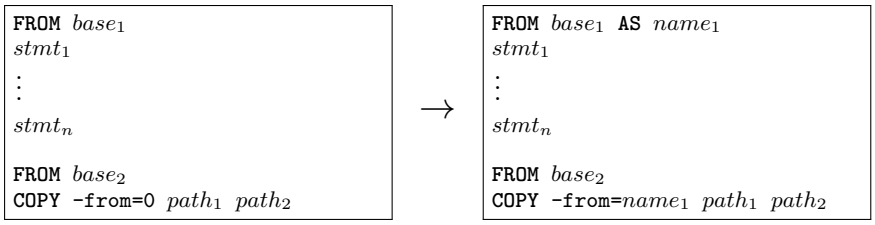
We adapted this representation to the Dockerfile domain in three ways. First, the structures represented by the rules consist of Dockerfile instructions, build stages, and embedded shell commands rather than traditional source-code or testing-framework constructs. Second, we introduced Docker-specific metavariables for elements such as base images, image tags, stage aliases, commands, paths, package lists, and users. Third, we explicitly represented applicability assumptions through a *Provided* clause, since the applicability of a Dockerfile transformation may depend on both build-time and runtime properties.

For each selected transformation, we followed the same procedure: (i) identify the corresponding smell, fix, or refactoring in the source literature; (ii) determine the minimal Dockerfile structure needed to represent the targeted practice; (iii) express the original and transformed structures as the LHS and RHS, respectively; (iv) introduce metavariables for project-specific elements; and (v) document the applicability assumptions associated with the transformation.

Accordingly, each rule contains four elements: an LHS representing the Dockerfile structure affected by the targeted smell or suboptimal practice; an RHS representing the transformed structure; metavariables abstracting over project-specific elements; and a *Provided* clause specifying the conditions under which the transformation is intended to preserve the relevant build and runtime behavior.

## 3.3 Catalog

Table 1 summarizes the ten formalized transformations in this study, including the targeted smell and the technical debt category defined by Ksontini et al. [16]. Each transformation is presented using a compact rule format. We first briefly describe the quality problem addressed by the transformation and then present its formalization as a before-and-after pattern [31, 30, 1, 21]. The left-hand side represents the original Dockerfile structure affected by the smell, while the right-hand side represents the transformed structure. Preconditions define

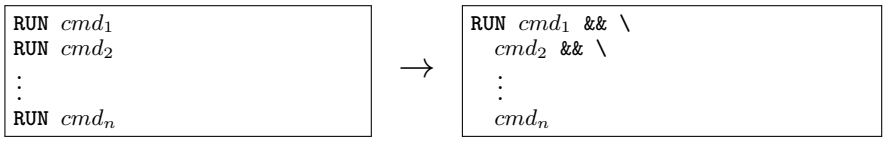


the assumptions required to preserve the intended behavior [22, 6, 23], and metavariables abstract over concrete Dockerfile elements such as image names, commands, paths, stages, and package lists.

**Table 1** Overview of the formalized Dockerfile transformations.

| ID | Transformation | Targeted smell | Tech. Debt Category |
|---|---|---|---|
| T1 | Multi-stage Build Naming | Index-based stage reference | Understandability; maintainability |
| T2 | Layer Optimization | Multiple consecutive `RUN` layers | Image size; build efficiency |
| T3 | Update Base Image (Avoid Heavy) | Heavy general-purpose base image | Image size; security |
| T4 | Update Base Image (Avoid Manual Install) | Manual installation of dependencies already available in existing images | Build time; maintainability |
| T5 | Avoid Root | Container executed as root | Security |
| T6 | Sort Instructions | Cache-invalidating instruction order | Build time |
| T7 | Explicit Version Pinning | Missing or `latest` base image tag | Reproducibility; stability |
| T8 | Extract Stage | Single-stage build containing build-time dependencies | Image size; modularity; security |
| T9 | Replace `ADD` with `COPY` | Use of `ADD` when only local copying is needed | Readability; predictability |
| T10 | Extract `RUN` Instructions | Complex inline shell command sequence | Modularity; maintainability |

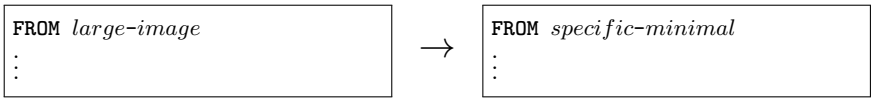
### 3.3.1 T1. Multi-stage Build Naming



This transformation replaces index-based references to build stages with semantic aliases, reducing coupling between `COPY` instructions and stage order (based on the *Add or rename Image alias* refactoring [17]).

**Where/Provided.** $name_1$ is the semantic stage alias replacing index `0`, which refers to the stage beginning with `FROM` $base_1$; $name_1$ must not already be used used elsewhere as a stage name, and all references to this stage are updated consistently.

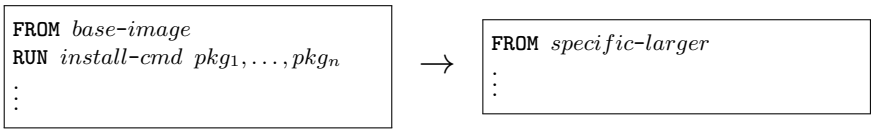
### 3.3.2 T2. Layer Optimization



This transformation merges consecutive `RUN` instructions into a single shell execution context, reducing unnecessary intermediate layers and allowing cleanup commands to take effect within the same layer (based on the *Inline Run instructions* refactoring [17]).

**Where/Provided.** $cmd_1, \ldots, cmd_n$ ($n \geq 2$) preserve their intended behavior when executed sequentially in the same shell context; intermediate layers are not intentionally used for caching, debugging, or isolating failure points.

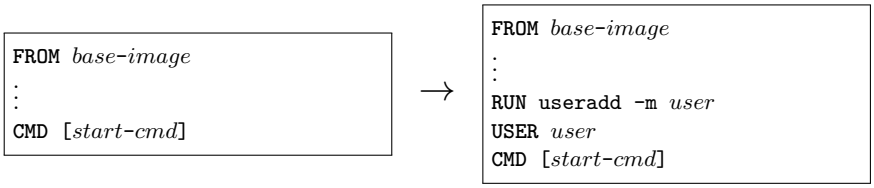
### 3.3.3 T3. Update Base Image (Avoid Heavy)



This transformation replaces a large, general-purpose base image with a lighter, purpose-built alternative, reducing unnecessary binaries, libraries, and tools in the final image (based on the *Update Base Image* refactoring [17]).

**Where/Provided.** $specific\text{-}minimal$ (e.g., an Alpine-based or distroless variant) is a image that provides the runtime environment and dependencies required by the application, without altering the expected execution behavior of the resulting image.

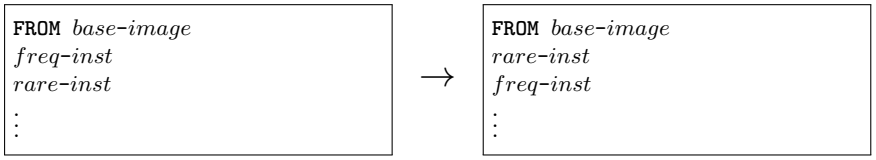
### 3.3.4 T4. Update Base Image (Avoid Manual Install)



This transformation replaces a generic base image plus manual dependency installation with a specialized base image that already includes the required dependencies, reducing redundant build steps and improving build reliability (based on the *Update Base Image* refactoring [17]).

**Where/Provided.** $specific\text{-}larger$ is a image that includes all packages $pkg_1, \ldots, pkg_n$ installed by $install\text{-}cmd$ in $base\text{-}image$, with compatible versions and configurations; removing $install\text{-}cmd$ does not remove dependencies required by later instructions, such as generated configuration files, environment changes, or users.

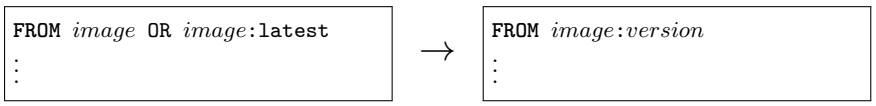
### 3.3.5 T5. Avoid Root



This transformation creates a dedicated non-root user and switches the container execution context before the runtime command, reducing the privileges available to the application (based on the *Avoid root* practice discussed by Rosa et al. [25]).

**Where/Provided.** $user$ does not already exist in $base\text{-}image$; $start\text{-}cmd$ does not require root privileges; and all files, directories, and ports required at runtime are accessible to $user$.

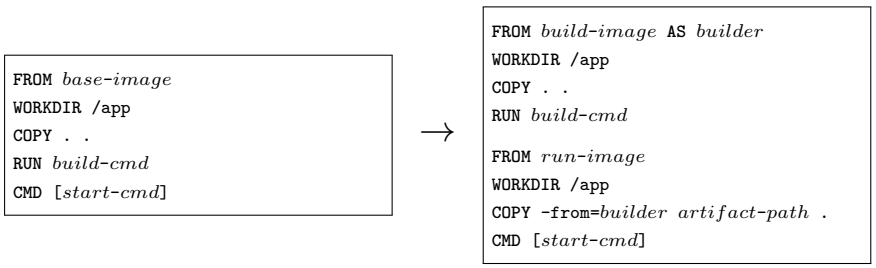
### 3.3.6 T6. Sort Instructions



This transformation reorders Dockerfile instructions from less frequently changing to more frequently changing ones, improving layer cache reuse and reducing unnecessary rebuilds of stable layers (based on the *Sort Instructions* refactoring [17]).

**Where/Provided.** *rare-inst* and *freq-inst* denote instructions whose inputs change rarely and frequently, respectively; *rare-inst* does not depend on artifacts produced by *freq-inst*, so their relative order does not affect the resulting image.

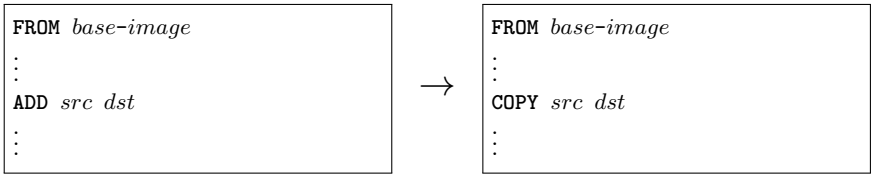
### 3.3.7 T7. Explicit Version Pinning



This transformation replaces an implicit or explicit use of `latest` with a specific base image version or digest, reducing build non-determinism and improving reproducibility (based on the *Update Base Image TAG* refactoring [17] and the *Explicit Version Pinning* practice discussed by Rosa et al. [25]).

**Where/Provided.** *version* identifies a specific tag or digest of *image*, is available in the target registry, and provides an environment compatible with the one expected by the application.

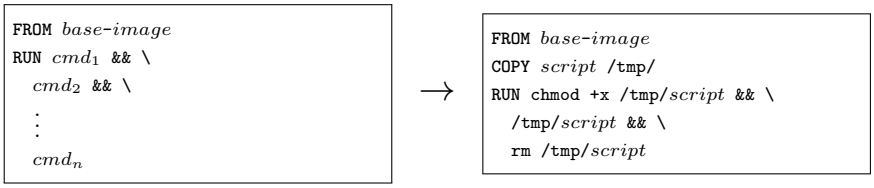
### 3.3.8 T8. Extract Stage



This transformation splits a single-stage Dockerfile into a builder stage and a runtime stage, keeping build-time dependencies, source code, and compilation tools out of the final image (based on the *Extract Stage* refactoring [17]).

**Where/Provided.** *build-image* provides the tools required by *build-cmd*, which produces the application artifacts at *artifact-path*; *run-image* provides the runtime dependencies required by *start-cmd*; the final image preserves the runtime-relevant artifacts and configuration needed to maintain the original behavior.

### 3.3.9 T9. Replace `ADD` with `COPY`



This transformation replaces `ADD` with the more explicit `COPY` instruction when only local file or directory copying is required, reducing ambiguity and avoiding unintended side effects such as automatic archive extraction (based on the *Replace ADD Instruction with COPY Instruction* refactoring [17]).

**Where/Provided.** *src* is a local file or directory in the build context, not a remote URL, and not an archive whose automatic extraction is required; *dst* denotes the destination path inside the image.

### 3.3.10 T10. Extract `RUN` Instructions

This transformation moves a long sequence of shell commands from an inline `RUN` instruction to an external script, aiming at improving modularity and maintainability of the build logic (based on the *Extract Run Instructions* refactoring [17]).

**Where/Provided.** $cmd_1, \ldots, cmd_n$ ($n \geq 2$) preserve their intended behavior when executed from the external script *script*, whose shell environment is compatible with the original inline `RUN` instruction.

## 4 Empirical Study

After defining the catalog of formalized Dockerfile transformations, we conducted an empirical study to evaluate how practitioners perceive the resulting Dockerfiles. The *goal* of the study was to assess practitioners' preferences between original and transformed Dockerfile and identify the reasons underlying those preferences. The *purpose* is to understand how such transformations improve Dockerfile quality and to identify potential barriers to their adoption in practice. The *perspective* is that of researchers and practitioners interested in Dockerfile quality and structured refactoring support. We defined the following two Research Questions (**RQs**) to guide our analysis:

**RQ$_1$** To what extent do practitioners prefer the transformed Dockerfile over the original?
**RQ$_2$** Why do practitioners prefer or reject the transformed Dockerfiles?

**RQ$_1$** quantifies the degree to which practitioners prefer the transformed Dockerfile over the original, using the ten concrete before-and-after instances employed as study stimuli. Since participants were not informed which version corresponded to the transformed one, this design allows us to objectively assess whether the resulting code is naturally perceived as superior to the original implementation. Because each formal rule was represented by a single concrete instance, the results characterize these evaluated instances rather than all possible applications of the corresponding transformation.

**RQ₂** builds on the preferences observed in **RQ₁** to qualify the engineering criteria and trade-offs practitioners consider when choosing between two Dockerfile implementations, such as readability, build efficiency, maintainability, reproducibility, and security.

To this end, we conducted a mixed-method study combining a survey and semi-structured interviews. We followed empirical software engineering reporting guidelines [12] and the *ACM/SIGSOFT Empirical Standards*[1].

## 4.1 Research Method

We designed the study as a mixed-method evaluation of the catalog presented in Section 3. For each transformation, we instantiated the formal rule into a pair of Dockerfile snippets: one representing the original smelly implementation and another representing the transformed version. The order of the alternatives was randomized, and participants were not informed which Dockerfile corresponded to the original or transformed version, to avoid bias. Figure 2 illustrates how the comparison was presented.

**A**

```
FROM ubuntu:24.04
RUN apt-get update
RUN apt-get install -y python3
RUN apt-get install -y nodejs
RUN apt-get clean
```

**B**

```
FROM ubuntu:24.04
RUN apt-get update && \
   apt-get install -y python3 nodejs && \
   apt-get clean
```

**Figure 2** Example of how Dockerfile versions with and without a smell were presented to participants.

As a mixed-method study, we first conducted a survey to gain a broader quantitative view of practitioners' preferences across the ten transformations. Then, we conducted semi-structured interviews to provide qualitative explanations of the survey results. This design allowed us to investigate both *whether* practitioners preferred the transformed Dockerfiles and *why* they accepted or rejected each transformation.

### 4.1.1 Survey

As the first empirical method, we conducted a survey with 39 participants, including both practitioners and academics with prior experience writing Dockerfiles.

The survey was designed to collect participants' preferences regarding the Dockerfile versions and optional qualitative comments explaining their choices. The overall study design followed the methodological guidelines proposed by Kitchenham and Pfleeger [14].

The survey target audience consisted of individuals with prior experience creating or maintaining Dockerfiles, whether in professional or academic contexts. We intentionally included participants with diverse levels of experience and expertise to capture perceptions from a heterogeneous Docker user population.

#### Survey Design

The questionnaire consisted of 24 questions organized into two main categories, as shown in Table 2. The first category collected demographic information about the respondents (SQ1–SQ4). The second category captured participants' perceptions of Dockerfile alternatives

[1] Available at `https://github.com/acmsigsoft/EmpiricalStandards`.

through repeated pairwise comparisons, in which participants answered a preference question (SQ5) and could optionally provide an open-ended justification (SQ6). The questionnaire concluded with an acknowledgment section thanking participants for their contribution.

**Table 2** Survey Questionnaire.

| Category | ID | Question | Answer Format |
|---|---|---|---|
| Demographics | SQ1 | How many years of experience do you have with Docker? | Up to 1 – 5 or more |
| | SQ2 | How do you rate your proficiency with Docker? | (Novice) 1 – 5 (Expert) |
| | SQ3 | What is your primary field of experience? | Academic, Professional, Other |
| | SQ4 | What is your level of formal education? | High School – PhD |
| Perception | SQ5 | Which Dockerfile do you prefer? | Strongly prefer A; Prefer A; Neutral; Prefer B; Strongly prefer B |
| | SQ6 | Any comments? | Open Text Answer |

### Pilot Test

We piloted the questionnaire with four participants to assess its clarity and estimate completion time. The pilot involved four participants with varying Docker experience (1–5 years); completion times ranged from 22 to 28 minutes, averaging approximately 25 minutes. We then refined the Dockerfiles and instructions to improve clarity.

### Survey Recruitment

We recruited participants through public invitations posted in online communities related to Docker and software development, including the Docker Official Forum, Discord servers, and Reddit, as well as through internal academic channels. The invitation described the study goal, expected duration, and eligibility criterion: prior experience with Dockerfiles. This strategy is consistent with prior studies on developers' perceptions of refactorings [31].

The recruitment followed a convenience and self-selection sampling strategy. We obtained 39 valid responses, which is comparable to related work with Dockerfile practitioners, such as the study by Rosa et al. [25], which had 37 participants.

## 4.1.2 Semi-structured Interview

As the second empirical method, we conducted semi-structured interviews with 20 participants to complement the survey findings with deeper qualitative insights. While the survey provided a broader view of acceptance levels, the interviews were designed to investigate the reasoning behind participants' preferences and to uncover trade-offs or concerns that were not easily captured in closed-ended responses.

### Interview Design

The interviews followed a semi-structured protocol [28, 27, 20] divided into three categories. First, we collected the same demographic information used in the survey (IQ1–IQ4) to ensure consistency across methods. Then, participants were presented with the same Dockerfile

comparison scenarios and asked to indicate their preferred version (IQ5), explain their reasoning (IQ6), and answer follow-up questions when needed (IQ7). Finally, the interview concluded with a closing section inviting additional remarks and thanking participants. The protocol structure is summarized in Table 3.

**Table 3** Interview Protocol.

| Category | ID | Question / Topic | Answer Format |
|---|---|---|---|
| Demographics | IQ1–4 | Same as SQ1–SQ4 in Table 2 | Same as SQ1–SQ4 |
| Perception | IQ5 | Which Dockerfile do you prefer? (Choice A vs. Choice B) | Open |
| | IQ6 | Why do you prefer this version? | Open |
| | IQ7 | [Follow-up] Could you elaborate on these aspects? | Open |

### Pilot Test

Before the data collection, we piloted the interview protocol with two participants to assess the clarity of the questions, the adequacy of the Dockerfile comparison material, the expected duration, and the recording procedure. Based on the pilot, we clarified the interview questions and standardized how sessions were recorded and annotated. No substantial changes were made to the Dockerfile comparison material.

### Interview Recruitment and Procedure

We recruited interview participants through convenience and snowball sampling, which are commonly used in empirical software engineering studies involving practitioners [32]. Invitations were distributed through academic mailing lists and shared with students, researchers, and industry contacts, who were asked to forward them to practitioners with experience creating, maintaining, or reviewing Dockerfiles. To mitigate learning bias, we only invited participants who had not previously answered the survey.

We conducted 20 remote interviews via Google Meet between September and October 2025, a number consistent with qualitative empirical studies in software engineering [2]. Each session lasted approximately 20 minutes and, with participants' consent, was audio- and screen-recorded to support transcription and analysis. The interviews complemented the survey by allowing us to go beyond preference distributions and investigate the reasons behind practitioners' preferences, trade-offs, and rejections of specific Dockerfile transformations. All interview recordings were manually transcribed.

## 4.2 Data Analysis

Once we had completed data collection, we adopted a mixed-methods analysis using quantitative and qualitative techniques. Quantitative analysis was used to characterize participants and summarize stated preferences, while qualitative analysis was used to understand the reasoning behind those preferences.

Quantitative analysis was applied to demographic data and preference choices from both methods. We computed descriptive statistics to characterize participants by Docker experience, self-assessed proficiency, and primary field of work. For the survey (SQ5), responses were aggregated using a binary agree/disagree scheme. For the interviews (IQ5),

we categorized participants' explicit preferences for one of the two alternatives. We adopted this aggregation strategy to combine survey and interview data at the transformation level. The resulting data were subsequently aggregated to identify overall acceptance trends.

For the qualitative analysis, we analyzed the open-ended survey comments (SQ6) and interview responses (IQ6–IQ7) using thematic analysis following Braun and Clarke [3]. The unit of analysis was a participant's justification for one Dockerfile comparison, and a response could receive multiple codes when it addressed multiple engineering concerns.

We then coded participants' justifications from the pairwise comparison tasks, assigning each response to an engineering value or constraint (e.g., "READABILITY," "OPTIMIZATION," "SECURITY," or "KNOWLEDGE GAP"). To identify distinct behavioral patterns, the coded data were divided into two subsets based on participants' decisions: rationales for agreement (i.e., selecting the transformed Dockerfile) and rationales for disagreement (i.e., preferring the original version).

Finally, we quantified the frequency of each theme within these subsets, enabling us to identify primary drivers of adoption and the main barriers, as discussed in Section 5.2.

# 5 Analysis of the Results

We gathered data from a total of **59 participants**: 39 from the survey and 20 from the interviews. Table 4 summarizes the distribution of experience, proficiency, and primary fields of work across both groups. Participants had varying levels of Docker experience: 44% reported five or more years of experience, with 23.7% recognized as Docker experts.

**Table 4** Demographic Distribution of All Participants.

| **Characteristic** | **Total (N = 59)** |
|---|---|
| *Experience and Proficiency* | *Mean ± SD* |
| Years of Experience | 3.37 ± 1.63 |
| Docker Proficiency (1 - 5) | 3.42 ± 1.18 |
| *Primary Field of Work* | *Count (%)* |
| Professional | 51 (86.4%) |
| Academic | 8 (13.6%) |

## 5.1 RQ1: Preference for Transformed Dockerfiles

To answer $\mathbf{RQ_1}$, we analyzed quantitative data to assess the extent to which developers prefer code generated by the formalized transformations to the original implementations.

As shown in Figure 3, the transformed versions were preferred in 76.5% of the cases (excluding neutral responses). Acceptance levels varied significantly by smell type, allowing us to categorize the transformations into three groups.

A first group includes transformations with high acceptance rates (above 80%), namely *T1. Multi-stage Build Naming*, *T2. Layer Optimization*, *T3. Update Base Image (Avoid Heavy)*, *T4. Update Base Image (Avoid Manual Install)*, *T7. Explicit Version Pinning*, and *T9. Replace ADD with COPY*. Acceptance rates in this category ranged from 94.7% to 82.5%. A second group comprises transformations with moderate acceptance rates (between 50% and 80%), including *T5. Avoid Root*, *T6. Sort Instructions*, and *T8. Extract Stage*. These transformations were generally well received but generated more disagreement among

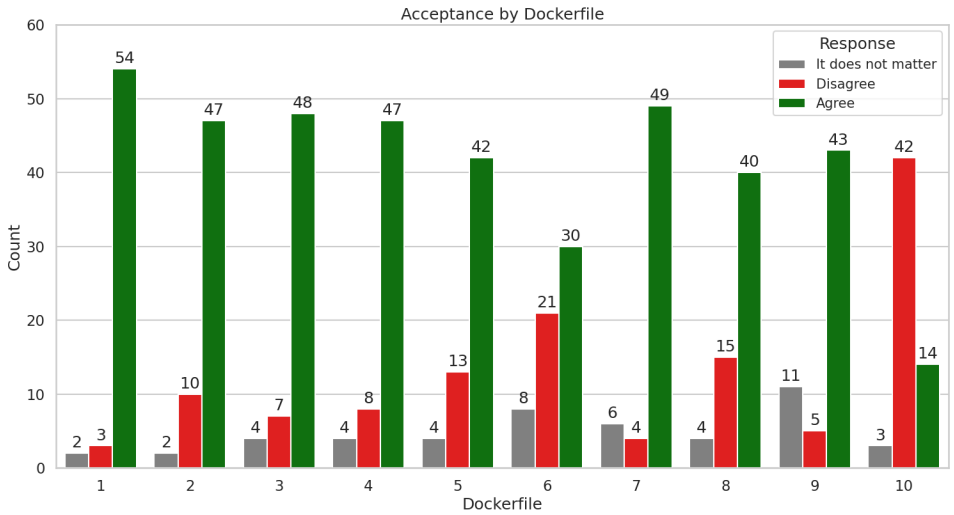


**Figure 3** Acceptance of the evaluated transformations.

practitioners, with support ranging from 76.4% for *T5. Avoid Root* to 58.8% for *T6. Sort Instructions*. Finally, *T10. Extract RUN Instructions* was the only transformation with low acceptance (below 50%), receiving an acceptance rate of 25.0%. This indicates a strong preference for keeping build logic inline rather than extracting it into external scripts. It is important to note that this result should not be generalized to all applications of *Extract RUN Instructions*, as preferences may depend on factors such as the size and complexity of the extracted logic, script reuse, naming, and the surrounding project context.

Across all groups, a clear pattern emerges: transformations that provide immediate and recognizable improvements in stability, security, and build efficiency tend to be widely accepted, whereas those that introduce structural changes or potential readability trade-offs tend to generate more disagreement. These findings suggest that the acceptance of Dockerfile transformations depends not only on their technical benefits but also on their impact on code readability and developers' workflows.

**RQ1.** Practitioners generally preferred the transformed Dockerfiles, with an overall acceptance rate of 76.5%. Transformations improving stability, security, and building efficiency achieved the highest agreement, whereas transformations affecting readability or locality of behavior received more mixed reactions. These findings suggest that acceptance of Dockerfile refactorings depends not only on their technical benefits but also on how well they preserve developers' workflows and code inspectability.

## 5.2 RQ2: Rationale Behind Developer Preferences

The analysis of participants' justifications reveals that preferences are driven by a combination of perceived technical benefits and concerns about code comprehension and workflow. Overall, practitioners prefer transformations when their advantages are concrete and immediately recognizable, while resistance emerged when changes affected readability, debugging, or required deeper knowledge of Docker semantics.

Across reasons for **accepting** transformations, the most frequent motivation was optimization (32%), followed by readability (17%), stability (12%), and security (11%), as shown in Figure 4. Participants consistently highlighted improvements such as reduced image size, fewer layers, faster builds, and increased predictability. For example, in the case of T2 (*Layer*

*Optimization*), respondents explicitly referred to the reduction of layers and resulting smaller images. Similarly, T7 (*Explicit Version Pinning*) was valued for improving reproducibility and preventing unexpected breakages, while T5 (*Avoid Root*) was associated with reducing the attack surface. Overall, participants' justifications aligned with the intended goals of the transformations, suggesting that clearly visible benefits strongly influence acceptance.

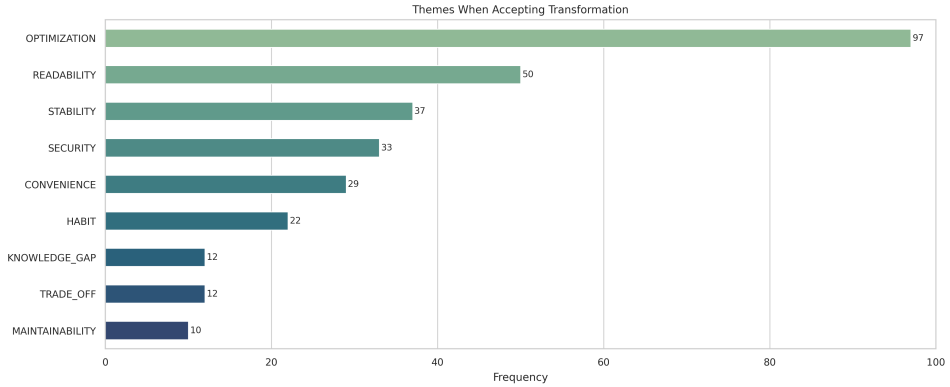

**Figure 4** Distribution of themes cited for **accepting** transformations.

At the same time, participants' preferences revealed important trade-offs. Readability and ease of understanding were the dominant reasons for **rejecting** transformed versions, accounting for 42% of the disagreement-related themes shown in Figure 5. Transformations that relied on less visible Docker-specific mechanisms, introduced additional complexity, or changed the Dockerfile's structure tended to receive more mixed evaluations. The following cases illustrate these three distinct sources of disagreement respectively: knowledge of caching semantics (T6), structural complexity (T8), and locality of build logic (T10).

**T6 (*Sort Instructions*)** received a comparatively mixed response. Qualitative comments show that most participants who preferred the original version did not identify the cache-reuse benefit associated with instruction ordering, whereas those who recognized this mechanism tended to favor the transformed version. This suggests that the perceived value of some transformations depends on whether their effect is visible in the code itself or requires knowledge of Docker-specific mechanisms.

**T8 (*Extract Stage*)** illustrates a different trade-off. Participants favoring the transformed multi-stage instance emphasized reduced image size and improved security, while those favoring the original version highlighted increased complexity and lower readability. This suggests that multi-stage extraction may be perceived differently depending on whether the reduction in runtime dependencies compensates for the additional structural complexity introduced by multiple stages.

**T10 (*Extract RUN Instructions*)** produced the strongest disagreement. Participants' comments indicate that moving shell commands to another file introduced indirection and required developers to navigate outside the Dockerfile to understand the build. The result appears to reflect a trade-off between locality and modularity rather than a general rejection of extracting build logic. Since our study used a single concrete extraction, the perceived benefit likely depends on the length, complexity, reuse, and testability of the extracted commands; T10 is thus better interpreted as a context-dependent transformation than as an unconditional fix.

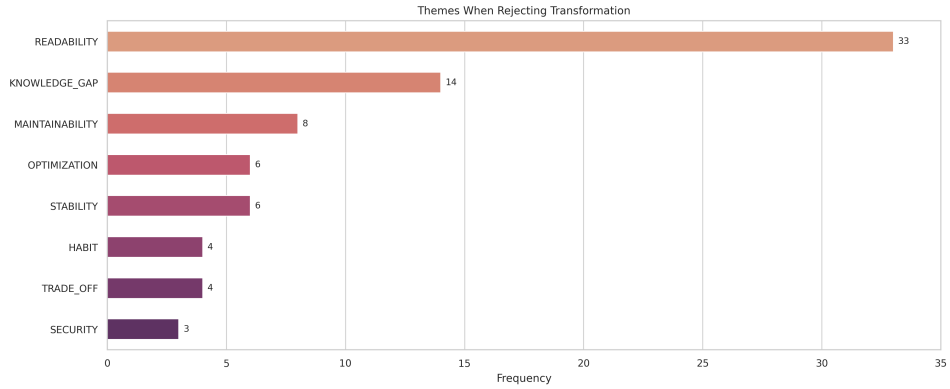

**Figure 5** Distribution of themes cited for **rejecting** transformations.

Knowledge gaps were the second most frequent factor associated with rejecting transformations (18%). Besides T6 (*Sort Instructions*), T9 (*Replace ADD with COPY*) was sometimes perceived as inconsequential due to limited awareness of the semantic differences between the instructions. Such responses may reflect uncertainty about a transformation's benefits rather than disagreement with the transformation itself.

Taken together, these results highlight that preferences depend not only on the technical benefits of a transformation, but also on how it affects the local structure and inspectability of the Dockerfile. This is consistent with prior empirical evidence showing that developers evaluate engineering practices not only in terms of functionality, but also according to their perceived impact on maintainability and development effort [8, 10, 11]. Transformations are more likely to be accepted when they provide clear and immediate benefits without compromising readability or increasing cognitive load. Conversely, when improvements are less visible or introduce structural complexity, practitioners tend to favor solutions that preserve clarity and ease of inspection.

**RQ2.** Developers primarily accepted transformations for optimization, readability, and security benefits, while rejecting those that reduced readability, debuggability, or the locality of build logic. Knowledge gaps about Docker semantics also influenced several decisions. These results indicate that effective IaC refactoring tools should balance optimization with developer-centric concerns and explicitly communicate the rationale and impact of transformations.

## 6 Threats to Validity

We discuss potential threats to validity and the strategies adopted to mitigate them [33].

**Construct Validity.** Preference is used as a proxy for perceived quality, which may not fully capture real-world effectiveness, and the binary agree/disagree aggregation may abstract away nuanced opinions. We mitigated this by combining quantitative preferences with qualitative justifications. A further threat concerns behavior preservation: the transformation rules include preconditions intended to delimit behavior-preserving applications, but our study evaluates practitioners' preferences rather than semantic equivalence, and we did not build, execute, or compare the resulting images. Future work should complement this evaluation with build execution and runtime testing.

**Internal Validity.** Potential biases may arise from presenting Dockerfiles in isolation, without project context, and from participants' personal habits or prior experience. We mitigated these risks by randomizing the order of alternatives, keeping participants blind to which version was transformed, and complementing survey data with interviews. Additionally, each rule was represented by a single before-and-after instance, so preferences may have been influenced by the specific commands, images, or formatting used – T10's low acceptance, for example, may partly reflect the particular extraction shown rather than the general concept. Results should thus be generalized to other applications of the same rules with caution; evaluating multiple instances per transformation is left for future work.

**Conclusion Validity.** The sample size (59 participants) is moderate, and response variability across transformations may affect statistical robustness. We mitigated this by triangulating results across survey and interviews and focusing on consistent patterns; the convergence between quantitative and qualitative findings increases confidence in our conclusions.

**External Validity.** Generalizability is limited by the participant sample and study setting. Although the sample included practitioners with different levels of Docker experience, it may not fully represent the global Docker community, and Dockerfiles were evaluated in isolation rather than within broader project context. We partially mitigated this by leveraging a heterogeneous participant pool and targeting widely used Docker practices.

## 7 Conclusion

We presented a catalog of formalized transformations for removing Dockerfile smells, expressed as explicit rules intended to preserve behavior under stated applicability conditions. We empirically evaluated practitioners' perceptions of concrete instances derived from these transformations through a mixed-method study involving 59 participants, combining quantitative preference data with qualitative insights.

Our findings show that transformations improving determinism, security, and build efficiency are widely accepted, while those affecting readability or locality of behavior are more controversial. This suggests that practitioners' perceptions of Dockerfile refactoring depend not only on expected technical benefits but also on their impact on developers' workflows, readability, and debugging practices.

These results highlight the need for refactoring approaches and tools that balance optimization with developer-centric concerns. Future work includes extending the catalog, evaluating transformations in real-world settings, and improving tool support to make transformations more transparent and actionable.

## Data Availability Statement

We provide a replication package available at Zenodo (`https://doi.org/10.5281/zenodo.20260903`). The package includes the study materials, anonymized data, coding schemas and analysis scripts. Raw recordings, comments, and interview transcripts are not released to protect participant confidentiality.

## Abstract

**Background.** Software bugs remain a critical challenge in development, necessitating effective Automated Program Repair (APR) techniques. While Large Language Model (LLM)-based APR systems have shown promise, prior studies primarily focus on overall repair effectiveness. The effects of bug complexity, fault localization, reasoning settings, and repair cost-effectiveness remain insufficiently explored.

**Aims.** This study presents a comprehensive empirical analysis of LLM-based APR, focusing on how repair performance is shaped by bug complexity, fault localization, reasoning settings, and costs.

**Method.** We construct a curated dataset by collecting algorithmic bugs from AtCoder, a competitive programming platform. We evaluate two APR techniques (ChatRepair and CodeCorrector) using three LLMs (DeepSeek, GPT, and Llama), with multiple model variants and reasoning settings, and examine their performance across diverse levels of bug complexity and localization strategies through a multi-dimensional empirical framework and statistical analysis.

**Results.** Although structurally complex bugs and imprecise fault localization make repair more challenging, LLM-based APR techniques still achieve competitive repair effectiveness. Imprecise fault localization can substantially enlarge the performance gap between APR techniques. Furthermore, higher-cost LLMs and stronger reasoning settings do not consistently yield better cost-efficiency, revealing a nontrivial trade-off between repair effectiveness and computational cost. We further observe that the impact of reasoning strategies varies considerably across different LLM families, affecting both repair effectiveness and cost-efficiency.

**Conclusions.** Over 50% of moderately complex bugs can be repaired by low-cost LLM-based APR techniques. The repair effectiveness gap between APR techniques becomes larger as fault localization becomes less precise. GPT-5 repairs 7 and 39 more complex bugs than DeepSeek-V4-pro and DeepSeek-V3.2, respectively; whereas the total repair cost of DeepSeek-V3.2 across the non-reasoning and reasoning stages is only approximately 4.6% and 7.7% of GPT-5 and DeepSeek-V4-pro, respectively.

## 1 Introduction

In recent years, the rapid advancement of Generative AI, driven by intense competition among technology companies, has significantly accelerated the development of Large Language Models (LLMs) [29]. Current LLMs have shown substantial improvements in their ability to understand, reason, and generate programs [47, 3, 41]. As a result, they have been increasingly applied to a wide range of software engineering tasks, including code generation, code summarization, and bug detection [14, 22, 18].

In the context of Automated Program Repair (APR), LLM-based approaches have demonstrated significant advantages over traditional techniques, achieving strong performance across widely used benchmarks such as Defects4J [19], Bugs.jar [40], and QuixBugs [24]. Notably, many APR techniques achieve near-perfect performance on QuixBugs and IntroClass [12], small-scale algorithmic datasets primarily composed of simple, single-hunk bugs, suggesting that these datasets may be insufficiently challenging for evaluating the effectiveness of modern LLM-based APR approaches. Also, as LLMs exhibit strong performance in code understanding and reasoning, recent studies have increasingly explored end-to-end or self-directed APR approaches that reduce reliance on externally provided fault localization (FL) information [17, 21]. Nevertheless, the impact of the absence of FL on repair effectiveness has not been systematically evaluated in the agent era. To address these unexplored gaps, our study introduces a more challenging algorithmic dataset, featuring bugs with varied complexity levels, and uses the tools of Git [43], srcML [6], and GumTreeDiff [11] to systematically and automatically categorize bugs based on their complexity, enabling a fine-grained empirical analysis of repair performance across different bug complexity levels as well as under accurate, vague, or no fault localization settings.

Additionally, the reliance on commercial LLM APIs produces non-negligible computational costs [44]. APR tasks often require generating numerous candidate patches [23, 51], resulting in substantial output token usage, particularly under reasoning-intensive settings [49, 13]. Consequently, different LLM choices and reasoning settings can lead to significant cost discrepancies. Such costs are often overlooked in prior APR evaluations, despite being critical for practical deployment. In our study, we incorporate cost-efficiency metrics and standardize the unit to \$1 for fair comparison. Specifically, we define Repaired Bugs/\$ and Attempts/\$ as the numbers of successfully repaired bugs and repair attempts divided by the total API cost, respectively, where the cost is calculated from input/output token usage and the corresponding API prices.

We present a comprehensive evaluation of two LLM-based APR techniques across three LLMs, including multiple versions and reasoning settings. We employ multi-dimensional metrics (number of compilable patches, plausible patches, and repaired bugs, Top $-$ $k$, consistency, and cost-efficiency metrics), and statistical tests to address the following research questions (RQs):

**RQ1.** *How does bug complexity affect the repair performance of LLM-based APR?*

**RQ2.** *To what extent does fault localization influence the effectiveness of LLM-based APR?*

**RQ3.** *How do LLM choices and reasoning settings impact the repair performance–cost trade-off in APR?*

The results of this study show that:

- Repair performance varies substantially across bug complexity, with the simplest complexity bugs being consistently the easiest to fix, as expected, but repair performance remains at a relatively considerable level as complexity increases, suggesting that LLM-based APR approaches maintain a stable reasoning ability even on structurally complex bugs.
- FL plays a critical role in improving both repair effectiveness and patch consistency. Although more precise localization generally leads to better repair performance, appropriate APR frameworks can still maintain relatively stable repair effectiveness in settings with vague or missing localization, suggesting potential for practical end-to-end APR scenarios. Also, the impact of FL precision on repair effectiveness decreases as bug complexity increases.
- More costly LLMs and reasoning strategies do not always produce proportional repair improvements; the increased cost should be considered seriously, and reasoning strategies do not consistently yield ideal outcomes, revealing a nontrivial trade-off between performance and efficiency.

Our contributions include:

**(i)** We empirically analyze the impact of bug complexity and fault localization on LLM-based APR performance, and incorporate unit-standardized cost-efficiency metrics to quantify the trade-off between repair effectiveness and computational cost. We also provide an extensible experimentation infrastructure to support future studies, replication efforts, and systematic evaluation of LLM-based APR techniques.

**(ii)** Our study offers novel insights into how repair effectiveness varies with bug complexity and reveals the nontrivial cost implications of different LLM choices and reasoning settings. In particular, by systematically evaluating settings with accurate, vague, and no fault localization, we demonstrate the feasibility and potential of end-to-end LLM-based APR.

**(iii)** Additionally, our results across multiple LLMs and reasoning strategies provide practical guidance for selecting appropriate LLMs under the trade-off between the repair performance and economic cost, highlighting the importance of balancing repair performance and computational cost.

## 2 Background and Related Work

This section provides a relevant review of the literature and highlights the limitations of existing studies.

### 2.1 Previous Evaluations of LLM-based APR

Recent evaluations of APR are primarily based on the Defects4J Benchmark [19, 26], which has become the dominant benchmark for APR evaluation. However, heavy reliance on a single benchmark can limit the diversity of bug types and weaken the evaluation of APR approaches' generalizability. Nevertheless, several variants of Defects4J have been proposed, including DEFECTS4J-TRANS [20], and MuBench [33]. These benchmarks still primarily

contain software-engineering–oriented bugs [39]. Meanwhile, algorithm-oriented datasets such as QuixBugs [24], IntroClass, and ManyBugs [12] have been widely utilized to evaluate the generalizability of APR techniques. However, the difficulty of these datasets is often insufficient to challenge recent LLM-based APR approaches [46], thereby leading to an overestimation of their effectiveness. In addition, the continued reuse of long-standing benchmark datasets introduces data leakage issues [39], potentially leading to biased evaluation results. Furthermore, Bean et al. [4] point out that the lack of statistical testing in the majority of benchmarks reduces the reliability of empirical findings.

We collect recent real-world bugs from AtCoder [15] as an extension of algorithm-oriented datasets. Then, Git, srcML, and GumTreeDiff are utilized to categorize bugs based on complexity. Finally, we conduct an empirical evaluation of LLM-based APR under different bug complexity and FL settings, with a cost-efficiency and statistical analysis.

## 2.2 APR Techniques

APR techniques have advanced significantly with the development of LLMs' code-reasoning and code-generation capabilities [52]. With the success of LLMs in code reasoning and generation [16], recent studies have increasingly explored their applications in APR. Xia and Zhang [46] introduced ChatRepair, which iteratively generates and refines patches by leveraging feedback from both failed and successful repair attempts, and has been widely viewed as a representative baseline in subsequent studies. For instance, Yin et al. [48] proposed ThinkRepair, which uses Chain-of-Thought (CoT) prompting [45] to enable reasoning prior to patch generation. Bouzenia et al. [5] introduced RepairAgent, the first autonomous agent-based framework for APR. Li et al. [21] further proposed CodeCorrector, an end-to-end framework that first analyzes programs to infer repair directions and then generates patches, achieving the best performance on the Defects4J v1.2 dataset.

In this study, we select ChatRepair as a representative LLM-based APR approach and CodeCorrector as a recent LLM-based method that demonstrates strong performance in prior studies.

## 2.3 Evaluation Metrics

Existing APR evaluation metrics primarily focus on repair effectiveness, including the number of repaired bugs, $Top-k$, compilable patches, and plausible patches [10]. To further assess patch quality, Dai et al. [7] introduced the consistency metric, which measures the extent of changes between patches and buggy programs. However, these metrics fail to capture cost-efficiency, which has become increasingly important in the empirical study of LLM-based APR. Although recent studies have begun to report costs [46, 5, 21], they use inconsistent units, such as cost per bug, cost per successful repair, or cost per attempt, making it difficult to perform fair, direct comparisons across approaches. This lack of a unified cost metric limits the systematic evaluation of performance–cost trade-offs. Thus, we standardize costs to a common monetary unit, enabling a direct trade-off between repair performance and cost.

# 3 Research Design

In this section, we discuss the research methodology.

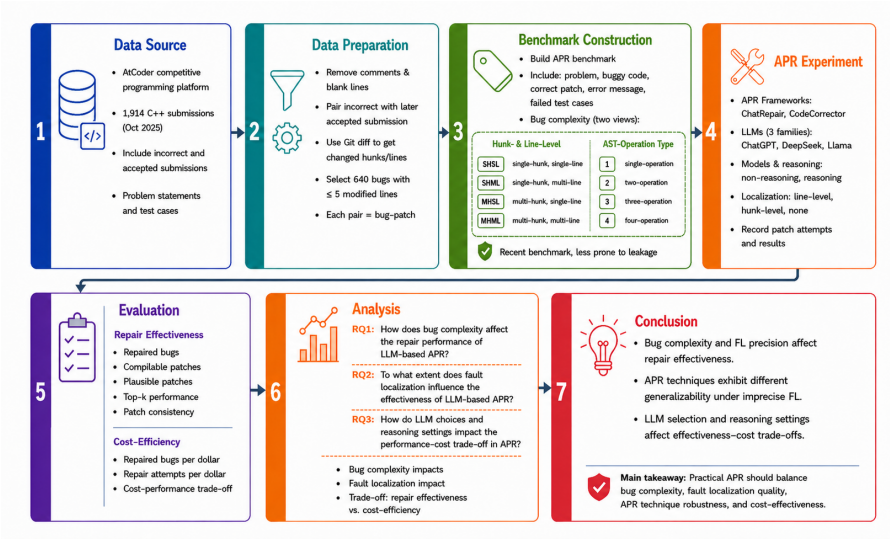

**Figure 1** Flow of the research method.

## 3.1 Experimental Infrastructure

The experimental infrastructure is deployed on computing servers with isolated execution environments to ensure controlled access and protected communication. Shared storage and distributed computing resources are utilized to support large-scale APR experiments across multiple machines, improving the overall experimental efficiency. The experimental infrastructure consists of five components: the dataset, APR techniques, LLMs, additional tools, and Python scripts.

The dataset is constructed from AtCoder and includes problem descriptions, pairs of incorrect and correct C++ programs, and corresponding test cases (Section 3.3). The tools include the APR tools, along with Git, srcML, and GumTreeDiff. The AtCoder Library (ACL) is included as an external dependency to support compilation. Custom Python scripts are used for data analysis and dataset filtering. All the above components are maintained within our isolated environment.

We utilize multiple LLMs in our study: gpt-5-2025-08-07 (GPT-5) [32], gpt-4o-mini-2024-07-18 (GPT-4o-mini) [31], DeepSeek-V3.2 [8], DeepSeek-V4-pro [9], Llama-3.1-8B [2], and Llama-3.1-405B [1]. GPT-5 and GPT-4o-mini use the OpenAI API. DeepSeek-V3.2 and DeepSeek-V4-pro use the DeepSeek API. Llama-3.1 is deployed in our experimentation infrastructure.

## 3.2 Experimental Workflow

Figure 1 illustrates the overall experimental infrastructure and workflow of our study. We first collect buggy and corrected programs from AtCoder and construct an automated benchmark and evaluation pipeline for LLM-based APR experiments (details are provided in subsection 3.3).

Next, we analyze bug complexity from multiple perspectives. Git-based differencing is utilized to extract hunk-line complexity information, while srcML [6] and GumTreeDiff [11] are employed to measure structural complexity at the Abstract Syntax Tree (AST) level (details are provided in subsection 3.4).

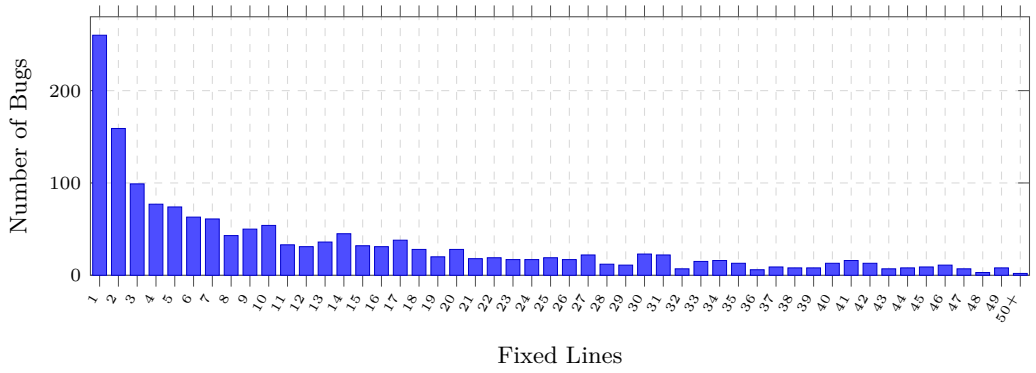

**Figure 2** Distribution of Fixed Size Across Raw Data.

Based on the constructed benchmark and complexity analysis, we deploy APR frameworks and integrate multiple LLM APIs with different reasoning settings to conduct automated repair experiments under FL settings (details are provided in subsection 3.5).

Finally, we perform a comprehensive empirical evaluation to investigate the impact of bug complexity, fault localization, and cost-efficiency trade-offs on the performance of LLM-based APR techniques. The corresponding findings and experimental analyses are presented in section 4.

## 3.3 Dataset

Existing APR benchmarks have been widely used, raising concerns about data contamination in the evaluation of LLM-based APR. To mitigate this risk, we construct our dataset from the recent AtCoder submissions rather than relying on existing benchmarks. We focus on C++ programs because comparing FL settings and bug complexity across programming languages with different characteristics could introduce additional bias. This design enables a more controlled evaluation of LLM-based APR.

In this study, we use AtCoder, a Japanese competitive programming platform, and collect 1,914 C++ source code submissions in October, 2025. Our data comes from regular contests, which typically include algorithmically challenging problems designed to assess intermediate-to-advanced programming skills. We pair every incorrect program and correct program from the same participant as a pair of a bug and a correct patch (bug-patch pair). For each bug-patch pair, we use the `git diff` command to generate a diff file that captures the corresponding code changes.

Before generating diff files using Git, we remove all comments and redundant blank lines. The diff files reflect line-level code changes, where '-' denotes deleted (buggy) lines $N_-$, and '+' denotes added (patch) lines $N_+$. For each hunk, the number of fixed lines is defined as $N_{\text{fixed}} = \max(N_+, N_-)$.

The distribution of bug-fix sizes across the original 1,914 C++ files is shown in Figure 2. Based on preliminary experiments comparing different fixed line thresholds on samples drawn from the full dataset, we observe that APR becomes considerably more difficult and computationally expensive as the number of fixed lines increases. Considering both repair feasibility and computational cost, we set a threshold of five fixed lines to focus on small-scope program repair. Finally, 640 bugs remain for our empirical study.

**Table 1** Hunk-line complexity.

| Bug Type | # Bugs |
|---|---|
| Single Hunk Single Line | 251 |
| Single Hunk Multi Line | 226 |
| Multi Hunk Single Line | 67 |
| Multi Hunk Multi Line | 96 |
| Total | 640 |

**Table 2** AST operation-type complexity.

| Bug Type | # Bugs |
|---|---|
| Single Operation | 278 |
| Two Operations | 158 |
| Three Operations | 121 |
| Four Operations | 83 |
| Total | 640 |

## 3.4 Bug Complexity

**Buggy hunk-line-level complexity.** The diff files generated by Git not only identify buggy and patched lines but also organize code changes into hunks. We use Git to generate diff files for every bug-patch pair. Based on the number of hunks and the number of fixed lines within each hunk, we categorize bugs into four categories: Single-Hunk-Single-Line (SHSL), Single-Hunk-Multi-Line (SHML), Multi-Hunk-Single-Line (MHSL), and Multi-Hunk-Multi-Line (MHML). The categorization rule is defined in Equation 1. The number of hunks can be obtained directly from Git diff files. If any hunk contains more than one fixed line, the bug is classified as a multi-line bug.

$$\begin{cases} \text{SHSL}, & H = 1 \wedge \forall h_i \in H,\ L(h_i) = 1 \\ \text{SHML}, & H = 1 \wedge \exists h_i \in H,\ L(h_i) > 1 \\ \text{MHSL}, & H > 1 \wedge \forall h_i \in H,\ L(h_i) = 1 \\ \text{MHML}, & H > 1 \wedge \exists h_i \in H,\ L(h_i) > 1 \end{cases} \tag{1}$$

where $H$ denotes the total number of hunks in a bug, $h_i$ represents the $i$-th hunk ($1 \leq i \leq H$), and $L(h_i)$ denotes the number of fixed lines in hunk $h_i$.

**AST operation-type complexity.** We employ srcML to construct XML-based structural representations of programs [6] and further utilize GumTreeDiff to extract AST-level edit operations between buggy and corrected program pairs [11]. Unlike hunk-line-level complexity, this metric measures structural differences at the AST node level, providing a finer-grained view of bug complexity.

The AST edit distance [42] between a buggy and a correct program is defined by four edit operations: insert, delete, relabel, and move. In our study, bugs are further categorized based on the diversity of edit operations required for repair. Figure 3 illustrates how the AST edit-operation-type complexity is categorized.

Table 1 and Table 2 present the number of bugs in each type under the hunk-line-level and AST operation-type complexity, respectively. We conduct empirical evaluations to analyze how bug complexity affects LLM-based APR performance.

## 3.5 Fault Localization And APR Settings

We use three FL strategies to explore their impact on LLM-based APR: buggy line-level FL, buggy hunk-level FL, and no FL. Figure 4 presents the examples of line-level FL and hunk-level FL according to the diff file.

Different LLMs provide different mechanisms for controlling reasoning behavior. (a) DeepSeek-V3.2 provides two model variants: *DeepSeek-V3.2-chat* and *DeepSeek-V3.2-reasoner*. For DeepSeek-V4-pro, the reasoning mode can be enabled or disabled through

the `thinking_type` parameter in the DeepSeek API. Additionally, the `reasoning_effort` parameter can be configured as `high` or `max`. (b) GPT models do not provide separate chat or reasoner variants; instead, reasoning intensity can only be controlled through the `reasoning.effort` parameter, with settings such as `medium`, `high`, and `xhigh`. For Llama models, there is currently no explicit mechanism to directly control reasoning settings.

Furthermore, the temperature for all LLMs is set to 1.0 [38] for all experiments. For ChatRepair, we set the maximum number of conversation rounds to 3 [46]. For both ChatRepair and CodeCorrector, we provide the problem background, the buggy code, the error message, and at most 3 failed test cases. We retain the original prompts reported in the corresponding studies [46, 21], and we do not perform model-specific parameter tuning, allowing the comparison to focus on the influence of the APR frameworks, FL strategies, and LLM effectiveness.

## 3.6 Experimental Design

To balance experimental comprehensiveness and computational cost, we adopt a three-stage experimental design.

First, we evaluate two APR tools with three different low-cost LLMs on the complete set of 640 bugs under line-level FL: *DeepSeek-V3.2-chat*, *GPT-4o-mini*, and *Llama-3.1-8B*. The maximum number of repair rounds is set to 10 as in [34]. We conduct a comprehensive empirical analysis of various APR techniques and LLM combinations with respect to repair effectiveness and cost-efficiency.

Next, we select the best-performing LLM from the first stage and further evaluate it on all 640 bugs at line-level, hunk-level, and no-FL. The results are then compared across three FL strategies to analyze the impact of different FL precision on two LLM-based APR techniques. For the first two stages, reasoning mode is disabled across all LLMs, allowing us to identify bugs that can already be repaired under non-reasoning configurations before evaluating more computationally expensive reasoning-enabled models.

To further investigate the repair effectiveness and cost-efficiency of advanced LLMs and reasoning settings under more challenging repair scenarios, we adopt a filtering strategy to focus the evaluation on bugs with moderate repair difficulty while controlling the computational cost of evaluating advanced LLMs. Specifically, we exclude SHSL bugs, single-operation-type bugs, and four-operation-type bugs. In addition, bugs that can already be successfully repaired by at least five APR techniques–LLM combinations in the first-stage experiments are removed. Consequently, the remaining benchmark focuses on bugs with moderate structural complexity and lower repairability under low-cost APR configurations. After filtering, 211 bugs remain for empirical analysis. We further select the better-performing APR technique from the previous stages as the representative APR method for subsequent experiments.

In this stage, we evaluate four advanced LLMs: *DeepSeek-V4-pro*, *DeepSeek-V3.2*, *GPT-5*, and *Llama-3.1-405B*. The maximum number of repair rounds is increased to 13. During the first 10 rounds, reasoning mode is disabled. If a bug remains unfixed, reasoning mode is enabled for the final three rounds. For *GPT-5*, *DeepSeek-V3.2*, and *DeepSeek-V4-pro*, the reasoning effort is configured as `high`.

**Experimental Token Consumption.** To facilitate the reproduction of our experiments, we report the total input and output tokens consumed by each evaluated LLM that incurred API costs. DeepSeek-V3.2 consumed 116.5M input tokens and 42.7M output tokens. GPT-4o-mini used 49.5M input tokens and 14.4M output tokens. DeepSeek-V4-pro consumed 6.3M input tokens and 9.9M output tokens, GPT-5 consumed 3.4M input tokens and 7.7M output tokens, and Llama-3.1-405B consumed 6.3M input tokens and 1.7M output tokens.

**API Response Time.** We also report the approximate response time per repair request. Without reasoning mode, all evaluated LLMs require approximately 1–3 minutes per request. With reasoning enabled, DeepSeek-V3.2 and DeepSeek-V4-pro required approximately 40–60 minutes per request, while GPT-5 required about 30 minutes.

# 4 Results and Empirical Analysis

In this section, we show the results of our empirical experiment.

## 4.1 APR Performance With Different LLMs

Table 3 presents the repair performance of CodeCorrector and ChatRepair with three base LLMs under the non-reasoning setting. In this experiment, line-level FL is provided within the incorrect programs, and the maximum repair round is set to 10. CodeCorrector stops after generating the first plausible patch, whereas ChatRepair continues generating candidate patches.

Overall, DeepSeek-V3.2-chat achieves substantially stronger repair effectiveness than GPT-4o-mini across both APR frameworks. When integrated with DeepSeek-V3.2-chat, both CodeCorrector and ChatRepair repair more than twice as many bugs as they do with GPT-4o-mini (295, 292 vs. 126, 140), whereas Llama-3.1-8B demonstrates very limited repair behavior: only 11 bugs were corrected with CodeCorrector and 50 with ChatRepair.

**Table 3** Comparison of repair effectiveness between CodeCorrector and ChatRepair frameworks using three base LLMs on the full benchmark.

| | CodeCorrector | | | ChatRepair | | |
|---|---|---|---|---|---|---|
| | **DeepSeek-V3.2-chat** | **GPT-4o-mini** | **Llama-3.1-8B** | **DeepSeek-V3.2-chat** | **GPT-4o-mini** | **Llama-3.1-8B** |
| Repaired Bugs | 295/640 | 126/640 | 11/640 | 292/640 | 140/640 | 50/640 |
| Attempts | 4003 | 5373 | 6305 | 6400 | 6400 | 6400 |
| Unique Patches | 3117(77.9%) | 4425(82.4%) | 5833(92.5%) | 2623(41.0%) | 3774(59.0%) | 5111(80.0%) |
| Compilable Patches | 2830(70.7%) | 3899(72.6%) | 1466(23.3%) | 2523(39.4%) | 3511(54.9%) | 3122(48.8%) |
| Plausible Patches | 295 | 126 | 11 | 421 | 247 | 76 |
| Repaired Bugs / $ | 47.62 | 17.86 | – | 71.43 | 20.41 | – |
| Attempts / $ | 646.17 | 761.48 | – | 1565.56 | 932.94 | – |

In addition, DeepSeek-V3.2-chat exhibits noticeably better cost-efficiency. DeepSeek-V3.2-chat repairs 47.62 bugs per dollar under CodeCorrector, compared with only 17.86 bugs per dollar for GPT-4o-mini, representing approximately 2.7× higher cost-efficiency. Similarly, under ChatRepair, DeepSeek achieves 71.43 repaired bugs per dollar, whereas GPT-4o-mini repairs only 20.41 bugs per dollar, corresponding to approximately 3.5× higher cost-efficiency.

***Finding 1:*** *Among relatively low-cost LLMs, DeepSeek-V3.2-chat demonstrates the strongest overall APR effectiveness, achieving significantly better repair results and cost-efficiency than GPT-4o-mini, whereas Llama-3.1-8B exhibits limited repair effectiveness despite its negligible inference cost.*

**Bug Complexity.** We then analyze how bug complexity affects overall repairability, where a bug is considered repaired if any evaluated APR technique and LLM configuration can fix it. Table 4 and Table 5 present the pairwise $2 \times 2$ contingency tables and Pearson chi-square test results for the numbers of fixed and unfixed bugs across different bug complexity categories. Pairwise chi-square tests are conducted to assess whether differences in repair rates across complexity categories are statistically significant. Following [27], we consider differences statistically significant when $p < 0.05$, while $p < 0.005$ indicates sufficient evidence against the null hypothesis.

SHSL and single-operation-type bugs exhibit the lowest structural complexity and consequently achieve the highest repair rates among all categories, reaching 78.5% and 75.2%, respectively. Furthermore, all pairwise comparisons between these two categories and the remaining complexity categories yield $p < 0.005$, providing strong statistical evidence that SHSL and single-operation-type bugs are substantially easier for APR techniques to repair. However, the SHML, MHSL, MHML, two-operation, and three-operation bugs also achieve repair rates above 50%.

For hunk-line-level complexity, no statistically significant difference in repair is observed among multi-line bug categories ($p > 0.05$). In contrast, although no statistically significant difference is observed between two-operation-type and three-operation-type bugs ($p = 0.78$), four-operation-type bugs exhibit significantly lower repair effectiveness than other operation-type categories ($p < 0.05$). Thus, AST operation complexity further distinguishes highly complex bugs, with statistical analysis showing that four-operation bugs exhibit the most complex repair structure.

Darker cells indicate smaller p-values.

***Finding 2:*** *SHSL and single-operation-type bugs are the easiest to repair, whereas four-operation-type bugs remain the most challenging. The repair rates of moderate-complexity categories exceed 50%, indicating that LLM-based APR techniques maintain strong repair effectiveness. Although four-operation-type bugs exhibit lower repair performance, their repair rates remain considerable. These results suggest that low-cost LLM-based APR techniques retain substantial repair effectiveness even for structurally complex bugs.*

**RQ1 Summary.** Bug complexity significantly affects repair effectiveness. Chi-square test results suggest three approximate levels of repair difficulty across different bug complexity categories. Overall, repair effectiveness decreases with increasing bug complexity, while the simplest bugs remain substantially easier to repair. Although four-operation bugs are the hardest to repair, APR techniques still maintain considerable repair capability for structurally complex bugs. Over 50% of moderate-complexity bugs can still be repaired successfully. These results demonstrate the potential of low-cost LLM-based APR techniques for handling challenging real-world repair scenarios.

| Attempts / $ | 646.17 | 462.52 | 923.18 | 1565.56 | 659.13 | 1486.64 |

**Table 7** Comparison of repair consistency under different FL strategies.

| FL Strategy | **CodeCorrector** | **ChatRepair** |
|---|---|---|
| Line-level FL | 0.85 | 0.92 |
| Hunk-level FL | 0.75 | 0.83 |
| w/o FL | 0.54 | 0.85 |

## 4.2 Fault Localization Evaluation

Given DeepSeek-V3.2-chat's best performance in the previous experiment, we further evaluate the impact of different FL strategies on APR performance using this LLM with both APR techniques. In this experiment, the maximum repair round is still set to 10.

Table 6 shows that CodeCorrector and ChatRepair achieve nearly identical repair effectiveness under line-level FL, with CodeCorrector even repairing three more bugs. However, when only hunk-level FL or no FL is provided, ChatRepair demonstrates consistently greater stability and generalizability. Under hunk-level FL, ChatRepair repairs 58 more bugs than CodeCorrector, and this gap further increases to 93 bugs when FL is unavailable.

***Finding 3:*** *The performance gap between APR techniques increases markedly as FL becomes less precise, indicating that repair stability and generalizability are critical for real-world APR scenarios. Different APR techniques may achieve similar repair rates under precise line-level FL, but their repair rates diverge substantially under imprecise FL settings.*

We further introduce the *code consistency rate* (CCR) to measure how well repaired programs preserve the original code's structure. $\mathbf{CCR = r/k}$ defines the consistency metric, where $k$ denotes the total number of code lines in the repaired program, and $r$ denotes the number of preserved code lines after repair.

According to Table 7, line-level FL achieves the highest patch consistency across all FL settings for both APR techniques. ChatRepair generally generates patches with higher structural consistency than CodeCorrector, particularly without FL (0.85 vs. 0.54).

***Finding 4:*** *FL not only improves repair effectiveness but also helps generate patches that remain more structurally consistent with the original programs. The design of APR techniques also significantly impacts the structural consistency of generated patches.*

We use logistic regression [28] to examine the extent to which reduced FL precision affects the likelihood of successful repair. We set line-level FL as the reference category and analyze each complexity level independently. The results are reported using odds ratios (ORs) and corresponding $p$-values. Smaller OR values reflect a greater reduction in the odds of successful repair.

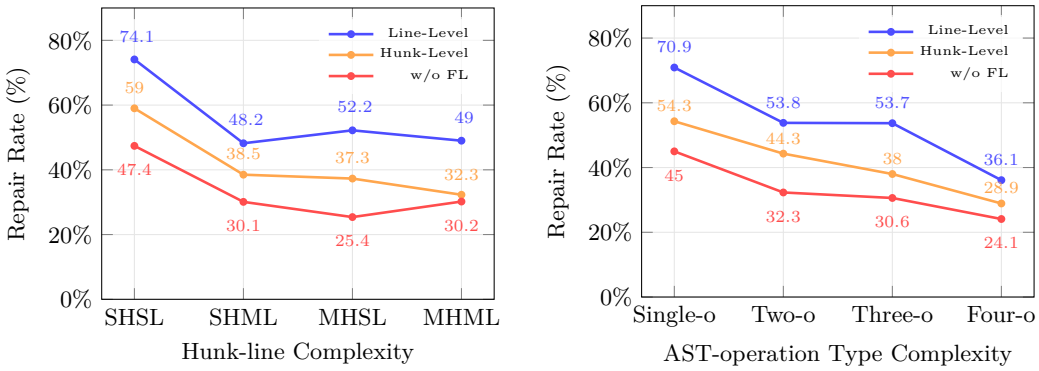

**Figure 5** Repair rate under different bug complexity categories.

**Table 8** Logistic regression results of FL effects on repair success under different complexity categories.

**(a)** Hunk-line complexity categories.

| Scope | Hunk-level FL | | No FL | |
|---|---|---|---|---|
| | OR | p | OR | p |
| Overall | 0.582 | < .001 | 0.399 | < .001 |
| SHSL | 0.502 | < .001 | 0.315 | < .001 |
| SHML | 0.672 | 0.037 | 0.462 | < .001 |
| MHSL | 0.544 | 0.084 | 0.311 | 0.002 |
| MHML | 0.497 | 0.019 | 0.451 | 0.008 |

**(b)** AST-operation complexity categories.

| Scope | Hunk-level FL | | No FL | |
|---|---|---|---|---|
| | OR | p | OR | p |
| Overall | 0.582 | < .001 | 0.399 | < .001 |
| single-op | 0.489 | < .001 | 0.336 | < .001 |
| two-op | 0.683 | 0.092 | 0.409 | < .001 |
| three-op | 0.528 | 0.015 | 0.379 | < .001 |
| four-op | 0.719 | 0.321 | 0.561 | 0.092 |

Figure 5 shows that repair rates consistently decrease across all complexity categories as FL becomes less precise (blue vs. orange vs. red). According to Table 8, both hunk-level FL and no-FL settings yield overall $p$-values smaller than 0.001, indicating that FL precision has a statistically significant effect on overall repair effectiveness.

We further observe that the simplest bugs (SHSL and single-operation bugs) appear sensitive to reductions in FL precision, as both hunk-level FL and no-FL settings produce very low odds ratios, also with $p < 0.001$. In contrast, the highest complexity bugs (four-operation bugs) exhibit the least noticeable repair degradation under hunk-level FL and no-FL settings, as the odds ratios remain relatively higher and the FL degradation effects are not statistically significant ($p = 0.092 > 0.05$).

***Finding 5:*** *Repair rates consistently decrease as FL becomes less precise across all bug complexity categories, indicating that FL precision remains important regardless of bug complexity. However, as bug complexity increases, repair effectiveness becomes less dependent on precise FL, suggesting it is more likely reliant on structural understanding and reasoning of program logic.*

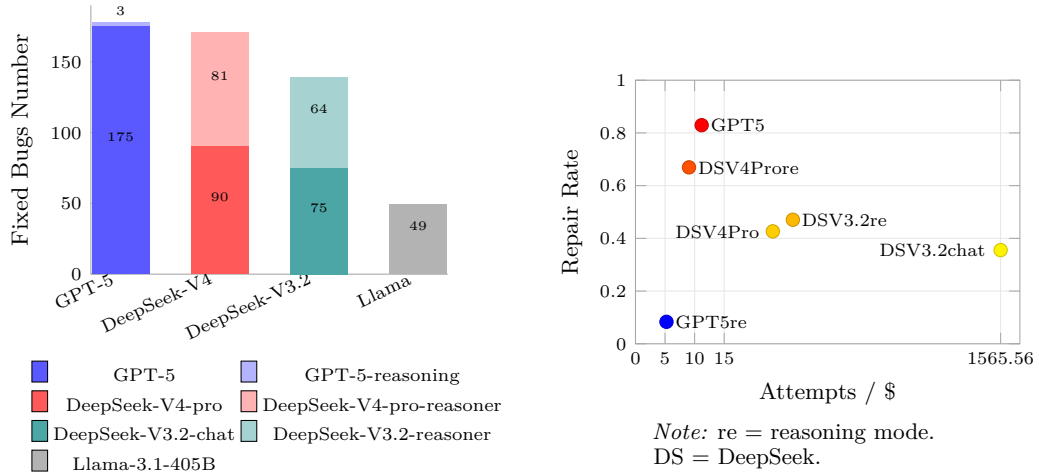
**RQ2 Summary.** FL still plays a critical role in the bug repair process. More precise FL not only improves overall repair rates but also helps APR techniques generate more consistent patches. Furthermore, APR techniques with similar repair performance under the same FL strategy can exhibit substantially different effectiveness as FL becomes increasingly imprecise, resulting in progressively larger performance gaps among APR approaches. These results highlight the importance of the stability and generalizability of APR techniques for handling realistic bug-repair scenarios. Moreover, as bug structures become increasingly complex, the relative importance of FL precision decreases, indicating the growing significance of reasoning and program understanding.

**Table 9** The Advanced LLMs Performance.

| | Repaired Bugs | Attempts | Repaired Bugs / $ | Attempts / $ |
|---|---|---|---|---|
| GPT-5 | 175/211 | 666 | 2.94 | 11.19 |
| GPT-5-reasoning | 3/36 | 106 | 0.15 | 5.24 |
| DeepSeek-V3.2-chat | 75/211 | 1550 | 75.75 | 1565.56 |
| DeepSeek-V3.2-reasoner | 64/136 | 318 | 23.97 | 119.10 |
| DeepSeek-V4-pro | 90/211 | 1475 | 4.17 | 68.29 |
| DeepSeek-V4-pro-reasoner | 81/121 | 232 | 3.16 | 9.05 |
| Llama-3.1-405B | 49/211 | 1801 | - | - |

## 4.3 APR With Advanced LLMs

ChatRepair demonstrates overall better performance than CodeCorrector in sections 4.1 and 4.2, so this study chooses ChatRepair to evaluate performance and cost-efficiency for advanced LLM-based approaches. To reduce API cost, ChatRepair stops when generating the first plausible patch. Subsection 3.6 describes the experimental environment, and Table 9 presents the results of ChatRepair combined with four LLMs and two reasoning settings.



Cost analysis shows that inference costs increase substantially when more advanced LLMs are adopted. DeepSeek-V3.2-chat supports approximately 1,565.56 repair attempts per dollar in non-reasoning mode and 119.10 in reasoning mode, whereas DeepSeek-V4-pro decreases to 68.29 in non-reasoning mode, and 9.05 in reasoning mode. GPT-5 supports only 11.19 attempts per dollar in non-reasoning mode and 5.24 attempts per dollar in reasoning mode. These results show that the cost increases considerably as larger and reasoning-oriented LLMs are used. Compared with the advanced LLMs, DeepSeek-V3.2 is much cheaper than GPT-5 and DeepSeek-V4-pro. Therefore, both the choice and reasoning settings of LLMs heavily impact the cost-efficiency.

The performance of different LLMs varies substantially under non-reasoning and reasoning settings. Figure 6 (a) presents the number of additionally repaired bugs achieved by each LLM when reasoning mode is enabled.

GPT-5 repairs 175 bugs under non-reasoning mode, achieving the highest number of repaired bugs among all evaluated models, while DeepSeek-V4-pro and DeepSeek-V3.2 repair 90 and 75 bugs, respectively. However, when the reasoning effort is increased to high, GPT-5 repairs only 3 additional bugs. In contrast, enabling high-reasoning-mode effort allows DeepSeek-V3.2 and DeepSeek-V4-pro to repair 64 and 81 additional bugs, respectively.

***Finding 6:*** *Both LLM selection and reasoning settings have significant impacts on repair effectiveness and cost, while the effectiveness of reasoning strategies differs across LLM families. Enabling reasoning mode provides only limited repair improvement for GPT-5, whereas DeepSeek-V3.2 and DeepSeek-V4-pro benefit considerably more from reasoning-based settings, repairing many bugs that cannot be fixed under non-reasoning configurations.*

Figure 6 (b) presents the repair rates of different LLMs and reasoning settings under the cost metric of attempts per dollar (Attempts/$). Combined with Figure 6 (a), GPT-5 repairs 175 bugs under the non-reasoning setting, which is higher than all other evaluated LLMs under both reasoning and non-reasoning settings (171 for DeepSeek-V4-pro and 139 for DeepSeek-V3.2). Moreover, GPT-5 under the non-reasoning setting is even cheaper than DeepSeek-V4-pro under the reasoning setting in terms of attempts per dollar (11.19 vs. 9.05). Although GPT-5 under the non-reasoning setting is more expensive than DeepSeek-V3.2 under the reasoning setting, the repair rate is markedly higher.

**(a)** Repair Effectiveness. **(b)** Cost efficiency.

**Figure 6** Repair effectiveness and cost efficiency of advanced LLMs.

Figure 6 (b) shows that under the non-reasoning setting, DeepSeek-V3.2 achieves competitive repair performance compared with DeepSeek-V4-pro, while maintaining a substantially lower cost. Therefore, using DeepSeek-V3.2 in non-reasoning mode for overall bug repair, and subsequently applying GPT-5 in non-reasoning mode to repair the remaining unresolved bugs, provides a more effective trade-off between repair performance and cost.

***Finding 7:*** *GPT-5 achieves the strongest overall repair effectiveness, whereas DeepSeek-V3.2-chat demonstrates significantly better cost-efficiency. Combining cost-efficient LLMs with more advanced LLMs for unresolved bugs can therefore achieve a better balance between repair effectiveness and cost-efficiency in LLM-based APR techniques.*

Table 10 presents the $Top-k$ metric for both APR techniques across three LLM families and three different FL strategies. The first five repair rounds usually resolve the largest proportion of bugs across evaluated APR techniques, LLMs, and FL settings. However, the marginal repair gain decreases considerably as additional repair rounds are introduced, with later rounds contributing only a limited number of newly repaired bugs.

***Finding 8:*** *The majority of bugs are repaired within the first five repair rounds, whereas the marginal repair effectiveness decreases significantly in later rounds.*

**RQ3 Summary.** Using advanced LLMs and reasoning modes improves repair rates and enables APR techniques to fix more structurally complex bugs. However, these improvements come with substantially higher costs, making the trade-off between repair performance and cost increasingly important. Moreover, the benefits of reasoning modes vary across different LLM families. In our experiments, GPT-5 shows the smallest gain from reasoning, whereas the DeepSeek series repairs many additional bugs that cannot be fixed in non-reasoning mode. We further find that applying cost-efficient LLMs first, and then using advanced LLMs to repair the remaining unresolved bugs, can achieve a better balance between repair effectiveness and cost.

**Table 10** Repair performance (Top-$k$) across APR configurations. Values are reported as incremental fixes and cumulative total in parentheses.

| APR | LLMs | FL | Top-1 | Top-2 | Top-3 | Top-4 | Top-5 | Top-10 |

## 5 Discussion

We investigated the effectiveness of LLM-based APR under different bug complexity categories and fault localization strategies. The results reveal several insights regarding the repair effectiveness and cost-efficiency of the evaluated LLM-based APR techniques, providing useful guidance for future APR research and practical deployment.

**Impacts of bug complexity.** Our results show that bug complexity substantially affects the effectiveness of LLM-based APR techniques. The simplest bugs achieve much higher repair rates, while structurally complex bugs containing multiple buggy lines or diverse AST edit operations remain more challenging.

The repair performance across different bug complexity levels suggests that future APR evaluations could pay more attention to complex repair scenarios rather than to single-line or single-operation bugs. Structurally complex bugs may better reflect some of the challenges encountered in practical APR tasks. New benchmarks and standard performance metrics could consider evaluations across different bug categories, domains, and complexity levels to better characterize tool performance [10, 36, 39].

**Impacts of fault localization.** Precise FL not only improves repair effectiveness, but also helps APR techniques generate patches that are more consistent with the original program logic. Such consistency may facilitate the understanding, validation, and maintenance of repaired programs.

Additionally, existing LLM-based APR methods are affected differently by less precise FL information. This difference highlights robustness to imprecise FL as an important requirement for practical APR techniques [10]. Since real-world FL is often noisy and incomplete, methods that maintain stable repair performance when the precision of FL decreases are more likely to be effective in practice. For complex bugs, the relatively smaller effect of FL precision indicates that FL may not be the only bottleneck. Repairing these bugs may also depend on reasoning ability and deeper program-understanding capabilities.

**The Trade-off Between Repair Effectiveness and Cost-efficiency.** Using more advanced LLMs and reasoning modes substantially increases computational cost, while often improving repair effectiveness. Based on the results presented in section 4.3, GPT-5 achieves the highest repair effectiveness, while DeepSeek-V3.2-chat provides the most cost-efficient repair performance. Our results suggest that such a two-stage strategy could be a promising direction for future investigation.

The marginal repair efficiency drops as the number of repair rounds increases [34, 50], which further impacts overall cost, especially when using advanced LLMs such as GPT-5 and DeepSeek-V4-pro in reasoning mode. Our results also suggest that selecting an appropriate maximum number of repair rounds is important for cost-efficiency.

## 6 Threats to Validity

**External Validity.** Our dataset is collected solely from the competitive programming platform AtCoder and focuses only on C++ programs, which are typically shorter but more algorithm-oriented [24, 12] than industrial software systems. Thus, the findings of our study may not generalize fully to real-world software projects with larger codebases, complex dependencies, and practical software engineering constraints. Furthermore, we evaluate only two APR techniques and three LLM series, and thus, the best-performing approaches identified in this study should not be regarded as definitive state-of-the-art APR solutions.

The evaluated LLMs have different knowledge cutoff dates, and we collect benchmark data after 2025-10-01, which is after the knowledge cutoff date of the GPT and Llama models we used. DeepSeek did not publish its knowledge cutoff date, so it remains difficult to completely rule out the possibility that some competitive programming solutions or related code patterns were exposed during model pretraining [30, 37].

**Internal Validity.** We set the temperature to 1.0 for all evaluated LLMs and used high reasoning-effort settings instead of the maximum settings for GPT-5, DeepSeek-V3.2-reasoner, and DeepSeek-V4-pro due to their substantial time costs. Different parameter configurations and reasoning settings may lead to variations in repair performance. In addition, API-based LLMs may produce nondeterministic outputs across different runs, which could also affect repair results. Furthermore, different prompting strategies, repair rounds, and stopping criteria may influence the effectiveness and cost-efficiency of APR.

**Construct Validity.** We determine repaired bugs mainly based on whether the generated patches can pass all collected test cases. However, the test cases may not be sufficiently comprehensive to fully validate the semantic correctness of repaired programs. Therefore, some plausible patches may still contain hidden defects or overfitting issues.

## 7 Conclusion and Future Work

This work conducts an empirical study on how bug complexity and FL affect LLM-based APR techniques. We utilize Git, srcML, and GumTreeDiff to categorize bug complexity from both hunk-line-level and AST-operation-level perspectives, and to evaluate APR effectiveness under accurate, vague, and no fault-localization settings.

The experimental results show that structurally complex bugs and imprecise FL often reduce repair effectiveness. Nevertheless, well-designed LLM-based APR techniques still maintain considerable repair rates under these challenging conditions. Furthermore, different LLMs exhibit clear trade-offs between repair effectiveness and cost-efficiency, highlighting the importance of balancing repair effectiveness and cost for practical APR tools.

Future work may develop a benchmark that can automatically collect, filter, and categorize bug complexity. Also, we will consider practical factors such as API response latency [35, 25] and overall inference time when evaluating the efficiency of LLM-based APR systems. We plan to explore additional LLM families, such as Gemini and Claude, to further evaluate the effectiveness of LLM-based APR. Finally, the agent-based APR frameworks should be further investigated, as agent-based techniques have become increasingly popular across various software engineering and reasoning tasks in recent years.

## Abstract

**Background.** Large Language Models (LLMs) have demonstrated strong performance across a variety of code-understanding tasks, leading many to believe that they can reason about program semantics. A fundamental test of this capability is assessing code functional equivalence. However, existing evaluations primarily focus on single-language settings or rely on synthetically generated code, raising concerns about whether current results reflect true semantic understanding.

**Aims.** We investigate whether LLMs can accurately judge functional equivalence across different programming languages in human-written code, a setting that requires deeper reasoning beyond superficial similarity.

**Method.**We introduce PolyHuman, a dataset of human-written programs in CPP, Java, and Python. Using this dataset, we evaluate intra- and inter-language equivalence detection across open-weight and proprietary LLMs, selecting GPT-o4-mini as a representative model to assess stability. We then manually analyze 81 cases of systematic disagreement in which models incorrectly judge functional equivalence, examining the code logic and the generated Chain-of-Thought reasoning. Finally, we categorize these failures and compare them across GPT-o4-mini, Claude-Opus-4.7, and Gemini-3-Flash to determine whether they reflect model-specific issues or broader limitations of state-of-the-art LLMs.

**Results.** We identify a difficulty-dependent breakdown in equivalence judgment (harder problems make the model increasingly prone to misclassifying non-equivalent code as equivalent), a model-specific sensitivity to programming language for the best-performing model (particularly a more conservative behavior on Python), and a partial reliance on similarity-based cues. GPT-o4-mini also shows substantial run-to-run instability under identical settings, indicating inconsistent rather than absent capability. Its failures are mainly due to (1) a lack of knowledge relevant to judging code functional equivalence and (2) abstraction-level reasoning failure, such as premature conclusion, semantic-level misunderstanding, and implementation-level error. We also observed that several analyzed failures involved loops and conditional branches.

**Conclusions.** Current LLMs do not reliably capture functional equivalence within or across languages. Our findings highlight the need for more realistic benchmarks and suggest improvements through better reasoning-path selection and by addressing reasoning gaps across the identified failure levels.

## 1 Introduction

Large Language Models (LLMs) have recently demonstrated remarkable progress in code understanding tasks, including generation, summarization, and bug fixing [16,39,44,45]. These advances have led to growing expectations that LLMs can reason about code semantics at a level comparable to human developers [1, 2, 45]. Another fundamental capability underlying such reasoning is assessing code functional equivalence, which is the ability to determine whether two programs produce identical outputs for all valid inputs [21,31,46]. This capability is critical for applications such as code refactoring [9], cross-language translation [27], code migration [3, 26], plagiarism detection [30, 38], and compiler optimization [20, 25].

Despite strong reported performance, we argue that current evaluations overestimate LLMs' true semantic understanding of code. Existing benchmarks for functional equivalence largely focus on intra-language settings [11, 40, 43] or rely on synthetically transformed programs [34, 49], where equivalence can often be inferred from superficial cues such as lexical similarity or minor structural changes [36, 46]. These evaluations fail to capture the complexity of independently written human programs. This limitation becomes pronounced in cross-language equivalence detection (e.g., after code translation [27]), where semantically identical programs may differ significantly in syntax, structure, and idiomatic patterns [24,28]. In such settings, shallow similarity signals break down, requiring deeper reasoning about program behavior [24, 46]. However, it remains unclear whether LLMs possess this capability or whether their apparent success is driven by dataset artifacts and heuristic shortcuts.

To address this gap, we conduct the first systematic investigation of LLMs' ability to judge functional equivalence across programming languages using human-written code. We introduce PolyHuman, a new benchmark constructed from competitive programming platforms, containing program pairs in CPP (i.e., C++), Java, and Python. Unlike prior datasets [34, 43, 49], PolyHuman captures realistic implementation variation, enabling a more rigorous evaluation of semantic reasoning. Using PolyHuman, we examine how well LLMs perform when comparing programs written within the same language versus across different programming languages, and whether their performance degrades in the presence of human-written implementations rather than synthetic transformations. We further analyze the factors that influence model predictions, including code complexity, similarity signals, and language-specific characteristics, and seek to uncover the underlying causes of model failures, particularly in cross-language scenarios where semantic reasoning is most critical.

Guided by these goals, our study addresses four research questions. $RQ_1$ asks *how LLMs assess functional equivalence in intra-language settings*, establishing a baseline for model performance. $RQ_2$ extends this to *inter-language settings*, examining accuracy degradation relative to the intra-language baseline (e.g., for language pairs such as CPP↔Java or Python↔Java) and the extent to which models generalize beyond language-specific syntax, thereby probing whether LLMs rely on genuine semantic reasoning or superficial cues. $RQ_3$ investigates *what factors influence LLM assessment of functional equivalence*, including the

relationship between lexical and structural similarity and prediction outcomes, the impact of code complexity, and models' sensitivity to specific programming languages, particularly in cross-language comparisons. Finally, $RQ_4$ examines *what causes LLM failure* in functional equivalence assessment, through a detailed error analysis of incorrect predictions that reveals systematic biases (e.g., overprediction of non-equivalence) and recurring error patterns.

Our results challenge the assumption that LLMs possess robust semantic code understanding, showing that: (1) LLM performance is inflated by datasets with balanced labels and syntactic transformations [21, 46]; (2) models exhibit systematic and model-dependent prediction biases, some skewing toward conservative "non-equivalent" judgments and others toward over-accepting equivalence, an effect most pronounced in cross-language settings; (3) human-written programs introduce substantial difficulty, exposing a significant gap between synthetic and real-world evaluation scenarios; and (4) the best-performing model's decisions are partially influenced by similarity signals, indicating incomplete and inconsistent reasoning mechanisms. Overall, our findings suggest that current LLMs do not reliably reason about functional equivalence, especially across languages, and that new evaluation paradigms are necessary to accurately assess semantic code understanding.

This paper makes four main contributions. First, we introduce PolyHuman, a dataset of human-written CPP, Java, and Python programs for evaluating functional equivalence within and across languages. Second, we conduct the first large-scale empirical study of LLMs on cross-language functional equivalence assessment. Third, to the best of authors' knowledge, we are the first to characterize LLM functional equivalence judgment and provide a systematic codebook revealing the capability gaps at each level. Finally, we derive a set of actionable implications for LLM researchers, agent system designers, and programming practitioners, offering concrete guidance on model selection, human oversight, and risk-aware deployment in code-related tasks.

## 2 Methodology

To evaluate whether LLMs can accurately judge functional equivalence, we design an empirical study over human-written programs in two settings: (1) *intra-language*, where both programs are written in the same programming language; and (2) *inter-language*, where they are written in different languages. To systematically investigate this problem, we adopt the Goal-Question-Metric (GQM) framework [4]. Our ***goal*** is to analyze the ability of LLMs to detect functional equivalence; ***for the purpose of*** assessing whether their performance reflects true semantic reasoning; ***with respect to*** accuracy across settings, performance degradation on human-written code, the influence of similarity and language, and the causes of models' failure; ***from the perspective of*** researchers and developers; ***in the context of*** human-written programs in CPP, Java, and Python.

### 2.1 PolyHuman Dataset Construction

To enable a realistic evaluation of functional equivalence detection, we construct PolyHuman, a dataset of human-written programs across programming languages, as detailed below.

**Data Source.** To construct PolyHuman, we build upon CodeContests [18], a large-scale dataset containing correct and incorrect human-written solutions to 13,610 programming problems, collected from five competitive programming platforms (e.g., Aizu, AtCoder, Codeforces). Each problem in CodeContests is annotated with a difficulty rating, from *A (easy)* to *G (expert level)*, derived from the original platform (e.g., Codeforces rating system).

We chose CodeContests because it includes realistic characteristics related to code length variation, language coverage (CPP, Java, and Python), and solution correctness. These characteristics enable us to analyze how problem complexity and domain influence LLM performance in functional equivalence assessment.

**Filtering Strategy.** Online judges report various submission outcomes, including wrong answer, time limit exceeded, memory limit exceeded, runtime error, and presentation error. In this study, we consider a solution to be *correct* if it passes all test cases, and *incorrect* otherwise. Under this definition, when evaluating code pairs, any combination of a "correct" and an "incorrect" solution inherently exhibits at least one point of behavioral divergence on the test suite. This encapsulation allows us to focus strictly on observable input-output behavior rather than specific failure causes, thereby operationally labeling such pairs as non-equivalent. We retain only CodeContests' solutions in three popular programming languages, namely CPP, Java, and Python. This filtering ensures the construction of both equivalent and non-equivalent pairs across and within languages.

**Sampling and Randomization.** For each selected programming problem, CodeContests contains multiple solutions for each language. To avoid bias toward specific implementations or coding styles, we adopt a randomized sampling strategy. Specifically, for each problem and programming language (CPP, Java, and Python), we randomly sample two correct (passing) solutions and one incorrect (failing) solution. These sampled solutions are then combined to construct intra-language and inter-language pairs. This process ensures diversity in implementations while preventing over-representation of any particular solution pattern.

**Sub-tasks and Code Pair.** From the filtered and sampled solutions, we construct four categories of code pairs, totaling 15 s. We treat pairs of correct solutions as functionally equivalent, and pairs containing one incorrect solution as non-equivalent. After filtering, we obtain 6,905 problems. Excluding problems with unknown difficulty yields the final PolyHuman dataset comprising 5,035 problems. Table 1 summarizes the pair categories.

**Table 1** Categories of code pairs used to construct the s.

| Category | Equivalence | Examples |
|---|---|---|
| Intra-language | Equivalent | JAVA_Pass1 vs. JAVA_Pass2; CPP_Pass1 vs. CPP_Pass2; PYTHON3_Pass1 vs. PYTHON3_Pass2 |
| Intra-language | Non-equivalent | JAVA_Pass1 vs. JAVA_Fail; CPP_Pass1 vs. CPP_Fail; PYTHON3_Pass1 vs. PYTHON3_Fail |
| Inter-language | Equivalent | JAVA_Pass1 vs. PYTHON3_Pass1; JAVA_Pass1 vs. CPP_Pass1; CPP_Pass1 vs. PYTHON3_Pass1 |
| Inter-language | Non-equivalent | JAVA_Fail vs. CPP_Pass1; JAVA_Fail vs. PYTHON3_Pass1; CPP_Fail vs. JAVA_Pass1; CPP_Fail vs. PYTHON3_Pass1; PYTHON3_Fail vs. JAVA_Pass1; PYTHON3_Fail vs. CPP_Pass1 |

## 2.2 Experiment Setup

This section describes the datasets, models, and experimental settings used in our evaluation.

**Baseline Benchmarks.** We consider two widely used benchmarks for code functional equivalence: EquiBench [46] and SeqCoBench [21]. EquiBench consists of 2,400 program pairs across four languages and six categories (*DCE*, *CUDA*, *x86-64*, *OJ-A*, *OJ-V*, and *OJ-VA*). In this study, we focus on *OJ-A* and *OJ-V*, which contain Python programs derived from

competitive programming platforms. The distinction between them lies in their construction: *OJ-A* contains pairs of independently written human programs, whereas *OJ-V* includes pairs generated through variable renaming transformations [8]. Each subset includes 200 equivalent and 200 non-equivalent pairs. SeqCoBench is a Python-based benchmark composed of code pairs generated through 20 types of semantic-preserving (e.g., Function/identifier renaming and Literal/value substitutions) and semantic-altering transformations (e.g., logic-changing operator flips and subtle semantic perturbations intended to preserve lexical similarity).

Since our work relies on running language models, which entail computational costs (for open-weight models) and monetary costs (for proprietary models), we evaluate on a subset of instances from the PolyHuman and SeqCoBench datasets. For SeqCoBench, we randomly sampled 500 instances. For PolyHuman, we used the first 500 instances as ordered in the dataset, which is not sorted by difficulty, model performance, or any other property. For EquiBench, we used all 800 instances (400 OJ-A + 400 OJ-V). Table 2 summarizes key statistics for EquiBench, SeqCoBench, and PolyHuman instances used in our study.

**Table 2** Dataset statistics comparison across EquiBench, SeqCoBench, and PolyHuman.

| Category | Metric | EquiBench | | SeqCoBench | PolyHuman | | |
|---|---|---|---|---|---|---|---|
| | | OJ-A | OJ-V | Sampled Subset | Each (15 total) | | |
| Language | | Python | Python | Python | CPP | Java | Python |
| Pairs | Equal | 200 | 200 | 250 | 500 | 500 | 500 |
| | Not Equal | 200 | 200 | 250 | 500 | 500 | 500 |
| Lines of Code | Min | 3 | 2 | 2 | 1 | 1 | 1 |
| | Max | 3,403 | 4,087 | 50 | 1,233 | 1,423 | 1,042 |
| | Avg. | 82 | 70 | 7.79 | 48.52 | 109.88 | 34.78 |

EquiBench (*OJ-A* and *OJ-V*) and SeqCoBench are balanced, Python-only benchmarks. Each EquiBench subset contains 200 pairs per label, with average LOC of 82 and 70, respectively. From SeqCoBench's balanced pool of 1,860 pairs per label, we sample 250 per label (average LOC: 7.79 in Table 2). PolyHuman spans CPP, Java, and Python through 15 label-homogeneous sub-tasks, each containing 500 pairs from the same 500 sampled problems (of 5,035 total); six sub-tasks are equivalent and nine non-equivalent (Table 1). Average LOC is 48.52, 109.88, and 34.78 for CPP, Java, and Python, respectively, consistent with known differences in language verbosity [29].

**Evaluated LLMs.** We evaluate nine language models shown in Table 3. These models were selected to cover both proprietary and open-source architectures with varying sizes and capabilities, enabling a comprehensive comparison of performance across different model families. All experiments are conducted using deterministic decoding (temperature = 0) to ensure reproducibility, except for GPT-o4-mini, whose temperature cannot be set.

**Prompting Strategy.** We adopt a consistent prompting strategy across all models and datasets to ensure fair comparison. For each code pair, a single prompt is issued to the model, containing the two programs to be evaluated. In both settings (i.e., *intra-language* and *inter-language*), the task remains identical; the model is asked to determine whether the two programs are functionally equivalent. The same prompt template is applied across EquiBench and PolyHuman; SeqCoBench does not include a problem description.

The prompt follows a zero-shot format and explicitly instructs the model to reason about program behavior rather than relying on superficial similarity. To reduce ambiguity and enforce consistent outputs, we constrain model responses to a binary decision ( *Yes* or *No*).

**Error Analysis.** To understand model failure modes, we conduct both quantitative and qualitative analyses of incorrect predictions. We examine error distributions (e.g., false positives vs. false negatives), analyze error rates across programming languages, and identify recurring patterns in misclassified pairs. Furthermore, we conduct a fine-grained comparative analysis on a curated set of challenging instances (i.e., those on which GPT-o4-mini repeatedly produces incorrect predictions). In these instances, we compare the behavior of GPT-o4-mini, Gemini-3-Flash, and Claude-Opus-4.7 to characterize where and why models diverge, uncovering model-specific failure modes such as premature conclusions and knowledge gaps.

# 3 Results and Discussion

## 3.1 LLM Performance for Same Programming Language Pairs ($RQ_1$)

**$RQ_1$** compares EquiBench [46] (*OJ-A* and *OJ-V*), SeqCoBench [21], and PolyHuman intra-language pairs using the common models, prompt, and accuracy metric described in Section 2.2. This unified evaluation bridges gaps in prior studies: EquiBench does not include code-specialized LLMs, while SeqCoBench does not evaluate closed-source, proprietary models. By standardizing both models and metrics, we enable a more consistent and comprehensive comparison across benchmarks. We additionally inspect label-specific prediction rates to identify systematic decision biases. Table 3 shows the LLMs' accuracy on the baselines (EquiBench and SeqCoBench) and intra-language instances from PolyHuman.

**Table 3** Model accuracy across baseline datasets and PolyHuman intra-language tasks.

| Model | Baselines | | | PolyHuman (Intra-language) | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | EquiBench | | SeqCoBench | Pass vs Pass | | | Pass vs Fail | | |
| | OJ-V | OJ-A | | CPP | Java | Python | CPP | Java | Python |
| GPT-o4-mini | 0.91 | 0.82 | 0.97 | 0.83 | 0.84 | 0.80 | 0.83 | 0.89 | 0.93 |
| GPT-OSS-20B | 0.89 | 0.74 | 0.95 | 0.59 | 0.62 | 0.66 | 0.91 | 0.94 | 0.93 |
| Llama-3.1-8B-Instruct | 0.54 | 0.54 | 0.84 | 0.98 | 0.98 | 0.98 | 0.05 | 0.04 | 0.07 |
| Llama-3.2-3B-Instruct | 0.52 | 0.53 | 0.66 | 0.54 | 0.44 | 0.78 | 0.53 | 0.66 | 0.28 |
| Mistral-7B-Instruct-v0.3 | 0.51 | 0.51 | 0.50 | 1.00 | 1.00 | 1.00 | 0.03 | 0.02 | 0.02 |
| Qwen2.5-Coder-7B-Instruct | 0.67 | 0.64 | 0.89 | 0.66 | 0.75 | 0.66 | 0.54 | 0.40 | 0.54 |
| Qwen2.5-Coder-14B-Instruct | 0.74 | 0.71 | 0.87 | 0.60 | 0.56 | 0.50 | 0.65 | 0.66 | 0.71 |
| CodeLlama-7B | 0.57 | 0.54 | 0.77 | 0.98 | 0.99 | 0.96 | 0.03 | 0.01 | 0.06 |
| CodeLlama-13B | 0.57 | 0.54 | 0.75 | 0.31 | 0.53 | 0.30 | 0.74 | 0.52 | 0.76 |
| **Average** | 0.66 | 0.62 | 0.80 | 0.72 | 0.75 | 0.74 | 0.48 | 0.46 | 0.48 |

*Note: Each cell reports the accuracy of pairs in the same programming language.*

**Bias-Induced Accuracy Illusion in Models.** We observe that several LLMs exhibit strong label prediction bias in code functional equivalence tasks. Although their accuracy on EquiBench [46] is often close to 50%, this does not indicate random behavior. Instead, models tend to collapse into near-constant predictions (e.g., predominantly predicting *Yes* or *No*). Because EquiBench is balanced (50/50), such biased behavior can produce accuracy close to random guessing, creating an illusion of reasonable performance. Using PolyHuman, we uncover clear and systematic biases across models. For instance, Llama-based models and Qwen2.5-Coder tend to predict *non-equivalence*, whereas Mistral-7B-Instruct-v0.3 shows a tendency toward *equivalence*. This bias persists even in stronger models. For example, specifically in Python, GPT-o4-mini achieves only 0.80 accuracy on *Python Pass vs. Pass* pairs (where both code snippets are correct and equivalent), but 0.93 on *Python Pass vs. Fail* (where one snippet is correct and the other is faulty/non-equivalent). This discrepancy

indicates that the model is biased toward predicting non-equivalence, particularly within the Python language. This bias is particularly pronounced for GPT-OSS-20B across all three programming languages.

> **Finding 1:** Across the studied LLMs, each model exhibits its own systematic bias in equivalence judgments, consistently skewing toward either false positives or false negatives rather than erring symmetrically.

**Human-written code equivalence tasks were more challenging for GPT-o4-mini.** Using GPT-o4-mini as a representative baseline [46], we observe a consistent performance decline as evaluation benchmarks shift from synthetic to human-written programs, reflecting the impact of increasing code realism. The model achieves near-perfect accuracy on synthetic datasets like SeqCoBench (0.97; Avg. LOC: 7.79) and high accuracy on OJ-V (0.91; Avg. LOC: 70), where equivalence is derived from simple variable renaming.

In contrast, performance decreases substantially on benchmarks with independently written implementations: OJ-A (0.82; Avg. LOC: 82) and PolyHuman's Python subset (0.87; Avg. LOC: 34.78), kept Python-only here for a like-for-like comparison with the other Python-based baselines. Furthermore, the performance on PolyHuman's Python pairs reveals a distinct systematic bias: while the model reliably detects non-equivalence (*Pass vs. Fail*, 0.93 accuracy), it struggles to recognize equivalence between structurally diverse implementations (*Pass vs. Pass*, 0.80 accuracy).

> **Finding 2:** For GPT-o4-mini, accuracy is high on synthetic datasets but drops sharply on human-written code, suggesting that independently written implementations introduce greater structural diversity, making equivalence detection more difficult. GPT-o4-mini and GPT-OSS-20B also tend to detect non-equivalent code more reliably than truly equivalent solutions with different implementations; averaged across all evaluated models, however, the opposite pattern holds (Pass-Pass $\approx$ 0.72–0.75 vs. Pass-Fail $\approx$ 0.46–0.48; Table 3), reflecting the over-acceptance bias exhibited by several other models.

## 3.2 LLM Performance for Different Programming Language Pairs ($RQ_2$)

To answer $\mathbf{RQ_2}$, we analyze how LLM performance varies when models judge functional equivalence across different programming languages. While in $RQ_1$ we focus on intra-language comparisons, in $RQ_2$ we evaluate inter-language pairs from PolyHuman, covering both equivalent and non-equivalent cases. With this analysis, we quantify performance differences across language combinations and examine whether specific languages or pair types are associated with systematic prediction biases. Table 4 reports the LLMs' accuracy across inter-language pairs. The first group of columns represents equivalent pairs, while the remaining columns represent non-equivalent pairs. In the latter, "F" marks the language associated with the failing case.

The results show that model behavior and performance vary across language pairs. To characterize these differences, we computed a decision gap for each LLM and programming language as $Gap = AccNonEq - AccEq$, where $AccEq$ and $AccNonEq$ represent the average accuracies on equivalent and non-equivalent pairs involving that language, respectively. A positive gap indicates a tendency to over-reject equivalence, whereas a negative gap suggests

**Table 4** Accuracy of functional equivalence detection across inter-language code pairs.

| Model | Equivalent pairs (Pass–Pass) | | | Non-equivalent pairs (Pass–Fail) | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | CPP ↔ Java | Java ↔ Python | Python ↔ CPP | Java(F) ↔ CPP | Java(F) ↔ Python | CPP(F) ↔ Java | CPP(F) ↔ Python | Python(F) ↔ Java | Python(F) ↔ CPP |
| GPT-o4-mini | 0.85 | 0.82 | 0.81 | 0.93 | 0.90 | 0.89 | 0.87 | 0.92 | 0.92 |
| GPT-OSS-20B | 0.63 | 0.62 | 0.64 | 0.92 | 0.91 | 0.88 | 0.86 | 0.90 | 0.92 |
| Llama-3.1-8B-Instruct | 1.00 | 0.99 | 0.99 | 0.02 | 0.03 | 0.02 | 0.03 | 0.02 | 0.02 |
| Llama-3.2-3B-Instruct | 0.51 | 0.61 | 0.72 | 0.56 | 0.44 | 0.54 | 0.35 | 0.53 | 0.31 |
| Mistral-7B-Instruct-v0.3 | 1.00 | 1.00 | 1.00 | 0.01 | 0.01 | 0.01 | 0.01 | 0.01 | 0.02 |
| Qwen2.5-Coder-7B-Instruct | 0.80 | 0.63 | 0.67 | 0.38 | 0.47 | 0.31 | 0.48 | 0.30 | 0.43 |
| Qwen2.5-Coder-14B-Instruct | 0.62 | 0.55 | 0.53 | 0.55 | 0.60 | 0.58 | 0.62 | 0.63 | 0.60 |
| CodeLlama-7B | 0.99 | 0.97 | 0.98 | 0.03 | 0.04 | 0.01 | 0.05 | 0.02 | 0.02 |
| CodeLlama-13B | 0.48 | 0.30 | 0.22 | 0.67 | 0.73 | 0.59 | 0.81 | 0.64 | 0.78 |

a tendency to over-accept equivalence. Table 5 presents the bias gaps, with colors to highlight the direction: red indicates a bias toward non-equivalence (positive gap), blue indicates a bias toward equivalence (negative gap), and gray represents near-balanced behavior.

**Table 5** Model-level decision gap across equivalent and non-equivalent inter-language pairs.

| Model | CPP | | | Java | | | Python | | |
|---|---|---|---|---|---|---|---|---|---|
| | AccEq | AccNonEq | Gap | AccEq | AccNonEq | Gap | AccEq | AccNonEq | Gap |
| GPT-o4-mini | 0.830 | 0.902 | 0.072 | 0.835 | 0.910 | 0.075 | 0.815 | 0.902 | 0.088 |
| GPT-OSS-20B | 0.635 | 0.895 | 0.260 | 0.625 | 0.902 | 0.277 | 0.630 | 0.898 | 0.267 |
| Llama-3.1-8B-Instruct | 0.995 | 0.023 | -0.972 | 0.995 | 0.023 | -0.972 | 0.990 | 0.025 | -0.965 |
| Llama-3.2-3B-Instruct | 0.615 | 0.440 | -0.175 | 0.560 | 0.518 | -0.042 | 0.665 | 0.408 | -0.258 |
| Mistral-7B-Instruct-v0.3 | 1.000 | 0.012 | -0.988 | 1.000 | 0.010 | -0.990 | 1.000 | 0.012 | -0.988 |
| Qwen2.5-Coder-7B-Instruct | 0.735 | 0.400 | -0.335 | 0.715 | 0.365 | -0.350 | 0.650 | 0.420 | -0.230 |
| Qwen2.5-Coder-14B-Instruct | 0.575 | 0.588 | 0.013 | 0.585 | 0.590 | 0.005 | 0.540 | 0.612 | 0.073 |
| CodeLlama-7B | 0.985 | 0.028 | -0.958 | 0.980 | 0.025 | -0.955 | 0.975 | 0.032 | -0.942 |
| CodeLlama-13B | 0.350 | 0.713 | 0.363 | 0.390 | 0.658 | 0.267 | 0.260 | 0.740 | 0.480 |

We observe three distinct decision profiles based on the performance gap between equivalent and non-equivalent pairs. First, **over-rejection of equivalence** is exhibited by GPT-o4-mini, GPT-OSS-20B, Qwen2.5-Coder-14B-Instruct, and CodeLlama-13B, all showing positive gaps across languages. This bias is strongest in CodeLlama-13B, particularly for Python pairs ($Gap = 0.480$, $AccEq = 0.260$, $AccNonEq = 0.740$). Second, **extreme over-acceptance** is found in Llama-3.1-8B-Instruct, Mistral-7B-Instruct-v0.3, and CodeLlama-7B, which present negative gaps. Notably, Mistral-7B-Instruct-v0.3 achieves $AccEq = 1.000$ across all languages but fails entirely on non-equivalent pairs. Third, **mild over-acceptance** is observed in Llama-3.2-3B-Instruct and Qwen2.5-Coder-7B-Instruct, which display intermediate negative gaps.

Among the evaluated models, Qwen2.5-Coder-14B-Instruct shows the most balanced gap. Its gaps remain close to zero for CPP ($Gap = 0.013$) and Java ($Gap = 0.005$), with only a small positive gap for Python ($Gap = 0.073$). This does not imply the highest absolute accuracy, but it suggests lower decision bias compared with models showing extreme positive or negative gaps. GPT-o4-mini is also competitive due to its relatively high accuracy on both equivalent and non-equivalent pairs, although its consistently positive gaps indicate a more conservative profile.

Additionally, Wilcoxon signed-rank tests [47] comparing $AccEq$ and $AccNonEq$ within each language find no statistically significant difference (CPP: $W = 13.0$, $p = 0.30$; Java: $W = 13.0$, $p = 0.30$; Python: $W = 14.0$, $p = 0.36$; $n = 9$). A Friedman test [10] comparing bias gaps ($Gap = AccNonEq - AccEq$) across languages is borderline ($\chi^2 = 5.35$, $df = 2$, $p = 0.069$, Kendall's $W = 0.297$), suggesting a possible but statistically inconclusive language effect. We therefore do not claim that language plays no role; rather, CPP, Java, and Python

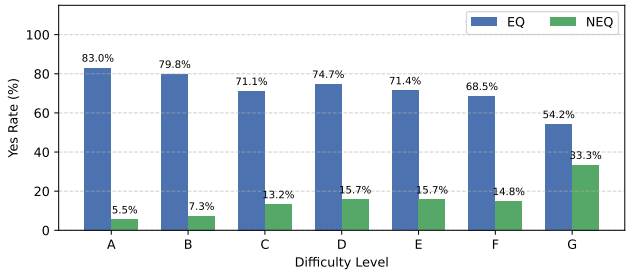

**Figure 1** GPT-o4-mini's *Yes* response rate across problem difficulty levels.

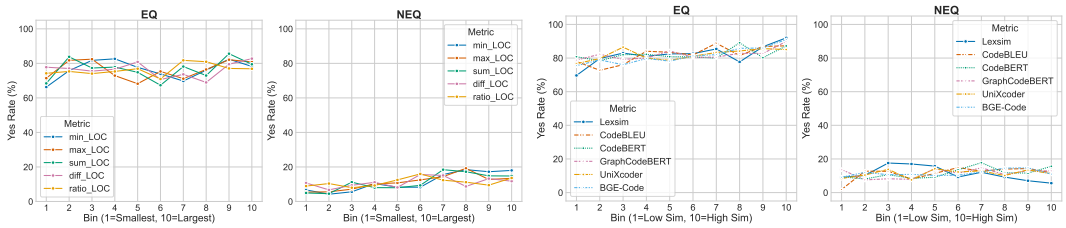
performance consistently track each model's own decision tendency more closely than any common language pattern, and the wide variation in gap magnitude across models (from $-0.988$ for Mistral-7B-Instruct-v0.3 to $+0.363$ for CodeLlama-13B in CPP) points to model identity as the more salient factor. This aggregate, cross-model test ($n = 9$) has limited power and does not rule out the model-specific Python effect found in $RQ_3$'s larger-sample regression ($\beta = -0.450$, $p = 0.001$; Table 6); language thus appears secondary and model-specific rather than a uniformly shared driver.

Practically, these results show that model-specific differences were larger than the common language effect in our evaluated set. For instance, Mistral-7B-Instruct-v0.3, Llama-3.1-8B-Instruct, and CodeLlama-7B exhibit high false-equivalence rates, whereas CodeLlama-13B over-rejects equivalence. To mitigate these complementary biases, ensemble-based judging strategies offer a promising solution [51]. This aligns with recent findings that LLM capabilities vary significantly across programming contexts and tasks [6, 15, 48, 50].



**Finding 3:** The studied LLMs do not behave equally in cross-language equivalence judgments: some tend to over-reject equivalence, while others tend to over-accept it. Among the models evaluated, Qwen2.5-Coder-14B-Instruct shows the most balanced behavior, while GPT-o4-mini offers the best overall trade-off. These results show that model choice matters: highly biased models should not be used alone, and combining complementary models may lead to more reliable judgments.

## 3.3 Factors Influencing the Best-Performing Model's Predictions ($RQ_3$)

To answer $\mathbf{RQ_3}$, we conduct an in-depth behavioral analysis of GPT-o4-mini (the top-performing model in $RQ_2$) to evaluate how code- and task-level features from PolyHuman influence its functional equivalence judgments. Specifically, we extract three categories of features: (1) problem difficulty (levels A to G); (2) code length (LOC); and (3) superficial similarity signals, including lexical similarity (*Lexsim*) [32], CodeBLEU [33], and embedding-based metrics from CodeBERT, GraphCodeBERT, UniXcoder, and BGE-Code [7, 17]. We then employ Spearman's $\rho$ [41] to assess the correlation between these similarity signals and model predictions. Finally, we construct a binary logistic regression model to quantify the explanatory power of these combined factors on the model's classification outcomes.

**Impact of Problem Difficulty.** Figure 1 shows the best-performing model's *Yes* response rate across difficulty levels (A–G) for equivalent (*Pass1 vs. Pass2*) and non-equivalent pairs (*Pass1 vs. Fail*). As difficulty increases, the *Yes* rate drops from 83.0% to 54.2% for equivalent pairs, but rises from 5.5% to 33.3% for non-equivalent ones. This indicates that higher difficulty degrades the model's discriminative power, increasing both false negatives and false positives, rather than merely making it more conservative.

**Finding 4:** For GPT-o4-mini, problem difficulty reduces the model's ability to distinguish equivalent from non-equivalent pairs: as difficulty increases, the model misses more true equivalences while also producing more false equivalence judgments.

**(a)** Code length. **(b)** Code similarity.

**Figure 2** GPT-o4-mini's *Yes* response rate across code length and similarity bins. Left panels report equivalent pairs (EQ), and right panels report non-equivalent pairs (NEQ).

**Impact of Code Length.** Figure 2a shows GPT-o4-mini's *Yes* response rate across LOC-based complexity bins. We consider five LOC-related measures: minimum LOC, maximum LOC, summed LOC, absolute LOC difference, and LOC ratio between the two programs. These measures allow us to distinguish the effect of overall input size from the effect of size imbalance between paired implementations.

Overall, we observed that code length affects NEQ pairs more clearly than EQ pairs. For EQ pairs, we observe high and stable *Yes* rates across LOC bins, suggesting that larger code pairs do not substantially hinder equivalence recognition. For NEQ pairs, however, we observe that the *Yes* rate increases in larger bins, indicating more false equivalence judgments as input size grows. This trend is stronger for *min_LOC*, *max_LOC*, and *sum_LOC* than for *diff_LOC* and *ratio_LOC*, suggesting that input size matters more than size imbalance.

**Finding 5:** Code length mainly affects non-equivalent pairs: as overall input size increases, the model becomes more likely to produce false equivalence judgments.

**Impact of Similarity Signals.** Figure 2b illustrates the best-performing model's *Yes* response rate across similarity bins for lexical (Lexsim), structural (CodeBLEU), and embedding-based metrics (CodeBERT, GraphCodeBERT, UniXcoder, BGE-Code).

Similarity signals strongly correlate with correct *Yes* judgments for equivalent (EQ) pairs, led by CodeBLEU ($\rho = 0.87, p = 0.001$) and UniXcoder ($\rho = 0.84, p = 0.002$), followed by BGE-Code, Lexsim, and GraphCodeBERT (all $p < 0.05$). For non-equivalent (NEQ) pairs, although overall *Yes* rates remain low, higher similarity induces a shortcut-learning bias that increases false equivalences. This bias is driven by structural and semantic features like CodeBERT ($\rho = 0.76, p = 0.011$) and CodeBLEU ($\rho = 0.70, p = 0.025$), whereas textual overlap (Lexsim) shows no significant impact ($p = 0.138$). Thus, similarity acts as a double-edged sword: aiding EQ detection while masking subtle differences in NEQ pairs.

**Finding 6:** For GPT-o4-mini, similarity is associated with correctly identifying equivalent pairs, especially for CodeBLEU and UniXcoder. However, in NEQ pairs, CodeBERT and CodeBLEU are associated with more false equivalence predictions, indicating a residual similarity bias.

**Regression Analysis.** We model GPT-o4-mini's *Yes* predictions using logistic regression with problem difficulty, *sum_LOC*, CodeBLEU, programming language, ground-truth label (EQ vs. NEQ), and a difficulty × label interaction as predictors. We use *sum_LOC* as the representative size metric because alternative LOC measures (min, max, and sum) show consistent trends. Although *sum_LOC* and difficulty are moderately correlated across languages and implementation states (Spearman's $\rho \in [0.36, 0.42]$, Kendall's $\tau \in [0.29, 0.33]$), the association is not strong enough to indicate severe collinearity, supporting their inclusion as distinct predictors. Table 6 shows that the included factors account for substantial variation in the model's responses (Pseudo $R^2 = 0.429$; $n = 2{,}969$ of 3,000 nominal instances, after excluding 5 problems with missing difficulty labels and 1 unparsable response).

**Table 6** Logistic regression of factors associated with the model's *True* predictions.

| Predictor | $\beta$ | SE | $p$-value | Odds Ratio |
|---|---|---|---|---|
| Intercept | 1.791 | 0.110 | $< 0.001^{***}$ | 5.993 |
| Difficulty | -0.350 | 0.067 | $< 0.001^{***}$ | 0.705 |
| Difficulty × NEQ | 0.804 | 0.103 | $< 0.001^{***}$ | 2.234 |
| NEQ (vs. EQ) | -3.755 | 0.115 | $< 0.001^{***}$ | 0.023 |
| Java (vs. CPP) | -0.183 | 0.145 | 0.208 | 0.833 |
| Python (vs. CPP) | -0.450 | 0.134 | $0.001^{**}$ | 0.637 |
| CodeBLEU | 0.212 | 0.053 | $< 0.001^{***}$ | 1.236 |
| sum_LOC | 0.056 | 0.060 | 0.353 | 1.058 |
| Observations: 2969 | Pseudo $R^2$: 0.429 | | $^{**}p < 0.01$ | $^{***}p < 0.001$ |

As expected, the ground-truth label is the dominant predictor: NEQ pairs are much less likely to receive a *Yes* prediction than EQ pairs (OR = 0.023, $p < 0.001$), indicating that the model discriminates substantively. However, difficulty has a conditional effect. For EQ pairs, higher difficulty reduces the likelihood of a *Yes* prediction ($\beta = -0.350$, OR = 0.705, $p < 0.001$), suggesting more false non-equivalence judgments. For NEQ pairs, the positive difficulty × NEQ interaction ($\beta = 0.804$, OR = 2.234, $p < 0.001$) indicates the opposite tendency: harder non-equivalent cases are more likely to be incorrectly accepted as equivalent. Similarity remains an independent predictor even after controlling for label, difficulty, language, and code length. CodeBLEU significantly increases the odds of a *Yes* prediction ($\beta = 0.212$, OR = 1.236, $p < 0.001$), suggesting a residual reliance on surface or structural resemblance. In contrast, *sum_LOC* is not significant ($p = 0.353$), indicating that code length does not independently explain the model's decisions once the other factors are controlled. Language effects are also limited but not absent: Java does not differ significantly from CPP ($p = 0.208$), whereas Python is associated with fewer *Yes* predictions ($\beta = -0.450$, OR = 0.637, $p = 0.001$), suggesting more conservative behavior for Python pairs.

Overall, the regression results refine the previous finding. Code similarity matters, but it is not the only driver of LLM equivalence judgments. The model's decisions are shaped by the interaction between ground-truth equivalence and difficulty, residual similarity effects, and language-specific behavior, while code size has no significant independent effect.

**Finding 7:** For GPT-o4-mini, equivalence judgments are not explained by similarity alone: logistic regression shows that its predictions are mainly shaped by the ground-truth label, difficulty conditioned on equivalence status, CodeBLEU, and Python-specific conservativeness, while code length has no significant independent effect.

## 3.4 Why LLMs Fail to Judge Code Functional Equivalence ($RQ_4$)

To answer $\mathbf{RQ_4}$, we analyzed misclassified code pairs from GPT-o4-mini to uncover the root causes of LLM failures. Rather than relying solely on aggregate metrics, we investigated whether errors stemmed from systematic prediction biases, superficial similarities, language-specific misunderstandings, abstraction mismatches, or stochastic instability.

Given PolyHuman's scale, we adopted an incremental evaluation strategy guided by thematic saturation [12, 13]. Each pair was evaluated three times using majority voting, and we terminated manual error classification when 16 consecutive erroneous instances yielded no new error categories. In total, we evaluated 900 instances across 60 problems. GPT-o4-mini exhibited an instability rate of 18% (162 instances with inconsistent predictions across runs). For the manual thematic analysis, we focused on systematic errors (i.e., instances where the model failed in at least two of the three runs) and leveraged a Chain-of-Thought (CoT) prompt (presented below) to elicit and analyze the model's underlying reasoning.

**Prompt used for $RQ_4$ error analysis.**

```
We define functionally equivalent as:  two code snippets produce the same output for every possible
input.  They may be written in different programming languages; ignore stylistic or structural
differences and focus only on input-output behaviour.

Your task:  determine whether <code1> and <code2>, which are both intended to solve the problem
described in <Problem>, are functionally equivalent.

<Problem> {problem} </Problem>
<code1> {code1_numbered} </code1>
<code2> {code2_numbered} </code2>

Think step-by-step before giving your final answer.

Respond only with a JSON object using the following schema:
{
  "verdict": "Yes" | "No",
  "reasoning": "<step-by-step explanation>",
  "key_lines": {
    "code1": [<integer line numbers>],
    "code2": [<integer line numbers>]
  }
}
```

From the 900 evaluated instances, we identified 81 cases that met the systematic disagreement criterion and manually analyzed them. Table 7 summarizes their distribution by pair type, covering same-language and cross-language pairs with equal or different outcomes. When considering subtask opportunity bounds (360 equivalent vs. 540 non-equivalent pairs), false negatives occurred at a slightly higher rate than false positives (9.72% vs. 8.52%, corresponding to 35 FNs and 46 FPs). In terms of sample composition, cross-language comparisons accounted for 46 of the 81 analyzed failure instances.

**Table 7** Pair-type distribution of the 81 manually analyzed instances.

| *Same language, equal outcome* | | *Same language, different outcome* | | *Different language, equal outcome* | | *Different language, different outcome* | |
|---|---|---|---|---|---|---|---|
| **Pair** | **N** | **Pair** | **N** | **Pair** | **N** | **Pair** | **N** |
| Java Pass1 vs. Java Pass2 | 9 | Java Pass1 vs. Java Fail | 8 | CPP Pass1 vs. Java Pass1 | 6 | Java Fail vs. Python Pass1 | 9 |
| Python Pass1 vs. Python Pass2 | 4 | CPP Pass1 vs. CPP Fail | 6 | Python Pass1 vs. CPP Pass1 | 5 | CPP Fail vs. Java Pass1 | 7 |
| CPP Pass1 vs. CPP Pass2 | 6 | Python Pass1 vs. Python Fail | 2 | Java Pass1 vs. Python Pass1 | 5 | Java Fail vs. CPP Pass1 | 6 |
| | | | | | | CPP Fail vs. Python Pass1 | 3 |
| | | | | | | Python Fail vs. Java Pass1 | 3 |
| | | | | | | Python Fail vs. CPP Pass1 | 2 |

To examine whether these failures were specific to GPT-o4-mini or reflected broader limitations of current LLMs, we evaluated two additional models on the same 81 instances using the same CoT prompt. We found that 24 instances were misclassified by all three models, suggesting intrinsically difficult cases. However, several GPT-o4-mini failures were correctly resolved by Claude-Opus-4.7, Gemini-3-Flash, or both (19 resolved by both), indicating model-

specific differences. In addition, nine GPT-o4-mini failures were corrected after applying CoT prompting. We consider a misclassification corrected when CoT prompting produces predictions consistent with the ground truth across three independent runs.

**Finding 8:** Among the three models evaluated on the 81 disagreements, failures reflect both shared semantic reasoning limitations and model-specific weaknesses. While 24 instances were missed by all models, other GPT-o4-mini failures were correctly resolved by Claude-Opus-4.7, Gemini-3-Flash, or after applying CoT prompting. This suggests that some failures reflect insufficient reasoning depth rather than a complete lack of capability. However, CoT alone was not enough to ensure robust equivalence detection.

**Qualitative analysis of failure modes.** Overall, our analysis pipeline filter proceeded as follows: 900 initial instances → 162 unstable instances → 81 systematic disagreements → 9 corrected by CoT → 72 coded failure cases (55 genuine model failures and 17 ground-truth issues). To better understand why LLMs fail, we manually inspected the remaining 72 misclassified cases and identified recurrent (sub-)categories of failure modes. We organize these 72 cases into three top-level categories: *Knowledge Failure* (part of the 55 model failures), *Abstraction-Level Reasoning Failure* (part of the 55 model failures), and *LLM Judgment Is Actually Correct* (the 17 ground-truth issues). These categories capture different mechanisms behind apparent failures: incorrect knowledge assumptions, breakdowns across abstraction levels, and defensible disagreements with the ground truth. The complete qualitative analysis, including the full set of coded instances and examples, is available in our replication package [42].

We can observe that most cases fall under *Abstraction-Level Reasoning Failure* (38/72, 52.8%), especially *Implementation-Level Detail Error* (21/72, 29.2%). This suggests that LLMs often produce plausible explanations but fail to verify concrete details such as index correspondence, state updates, control-flow paths, or variable evolution. We describe each category and sub-category in detail as follows: figures show only the relevant code evidence and failure mechanisms, while LLM claims are discussed in the text.

**A. Knowledge Failure (17).** This category captures cases in which the LLM lacks or misapplies factual knowledge relevant to judging code functional equivalence, causing its reasoning to rest on incorrect foundations. Figure 3 illustrates the representative examples.

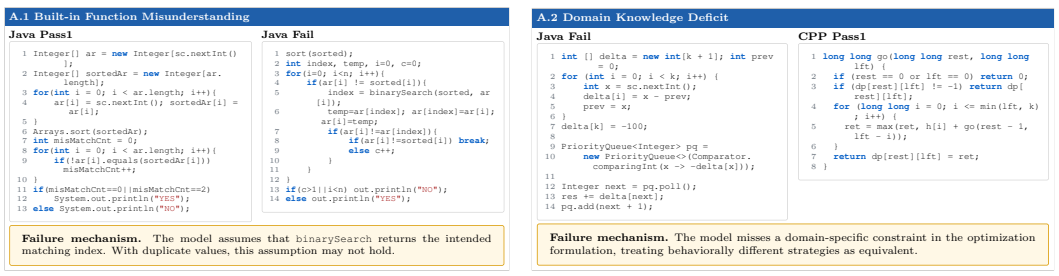


**Figure 3** Representative examples of knowledge failures.

**A.1 Language/Built-in Function Misunderstanding (11)** occurs when the LLM misinterprets the behavior of a programming language construct or built-in function. In *FP-row-19*, shown in Figure 3(A.1), the LLM claims that both snippets decide whether

an array can be sorted with at most one swap. However, its reasoning depends on the call to `binarySearch` in line 3. When duplicate elements are present, this call may return any matching index, not necessarily the index assumed by the model. As a result, the subsequent swap logic in lines 4–6 may not preserve the intended behavior.

- **A.2 Domain Knowledge Deficit (5)** captures cases where the model lacks the mathematical, algorithmic, or problem-specific knowledge to evaluate equivalence. In *FP-row-32*, shown in Figure 3(A.2), the LLM treats two optimization strategies as equivalent. However, the excerpt highlights a domain-specific adjustment in line 8, where `delta[k]` is set to `-100`. This value changes the optimization behavior, but the model overlooks its role and incorrectly assumes that the two strategies compute the same contribution.
- **A.3 Equivalence Criterion Confusion (1)** occurs when the LLM misinterprets what "functional equivalence" means in the context of this task. For example, it may treat passing all test cases on an online judge as sufficient evidence of functional equivalence or conflate semantic equivalence with functional equivalence.

**B. Abstraction-Level Reasoning Failure (38).** This category captures cases in which the LLM has relevant knowledge but fails while moving across levels of abstraction. The model may start from a plausible algorithmic interpretation, but the reasoning chain breaks before it correctly verifies the actual behavior of the two solutions. These failures are therefore not simply about whether the model recognizes the algorithm, but whether it can connect that recognition to a correct semantic and execution-level judgment. Figure 4 illustrates the representative examples.

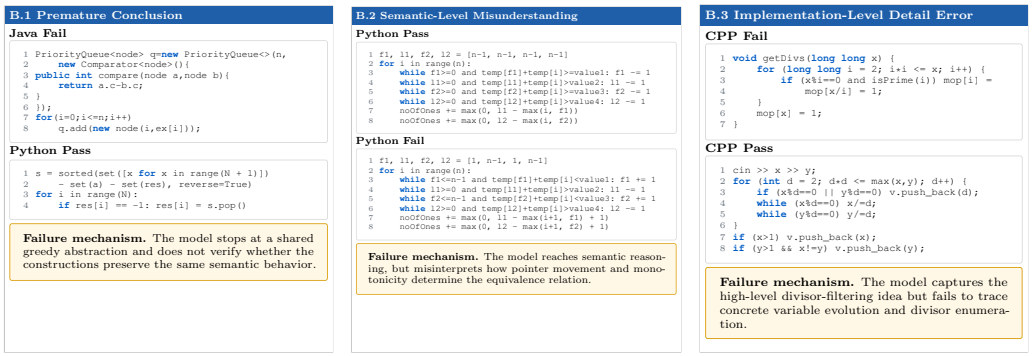

**Figure 4** Representative examples of abstraction-level reasoning failure.

- **B.1 Premature Conclusion (Pre-Semantic) (11)** occurs when the LLM stops at surface-level or algorithm-level similarity and concludes equivalence before performing a semantic comparison. In *FP-row-18*, shown in Figure 4(B.1), the LLM claims that both snippets implement the same greedy construction for preserving prefix MEX behavior. This claim is based on recognizing a priority-queue based selection in lines 1–7 of the first snippet and a set-based filling strategy in lines 1–3 of the second snippet. However, the model does not verify whether these two constructions preserve the same input-output behavior. The failure, therefore, occurs before a semantic comparison is performed.
- **B.2 Semantic-Level Misunderstanding (6)** occurs when the model reaches the semantic level but misinterprets the key behavioral property that determines equivalence. In *FP-row-13*, shown in Figure 4(B.2), the model correctly identifies pointer movement as relevant. The critical evidence appears in lines 3–6 of both snippets: in the first snippet,

pointers such as `f1` and `f2` move left, whereas in the second snippet they move right. The LLM interprets this directional difference as evidence of non-equivalence. However, its conclusion is based on an incorrect understanding of the monotonicity invariant governing the pair-counting logic. Thus, unlike B.1, the model does reason semantically, but the semantic interpretation is flawed.

- **B.3 Implementation-Level Detail Error (21)** occurs when the model captures the high-level intent but fails to verify concrete execution details. In *FP-row-6*, Figure 4(B.3), the LLM claims that both snippets enumerate candidate prime divisors and filter them across pairs. The key issue is in the concrete divisor extraction logic. In the first snippet, lines 2–4 add factors based on divisibility but do not update `x` by removing the factors already found. In contrast, the second snippet explicitly divides `x` and `y` inside the loops in lines 4–5, exposing remaining factors that may be added later in lines 7–8. The LLM overlooks this variable evolution, leading to an incorrect equivalence judgment.

**C. LLM Judgment Is Actually Correct (17).** This category captures cases in which the LLM's judgment is in fact correct; the disagreement between ground-truth and GPT-o4-mini prediction lies in the data construction or validation rather than in the LLM's reasoning. This category encompasses two sub-cases: either a counterexample exists that contradicts the ground-truth label, confirmed via manual execution of test cases; or the problem admits multiple valid outputs, such that the two code snippets are genuinely not functionally equivalent, representing an internal threat rather than an LLM's reasoning failure.

- **C.1 LLM Identifies a Genuine Counterexample (4)** refers to cases where the LLM successfully identifies a test case that produces different outputs from the two code snippets, or correctly recognizes a potential runtime error scenario (e.g., behavioral divergence caused by hash collisions).
- **C.2 Problem Has More Than One Valid Solution (13)** refers to cases where the original problem inherently admits multiple correct implementations. The LLM identifies an alternative valid solution beyond the reference answer, making its "not equivalent" judgment logically defensible.

**Finding 9:** Among the GPT-o4-mini errors analyzed qualitatively, the primary bottleneck is an inability to accurately trace microscopic dynamic execution paths and sequential variable evolution. Of the two additional models evaluated on these cases, Opus alone resolved 17 instances (14 Abstraction-Level Reasoning Failure) and Gemini alone resolved 12 (6 Knowledge Failure), suggesting Opus is comparatively stronger at abstraction-level reasoning and Gemini at knowledge-related cases. Additionally, we identified at least 17 ground-truth labeling flaws among the analyzed failure cases (1.89% of the total 900 instances).[1]

## 4 Actionable Implications

Our analysis of GPT-o4-mini shows that the model does not rely solely on surface-level code similarity when judging functional equivalence; instead, its predictions are shaped by a structured combination of factors operating at different levels of abstraction (quantitatively,

[1] Note that this represents a lower bound on dataset label noise, as manual inspection was restricted to targeted, non-random failure instances where the model disagreed with the ground truth.

these factors yield a Pseudo $R^2 = 0.429$, with ground-truth equivalence dominating over code similarity). However, these very factors also give rise to systematic failure patterns that manifest at distinct levels of abstraction. Based on these findings, we derive several actionable implications for researchers and practitioners.

**Implications for LLM Researchers.** Our findings reveal that GPT-o4-mini's failures stem primarily from deficient implementation-level comprehension and fragile domain knowledge, rather than mere surface similarity. However, surface-matching shortcuts persist: even when controlling for difficulty and ground-truth labels, GPT-o4-mini relies on code similarity to a small but statistically robust degree ($\beta = 0.212$, $p < 0.001$), suggesting that future work must prioritize fine-grained semantic modeling over generalized abstract reasoning. Crucially, the model breaks down consistently on three kinds of inputs: (1) tangled control flow (loops + branching), (2) structurally diverse human-written code, and (3) cross-language pairs, where a language-specific bias is evident as the model exhibits pronounced caution exclusively on Python ($\beta = -0.450$, OR $= 0.637$, $p = 0.001$) while CPP and Java remain indistinguishable ($p = 0.208$). Furthermore, average accuracy masks a severe asymmetric vulnerability driven by a powerful difficulty×equivalence interaction ($\beta = 0.804$, $p < 0.001$), meaning that on harder problems the model increasingly misclassifies non-equivalent code as equivalent. Therefore, future benchmarks should supplement aggregate accuracy with stratified metrics to prevent these asymmetric failures from remaining invisible.

**Implications for Agent and Multi-Agent System Researchers.** When LLMs (GPT-o4-mini, Claude-Opus-4.7, Gemini-3-Flash) encounter specific layer gaps, their capacity for self-correction is substantially diminished, suggesting that human-in-the-loop validation may be valuable in high-risk settings [22]. Beyond individual agents, our analysis reveals complementary capability profiles across models: Claude-Opus-4.7 performed better on abstraction and intermediate reasoning, while Gemini-3-Flash shows a comparative advantage on cases requiring domain- or language-specific factual knowledge. Thus, multi-agent system designers can exploit this complementarity by assigning reasoning-intensive stages to the former and knowledge verification to the latter, enabling more effective model specialization.

**Implications for LLM-Assisted Programming Practitioners.** Practitioners should exercise heightened scrutiny when deploying models for code involving complex loops, iterations, and multi-layered conditional logic, as model reliability degrades significantly under these constructs. Furthermore, cross-run analysis indicates that isolated correct outputs reflect inconsistent capability rather than robust competence.

## 5 Threats to Validity

**Internal Validity.** PolyHuman labels two solutions passing all online judge test cases as functionally equivalent. However, test suites may not achieve full input coverage, and passing programs may still differ on unseen edge-case inputs. This threat is evidenced by Category C in our manual analysis, which accounts for 17 out of 900 instances (1.9%), though its overall impact remains limited. A further threat is data contamination: CodeContests is public and likely present in the training data of the evaluated models, so if anything this would bias results toward overestimating model performance, making our finding of poor functional-equivalence judgment a conservative estimate.

**External Validity.** PolyHuman is constructed from competitive programming platforms, where code tends to be algorithm-intensive and performance-oriented, which may not fully generalize to real-world code. Regarding model selection, our evaluation is primarily limited to open-source models in the 3B–20B parameter range, plus GPT-o4-mini due to resource constraints. However, the additional evaluation of Claude-Opus-4.7 and Gemini-3-Flash on the 81 manually analyzed instances in RQ4 partially mitigates this threat.

**Construct Validity.** Although accuracy is used as the primary metric for cross-dataset comparability, we mitigate its limitations by separately analyzing Pass vs. Pass and Pass vs. Fail pairs, which is equivalent to reporting True Positive Rate and True Negative Rate independently. This decomposition provides a more informative view of model behavior under prediction bias than aggregate accuracy alone.

**Conclusion Validity.** The manual classification of 81 failure cases into categories A, B, and C involves inherent subjectivity, as category boundaries depend on researcher interpretation. To mitigate this threat, all classifications were independently verified by the second author, disagreements resolved through discussion. We acknowledge that no formal inter-rater reliability measure (e.g., Cohen's Kappa) was computed, which limits the reproducibility of categorical assignments. All coded instances are made available in our replication package.

## 6 Related Work

**LLMs for Code Understanding.** LLMs have achieved strong performance across code generation, summarization, and translation [16], raising expectations that they can reason about program semantics like human developers. Yet a growing line of empirical SE research finds their performance highly inconsistent across tasks and settings [19, 23, 37]. Our work extends this critical evaluation to a capability not yet examined under realistic conditions: judging code functional equivalence.

**Functional Equivalence and Clone Detection.** Functional equivalence underpins refactoring, migration, and clone detection [5, 9, 14, 35]. Two recent benchmarks for LLMs target those tasks: EquiBench [46] and SeqCoBench [21]. While valuable, both construct non-equivalent pairs via controlled transformations (OJ-V for EquiBench), so the equivalent/non-equivalent distinction is often local and can be solved by similarity shortcuts rather than semantic reasoning. This mirrors the similarity-driven tendency in clone detection [36, 43], meaning high benchmark accuracy may not reflect true semantic understanding.

**Cross-Language Code Analysis.** Similarity shortcuts fail most clearly across languages, where equivalent programs differ drastically in syntax and idiom [24, 28]. LLMs are known to introduce bugs in cross-language translation [27] and struggle with cross-lingual clone detection [24], but these efforts address clone detection or translation rather than strict functional equivalence, and rely on synthetic data. Whether LLMs can reliably judge cross-language functional equivalence on human-written code remains open.

**Positioning.** We differ from prior work in three ways: (1) PolyHuman uses independently written human solutions rather than synthetic pairs; (2) we conduct the first systematic evaluation of cross-language functional equivalence judgment; and (3) beyond aggregate accuracy, we provide a mechanistic failure analysis across abstraction levels and discuss complementary-model strategies [51].

## 7 Conclusion

This paper investigates LLMs' ability to judge functional equivalence across programming languages. To address the issue that single-language and synthetic benchmarks overestimate LLMs' semantic understanding, we introduce PolyHuman, a novel dataset of human-written programs in CPP, Java, and Python.

Our main contributions are twofold. Quantitatively, we observe a sharp decline in performance on human-written code. We find that decision biases appear more strongly model-dependent than uniformly language-driven, suggesting that model selection and ensembling are more critical than language choice. Furthermore, while superficial similarity exerts a secondary influence, errors are highly difficulty-conditional: on complex problems, GPT-o4-mini increasingly misclassifies non-equivalent code as equivalent. Qualitatively, we identify two major classes of model failures, namely knowledge failures and abstraction-level reasoning failures, with the latter spanning presemantic, semantic, and implementation-level reasoning. GPT-o4-mini demonstrates sound reasoning across many problems, albeit with some instability. We also identified 17 ground-truth/data issues among the analyzed cases; because these cases were selected based on model disagreement, this proportion should not be interpreted as an estimate of the dataset's overall label-error rate.

Future work should investigate strategies to improve LLM semantic reasoning for code functional equivalence, particularly in cross-language and human-written scenarios. Promising directions include developing benchmarks with more diverse real-world programs, reducing reliance on superficial similarity signals, and improving reasoning stability across runs. Future studies may also explore ensemble and multi-agent approaches that combine complementary model strengths, as well as techniques for better tracing of execution paths and variable evolution in complex control-flow structures.

# Green AI: Cost of LLM-Based Code Completion

**Negar Alizadeh**

**Nishant Saurabh**
Utrecht University, Utrecht, The Netherlands

**Fernando Castor**
University of Twente, Enschede, The Netherlands

## Abstract

**Background.** Code completion is one of the most widely used applications of large language models (LLMs) in software development. In addition to proprietary coding assistants, powerful open-weight LLMs are increasingly adopted for locally deployed code completion systems, partly motivated by privacy concerns. Despite advances in LLM accuracy, the energy cost of inference in code completion tasks remains underexplored, particularly under large-context workloads and across programming languages.

**Aims.** This study investigates the trade-off between accuracy and energy consumption in LLM-based code completion and analyzes how workload characteristics, context size, and model scale influence inference energy usage.

**Method.** We evaluate 25 open-weight LLMs on two complementary code completion workloads: repository-level next-line completion (left-to-right prediction) with varying context sizes on the RepoBench dataset, and fill-in-the-middle (FIM) code completion across Python, Java, and Rust on the McEval dataset. We further analyze the influence of input tokens, output tokens, model size, and their interactions on energy consumption using correlation analysis and cluster-robust linear regression models.

**Results.** Our findings show that the dominant drivers of energy consumption depend strongly on the structure of the completion task. In RepoBench, energy consumption is primarily influenced by input context size and its interaction with model scale, whereas in McEval, output generation and its interaction with active parameter count become the dominant factors. We further observe that output generation is substantially more energy-intensive per token than prompt processing. Across both benchmarks, smaller and heavily quantized models frequently achieve Pareto-optimal trade-offs, often providing accuracy comparable to larger FP16 models while consuming substantially less energy.

**Conclusions.** The energy behavior of LLM inference in software engineering tasks depends strongly on workload structure, context length, and model scale. Our results suggest that increasing model size or context length does not necessarily lead to proportionally better completion quality, while quantization can substantially improve energy efficiency with limited accuracy degradation. These findings contribute toward more energy-aware deployment strategies for sustainable AI-assisted software development.

## 1 Introduction

Since the emergence of large language models (LLMs) and their rapid advancement in software development tasks, these models have become increasingly popular among software companies and individual programmers, with 84% of developers using or planning to use AI tools [51]. Furthermore, numerous IDEs now incorporate LLM-based code completion tools (e.g., GitHub Copilot, JetBrains AI Assistant, Gemini Code Assist, Claude Code, and Tabnine) and many AI-powered coding environments such as Cursor and Devin are emerging.

LLMs are known to be energy-intensive. Prior work has examined the energy consumption of language models [37, 45] with earlier work focusing mostly on the training phase [37, 38] and more recent papers also investigating the costs of inference [1, 18, 47, 56]. Training is orders of magnitude more expensive, but inference grows with scale and can represent the majority of the energy cost of LLMs for long-term energy use. Prior measurements report that approximately three-fifths of ML energy use is attributed to inference and two-fifths to training [45]. Despite this, most previous work has focused on natural language tasks, with few studies investigating the energy efficiency of LLMs in software development. Existing studies of inference energy indicate that energy usage varies across tasks [3, 38]. This highlights the importance of evaluating LLM performance and energy efficiency not only for natural language tasks but also for other domains such as programming. Even within coding tasks, performance and energy consumption may vary across programming languages due to differences in syntax complexity, ecosystem maturity, and training data availability. For example, Python's syntax is less verbose than Java's, with the former being dynamically typed and the latter statically typed. Furthermore, Rust has a unique type system among mainstream programming languages and comparatively less training data.

This study investigates the energy use of LLMs in code completion tasks. Previous studies on LLM inference energy focused primarily on output-intensive tasks, such as code generation and bug fixing [3], and input tokens are often considered relatively inexpensive in comparison [19, 46, 50]. However, in long-context software engineering workloads such as repository-level code completion, processing large input contexts can become a major energy bottleneck. In scenarios where input contexts consist of thousands of tokens while the output contains only a few lines, the relative contribution of input processing becomes significantly larger. This study aims to quantify the relative impact of input and output tokens across different code completion workloads. We focus our investigation on locally-deployable, open weight models. The ability to run these models locally enables us to obtain precise energy measurement while controlling for interference from external factors. The architecture of smaller models often mirrors that of larger ones and results are to some extent transferrable.

Our study examines two real-world code completion scenarios: (i) **Repository-level next-line completion**, where cross-file context is also included in the prompt; and (ii) **Infill code completion**, where the model fills in missing code using both preceding and succeeding context. We further investigate LLM performance and energy consumption across multiple programming languages, namely Python, Java, and Rust, with the goal of uncovering deeper insights into the energy–performance dynamics of LLMs in realistic coding tasks. We address the following research questions, aiming to contribute to more energy-aware development and deployment strategies for AI-assisted programming tools:

**RQ1** What is the trade-off between energy consumption and accuracy in code completion?

- **RQ1.1** How does the trade-off differ across programming languages?
- **RQ1.2** How does this trade-off vary across different context sizes?

**RQ2** What is the relative influence of input and output token counts on total energy consumption, and how do these drivers interact with model scale?

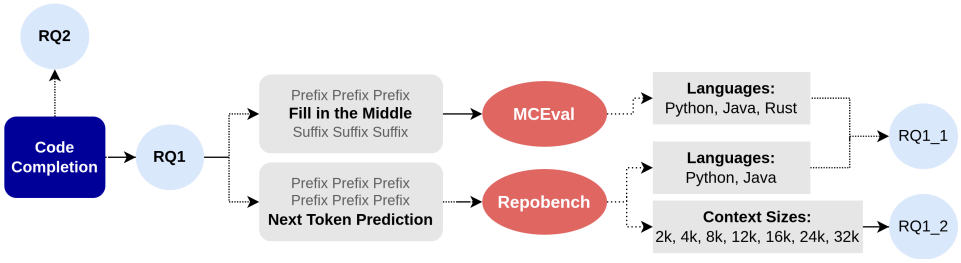

**Figure 1** Schematic representation of the study.

## 2 Research Method

**Figure 1** presents a schematic outline of our study along two directions, corresponding to the two primary categories of code completion [20]: Left-to-Right (L2R) prediction (aka. next token prediction) and Fill-in-the-Middle (FIM) prediction (aka. infilling).
Left-to-Right (L2R) completion refers to the traditional autoregressive setting (one token at a time) in which the model continues the code solely based on the preceding context. This paradigm is commonly used in repository-level completion tasks, where the model may receive large amounts of contextual information from multiple files, functions, and project-wide dependencies. As a result, L2R completion often involves long-context workloads that require processing thousands of input tokens before generating the prediction. In contrast, Fill-in-the-Middle (FIM) completion predicts missing code between a given prefix and suffix. This setting better reflects interactive editing scenarios in modern IDEs, where developers modify or insert code within existing files rather than only appending new content at the end. Our experimental setup is specifically designed to address each category using the appropriate methodology, as described in the remainder of this section.

### 2.1 Execution Environment

**To run LLMs locally**, an LLM inference engine is required. Several open-source LLM inference engines have recently emerged to enable local deployment and inference of open-weight LLMs, including PrivateGPT (57.4K GitHub stars), GPT4All (77.4K), llamafile (25.5K), vLLM (87.6K), Ollama (177K) at the time of this study. We selected Ollama (v0.13.0) due to its popularity, as reflected by its GitHub star metric. It is particularly useful for its support of multiple quantization levels, enabling efficient execution on commodity hardware. Furthermore, its seamless model-switching capability and extensive API features make it well-suited for exploration and reproducible experiments. Additionally, its strong adoption among developers, as reported in the 2025 Stack Overflow Developer Survey [51], further reinforces the external validity of our tool selection.

To monitor GPU utilization and **to measure power consumption**, as suggested in previous studies [3, 4, 6, 9], we use the Python interface (nvidia-ml-py v13.590.48) for the NVIDIA Management Library (NVML) [44]. For every running model, power usage is sampled every 100ms, and total energy consumption is estimated as the arithmetic mean of the recorded power samples multiplied by the elapsed execution time. While higher sampling frequencies yield a more detailed power profile, we adopt a 10Hz sampling rate, consistent with prior work [3], to avoid the runtime overhead associated with more frequent measurements. The reported power values represent net consumption, computed by subtracting the idle power of the GPU from the measured power. To measure GPU idle power, we executed the

nvidia-smi [43] command for 340 seconds, collecting 3400 samples at 100 ms intervals. 3400 collected observations provide a 98% confidence level that the true power consumption lies within ±2% of the observed values. The exact command we have used is provided in the replication package [2]. The mean measured idle power of the GPU was 46.82 W.

All experiments were conducted on a cluster equipped with an NVIDIA A100 80GB PCIe GPU [42] configured in "High Performance" mode, two AMD 7313 CPUs running at 3 GHz with 1 TB of system memory and 32 MB cache, and AlmaLinux 8.10 (64-bit) operating system configured with the "Performance" CPU governor. Each experiment was repeated three times to mitigate transient fluctuations, and the reported values represent the average across the three runs. No other jobs were allowed to run on the GPU during the experiments.

## 2.2 Dataset

**Repobench** [35] is designed for repository-level auto code completion. We used the code completion subset, which focuses on next-line prediction using three distinct settings: Cross-File-First simulates predicting code that hasn't yet appeared in the current file. This is the hardest task that requires LLMs to know about the external files. In Cross-File-Random cases, a random and non-first occurrence of a cross-file line is masked, so the code has already been partially introduced in the file, allowing the LLMs to leverage prior in-file context. Finally, the In-File split contains cases within a single file, where an in-file line unrelated to cross-file modules is masked. Compared to other repository-level benchmarks for code completion [12, 17, 32, 33, 40, 55], Repobench supports a wide range of context sizes, varying from 2000 to 128000 input tokens. This makes it particularly suitable for our study, as it allows us to better investigate the effect of input length on energy consumption. Considering the limitations imposed by the context length of the LLMs under examination, we were only able to carry out experiments on the data with a maximum of 32000 as their context limit. Then, for each context level, 100 samples were extracted for each split (300), resulting in 2100 code completion problems.

**McEval** [10] is a multilingual code evaluation benchmark, covering 40 languages. Its code completion task can be categorized into single-line completion, multi-line completion, and span completion. In single-line completion, only one line of code is masked, whereas in the other two settings multiple lines are masked. In multi-line completion, the masked lines are dispersed throughout the code, while in span completion they appear consecutively as a single block. To evaluate LLM performance for FIM purposes across different programming languages, we selected Python because it is the most widely used language for machine learning development, Java as a representative of popular compiled languages, and Rust as a less common but still mainstream language, reflecting scenarios where training data is relatively limited. The selected McEval subsets contain 340 Python, 355 Java, and 343 Rust completion tasks. While other languages such as C# or C++, could also be included, we deliberately limited our selection to these three for practical reasons. This choice can be acknowledged as a potential threat to validity.

## 2.3 Model Selection

To ensure diversity in both model scale and architecture, we collected models ranging from approximately 1B up to 20B parameters, focusing on model sizes practical for local deployment and inference. The list of models under evaluation covers multiple parameter ranges, including models below 4B parameters, several models in the 6B–8B range, and larger models from 13B to 20B parameters. To construct this set, we selected model families based on their

availability in GGUF format and their popularity on the Ollama platform, as indicated by pull counts. Two models (Granite 3.3 8B and Granite 3.3 2B) were not available on Ollama in full-precision and Q8 formats; therefore, we sourced their GGUF files directly from the official IBM Granite repository on Hugging Face [27].

We also included newer models with efficiency-driven approaches, as they are relevant to the energy-efficiency goals of this study. In particular, we included both dense and Mixture-of-Experts (MoE) architectures. Unlike dense models, where all parameters participate during inference, MoE models activate only a subset of their parameters for each token, potentially reducing inference cost while maintaining strong performance [22, 48]. Therefore, throughout this study, we report the number of active parameters for MoE models rather than the total parameter count. To investigate the trade-off between numerical precision, accuracy, and energy consumption, we evaluate models under multiple quantization levels, including FP16, Q8, and Q4, representing 16-bit floating-point, 8-bit, and 4-bit weight precision, respectively. **Quantization** reduces the numerical precision used to represent model weights, lowering memory usage and computational overhead during inference [15, 21, 31].

In line with our focus on code completion, we only include general-purpose and coding-specific models. For experiments using the RepoBench dataset, base versions of the models are required, whereas instruction-tuned variants are needed for the McEval dataset.

Base LLMs are pretrained models optimized for next-token prediction, whereas instruction-tuned are additionally trained to follow natural language instructions. Following the original benchmark papers, RepoBench [35] requires base models because the benchmark is designed to evaluate the completion of the next-line code at the repository-level in an autoregressive setting, where the model must continue the code directly from the provided context without relying on the following behavior of the instruction. In contrast, McEval [10] follows a prompt-based fill-in-the-middle setting, making instruction-tuned variants more appropriate for the evaluation scenario. Moreover, in the RepoBench setting, context length is particularly important because models with larger context windows can better capture long-range dependencies. We also considered the reputation and maturity of model developers, as models from established AI organizations tend to be better maintained and widely adopted. A complete overview of the evaluated models is provided in the online appendix [2].

## 2.4 Performance metrics

There are numerous metrics to evaluate the correctness of the code generated by LLMs. This section focuses on the key metrics frequently used to assess LLM performance. Given that this research cannot explore all possible metrics, it focuses on the metrics most frequently used to determine the performance of LLMs used for code completion. A recent systematic literature review of LLM-based code completion [26] identified Top-$k$ Accuracy, Levenshtein Edit Similarity (ES), Exact Match (EM), Mean Reciprocal Rank (MRR), and BLEU as the most commonly used evaluation metrics. For the RepoBench dataset, to ensure comparability and reproducibility, we use the same evaluation metrics as defined in the original RepoBench paper [35]: Normalized Edit Similarity and Exact Match. Although these metrics may appear overly strict, since functionally correct code can differ in naming conventions, they are appropriate in a repository-level setting. In such scenarios, the model is provided with extensive contextual information, including cross-file references and project-wide naming patterns. Therefore, we expect the LLM to generate a piece of code that is not only functionally correct but also adheres to the intended naming conventions for variables, functions, and classes. Moreover, even when the generated code is not fully correct, high textual similarity can still be practically useful in software development, as developers may adapt and refine the generated code instead of writing it entirely from scratch.

For the generated code in the McEval dataset, we utilized the Docker container prepared by the dataset authors to compute Pass@1 accuracy based on the provided test cases. This metric corresponds to the Plausible@1 criterion recommended in recent LLM evaluation guidelines [7]. Since McEval consists of relatively small and self-contained examples, it is feasible to execute the generated code and verify correctness through automated testing. All necessary environments are preinstalled in the Docker image, and the correctness is assessed by executing the generated code against the provided tests [10]. This approach is better suited for this use case, where no cross-file repository context is involved, ensuring that the evaluation reflects functional correctness rather than syntactic similarity.

In contrast, applying execution-based evaluation to RepoBench would require resolving repository dependencies and building complete software systems, which would substantially limit the scale and reproducibility of this study. Therefore, for RepoBench, we rely on similarity-based metrics instead. This approach is better suited for the repository-level setting while still allowing us to evaluate how well the generated code aligns with the expected implementation and project-wide conventions.

## 2.5 Experimental Procedure

To ensure consistency, we used identical hyperparameters for all models within each dataset. The temperature and top-p values were set to 0.2 and 0.95, respectively, as prior studies [11,35] suggest these settings yield better performance in code generation tasks.
For **RepoBench**, the maximum number of output tokens was set to 128, following the configuration of the original study. Only the context size was varied to accommodate different input lengths. To construct the prompts, we used the *construct_prompt* function provided with the dataset. For **McEval**, we first measured the length of the longest canonical solution for each language (Python: 1227 tokens, Java: 1274 tokens, Rust: 1017 tokens). We then set the maximum number of output tokens to 1300 to ensure coverage of the longest solutions across all three languages. The context size remained at its default value of 2000 tokens. As for the prompt, we used the *instruction* column provided in the dataset.

# 3 Results

In this section, we present our findings following the order of the research questions.

## 3.1 RQ1 – What is the trade-off between energy consumption and accuracy in code completion?

To address this RQ, we first collected the energy consumption of all LLMs while executing the complete workload. For McEval, we computed the mean Pass@1 score and total energy consumption across the complete workload of each language subset. Since both the size and the content of the workloads differ across subsets, we report the energy consumed per generated token (J/token) to enable a fair comparison between models. The same consideration applies to RepoBench, where the Python and Java subsets also contain different problems. Similar to McEval, we report aggregated energy consumption values together with the mean Edit Similarity scores. The results are presented in Tables 1 and 2. Due to page limitations, only the FP16 results are included in the main paper, while the results for 8-bit and 4-bit quantizations are provided in the online appendix [2]. To analyze the trade-off between accuracy and energy consumption, we employ the Pareto frontier, a multi-objective optimization method that identifies nondominated configurations across competing objectives.

**Table 1** Results of inference for instruction-tuned models in Python, Java and Rust on McEval. Total energy (E) is in Wh, elapsed time (T) is in seconds, J/t indicates the energy per generated token and P@1 indicates pass@1. Note that the workload across languages is not the same.

| Model | Python | | | | Java | | | | Rust | | | |

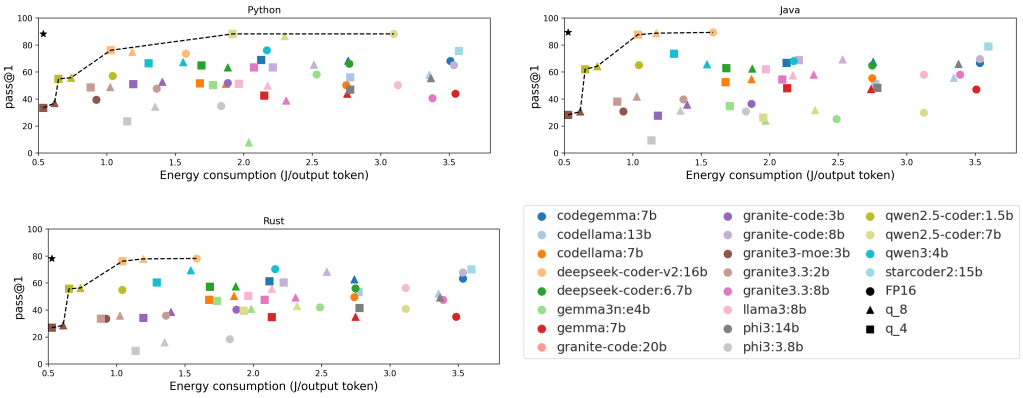

**Figure 2** Relation between accuracy and energy consumption (Joule/token) for different languages in McEval. The black dashed line indicates the Pareto frontier and ★ denotes the ideal point.

### 3.1.1 RQ1.1 – How does the energy-accuracy trade-off vary across programming languages?

To further investigate whether the observed trade-offs differ across programming languages, we performed statistical analyses on the achieved accuracy scores. In the McEval dataset (Table 1), applying Friedman's test revealed a significant effect of programming language on Pass@1 ($\chi^2 = 40.36$, $p < 0.001$). Post-hoc Wilcoxon signed-rank tests with Bonferroni correction ($\alpha = 0.0167$) showed no significant difference between Python and Java ($p = 0.90$). However, both Python and Java significantly outperformed Rust ($p < 0.001$), with median paired differences of 5.75 and 5.01, respectively. We did not perform similar tests for energy and time because the workloads differ across programming languages.

**Table 2** Results of inference for base models in Python and Java on RepoBench. Total energy is reported in Wh, elapsed time in seconds, J/t indicates the energy per generated token and ES stands for Edit Similarity. The full list of models and Exact Match results is provided in the online appendix [2]. Note that the workload across context sizes and languages is not the same.

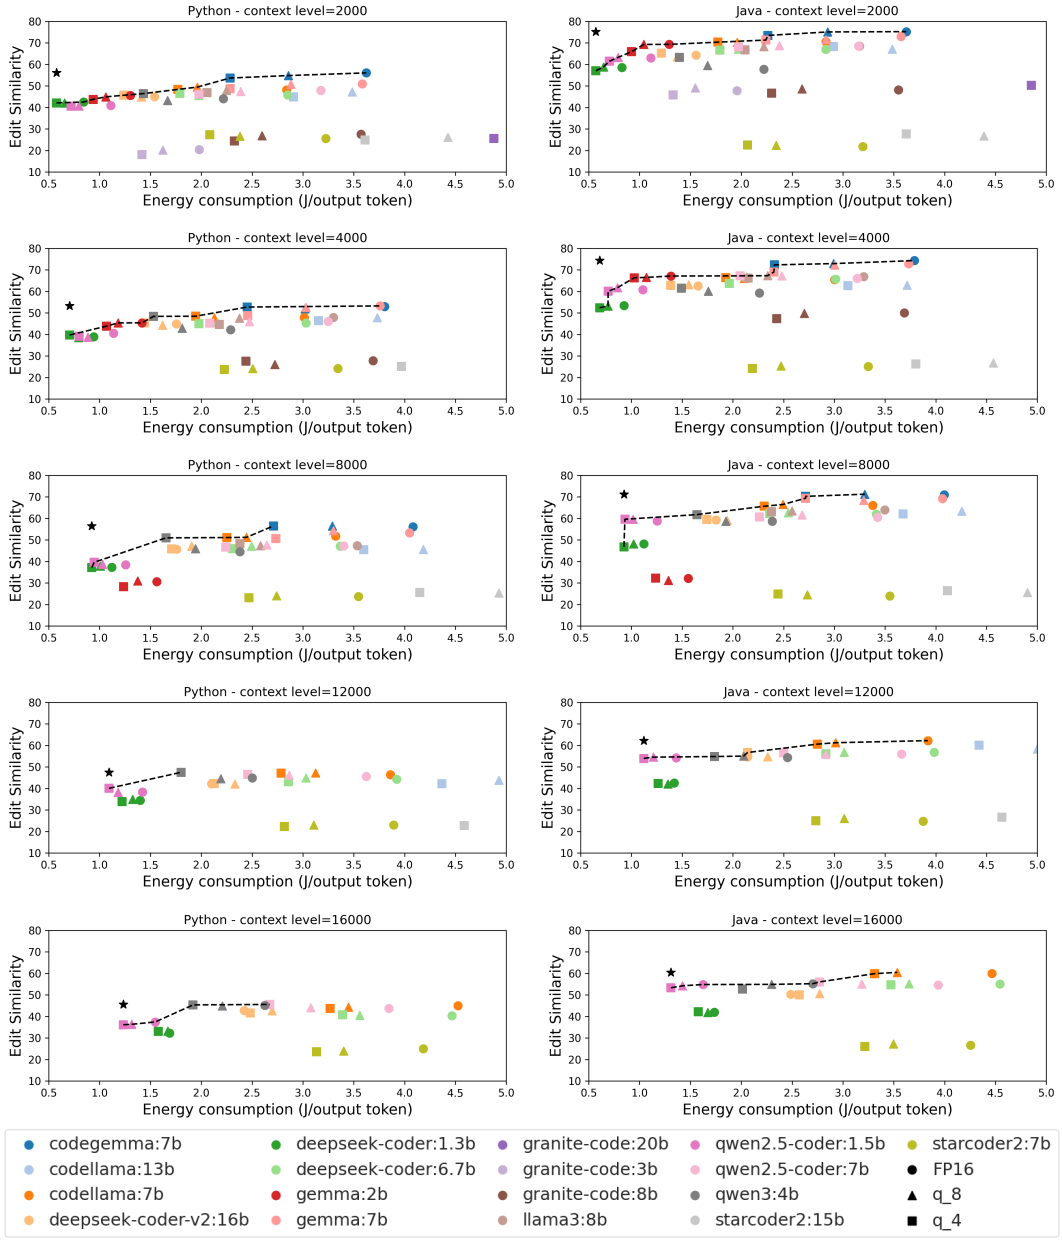

**Figure 3** Relation between accuracy and energy per generated token (Joule/token) for different context levels in Repobench dataset. The left column is the results for generating Python code, and the right column depicts the results for generating Java code. The black dashed line indicates the Pareto frontier. The ★ denotes the ideal point. (Data points exceeding the x-axis limit are not displayed.)

In the RepoBench dataset (Table 2), we report Edit Similarity (ES) as a proxy for accuracy. A Wilcoxon signed-rank test reveals a statistically significant difference between Python and Java ($W = 103.0$, $p < 0.001$). Java achieved a higher median ES (56.43) compared to Python (43.02), with a median paired difference of $-14.90$. One possible explanation for these findings lies in the characteristics of the programming languages. Python, being dynamically typed, and Java, being statically typed, may influence how LLMs perform under

syntax-based evaluation metrics such as ES. In particular, the stricter and more explicit structure of Java code could partially explain its higher ES scores. However, when evaluated using execution-based metrics such as Pass@1 (as in McEval), the performance of Python and Java becomes comparable. In contrast, Rust is consistently outperformed by both Python and Java. This may be due to the relatively smaller amount of Rust code available in the training corpora of contemporary LLMs.

As shown in Figure 2, in McEval, both quantized variants of the small `Qwen2.5-coder:1.5b` model are located close to the ideal point while still achieving competitive Pass@1 scores across all three languages. This indicates that smaller quantized models can provide a favorable balance between energy efficiency and accuracy. Among the larger models, the 4-bit quantized variant of `Deepseek-coder-v2:16b` stands out as one of the most efficient high-performing models. Despite containing 16B total parameters, this MoE model activates only approximately 4B parameters during inference, allowing it to achieve the highest Pass@1 scores in Java and Rust while remaining on the Pareto frontier. In Python, however, `Qwen2.5-coder:7b-q4` achieves the highest accuracy overall. The improvement over `Deepseek-coder-v2:16b-q4` is approximately 16% while requiring nearly twice as much energy per generated token.

Notably, the Pareto frontiers across languages are largely composed of the same model families, suggesting that the energy-accuracy trade-off remains relatively stable across programming languages. One exception is `Qwen2.5-coder:7b`, which performs particularly well in Python but is less competitive in Java and Rust. Most Pareto-optimal configurations correspond to quantized models. Even when FP16 models appear on the frontier, their quantized counterparts often achieve nearly identical accuracy while consuming substantially less energy per generated token. Several larger FP16 models are dominated by smaller quantized alternatives, indicating that increasing parameter count and precision does not necessarily yield better energy-accuracy trade-offs. Overall, quantized models frequently provide the best balance between accuracy and energy efficiency, with small accuracy degradation relative to their energy savings.

### 3.1.2 RQ1.2 – How does the energy-accuracy trade-off vary across different context sizes?

In RepoBench, as shown in Table 2, increasing the context size generally leads to a higher energy cost per generated token (J/token) in both Python and Java. For example, in Python, `Qwen2.5-coder:1.5b` increases from 1.11 J/token at a context size of 2000 to 2.00 J/token at 32000, with a similar trend observed in Java. This pattern is reflected in Figure 3, where models gradually shift toward higher J/token values as the context size increases. This trend is further summarized across models in the online appendix [2].

Although the workloads across different context sizes are not identical in terms of both content and size, they are designed to represent repository-level completion tasks of comparable complexity. We found out that increasing the context size does not consistently translate into substantial improvements in ES, suggesting diminishing returns from larger context windows. For some models, such as `Granite-code:20b` and `Gemma:7b`, ES slightly improves as larger contexts are provided. In contrast, for models such as `Codellama:7b` and `Codellama:13b`, performance gradually decreases with increasing context size. Other models, including `Qwen2.5-coder:1.5b` and `Qwen2.5-coder:7b`, exhibit modest improvements up to a certain context length, after which ES begins to decline.

Notably, the composition of the Pareto frontier remains relatively stable across context sizes, with quantized variants frequently appearing among the Pareto-optimal configurations. This confirms that increasing model precision or context size does not necessarily result

in proportionally better quality also in repository-level code completion. In several cases, quantized variants achieve nearly identical ES compared to their FP16 counterparts while consuming substantially less energy per generated token.

Model rankings were not stable in terms of per-token energy consumption across context sizes. In the models with size lower than 2B range, `Deepseek-coder:1.3b` exhibited lower J/token values than `Qwen2.5-coder:1.5b` up to a context size of 12K. However, at 16K context, `Qwen2.5-coder:1.5b` became more energy-efficient. A similar trend was observed in the 4B range between `Deepseek-coder-v2:16b-lite-base-fp16` and `Qwen3:4b-fp16`, both of which have approximately 4B active parameters. While the DeepSeek model remained more efficient at smaller contexts, `Qwen3:4b-fp16` achieved lower J/token values at 32K context. Likewise, among the 7B models, `Qwen2.5-coder:7b-base-fp16` became more energy-efficient than both `Codellama:7b-code-fp16` and `Deepseek-coder:6.7b-base-fp16` starting from 12K context size. These observations suggest that certain model families may exhibit better scalability under long-context workloads.

**Summary.** The trade-off between energy consumption and accuracy of LLMs is not always strict. In code completion, it is strongly influenced by the characteristics of the completion task, programming language, and context size. Increasing context size consistently raises energy consumption, while the corresponding accuracy improvements are often limited. Therefore, no single model consistently provides the best trade-off across all tasks, programming languages, and context sizes.
**Takeaway.** Practitioners should select models based on the programming language and expected context length of their target use case rather than a model's reported accuracy alone. Furthermore, model providers should report inference energy alongside accuracy.

## 3.2 RQ2 – What is the relative influence of input and output token counts on total energy consumption, and how do these drivers interact with model scale?

**Table 3** Spearman correlations between total energy consumption and the studied predictors, including input tokens, output tokens, active parameter count, and their interaction terms. Bonferroni correction was applied ($\alpha = 0.05/6 = 0.0083$) and all correlations remain significant.

| Predictor | RepoBench | McEval |
|---|---|---|
| Input Tokens | 0.57 | 0.24 |
| Output Tokens | 0.40 | 0.36 |
| Active Parameter Count | 0.60 | 0.75 |
| Input Tokens × Active Parameter Count | 0.94 | 0.79 |
| Output Tokens × Active Parameter Count | 0.67 | 0.92 |
| Input Tokens × Output Tokens | 0.58 | 0.40 |

To quantify the drivers of energy consumption, we first analyzed the pairwise relationships between energy usage, token counts (input and output), and active parameter count using correlation analysis. The results are presented in Table 3. We selected input and output token counts because both prompt processing and autoregressive generation contribute directly to inference cost. Active parameter count is a compact proxy for model scale and computational complexity, as larger models consistently consumed more energy than smaller ones under comparable workloads. For McEval, correlation was high for active parameter count and weak for the other two variables. This reflects the characteristics of this dataset: input and

output lengths are short, thus model scale dominates energy use. For RepoBench, output length is short, and input length is very long, so their impact is comparable to the model scale. In this case, energy use is moderately correlated with the three variables.

In addition, we included interaction terms between token counts and active parameter count to capture the intuition that the computational cost of processing or generating tokens depends not only on the number of tokens, but also on the size of the model performing the computation. Moreover, the interaction between input and output tokens was included to account for the fact that autoregressive generation depends on the size of the provided context. This effect is also reflected in the RepoBench Pareto plots (Figure 3), where models consistently require higher energy per generated token as context size increases, despite the output length being capped at 128 tokens. This suggests that generating the same number of output tokens may incur substantially different costs under short and long context workloads. As shown in Table 3, the first two interaction variables exhibit strong correlation with energy consumption across both benchmarks, while the interaction between input and output tokens is moderately correlated. These interaction terms are particularly relevant in our setting, since RepoBench emphasizes long-context processing whereas McEval contains generation-heavy workloads. To further analyze the contribution of these factors, we fitted multiple linear regression models using standardized variables ($\mu = 0, \sigma = 1$). As input token count, output token count, and active parameter count are measured on different scales, we standardized these predictors to enable direct comparison of their regression coefficients. The regression assumptions were reasonably satisfied, and the corresponding diagnostic plots are provided in the online appendix [2]. The general regression model is defined in Equation 1.

$$E = \beta_0 + \beta_1 I + \beta_2 O + \beta_3 P + \beta_4 I \cdot O + \beta_5 I \cdot P + \beta_6 O \cdot P + \beta_7 W + \beta_8 L + \varepsilon \tag{1}$$

where $E$ denotes total energy consumption (Wh), $I$ and $O$ represent the standardized input and output token counts, $P$ is the standardized active parameter count, $W$ denotes bit width (quantization), $L$ represents the programming language, and $\varepsilon$ is the error term. The interaction terms capture that the energy cost of generation depends jointly on context size and model scale. To facilitate interpretation of the regression coefficients, the standard deviations (SD) of the predictors are reported in Table 4. The dependent variable is the total energy consumption in Wh. As predictors, we included standardized input tokens, output tokens, and active parameter count, as well as interaction terms between these variables. Bit width and programming language were treated as categorical variables. To account for multiple observations from the same model families, we utilized Cluster-Robust Standard Errors, grouping by model families. This ensures our $p$-values are not artificially inflated by intra-model correlation. For RepoBench, the statistics and regressions are computed using the common models evaluated across all context sizes up to 16K to ensure consistent model coverage, as only a few models support 24K and 32K contexts. For McEval, all evaluated models are included. The regression results are presented in Table 5.

**Table 4** Standard deviations of the standardized predictors used in the regression models. Token statistics represent the aggregated number of tokens across all prompts within each benchmark.

| Benchmark | Input Tokens | Output Tokens | Parameter Count |
|---|---|---|---|
| RepoBench | 1,316,930.93 | 2,309.96 | 4,563.42 |
| McEval | 21,161.11 | 39,171.61 | 4,781.41 |

**Table 5** Regression coefficients ($\beta$), standard errors (SE), statistical significance ($p$-value), and model fit metrics for RepoBench and McEval. Cluster-robust standard errors are used (clustered by family). Q4 is used as the reference category for bit width, and Java is the reference language in both RepoBench and McEval.

For RepoBench, the regression model achieved a high $R^2$ (0.961), indicating that the selected predictors explain most observed variation in energy consumption. Input token count and active parameter count exhibit the strongest positive associations with energy usage, with coefficients of 22.98 and 26.60, respectively. In contrast, output token count has a smaller but statistically significant effect. This is expected, as repository-level context can grow substantially while generation length remains capped at 128 tokens to predict the next line.

Because the predictors were standardized, we can directly compare the regression coefficients to measure the real-world impact of scaling up data sizes. The coefficients represent the expected change in total energy consumption (in Wh) for every one-SD increase in that variable. For example, in RepoBench, a one-SD increase in input tokens corresponds to approximately 1.3 million (1,316,930) additional aggregated input tokens across the 300 prompt instances ($\sim$ 4333 tokens per prompt), which is associated with an increase of approximately 23 Wh in total energy consumption. On the other hand, a one-SD increase in output tokens (2310 tokens), imposes 4.9 Wh more energy in total energy usage.

To find out how many output tokens would generate that same 22.98 Wh ($\sim$ 23) increase, we can calculate their energy equivalence. While a 23 Wh increase in energy consumption is driven by an additional 1.3 million input tokens, that exact same 23 Wh energy increase would be triggered by generating just 10,857 aggregated output tokens ($\sim$ 36 token per prompt). Under the RepoBench workload configuration, generating a single token consumes as much energy as processing approximately 121 input tokens ($1,316,930/10,857$).

The interaction between input tokens and active parameter count is also statistically significant, indicating that the energy impact of increasing context size becomes larger for bigger models. Similarly, the interaction between input and output tokens is significant, suggesting that generation becomes more expensive when conditioned on larger contexts.

However, the interaction between output tokens and parameter count is not statistically significant, likely because the variation in generated output length is relatively limited in RepoBench compared to the variation in input size.

Bit width also has a statistically significant effect on energy consumption. Compared to the Q4 baseline, Q8 and FP16 variants require additional energy, confirming that quantization (lower bit width) can improve energy efficiency even after controlling for token counts and parameter count. Moreover, the programming language variable is statistically significant, suggesting that language-specific characteristics such as tokenization patterns and repository structure may influence energy consumption in long-context workloads.

For McEval, the regression model also achieved a high goodness of fit ($R^2 = 0.940$). However, the contribution of the predictors differs substantially from RepoBench. In this benchmark, input size is capped at approximately 2K tokens, while the generation length can reach up to 1300 tokens. As a result, output token count becomes one of the dominant predictors of energy consumption, with a coefficient of 23.50, whereas input token count is no longer statistically significant. This indicates that, in generation-heavy workloads, the decoding phase contributes more strongly to total energy usage than prompt processing.

The interaction between output tokens and parameter count is highly significant in McEval, indicating that generating longer outputs becomes increasingly expensive for larger models. In contrast, the interactions involving input tokens are not statistically significant, which aligns with the relatively limited variation in prompt length in this benchmark. Quantization effects remain statistically significant, with FP16 models showing substantially higher energy consumption than Q4 variants. However, unlike RepoBench, the programming language variables are not statistically significant after controlling for token counts and parameter count, suggesting that language-specific effects become less influential when the workload is dominated by generation rather than long-context processing. The regression behavior closely matches the intended workload characteristics of the two benchmarks.

These findings align with the earlier correlation analysis, where interaction terms exhibited the strongest associations with energy consumption in their respective code completion workload settings. Overall, the two benchmarks provide complementary perspectives on the energy behavior of LLM inference. RepoBench primarily captures the effect of long-context processing, where input size and its interaction with parameter count dominate energy consumption. In contrast, McEval emphasizes generation-heavy workloads, where output length and its interaction with parameter count become the primary drivers. Together, these results indicate that the dominant contributors to energy consumption depend strongly on the structure of the workload. Context-heavy software engineering tasks are mainly influenced by prompt processing costs, whereas generation-heavy tasks are primarily driven by autoregressive decoding behavior.

**Summary.** Our regression analysis shows that the dominant drivers of energy consumption strongly depend on the characteristics of the completion task. In RepoBench, energy usage is primarily influenced by input context size and its interaction with active parameter count, highlighting the cost of long-context processing. In contrast, McEval is mainly driven by output generation, its interaction with active parameter count, and quantization level, indicating that autoregressive decoding dominates in generation-heavy workloads. The results also reveal that output generation is substantially more energy-intensive on a per-token basis than prompt processing. Furthermore, the significance of the interaction terms suggests that the energy cost of processing and generating tokens is better explained by considering token counts and the scale of the model together.
**Takeaway.** Practitioners should select models carefully, as larger models do not necessarily yield better accuracy but can considerably increase energy consumption. Furthermore, limiting unnecessary input and output tokens can reduce inference energy.

## 4 Related Work

Recent research on LLMs for software engineering (SE) focuses on improving code completion accuracy, while the inference energy footprints remain underexplored. A systematic review [53] shows that 76% of Green AI literature was published recently and nearly half of these primary studies focus only on the training phase. Most remaining inference benchmarks are algorithm-agnostic or use image datasets. This leaves open questions about how inference energy scales across programming languages, context windows, and model precisions.

Several studies have investigated LLM-based code completion from an accuracy perspective, including efficient training strategies for fill-in-the-middle (FIM) models, syntax-aware infilling benchmarks, practical IDE-based evaluation settings, alignment techniques for improving code generation quality, and empirical analyses of LLM-generated software quality [8, 20, 29, 41, 49]. These studies provide valuable insights into code completion performance and software quality, but they do not primarily analyze the energy cost of inference.

Repository-level code completion has also received increasing attention, since real-world code completion often depends on information across multiple files. Recent studies emphasize long-context reasoning and cross-file dependency modeling through retrieval augmentation and contextual integration strategies [23, 24, 36]. Zhang et al. [55] proposed RepoCoder, which combines retrieval and generation for repository-level code completion, while Ding et al. [16] studied code completion by jointly modeling in-file and cross-file context. Recent work extends repository-level completion to specific domains, such as RTL code completion [54], and API-centric repository-level code completion [34]. These studies emphasize repository context and retrieval, but they mainly evaluate completion quality rather than the energy implications of processing larger contexts.

Beyond accuracy, related work studies sustainability in code generation. Some focus on the energy efficiency of the generated code itself, examining whether LLM-generated programs are more or less energy-efficient than human-written solutions [5, 14, 25, 28, 52]. This work is complementary to ours: it studies the runtime energy behavior of the produced software, whereas our study focuses on the energy usage of the LLM during the code completion.

Energy consumption of LLMs has also been studied from Green AI and inference-efficiency perspectives. Fernandez et al. [19] analyze the energy implications of LLM inference optimizations across diverse workloads, software stacks, hardware accelerators, and serving configurations. GreenMyLLM [13] studies the energy consumption of code assistants by simulating developer interactions and analyzing factors such as model size, quantization, streaming, and rejected suggestions. Jareno et al. [30] further investigate energy-efficient LLM inference from an SE perspective, proposing compiler-level optimization of the *llama.cpp* inference engine and showing that hardware-aware code transformations can reduce energy consumption without modifying the underlying model. More recently, SweetSpot [46] proposed an analytical model for predicting LLM inference energy efficiency as a function of input and output sequence lengths, highlighting non-linear efficiency regimes and energy "sweet spots" under controlled synthetic workloads. These works demonstrate the growing importance of inference energy, but they do not focus specifically on comparing realistic code completion workloads across context sizes, programming languages, and completion styles.

The studies closest to ours jointly consider LLM inference energy and SE tasks. Solovyeva and Castor [50] perform a phase-level analysis of LLM inference energy in software development benchmarks, distinguishing between input processing and output generation and showing that excessive generation can substantially increase energy consumption. Mehditabar et al. [39] propose BRACE, a benchmark-oriented framework for evaluating coding LLMs in

terms of both functional accuracy and energy efficiency. These studies are highly relevant, but they address different levels of analysis. The former focuses on phase-level inference behavior, while the latter provides a unified energy-accuracy benchmarking perspective.

Our work complements these studies by examining workload-level energy behavior in realistic code completion scenarios. We study both repository-level left-to-right completion with varying context sizes and multilingual fill-in-the-middle completion across Python, Java, and Rust. Rather than only ranking models by accuracy or energy, we analyze how input length, output length, active parameter count, quantization, programming language, and context size shape energy-accuracy trade-offs. We show that long-context repository completion and generation-heavy FIM completion stress LLM inference differently, and that energy-efficient model selection depends on the characteristics of the completion task.

## 5 Threats to Validity

A potential threat to **internal validity** relates to the occasional incomplete responses returned by the Ollama API. In a small number of cases (typically one or two prompts per model), the model failed to return a complete generation and skipped the query. This issue became more noticeable in RepoBench under large context sizes (e.g., beyond 16K tokens), where missing a single long-running prompt could noticeably reduce the measured elapsed time and energy consumption, potentially making some FP16 models appear more energy-efficient than lower-bit quantized variants. To mitigate this issue, we manually inspected the results and excluded incomplete executions when computing the energy cost per generated token. Another threat to internal validity arises from the limited number of repetitions per experimental configuration. Each setup was executed three times to capture transient runtime variability while keeping the overall computational cost manageable. Increasing the number of repetitions could further improve statistical confidence, but would significantly increase the required execution time and resource usage. Nevertheless, since each run processes hundreds of prompts over several minutes and GPU power is sampled at 10Hz, the measurements exhibit relatively stable utilization patterns, reducing the impact of transient fluctuations. Another threat concerns the approximation used for energy estimation. Total energy consumption was computed using the arithmetic mean of the sampled GPU power values multiplied by the elapsed execution time, rather than performing numerical integration over the full power trace. To assess the impact of this approximation, we conducted an additional validation experiment on the Java subset of RepoBench. The observed discrepancy between the two approaches remained small, with an average difference of 0.46% and a maximum deviation of 2.3%. Finally, energy was measured using a software-based GPU power profiler rather than external hardware instruments, which may affect measurement precision. However, the same procedure was applied consistently across all configurations.

A potential threat to **external validity** of our study concerns the selection of programming languages. Although Python, Java, and Rust cover dynamically typed, statically typed, and relatively lower-resource mainstream languages, the results may not generalize to all programming ecosystems or domain-specific languages. Another potential threat to external validity is that the measurements on the A100 platform are limited to GPU power obtained through NVML, since privileged access required for CPU-side energy measurements was unavailable on the cluster. Consequently, the reported energy values do not include the contribution of CPU, DRAM, or PCIe communication overheads. Although this may lead to an underestimation of total system-level energy consumption, all experiments were conducted under identical hardware configurations and comparable data transfer conditions, which helps preserve the validity of fair comparisons across models and workloads.

A potential threat to **conclusion validity** concerns regression assumptions. Diagnostic Q-Q plots exhibit deviations from normality in the residual tails. Alternative specifications using a log-transformed outcome and Gamma regression did not consistently improve the diagnostics. Therefore, we acknowledge these deviations as a limitation of the analysis.

## 6 Conclusion

This study investigated the trade-off between accuracy and energy consumption in LLM-based code completion across different programming languages, context sizes, and completion workloads. Using RepoBench and McEval, we evaluated a total of 25 open-weight LLMs under long-context repository-level completion and generation-heavy fill-in-the-middle completion scenarios. Our results show that the dominant drivers of energy consumption depend strongly on the characteristics of the completion task. In long-context workloads such as RepoBench, energy consumption is primarily influenced by input context size and its interaction with model scale. In contrast, generation-heavy workloads such as McEval are mainly driven by output generation and its interaction with active parameter count. These findings indicate that different software engineering tasks stress different components of LLM inference.
We further observed that output generation is substantially more energy-intensive per token than prompt processing. In addition, increasing context size consistently raised the energy cost per generated token, while the corresponding improvements in completion quality were often limited and highly model-dependent. Across both benchmarks, smaller and heavily quantized models frequently achieved Pareto-optimal trade-offs, often providing accuracy comparable to larger full precision models while consuming substantially less energy. Moreover, model rankings in terms of energy efficiency were not stable across context sizes, suggesting that certain model families scale more efficiently under long-context workloads. Overall, our findings demonstrate that larger models and longer contexts do not necessarily provide proportionally better completion quality, emphasizing the importance of energy-aware model selection and deployment strategies for AI-assisted software engineering tools.

Future work could complement our regression analysis with controlled ablation studies that vary one factor at a time while keeping others fixed, enabling a more precise understanding of how context length, output length, quantization, and model scale influence energy consumption. In addition, extending this analysis to emerging agentic workflows involving iterative multi-turn interactions, self-correction, and tool usage would help better understand the sustainability challenges of large-scale AI-assisted software engineering systems.

## Abstract

**Background.** The sustainable evolution of Open Source Software (OSS) depends not only on code production but also on continuous knowledge transfer and collaborative support within communities. However, existing contribution metrics primarily center on code commits and merges, overlooking the value of non-coding activities embedded in technical discussions. Among these activities, Non-explicit Mentoring (NEM) refers to guidance-oriented interactions in Pull Request (PR) and Issue discussions, where contributors convey technical knowledge, facilitate problem diagnosis, clarify design rationale, provide normative guidance, and share feedback within natural conversational contexts. Although prior studies acknowledge the existence of such behaviors, systematic quantitative investigations of their scale, structural patterns, and impact remain limited due to reliance on qualitative methods, insufficient automated detection techniques, and the scarcity of high-quality annotated datasets.

**Aims.** To address these challenges, this paper proposes MentoScope, a large language model (LLM)-based automated framework for fine-grained identification and classification of NEM in GitHub collaboration contexts.

**Method.** Built upon Llama-3.1-8B, MentoScope undergoes a three-stage training pipeline. First, continual pre-training (CPT) with LoRA is applied on 92,778 PRs and 118,569 Issues for OSS domain adaptation. Second, supervised fine-tuning (SFT) on 15,214 high-quality annotated samples enables recognition of 8 predefined NEM categories. Third, Odds Ratio Preference Optimization (ORPO) with 3,280 preference pairs aligns model outputs with human judgment to enhance classification robustness.

**Results.** MentoScope achieves F1-scores of 94.20% and 80.13% on NEM identification and classification tasks respectively, significantly outperforming all baselines, with ablation studies confirming the necessity of each training stage. Large-scale analysis of 591,154 comments from 500 OSS projects reveals that NEM is present in over 70% of collaborative interactions, with distributional patterns varying systematically across project scales and discussion contexts. Furthermore, survival analysis on 1,245 newcomer contributors shows that NEM recipients achieve a 12.6% improvement in PR merge rates and a 35% extension in average active tenure compared to the control group.

**Conclusion.** These findings demonstrate that NEM constitutes a prevalent and impactful collaborative behavior in open source communities, with significant implications for newcomer integration and community sustainability.

## 1 Introduction

OSS constitutes a cornerstone of modern digital infrastructure, whose sustainable evolution depends not only on code production but also on continuous knowledge transfer and collaborative support among community members [8, 47]. However, mainstream code hosting platforms such as GitHub and their associated analytics tools predominantly adopt code-centric contribution metrics, prioritizing quantifiable artifacts such as code merges and commit frequency while systematically overlooking non-coding activities that are critical to community health and developer growth [44]. This structural bias risks contributor burnout, impedes newcomer integration, and ultimately threatens the long-term resilience and sustainability of OSS communities [40].

While non-coding contributions encompass activities such as fundraising, community management, and outreach, these largely occur outside code hosting platforms and are difficult to track at scale. To ensure observability and reproducibility, this study focuses on GitHub interactions, centering on a valuable but overlooked contribution form, namely NEM. We define NEM as guidance-oriented behavior embedded in PR and Issue discussions through which contributors facilitate the technical growth and community integration of others. Unlike explicit mentoring through formal programs or onboarding documentation, NEM manifests within routine code review and technical discourse as fine-grained implicit knowledge transfer, comprising architectural rationale articulation, heuristic debugging guidance, and norm transmission through constructive feedback. Although present in publicly accessible discussion text, NEM remains undetectable by existing rule-based or coarse-grained approaches due to its semantic overlap with routine technical clarification, leaving it unrecognized within prevailing contribution assessment frameworks.

Researchers increasingly recognize that NEM knowledge transfer in OSS technical discussions plays an important role in community functioning and contributor development. Young et al. [44] broaden the understanding of OSS contributions through the "All Contributors" model, while Meluso et al. [29] and Robin et al. [22] show that support-oriented activities beyond software artifacts remain essential to community sustainability. At the role level, Trinkenreich et al. [42] and Javier et al. [2] highlight the indispensable role of non-coding contributions in project development. More directly, Feng et al. [14] find that implicit mentoring appears in 27.41% of PRs, indicating growing attention to guidance-oriented behaviors in OSS technical interactions. The CHAOSS project [3, 4] further incorporates mentorship and knowledge transfer into community health metrics. Collectively, these studies underscore the importance of NEM in open source communities.

Despite the recognized significance of NEM, systematic investigation remains constrained by several critical challenges. Methodologically, reliance on surveys and interviews [14, 22, 42] introduces subjectivity and limits scalability within GitHub's large-scale asynchronous environment. Technically, existing rule-based or conventional machine learning approaches [14, 44] lack the semantic precision to decode nuanced mentoring behaviors in complex technical discourse. Furthermore, prior research often operates at a coarse-grained level by focusing on implicit roles [2, 42] instead of specific behavioral types. Ultimately, the scarcity of high-quality,

fine-grained annotated benchmarks continues to hinder robust empirical analysis.Recent advances in LLM offer a promising solution for automating mentoring identification in large-scale GitHub discussions due to their robust semantic reasoning [7]. However, general-purpose LLMs often lack the deep understanding of OSS technical conventions and community norms required for direct application.

To address these challenges, we propose MentoScope, an LLM-based automated analysis framework that integrates a multi-stage training strategy for fine-grained identification and classification of NEM in GitHub PR and Issue comments. First, we perform CPT [50] on Llama-3.1-8B [31] using large-scale OSS discussion data to capture domain-specific linguistic patterns. Second, we introduce a classification scheme of NEM comprising 8 fine-grained categories and construct a manually annotated dataset to support SFT [12] of the model. Third, we apply ORPO [20] to align model outputs with expert judgments. Through this design, MentoScope not only detects the presence of NEM but also identifies its specific types, enabling technical support for studying knowledge transfer and contribution behaviors in OSS communities. MentoScope is evaluated on a labeled dataset of 15,214 PR and Issue comments, achieving F1-scores of 94.20% for NEM identification and 80.13% for fine-grained classification, significantly outperforming all baselines. Applied to 591,154 comments from 500 Github OSS projects, large-scale analysis reveals that NEM appears in over 70% of community interactions, with distributional variation across project scales and interaction contexts. Survival analysis and non-parametric tests on 1,245 newcomers further show that NEM recipients achieve a 12.6% improvement in PR merge rates and a 35% extension in average active periods relative to the control group, providing strong evidence that NEM facilitates knowledge transfer and drives sustainable open source community development.

Our contributions are as follows:

**(1)** We introduce a fine-grained classification scheme of 8 NEM behavioral categories in GitHub collaborations, establishing a standardized foundation for quantifying and analyzing mentoring dynamics in OSS communities.

**(2)** We propose MentoScope, a three-stage LLM training framework achieving 94.20% F1-score on binary NEM identification and 80.13% on fine-grained classification, substantially outperforming all baselines, with ablation studies validating each training stage.

**(3)** Large-scale analysis of 591,154 comments from 500 OSS projects reveals that NEM appears in over 70% of interactions, with prevalence varying by project scale and discussion context. Survival analysis further shows that newcomers receiving NEM exhibit a 12.6% increase in PR merge rates and a 35% longer active participation period, highlighting NEM's role in facilitating knowledge transfer and community sustainability.

## 2 Background

### 2.1 Contribution recognition in open source communities

Open source community sustainability depends on sustained contributor engagement, prompting communities to establish recognition mechanisms for identifying and rewarding contributions. GitHub, the largest code hosting platform, centers its recognition system on code contributions, defining contributors as users who commit to a repository's default branch via a GitHub-associated email, and ranking the top 100 contributors by commit frequency on its Insights page. While effective for quantifying explicit code contributions, these mechanisms fail to capture non-code contributions [29]. CHAOSS, launched by the Linux Foundation in 2017, addresses this gap through a comprehensive community health framework spanning 10 metric themes including contributor definition and contribution diversity [4], but its reliance on qualitative surveys and self-reported data limits scalability and applicability to large unstructured datasets.

## 2.2 Mentorship in open source communities

Knowledge transfer and newcomer integration are vital to OSS sustainability, with mentoring playing a central role [13, 15]. Mentoring in OSS communities takes two forms: explicit and NEM. Explicit mentoring involves formal mentor-apprentice relationships with clear roles, goals, and timelines, typically organized by communities or external organizations [16]. Representative programs include the Linux Foundation Mentorship Program and Google Summer of Code (GSoC) [23, 41], where participants receive dedicated one-on-one guidance. CHAOSS defines mentorship metrics to assess such programs' impact on participation, retention, diversity, and career development. NEM occurs informally within routine PR and Issue discussions, without a designated mentor or formal channel [14]. Unlike explicit mentoring, NEM lacks formal commitments and arises naturally alongside technical responses, often without the mentee's awareness. Although NEM is present in publicly accessible discussions, existing recognition mechanisms fail to capture it effectively [4, 44], as its identification requires fine-grained semantic reasoning beyond the capacity of rule-based or coarse-grained approaches. Consequently, valuable mentoring behaviors go unrecognized, potentially reducing mentor motivation to sustain such support.

## 2.3 LLMs for software engineering tasks

LLMs have become transformative in software engineering, excelling in code completion, repair, and review [46], and demonstrating strong potential for open source community analysis through their contextual understanding and complex reasoning capabilities [37]. However, identifying NEM in PR and Issue discussions requires deep reasoning about both technical accuracy and mentoring intent, and general-purpose models lack the OSS-specific terminology and community norms necessary for reliable direct application. Domain adaptation addresses this through four complementary strategies. CPT [50] internalizes domain language patterns from OSS-specific corpora. SFT [12] calibrates models for specific tasks using labeled data. Preference optimization methods such as PPO [38], DPO [34] and ORPO [20] improve the reliability of subjective tasks by comparing pairwise. Parameter-Efficient Fine-Tuning (PEFT) [11] reduces computational overhead by updating only a small parameter subset, enabling large-scale experimentation in resource-constrained settings.

# 3 Approach

## 3.1 Overview

This section presents MentoScope, an LLM-based framework for automated identification and fine-grained classification of NEM in GitHub PR and Issue discussions. As illustrated in Figure 1, MentoScope comprises four sequential stages: data preparation, CPT, SFT, and ORPO. Each stage is described in detail in the following subsections.

## 3.2 Data preparation

### 3.2.1 Classification scheme for NEM

To identify NEM in GitHub communities, this study constructs a classification framework through a two-phase approach combining theoretical deduction and empirical induction.

In the theoretical deduction phase, we draw on existing literature on OSS mentoring, including Feng et al.'s definition of implicit mentoring [14], task-oriented mentoring strategies [41], and the CHAOSS measurement framework on mentoring mechanisms and

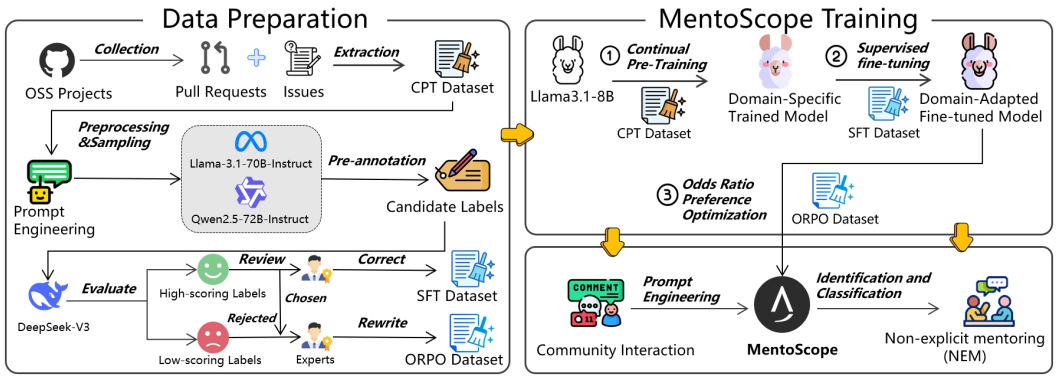

**Figure 1** Overview of the MentoScope framework, including data preparation, multi-stage training (CPT, SFT, and ORPO), and downstream NEM identification and analysis.

contributor diversity. Based on this foundation, NEM is decomposed into three dimensions: technical skill development, project knowledge transfer, and community culture assimilation, yielding 10 initial categories.

In the empirical induction phase, 1,200 PR and Issue comments with mentoring characteristics are randomly sampled from 10 high-activity OSS projects. Four researchers with software engineering backgrounds, including the authors, independently classify the data and iteratively refine the categories through constant comparison and negotiation. Specifically, "providing solutions", "debugging help", and "problem clarification" are merged into "Problem Solving Guidance" as all three serve the same function of guiding autonomous issue resolution; "environment configuration guidance" is expanded into "Workflow & Tooling Mastery" to reflect its broader coverage of project-specific toolchains and collaborative workflows. The resulting framework comprises 8 mutually exclusive categories, as detailed in Table 1.

### 3.2.2 Data collection and preprocessing

To support NEM analysis, we collect OSS project data from GitHub using a data collection strategy guided by three principles: representativeness, activity, and diversity. Repositories are filtered via the GitHub REST API and GitHub Archive metadata according to the following criteria: (1) more than 1,000 stars; (2) over 500 total PRs and Issues; (3) at least 50 commits within the past year, excluding stagnant projects. Major programming languages including C/C++, Java, and Python are covered to ensure linguistic diversity. A total of 500 OSS projects are selected. All PR and Issue discussions are crawled, capturing URLs, creation dates, authors, titles, descriptions, status changes, and commenter details. Automated comments are filtered using regular expressions and a bot list (e.g., github-actions[bot], dependabot), and short non-substantive replies and redundant emojis are removed. The resulting dataset comprises 591,154 high-quality comment records spanning 92,778 PRs, 118,569 Issues, and 101,835 users.

### 3.2.3 Dataset construction

To support the three-stage training pipeline of MentoScope, three distinct datasets are constructed.

**Table 1** Fine-grained classification scheme for NEM.

| Category | Description | Examples |
|---|---|---|
| A. Code Quality & Best Practices | Guidance on code implementation targeting maintainability, performance, and security principles. | Recommending design patterns; explaining security risks; teaching unit testing. |
| B. Problem Solving Guidance | Strategic guidance helping contributors resolve issues independently without providing direct solutions. | Suggesting debugging strategies; explaining log anomalies; guiding race condition analysis. |
| C. Technical Concept Explanation | Explaining foundational or project-specific concepts and terminology to bridge knowledge gaps. | Explaining asynchronous I/O; clarifying cryptographic algorithm principles. |
| D. Project Rationale & History | Explaining project-specific design philosophy, architectural evolution, and past decision contexts. | Explaining library exclusion decisions; clarifying historical coupling reasons; linking to past architectural discussions. |
| E. Workflow & Tooling Mastery | Guiding contributors on project-specific workflows, tooling, environment configuration, and CI/CD pipelines. | Assisting with environment setup; instructing on rebase over merge for clean commit history. |
| F. Community Norms & Process Onboarding | Guiding newcomers through contribution guidelines, communication etiquette, and governance rules to facilitate community integration. | Reminding commit message formatting; correcting inappropriate communication; guiding proper attribution. |
| G. Collaborative Mediation | Facilitating resolution of technical disagreements through compromise solutions or decision-making frameworks. | Providing trade-off analysis; guiding toward technical consensus; resolving discussion deadlocks. |
| H. Strategic Motivation & Recognition | Strengthening community belonging through positive feedback, contribution affirmation, or career development advice. | Affirming a newcomer's first PR value; encouraging broader maintenance responsibilities. |

▶ **CPT dataset construction.** The CPT dataset is designed to inject OSS specific language patterns and interaction dynamics through large-scale unsupervised pretraining. For each of the 92,778 PRs and 118,569 Issues, a context reconstruction strategy is applied in which the title and description are concatenated to establish topical context, followed by chronological linearization of associated comments. This structure preserves the narrative and temporal order of technical discussions, enabling the model to learn long-range contextual dependencies. The resulting CPT dataset comprises 211,347 samples.

▶ **SFT dataset construction.** The SFT dataset equips the model with the ability to identify and classify NEM behaviors through a three-stage annotation pipeline consisting of LLM pre-annotation, automatic filtering, and expert review. Zero-shot prompting is applied to Qwen2.5-72B-Instruct [33] and Llama-3.1-70B-Instruct [30] to perform semantic analysis on each comment. DeepSeek-V3 [24] then evaluates annotation quality across three dimensions: recognition accuracy (weight 0.4), classification accuracy (weight 0.4), and analytical completeness (weight 0.2). A weighted quality score is computed as $\text{Score} = 0.4 \times \text{Recognition Accuracy} + 0.4 \times \text{Classification Accuracy} + 0.2 \times \text{Analytical Completeness}$, which is used to select candidates for expert review. Three technical experts review the annotations, achieving a Fleiss' Kappa of 0.86, and disagreements are resolved through majority voting. The final SFT dataset contains 15,214 high-quality annotated samples.

▶ **ORPO dataset construction.** A total of 3,280 samples are randomly drawn from the remaining comment pool with no overlap with the SFT dataset. Preference pairs are constructed by reusing the annotation and scoring mechanisms from the SFT stage, where the highest-scoring annotation serves as the chosen response and a lower-scoring annotation exhibiting recognition bias or analytical omissions serves as the rejected response. Samples with insufficient quality distinctions are manually reconstructed to ensure each pair clearly contrasts correct reasoning with typical error patterns. For instance, a problem clarification comment mislabeled as "Workflow & Tooling Mastery" is relabeled as "Technical Concept Explanation", a more plausible confusable category, to maximize training discriminability.

## 3.3 CPT: OSS domain adaptation

CPT [50] adapts the general-purpose LLM to the OSS domain by training on large-scale unlabeled GitHub PR and Issue discussions, including titles, descriptions, and comments. This stage is essential because GitHub interactions contain abundant domain-specific terminology, code snippets, implicit context, and distinctive technical communication styles that cannot be adequately captured through fine-tuning alone. Llama-3.1-8B is selected as the base model based on its open-source availability, moderate parameter scale, and strong fine-tuning capability. In preliminary experiments on 100 benchmark samples, Llama-3.1-8B is compared against models of comparable scale, including Qwen2.5-7B [6], and Gemma-2-9B [18], demonstrating superior stability and overall performance.

To ensure computational efficiency during CPT while preserving parameter integrity, Low-Rank Adaptation (LoRA) [21] is employed. LoRA injects trainable low-rank matrices into specific layers of the pre-trained model, representing weight updates as a low-rank decomposition $\Delta W = BA$, where $B \in \mathbb{R}^{d\times r}$, $A \in \mathbb{R}^{r\times k}$, and $r \ll \min(d, k)$, rather than modifying the original weight matrix $W_0 \in \mathbb{R}^{d\times k}$ directly. During CPT, the base model (Llama-3.1-8B) parameters remain frozen and only the LoRA adapters are optimized.

The objective of continual pre-training is to enhance the model's capability to predict the next token conditioned on preceding context, which corresponds to a standard language modeling task. During training, we employ the cross-entropy loss to quantify the discrepancy between the predicted token distribution and the ground-truth next-token distribution.

For a sample in the CPT dataset corresponding to a complete discussion sequence of a PR or Issue, let its length be $T_i$ and denote the token sequence as $\mathbf{w}_i = (w_{i,1}, w_{i,2}, \ldots, w_{i,T_i})$. The overall continual pre-training loss is defined as:

$$L_{\text{CPT}} = -\frac{1}{|D_{\text{CPT}}|} \sum_{i=1}^{|D_{\text{CPT}}|} \sum_{t=1}^{T_i} \log P\big(w_{i,t} \mid w_{i,<t}; \theta, \Phi\big) \tag{1}$$

where $|D_{\text{CPT}}|$ denotes the total number of CPT samples and $T_i$ the length of the $i$-th sample. The token $w_{i,t}$ is the target token at position $t$, and $w_{i,<t}$ represents all preceding tokens serving as context. The term $P(w_{i,t} \mid w_{i,<t}; \theta, \Phi)$ is the model's predicted probability of generating $w_{i,t}$ given its context, parameterized by the frozen base model parameters $\theta$ and the trainable LoRA parameters $\Phi$ comprising matrices $A$ and $B$. Gradients are computed via backpropagation and only $\Phi$ is updated to minimize $L_{\text{CPT}}$, while $\theta$ remains unchanged to preserve the linguistic competence of the pre-trained model.

Through this process, the Llama-3.1-8B model acquires OSS-specific technical terminology, abbreviations, code references, and implicit communication patterns from developer discussions, achieving domain adaptation within its latent representation space. After training, the learned LoRA weights are merged back into the base model to obtain a domain-adapted backbone, defined as $W_{\text{merged}} = W_0 + \alpha_{\text{LoRA}} \cdot BA$, where $\alpha_{\text{LoRA}}$ denotes the scaling factor controlling the contribution of the LoRA adaptation weights.

## 3.4 SFT: NEM identification and classification

SFT [12] further optimizes the domain-adapted base model to accurately identify and classify NEM behaviors in PR and Issue comments. To this end, we design prompts that guide the model to transform unstructured comments into structured outputs aligned with our research requirements. Following established prompt design principles of providing necessary context, defining clear task instructions, and specifying output format [25, 27], we construct the following prompt:

**System Context**
You are an expert software engineer and senior OSS maintainer specializing in analyzing developer interactions to identify Non-explicit Mentoring (NEM). NEM refers to spontaneous guidance embedded in technical discussions, through which experienced contributors support others' technical growth or community integration.

**Task Description**
Analyze the given GitHub comment and determine whether it contains NEM. If present, classify the comment into one or more NEM categories based on the classification scheme. Multiple categories may apply.

**Input Data**
Interaction Type: {{Interaction Type}}
Title: {{Title}}
Discussion Summary: {{Summary}}
Target Comment Content: {{Comment}}

**Mentoring classification scheme**
Classify the comment into one or more of the following categories:
{{Scheme Definition}}

**Output Format**
Provide the result in strict JSON format:

```
{
  "contains_nem": true / false,
  "categories": [
    {
      "category_name": "Category name from classification scheme",
      "evidence": "Brief justification based on comment content."
    }
  ]
}
```

In the prompt template, {{Interaction Type}} specifies whether the comment originates from a PR or an Issue. {{Title}} represents the title of the PR or Issue, and {{Summary}} provides a concise overview of its main description; full descriptions are summarized in advance to avoid exceeding context window limits and to reduce noise from lengthy code snippets or environmental details. {{Comment}} denotes the specific text under analysis, serving as the direct input for NEM identification and classification.

Each annotated sample in the SFT dataset is converted into a $\langle \text{Prompt}, \text{Response} \rangle$ pair for supervised learning. The training objective is to minimize the discrepancy between model predictions and human annotations. As the SFT dataset is smaller than the CPT dataset and the task requires precise instruction-following and structured output, full-parameter fine-tuning is adopted. For each sample $(x, y)$, where $x$ is the input prompt and $y$ is the human-annotated target response, the loss function is defined as:

$$\mathcal{L}_{\text{SFT}} = -\frac{1}{|\mathcal{D}_{\text{SFT}}|} \sum_{(x,y)\in\mathcal{D}_{\text{SFT}}} \sum_{t=1}^{|y|} \log P(y_t \mid x, y_{<t}; \theta) \tag{2}$$

where $|\mathcal{D}_{\text{SFT}}|$ is the total number of SFT samples, $|y|$ the length of the target sequence, $y_t$ the $t$-th output token, and $y_{<t}$ the preceding $t-1$ tokens. The term $P(y_t \mid x, y_{<t}; \theta)$ denotes the model's predicted probability of generating $y_t$ given the input prompt $x$ and the preceding tokens $y_{<t}$, with $\theta$ representing the full set of model parameters initialized from the CPT-adapted backbone with merged LoRA weights. The model minimizes $\mathcal{L}_{\text{SFT}}$ via backpropagation to update $\theta$, learning to perform NEM identification and classification based on prompt instructions and contextual input, thereby generating structured outputs that follow the prescribed format.

## 3.5 ORPO: Preference alignment for error mitigation

Although SFT maximizes the probability of generating correct responses, it does not differentiate between outputs of varying quality, leaving the model prone to plausible but erroneous analyses in ambiguous contexts. To address this, we incorporate ORPO [20], a preference alignment method that integrates supervised fine-tuning and preference alignment into a single optimization objective, eliminating the need for a reference model while increasing the generation probability of chosen responses and suppressing that of rejected ones.

The ORPO training dataset consists of triplets $(x, y_c, y_r)$, where $x$ is the input prompt following the SFT format, $y_c$ is a human-verified high-quality NEM analysis, and $y_r$ is a rejected response containing recognition biases or logical errors. ORPO reinforces preferred outputs by optimizing the log odds ratio between $y_c$ and $y_r$. For an input $x$, the odds of generating $y$ are defined as $\text{odds}_\theta(y \mid x) = P_\theta(y \mid x)/(1 - P_\theta(y \mid x))$, where $P_\theta(y \mid x)$ denotes the probability of generating the complete sequence $y$. The corresponding odds ratio is $\text{OR}_\theta(y_c, y_r \mid x) = \text{odds}_\theta(y_c \mid x)/\text{odds}_\theta(y_r \mid x)$, measuring the model's relative preference for the chosen response over the rejected response.

After introducing the concept of the odds ratio, the loss function of ORPO is defined as:

$$\mathcal{L}_{\text{ORPO}} = -\frac{1}{|\mathcal{D}_{\text{ORPO}}|} \sum_{(x,y_c,y_r)\in\mathcal{D}_{\text{ORPO}}} (\log P_\theta(y_c \mid x) \ + \lambda \log \sigma(\log \text{OR}_\theta(y_c, y_r \mid x))) \tag{3}$$

Here, $\theta$ denotes the trainable model parameters initialized from the SFT-adapted model. $|\mathcal{D}_{\text{ORPO}}|$ is the total number of ORPO samples. The first term in the loss function is a negative log-likelihood term that encourages the model to increase the generation probability of the chosen response $y_c$. The second term is a preference term that maximizes the log odds ratio of $y_c$ relative to the rejected response $y_r$, where $\sigma$ denotes the sigmoid function. The hyperparameter $\lambda$ controls the relative weight of the two terms, with larger values making the preference term more dominant. By minimizing $\mathcal{L}_{\text{ORPO}}$ in Equation (6), the model simultaneously increases the generation probability of the chosen response $y_c$ and enlarges its probability margin over the rejected response $y_r$. This joint optimization enables the model to produce accurate NEM analyses while suppressing known error patterns, thereby improving the robustness and overall accuracy of MentoScope.

The resulting model after the ORPO stage constitutes the final MentoScope model, which integrates the general capabilities of the base model, the domain knowledge from CPT, the task execution ability from SFT, and the preference alignment with human experts through ORPO, enabling accurate and reliable identification and classification of NEM in open source community interactions.

# 4 Experimental setup

## 4.1 Research questions

This section presents the evaluation of MentoScope on GitHub data, addressing the following research questions:

**(1)** RQ1: How effectively does MentoScope identify and classify NEM?
**(2)** RQ2: How do different components of MentoScope contribute to overall performance?
**(3)** RQ3: How is NEM distributed across different contextual settings?
**(4)** RQ4: How does NEM influence newcomer retention and performance?

## 4.2 Datasets

▶ **CPT dataset.** This dataset adapts general-purpose LLMs to the OSS domain, constructed from 500 OSS projects collected in Section 3.2.3, encompassing 92,778 PRs and 118,569 Issues. Through contextual reconstruction and linear integration of titles, descriptions, and associated comments, a pre-training dataset of 211,347 samples is produced.

▶ **SFT dataset.** To support accurate NEM identification and classification, 15,214 high-quality annotated samples are produced from 591,154 comments across 500 OSS projects via a three-stage pipeline of LLM pre-annotation, automated filtering, and expert verification. The dataset is split into training (10,650), validation (1,521), and test (3,043) datasets at a 7:1:2 ratio. The test dataset also serves as the unified benchmark for evaluating the overall MentoScope framework, ensuring consistent comparison across all experimental settings.

▶ **ORPO dataset.** To further enhance discriminative capability through preference alignment, 3,280 samples are randomly drawn from the remaining comment pool with no overlap with the SFT dataset, and preference pairs comprising chosen and rejected responses are constructed. Each pair is manually verified and refined to ensure a clear and justified quality gap between positive and negative samples. As preference optimization typically adopts a low-epoch training strategy to mitigate catastrophic forgetting, all samples are used for training.

## 4.3 Baselines

Prior work primarily relies on questionnaire-based qualitative analysis. Feng et al. [14] apply traditional machine learning models including random forest to coarsely distinguish implicit guidance from routine PR interactions, without differentiating specific guidance types. Cobos et al. [7] integrate LLMs with prompt engineering to classify Issue comments by sentiment polarity, focusing on ethical dimensions such as constructive and abusive language. Building on these approaches, we evaluate MentoScope against three categories of baselines.

▶ **ML-based methods.** Naive Bayes [28], K-Nearest Neighbors [9], and XGBoost [5] serve as lexical baselines, all using TF-IDF [39] features without contextual semantic encoding, enabling assessment of whether lexical-statistical signals alone suffice for NEM identification.

▶ **PTM-based methods.** BERT [10], RoBERTa [26], and T5 [35] are employed to examine the contribution of contextual semantic representation. BERT and RoBERTa are fine-tuned with a linear classification head, while T5 is cast as a sequence-to-label generation task. All models are fine-tuned on the SFT dataset and evaluated on the same test set.

▶ **LLM-based methods.** Open source LLMs of comparable parameter scale are included as baselines, namely Qwen2.5-7B [6], Llama-3.1-8B [19], Mistral-7B-v0.3 [32], and Gemma-2-9B [17], each evaluated under zero-shot and few-shot settings. The zero-shot setting directly applies the prompt in Section 3.4, while the few-shot setting incorporates labeled examples to enable in-context learning of NEM definitions.

## 4.4 Metrics

NEM identification is characterized as a binary classification task that determines whether a PR or Issue comment contains any form of NEM. We evaluate this task using Accuracy, Precision, Recall, and F1-score, defined as $\mathit{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN}$, $\mathit{Precision} = \frac{TP}{TP+FP}$, $\mathit{Recall} = \frac{TP}{TP+FN}$, and $\mathit{F1\text{-}Score} = \frac{2 \cdot \mathit{Precision} \cdot \mathit{Recall}}{\mathit{Precision}+\mathit{Recall}}$. Here, $TP$ and $TN$ denote correctly predicted positive and negative samples, whereas $FP$ and $FN$ denote false positives and false negatives.

NEM classification is characterized as a multi-label classification task, where a single comment may involve one or more NEM categories. We consider eight categories, listed in Table 1, and evaluate classification performance using Jaccard Accuracy together with micro-averaged Precision, Recall, and F1-score. These metrics are computed only on comments for which NEM is correctly identified, thereby measuring categorization performance conditioned on successful detection.

For each sample $i$, the Jaccard Score is defined as $\mathit{Jaccard\text{-}Score}_i = \frac{|Y_{true,i} \cap Y_{pred,i}|}{|Y_{true,i} \cup Y_{pred,i}|}$, where $Y_{true,i}$ and $Y_{pred,i}$ denote the ground-truth and predicted label sets. Jaccard Accuracy is defined as the mean Jaccard Score over all $N$ samples, that is, $\mathit{Jaccard\text{-}Accuracy} = \frac{1}{N}\sum_{i=1}^{N} \mathit{Jaccard\text{-}Score}_i$.

To assess overall performance in the multi-label setting, we further report micro-averaged Precision, Recall, and F1-score, which aggregate predictions across all $C = 8$ categories and are suitable for imbalanced data. Specifically, $\mathit{Micro\text{-}Precision} = \frac{\sum_{c=1}^{C} TP_c}{\sum_{c=1}^{C}(TP_c+FP_c)}$, $\mathit{Micro\text{-}Recall} = \frac{\sum_{c=1}^{C} TP_c}{\sum_{c=1}^{C}(TP_c+FN_c)}$, and $\mathit{Micro\text{-}F1\text{-}Score} = \frac{2 \cdot (\mathit{Micro\text{-}Precision} \cdot \mathit{Micro\text{-}Recall})}{\mathit{Micro\text{-}Precision}+\mathit{Micro\text{-}Recall}}$, where $TP_c$, $FP_c$, and $FN_c$ denote the numbers of true positives, false positives, and false negatives for category $c$, respectively.

## 4.5 Implementation details

The MentoScope training pipeline is implemented on the ms-swift framework [48], an official fine-tuning and deployment framework provided by the ModelScope community, and proceeds through the CPT, SFT, and ORPO stages. In the CPT stage, LoRA-based parameter-efficient fine-tuning is applied with rank 64, scaling factor 128, and all linear layers as target modules. The maximum sequence length is set to 8,192, the effective batch size is set to 32 through 4-step gradient accumulation, the learning rate is set to $1 \times 10^{-5}$, and the model is trained for 1 epoch. Both SFT and ORPO adopt full-parameter fine-tuning with a maximum sequence length of 4,096, a learning rate of $1 \times 10^{-4}$, and the same effective batch size. SFT is trained for 3 epochs to fit the annotated label distribution, whereas ORPO is trained for 1 epoch to reinforce preference for high-quality responses. All experiments are conducted on 8 NVIDIA H100 (80GB) GPUs. During inference, greedy decoding is applied with $\mathit{temperature} = 0$ and $\mathit{do\_sample} = \text{False}$ to ensure reproducible results.

# 5 Evaluation and discussion

## 5.1 Effectiveness of NEM identification and classification

Table 2 presents the performance comparison of MentoScope and baseline methods on NEM identification and classification. MentoScope achieves F1-scores of 94.20% and 80.13% on identification and classification respectively, outperforming the best general LLM baseline (Llama-3.1-8B 5-shot) by 6.38% and 3.60%. ML-based methods fall substantially behind.

**Table 2** Performance comparison between MentoScope and baselines on NEM identification and classification tasks.

| Model | NEM Identification (%) | | | | NEM Classification (%) | | | |
|---|---|---|---|---|---|---|---|---|
| | ACC | P | R | F1 | ACC | P | R | F1 |
| *ML-based methods* | | | | | | | | |
| KNN | 62.34 | 87.85 | 62.16 | 72.81 | 48.40 | 50.63 | 47.66 | 49.10 |
| Naive Bayes | 68.72 | 85.63 | 71.81 | 78.11 | 46.56 | 52.63 | 48.23 | 50.33 |
| XGBoost | 71.63 | 81.76 | 76.98 | 79.30 | 50.97 | 61.65 | 50.46 | 55.50 |

| *LLM-based methods (0-shot)* | | | | | | | | |
| Mistral-7B-v0.3 | 64.15 | 87.24 | 64.30 | 74.03 | 51.88 | 54.26 | 52.44 | 53.33 |
| Qwen2.5-7B | 65.32 | 86.56 | 65.16 | 74.35 | 53.09 | 53.62 | 57.92 | 55.69 |
| Llama-3.1-8B | 65.81 | 88.18 | 65.52 | 75.18 | 58.96 | 62.23 | 58.30 | 60.20 |
| Gemma-2-9B | 65.50 | 88.61 | 64.79 | 74.85 | 57.45 | 60.55 | 56.73 | 58.58 |
| *LLM-based methods (5-shot)* | | | | | | | | |
| Mistral-7B-v0.3 | 77.90 | 87.58 | 84.89 | 86.21 | 68.24 | 73.35 | 71.43 | 72.38 |
| Qwen2.5-7B | 82.17 | 90.56 | 83.52 | 86.90 | 70.48 | 76.25 | 73.20 | 74.70 |
| Llama-3.1-8B | 83.98 | 91.09 | 84.78 | 87.82 | 72.35 | 78.71 | 74.46 | 76.53 |
| Gemma-2-9B | 83.72 | 89.98 | 84.47 | 87.14 | 71.84 | 78.57 | 73.94 | 76.18 |
| **MentoScope** | **88.30** | **95.74** | **92.70** | **94.20** | **75.73** | **82.28** | **78.09** | **80.13** |

KNN achieves high precision (87.85%) but extremely low recall (62.16%) on identification, while XGBoost, the strongest ML baseline, reaches only 55.50% classification F1-score, highlighting the inability of shallow TF-IDF features to capture the implicit semantics of NEM behaviors. PTM-based models such as BERT perform adequately on identification ($F1 >$ 85%) but deteriorate on fine-grained classification requiring deep semantic understanding. T5, the best PTM baseline, trails MentoScope by 6.67% in classification F1-score, indicating that standard pretrained models lack the OSS domain specificity needed to distinguish fine-grained NEM categories.

General LLMs struggle in zero-shot settings, typically scoring below 75% and 61% in identification and classification F1-scores, respectively. This reflects their difficulty in grasping the precise academic boundaries of NEM. Providing 5-shot examples significantly enhances LLM performance with an average F1-score increase of 12%, proving that in-context examples help align model comprehension with mentoring behaviors. However, a distinct gap persists compared to the fully optimized MentoScope.

Ultimately, MentoScope achieves exceptionally high precision (95.74%) while maintaining high recall (92.70%). In practical NEM identification, this high precision crucially minimizes false positives, preventing standard bug-fix discussions from being misjudged as mentoring. This accuracy is vital for subsequently quantifying developer contributions and establishing fair community recognition mechanisms.

**Answer to RQ1:** MentoScope consistently outperforms all baselines, achieving F1-scores of 94.20% for NEM identification and 80.13% for NEM classification, which confirms the effectiveness of the multi-stage training pipeline for identifying and categorizing NEM in open source community interactions.

**Table 3** Performance on NEM identification and NEM classification.

| Model | NEM Identification (%) | | | | NEM Classification (%) | | | |
|---|---|---|---|---|---|---|---|---|
| | ACC | P | R | F1 | ACC | P | R | F1 |
| w/o CPT | 86.70 | 93.50 | 90.61 | 92.03 | 72.11 | 80.31 | 74.32 | 77.20 |
| w/o SFT | 78.30 | 89.71 | 81.08 | 85.18 | 65.03 | 70.91 | 68.13 | 69.49 |
| w/o ORPO | 83.60 | 91.56 | 87.96 | 89.72 | 70.13 | 76.69 | 72.41 | 74.49 |
| w/o Title | 86.50 | 93.42 | 90.96 | 92.17 | 73.39 | 80.23 | 74.92 | 78.02 |
| w/o Summary | 80.90 | 91.29 | 85.59 | 88.35 | 71.16 | 77.39 | 75.47 | 76.42 |
| MentoScope | **88.30** | **95.74** | **92.70** | **94.20** | **75.73** | **82.28** | **78.09** | **80.13** |

## 5.2 Impact of component design on performance

To evaluate the contribution of MentoScope's core components and input representations, we design several ablation variants for comparative analysis. The experimental factors include the multi-stage training strategy (CPT, SFT, ORPO) and prompt-level contextual enhancements (Title, Summary). The variants under evaluation are as follows:

- **w/o CPT**: Removes continual pretraining to assess the effect of domain adaptation.
- **w/o SFT**: Omits supervised fine-tuning to evaluate the necessity of task-specific instruction alignment.
- **w/o ORPO**: Disables preference optimization to measure the effect of contrastive preference learning on resolving ambiguous decision boundaries.
- **w/o Title** and **w/o Summary**: Individually removes the PR/Issue title and textual summary from the prompt to examine the contribution of global contextual information to local comment interpretation.

Table 3 shows that the three training stages contribute unevenly to overall performance. Removing SFT causes the most substantial degradation, with identification and classification F1-scores dropping by 9.02% and 10.64% to 85.18% and 69.49% respectively, confirming that SFT serves as the primary mechanism for acquiring task-specific discriminative capability. Removing ORPO reduces identification and classification F1-scores by 4.48% and 5.64% to 89.72% and 74.49%, indicating that preference alignment improves robustness on semantically ambiguous inputs. Excluding CPT results in comparatively moderate reductions of 2.17% and 2.93%, demonstrating that domain-adaptive pretraining provides valuable contextual priors that benefit subsequent training stages.

The ablation results on prompt components highlight the importance of contextual input design. Removing the PR/Issue summary causes the most substantial degradation, with F1-scores dropping by 5.85% on identification and 3.71% on classification, as raw descriptions introduce noise and increase inference overhead while diluting task-relevant semantic cues. A structured summary thus serves as an effective information compression mechanism that supplies high-density signals for NEM detection. Removing the title has a more limited effect, with reductions of 2.03% and 2.11% on identification and classification respectively, indicating that titles provide a concise topic indicator whose marginal contribution diminishes when a high-quality summary is present.

**Answer to RQ2:** Ablation results indicate that each component of MentoScope contributes positively to overall performance. Through a multi-stage training process and an optimized prompt design, the framework integrates domain adaptation, task-specific learning, and preference optimization, leading to strong performance in both NEM identification and NEM classification tasks.

**Table 4** Distribution of NEM categories.

| NEM Category | Proportion (%) |
|---|---|
| Code Quality & Best Practices | 14.28 |
| Problem Solving Guidance | 23.45 |
| Technical Concept Explanation | 3.12 |
| Project Rationale & History | 7.92 |
| Workflow & Tooling Mastery | 5.67 |
| Community Norms & Process Onboarding | 4.15 |
| Collaborative Mediation | 1.84 |
| Strategic Motivation & Recognition | 12.36 |
| Regular Discussion (Non-NEM) | 27.21 |

**Table 5** Distribution of NEM categories across project sizes (%).

| NEM Category | Small | Medium | Large |
|---|---|---|---|
| Code Quality & Best Practices | 11.24 | 14.56 | 17.04 |
| Problem Solving Guidance | 21.15 | 23.12 | 26.08 |
| Technical Concept Explanation | 2.54 | 3.10 | 3.72 |
| Project Rationale & History | 5.12 | 8.24 | 10.40 |
| Workflow & Tooling Mastery | 6.84 | 5.52 | 4.65 |
| Community Norms & Process Onboarding | 5.42 | 4.02 | 3.01 |
| Collaborative Mediation | 1.10 | 1.95 | 2.47 |
| Strategic Motivation & Recognition | 16.51 | 12.18 | 8.39 |
| Regular Discussion (Non-NEM) | 30.08 | 27.31 | 24.24 |

## 5.3 Distribution patterns of NEM across contexts

After establishing the effectiveness of MentoScope, we apply it to 591,154 comments from 500 GitHub projects collected in Section 3.2.2 to examine NEM distribution in real-world settings. For clearer comparative analysis, regular discussion (Non-NEM) is included as a reference category.

Table 4 presents the distribution of eight NEM behavior types in open source community interactions. NEM accounts for 72.79% of GitHub collaborations, substantially exceeding routine transactional discussions (27.21%). "Problem Solving Guidance" (23.45%) and "Code Quality & Best Practices" (14.28%) together comprise nearly 40% of NEM instances, indicating that contributors predominantly guide debugging and convey engineering practices rather than providing direct solutions, facilitating the transition from novice to experienced contributors. "Strategic Motivation & Recognition" (12.36%) underscores the role of positive reinforcement in sustaining community cohesion. "Project Rationale & History" (7.92%) reflects the long-tail nature of OSS discussions, where higher-level mentoring on architectural evolution remains rare. "Collaborative Mediation", though the smallest category (1.84%), is critical for maintaining decision-making consistency. The balanced distribution of "Workflow & Tooling Mastery" and "Community Norms & Process Onboarding" reflects sustained community efforts to onboard new members.

To investigate NEM distribution across OSS projects of varying scales, 500 OSS projects are classified into three categories via multidimensional weighted clustering based on core contributor count, total lines of code (LOC), and PR count. Small-scale projects have fewer than 5 core maintainers and typically comprise emerging tools or libraries with narrowly scoped functionality. Medium-scale projects have 5 to 20 core maintainers, with established collaboration workflows and a stable user base. Large-scale projects have more than 20 core maintainers and represent ecosystem-level projects with high sociotechnical complexity.

Table 5 presents the distribution of NEM categories across projects of varying scales. "Problem Solving Guidance", "Code Quality & Best Practices", and "Project Rationale & History" increase monotonically with project scale, reflecting greater architectural complexity

**Table 6** Distribution of NEM categories across PR and Issue comments.

| NEM Category | PR (%) | Issue (%) |
|---|---|---|
| Code Quality & Best Practices | 24.15 | 4.41 |
| Problem Solving Guidance | 15.30 | 31.60 |
| Technical Concept Explanation | 2.05 | 4.19 |
| Project Rationale & History | 7.12 | 8.72 |
| Workflow & Tooling Mastery | 6.24 | 5.10 |
| Community Norms & Process Onboarding | 4.88 | 3.42 |
| Collaborative Mediation | 1.35 | 2.33 |
| Strategic Motivation & Recognition | 16.24 | 8.48 |
| Regular Discussion (Non-NEM) | 22.67 | 31.75 |

and cognitive load in larger projects, where "Regular Discussion(Non-NEM)" reaches its lowest proportion (24.24%), indicating higher mentoring density. Small-scale projects exhibit affective and normative guidance patterns, with "Strategic Motivation & Recognition" and "Community Norms & Process Onboarding" occurring at substantially higher rates, revealing retention strategies aimed at alleviating contributor scarcity and lowering participation barriers. This structural shift from institutionalized technical norms in large-scale projects to interpersonal motivational mechanisms in small-scale ones demonstrates that NEM adaptively adjusts its knowledge transfer and member cultivation functions according to community scale and organizational structure.

Table 6 presents the distribution of NEM categories across PR and Issue discussions. In PR discussions, "Code Quality & Best Practices" predominates (24.15%), consistent with code review as a quality control mechanism, while "Strategic Motivation & Recognition" occurs at a substantially higher rate (16.24%), reflecting maintainers' tendency to reinforce contributors' sense of achievement upon code submission. In Issue discussions, "Problem Solving Guidance" is most prevalent (31.60%), with elevated frequencies of "Technical Concept Explanation" and "Collaborative Mediation" indicating that conceptual clarification and resolution of technical disagreements are primarily addressed at this stage. These patterns demonstrate the functional complementarity of NEM across collaboration contexts, with Issue discussions supporting problem exploration and PR discussions emphasizing norm reinforcement and contribution recognition.

**Answer to RQ3:** Empirical analysis reveals that NEM accounts for over 72% of community interactions, with distribution varying by project scale and collaboration context. Large-scale projects emphasize technical norm transmission while small-scale projects exhibit stronger affective and normative guidance; Issue discussions prioritize conceptual clarification while PR discussions focus on quality reinforcement, demonstrating that NEM constitutes a context-adaptive form of implicit knowledge transfer in OSS communities.

## 5.4 RQ4: Impact of NEM on newcomer retention and performance

Based on the observed prevalence and contextual distribution of NEM, we further assess its impact on newcomer retention and performance. We identify 1,245 newcomer contributors from the 500 projects, defined as developers submitting their first PR within a project, and divide them into two groups: (1) the NEM group, consisting of newcomers who receive at least one instance of NEM during their initial PR or Issue interactions, and (2) the control group, comprising those who engage only in routine transactional discussions. We track their activity over a 12-month period and compare outcomes in terms of community retention and technical performance using survival analysis and non-parametric statistical tests.

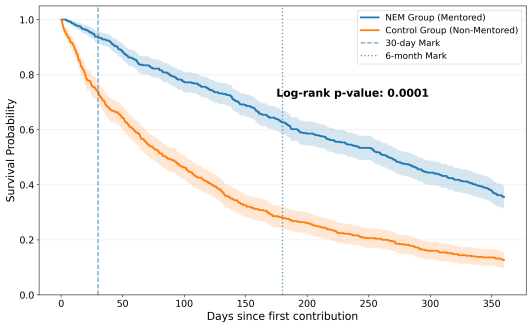

**Figure 2** Kaplan–Meier survival curves: newcomer retention.

To assess the longitudinal effect of NEM on newcomer retention, survival analysis is employed, defining contributor disengagement as the absence of activity for more than 6 months following the first PR submission. As shown in Figure 2, Kaplan-Meier survival curves reveal significant retention differences between the two groups. Within the first 30 days, the NEM group maintains a survival rate above 85%, while approximately 30% of control group members cease all interactions within one month. A log-rank test confirms a statistically significant difference between the two curves ($p < 0.001$). At the sixth month, newcomers receiving NEM exhibit an average active tenure approximately 35% longer than the control group, with this advantage remaining robust at the twelfth month.

PR merge rate is used as the primary metric for newcomers' short-term technical performance. The Wilcoxon rank-sum test [36] shows that the NEM group achieves a significantly higher average merge rate than the control group (74.82% vs. 62.16%, $p < 0.001$), with a meaningful effect size. This result suggests that NEM provides substantive knowledge support rather than simple social interaction. Guidance such as "Problem-Solving Guidance" and "Code Quality & Best Practices" helps newcomers quickly align with project conventions, reducing PR rejections caused by technical misunderstanding or limited norm awareness.

**Answer to RQ4:** Empirical results show that NEM has a significant positive effect on newcomer contributors. Newcomers who receive NEM achieve an approximately 12.6% higher PR merge rate, along with significantly stronger long-term retention and longer community activity cycles than the control group. These findings confirm the value of NEM as an effective knowledge transfer mechanism.

## 6 Threats to Validity

**Internal validity.** The definition of NEM involves inherent sociological subjectivity, and perceptions of mentoring may vary across cultural contexts. Annotation subjectivity and inconsistency may affect model training outcomes, which we mitigate through a three-stage pipeline combining LLM pre-annotation, automated filtering, and expert review.

**External validity.** This study is conducted on GitHub OSS projects, and the findings are therefore primarily applicable to GitHub collaboration contexts. Generalizability to other platforms or domains with distinct development constraints warrants further investigation. Additionally, although the survival analysis in RQ4 controls for multiple observable covariates, newcomers' sustained activity may still be subject to project-external factors.

# 7 Related work

## 7.1 Analyzing mentoring behaviors in OSS

Mentorship has long been recognized as a critical factor in open source community sustainability [15]. Early studies on formal mentorship examined role models, guidance strategies, and collaboration dynamics [16], finding that while formal mentorship improves contributor retention, its effectiveness is moderated by project characteristics and social support conditions [13]. Recent attention has shifted toward the more pervasive NEM behaviors. Steinmacher et al. [42] reveal through qualitative analysis the hidden efforts and challenges faced by mentors across technical, social, and motivational dimensions. Feng et al. [14] define NEM as informal mentoring embedded in PR comments and demonstrate its prevalence and positive community effects. However, existing studies rely predominantly on manual analysis or traditional machine learning models, with clear limitations in automated fine-grained NEM classification; impact assessments largely employ questionnaires or interviews, lacking large-scale empirical grounding. This study proposes MentoScope to address these gaps through automated NEM identification and large-scale distributional analysis.

## 7.2 LLM-based analysis of OSS developer activities

The advancement of LLMs enables deep semantic extraction from large volumes of developer interactions, overcoming the analytical limitations of traditional text mining. Previous work has applied LLMs to understand the intention of developers [1], assess ideological themes [45], construct behavior taxonomies [43], and analyze gendered collaboration patterns [49]. Distinct from these studies on general developer behaviors, this work focuses on NEM as an underexplored yet practically significant behavior type. MentoScope integrates CPT, SFT, and ORPO to adapt a general-purpose LLM to the software engineering domain, enabling precise identification of fine-grained mentoring behaviors in PR comments and supporting large-scale analysis of implicit knowledge transfer among developers.

# 8 Conclusion

This paper investigates NEM in open source communities as a fine-grained form of guidance-oriented knowledge transfer embedded in PR and Issue discussions. We propose MentoScope, a three-stage LLM framework integrating CPT, SFT, and ORPO, which achieves state-of-the-art performance on automated NEM identification and classification. Large-scale empirical analysis further reveals the prevalence of NEM, its distributional differences across project contexts, and its positive association with newcomer retention and contribution outcomes.

## Abstract

**Background.** LLM coding assistants are widely used in development, but evidence about their reliability mostly comes from mainstream languages such as Python and Java. Their behaviour on emerging languages, where public code and documentation are scarce, is far less clear.

**Aims.** We ask how capable current LLMs are on Cangjie, an emerging language in the HarmonyOS ecosystem, and which assistive technique is worth its token cost.

**Method.** We build CangjieBench, 248 manually translated tasks derived from HumanEval and ClassEval, run under Text-to-Code and Code-to-Code modalities. We evaluate six LLMs under five methods: direct generation, syntax-constrained prompting, retrieval over documentation, retrieval over code, and agent-based workflows. We report Pass@1, compile rate, token cost, and a seven-category failure taxonomy validated by two LLM annotators ($\kappa \geq 0.98$).

**Results.** Direct generation is unusable on most models, and over four-fifths of failed samples carry foreign syntax that the Cangjie compiler rejects. A 2,146-token syntax reference gives the best accuracy-to-cost trade-off among prompt-based methods. The best agent configuration reaches the highest Pass@1 at 10–120x the token cost of a single prompt, while weaker agents cannot match a syntax-constrained call on the same backbone. A Python reference does not always help: on Code-to-Code it can pull models toward Python idioms and drop compile rates below Text-to-Code.

**Conclusions.** No single method dominates both accuracy and token cost. A practical assistant for an emerging language should ship a concise syntax cheat sheet first, escalate to curated retrieval for API-heavy tasks, and reserve agent loops for tasks that need multi-turn repair. The replication package is at `https://github.com/cjhCoder7/CangjieBench`.

## 1 Introduction

Large language models (LLMs) now power IDE completions and agent CLIs [2, 23, 10] that generate, translate, and repair code in real projects, but most of the evidence that they do this well rests on a narrow set of languages. HumanEval [5] and MBPP [3] evaluate Python, the benchmarks most often reported for new models [13] still centre on Python, Java, and JavaScript, and MultiPL-E [4] shows that once evaluation moves to less represented languages the gap between a model's Python score and its score elsewhere can be large. For languages outside this core, far less is known about whether current models are usable, which assistive technique is worth its token cost, and what the typical failure modes look like.

Emerging languages make the problem worse. A young language has little public code, its documentation is still being written, and its idioms have not stabilised, so the base model, the retrieval index, and the agent scaffolding all have less material to draw on than on Python or Java, and claims established on Python, such as "retrieval adds a few points of Pass@1" or "agent loops recover most compile errors", do not automatically carry over and have to be re-measured.

Cangjie is such a language. Released in 2024 as the native language of the HarmonyOS application ecosystem [12], Cangjie is statically typed and memory-safe, with syntax and type rules that differ from both Python and Java. HarmonyOS now ships on hundreds of millions of devices, so its developers are the intended audience for a Cangjie coding assistant, yet the volume of Cangjie seen at training time is small and the assistant has less prior knowledge of the language than developers expect. For a team adopting Cangjie today, three questions are open: how capable current models are without help, whether assistive techniques that work for Python transfer, and how the choice between prompt, retrieval, and agent affects accuracy and token cost.

Existing evaluations do not close this gap. Prior work on low-resource languages has mostly targeted domain-specific languages such as Verilog [20] or Solidity [27], where any performance drop mixes missing domain knowledge with missing language knowledge. Cross-language benchmarks such as MultiPL-E and HumanEval-XL [26] translate HumanEval into many targets but do not compare assistive methods or report token cost, and empirical studies of prompt engineering, retrieval-augmented generation [39], and agent-based workflows [35] are almost entirely set in Python and rarely put these methods on the same accuracy-against-cost axis. A study of a modern, statically-typed emerging general-purpose language that brings these factors together is missing.

We address that gap with an empirical study organised around four research questions:

- **RQ1 (accuracy).** How do direct generation, syntax-constrained prompting, documentation retrieval, code-example retrieval, and agent-based workflows compare on Cangjie pass rate?

- **RQ2 (token cost).** How much does each method cost in input and output tokens, and how does the cost ranking compare with the pass-rate ranking?
- **RQ3 (transfer).** Is Code-to-Code translation from Python easier than Text-to-Code generation, and does a Python reference induce negative transfer toward Python idioms?
- **RQ4 (failure modes).** What is the distribution of foreign-syntax drift, API misuse, type and mutability errors, duplicate-definition or harness conflicts, runtime exceptions, and logic errors, and how does it shift across methods, models, and tasks?

To answer these questions, we build **CangjieBench**, a 248-task benchmark with 164 function-level problems manually translated from HumanEval and 84 class-level problems from ClassEval [8], each shipping with a Cangjie reference solution and a harness that compiles the generated code, links it against the reference tests, and runs the result. On this benchmark we evaluate six recent LLMs (DeepSeek-V3 [19], ERNIE-4.5 [31], Kimi-K2 [32], Qwen3-235B-2507 and Qwen3-Coder-480B [38], and GPT-5 [24]) under five methods: direct generation, syntax-constrained prompting with a concise rule set, retrieval over Cangjie documentation, retrieval over curated code examples, and an agent-based workflow that reads documentation, runs the compiler, and revises across turns. Every task runs under two modalities, Text-to-Code and Code-to-Code, and for each run we record Pass@1, compile rate, token usage, and the category of the first observed failure, seeded by manual labelling of 788 failed GPT-5 samples and applied to the full benchmark by two LLM annotators whose agreement we cross-check ($\kappa \geq 0.98$).

Four observations recur across RQ1–RQ4. Direct generation is unreliable on most models, as code typically fails before the tests run and over four-fifths of failed samples carry foreign syntax the compiler will not accept. Among prompt-based methods a concise syntax rule set gives the best accuracy-to-cost trade-off and retrieval does not match it once its token cost is counted, while the best agent configuration reaches the highest absolute pass rate but spends an order of magnitude more tokens than any single-shot method. A Python reference does not always help, and on several cells it pulls the model toward Python idioms so that Code-to-Code compile rate drops below Text-to-Code, a negative-transfer pattern rather than a boost. Finally, the failure mix shifts with method, as prompt-only runs are dominated by syntax and API errors while agent runs are the only C2C configuration where logic errors reach a non-trivial share, since their failed samples regularly clear the compiler.

Taking the benchmark, the evaluation, and the failure analysis together, this paper makes three contributions.

- **CangjieBench**, a 248-task function- and class-level benchmark for Cangjie, with reference solutions, compile-and-test harnesses, and a public replication package.
- A head-to-head evaluation of six LLMs across five methods and two modalities that reports pass rate, compile rate, and token cost separately, making the accuracy-cost trade-off explicit rather than collapsing it into one score.
- A failure taxonomy for Cangjie code generation, with per-method distributions and an analysis of where current models break on an emerging language.

## 2 Background and Related Work

**Low-Resource Language Benchmarks.** LLMs perform well on high-resource languages [4] but drop sharply on low-resource ones, largely due to training-data scarcity. MultiPL-E extended HumanEval and MBPP to eighteen languages, and more recent benchmarks focus on individual targets such as Verilog [20, 29], Solidity [27], TeX [16], VHDL [33], shell scripting [34], GPU kernels [25], and SQL [18]. On the translation side, ClassEval-T [37]

extends class-level evaluation to translation tasks, and MERA Code [7] unifies tasks across languages. A recent survey [15] organises this space. Two gaps remain for our study. First, **entanglement with domain knowledge**: domain-specific language (DSL) benchmarks mix language novelty with domain constraints, so an observed drop mixes unfamiliar syntax with unfamiliar hardware or contract semantics. Second, **data-leakage risk**: languages traditionally labelled low-resource, such as Lua [22] and R [43], have long histories and still appear in modern pre-training corpora, weakening contamination controls. Cangjie addresses both: as a general-purpose language it keeps the domain constant, and its 2024 release keeps pre-training exposure small.

**Methods of Code Generation.** Modern code generation builds on foundation models such as GPT-5, Qwen3, and Gemini [9], together with three broad families of assistive methods: *Prompt Engineering* [30, 28], *Retrieval-Augmented Generation* [21], and *Agentic Frameworks* [35]. At the project level, recent work also studies multi-agent collaboration over larger codebases [42]. For Python-to-target-language translation specifically, prior work spans parallel corpora such as AVATAR [1], function-level decomposition [41], execution-guided repair [11], interpretable error correction [36], and language-pair benchmarks such as CRUST-Bench for C-to-Rust [17]. Previous studies on low-resource code, however, usually limit evaluation to direct zero-shot or few-shot prompting and rarely report token cost alongside accuracy. We place all three families on the same footing, with the same tasks, models, and target language, so that differences in accuracy and token cost can be attributed to the method rather than to incomparable setups.

## 3 CangjieBench Construction

Multilingual suites such as MultiPL-E do not include Cangjie, and DSL benchmarks entangle language novelty with domain knowledge. We therefore build **CangjieBench**, which targets Cangjie directly, runs both Text-to-Code generation and Python-to-Cangjie translation on the same problem set, and grades each sample by compiling and executing it on the Cangjie toolchain. As Figure 1 shows, it has three components: a manually translated dataset of 248 Cangjie problems, two evaluation tasks under different input modalities, and a framework that compiles and runs each sample inside a Docker sandbox (Section 9).

### 3.1 Dataset Construction

Publicly available Cangjie code is scarce and dominated by official samples a pre-trained model has likely seen, so the usual crawl-and-deduplicate pipeline is not viable. We instead build CangjieBench by manually translating two widely used Python benchmarks, *HumanEval* and *ClassEval*, covering function-level and class-level problems. HumanEval [5] consists of 164 hand-written Python problems, each with a function signature, docstring, and unit tests, and is the de facto standard for function-level generation despite a known bias toward algorithmic tasks and limited API diversity. ClassEval [8] extends this to the class level with 100 problems that require complete Python classes, testing the multi-method cohesion and cross-method state management absent from function-level benchmarks. Both datasets are self-contained, one task per file with no cross-file dependencies, unlike repository-level benchmarks such as CoderEval [40] and SWE-bench [14], which keeps the ground truth easy to verify by hand and makes each task small enough that any failure can be attributed to the model's handling of Cangjie rather than to ambiguity about which file to edit.

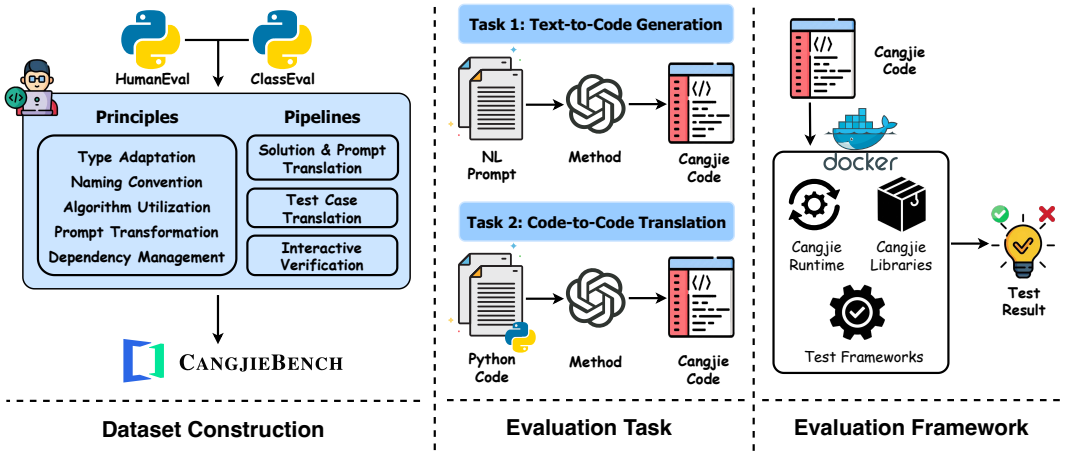

**Figure 1** Overview of the CangjieBench framework: dataset construction, evaluation tasks, and evaluation sandbox.

To keep the translation faithful, we follow a fixed set of construction rules throughout, derived from the authors' experience building Cangjie programs since its 2024 release. No existing benchmark methodology addresses Cangjie, so rather than adopt one we developed the rules during a pilot translation of roughly 30 tasks and applied them to all 248.

- **Type Adaptation.** We map Python primitives onto their strict Cangjie equivalents (`int`→`Int64`, `float`→`Float64`, `str`→`String`, `bool`→`Bool`) and Python lists and dictionaries onto `ArrayList` and `HashMap`. Where a Python signature relies on dynamic typing, we use Cangjie's `Any` interface and add explicit casts only where the harness needs a concrete value.
- **Naming Convention.** We keep the original *snake_case* identifiers rather than camel case, which preserves the link to the source task and rules out a trivial failure where the model looks for the wrong identifier.
- **Algorithm Utilization.** Cangjie reference solutions reproduce the control flow of the Python solutions step by step, including branching, loops, and recursion, without substituting a more idiomatic algorithm, since the goal is to grade how well a model expresses a known algorithm in Cangjie rather than the algorithm itself.
- **Prompt Transformation.** HumanEval and ClassEval prompts embed Python fragments such as signatures, docstrings with type hints, and few-shot examples, and we rewrite every fragment into Cangjie form so that the description and any embedded code both refer to the target language, since a mixed-language prompt would leave us unable to tell whether the model was responding to the prompt or patching over the inconsistency.
- **Dependency Management.** We substitute the matching Cangjie standard library for standard Python modules. Tasks depending on third-party Python libraries with no Cangjie equivalent, such as `sqlite3`, `PIL`, and `sklearn`, are excluded rather than reimplemented, since a from-scratch replacement would measure library quality rather than model capability, and Table 1 lists all 16, but we implement very small utilities such as `hashlib.md5` so that tasks needing only a hash function stay in.

The construction was carried out in three steps over roughly 1.5 months. First, the first author translated every prompt and reference solution and wrote a matching Cangjie test suite. Second, two other authors with substantial Cangjie experience independently reviewed each translated problem, solution, and test case, resolving disagreements by discussion and,

**Table 1** ClassEval tasks excluded from CangjieBench and the Python-specific library responsible for the exclusion.

| Problem ID | Problem Name | Exclusion Reason |
|---|---|---|
| ClassEval_14 | `BookManagementDB` | Relies on `sqlite3` for database operations |
| ClassEval_25 | `CookiesUtil` | Relies on `json` for data serialisation |
| ClassEval_28 | `DatabaseProcessor` | Relies on `sqlite3` for database operations |
| ClassEval_34 | `DocFileHandler` | Relies on `docx` for Word document processing |
| ClassEval_38 | `ExcelProcessor` | Relies on `openpyxl` for spreadsheet manipulation |
| ClassEval_44 | `HtmlUtil` | Relies on `bs4` and `gensim` for HTML/NLP processing |
| ClassEval_45 | `ImageProcessor` | Relies on `PIL` for image processing |
| ClassEval_50 | `JSONProcessor` | Relies on `json` for data serialisation |
| ClassEval_52 | `Lemmatization` | Relies on `nltk` for NLP processing |
| ClassEval_60 | `MovieTicketDB` | Relies on `sqlite3` for database operations |
| ClassEval_69 | `PDFHandler` | Relies on `PyPDF2` for PDF manipulation |
| ClassEval_83 | `StudentDatabaseProcessor` | Relies on `sqlite3` for database operations |
| ClassEval_84 | `TextFileProcessor` | Relies on `json` for data serialisation |
| ClassEval_92 | `UserLoginDB` | Relies on `sqlite3` for database operations |
| ClassEval_98 | `XMLProcessor` | Relies on `xml` for XML parsing |
| ClassEval_99 | `ZipFileProcessor` | Relies on `zipfile` for archive management |

where needed, by rerunning the tests against alternative references. Third, we ran every suite against its reference solution and against deliberate perturbations such as wrong return types, off-by-one boundaries, and known-buggy substitutes, confirming that the tests both accept the correct answer and reject common incorrect ones.

After review, CangjieBench contains **248** tasks: all **164** HumanEval problems, which map cleanly onto Cangjie's standard library, plus **84** of the original 100 ClassEval problems, with Table 1 listing the 16 excluded for Python-specific dependencies. The two subsets give two granularities: HumanEval probes whether a model can write a single correctly typed routine, while ClassEval asks it to lay out a multi-method class and respect the Cangjie object model across method boundaries.

## 3.2 Evaluation Tasks

Every task runs under two modalities that share the same reference solution and test harness. In *Text-to-Code*, the model receives only a natural-language description and produces a Cangjie implementation from scratch, isolating its ability to generate Cangjie without a per-task anchor. In *Code-to-Code*, the model additionally receives the corresponding Python reference and must produce a behaviourally equivalent Cangjie implementation, mirroring a team porting an existing Python codebase and letting us measure whether a known-good Python solution helps or instead anchors the model on Python idioms.

We grade correctness by running the per-task Cangjie test suite. A HumanEval-derived sample passes if the generated function compiles and clears all test cases, and a ClassEval sample must pass every method-level test plus a class-level integration test, so that a class whose methods pass in isolation but fail when composed is still flagged incorrect.

## 3.3 Evaluation Framework

The evaluation framework is a Docker-based sandbox that pins the Cangjie toolchain, standard library, and test runner to a single image and executes each sample in a fresh container. Pinning lets us compare timing and error messages across models, methods, and machines on

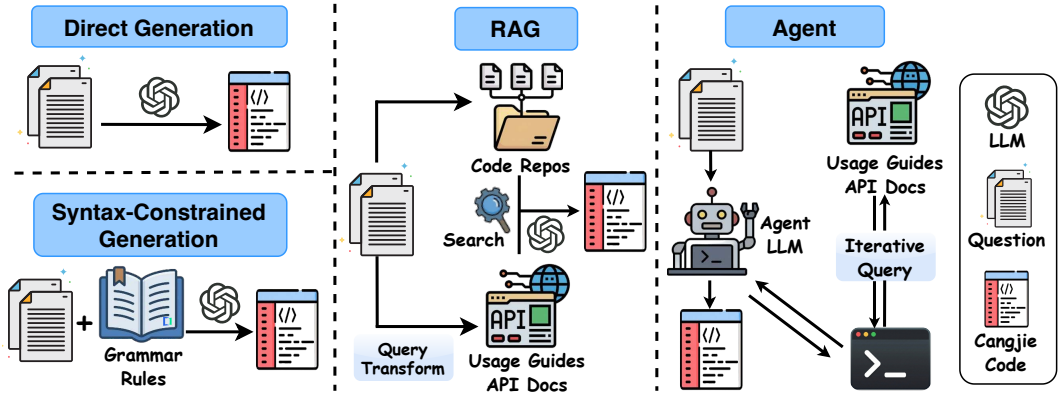

**Figure 2** The four method families evaluated on CangjieBench. Direct generation is the baseline. The other three families add Cangjie-specific context in different ways.

equal terms, and isolating each run protects the host from agent-generated code the model has only partially understood. For every sample the harness records whether compilation succeeded, whether all tests passed, the compiler and runtime stderr, and the wall-clock time, the raw signals on which the failure analysis in Section 5 is built.

## 4 Methods

We exclude training methods, since the goal is not to engineer a Cangjie-specialised model but to ask how far an off-the-shelf foundation model can be pushed on an emerging language using techniques a team would normally have at hand. We evaluate four method families common in practice, summarised in Figure 2: *Direct Generation*, *Syntax-Constrained Prompting*, *Retrieval-Augmented Generation* with two variants (RAG-Docs and RAG-Code), and *Agent-based workflows*.

### 4.1 Method Families

**Direct Generation.** The model receives the natural-language problem description, plus the Python reference solution under Code-to-Code, wrapped in a fixed prompt template with no grammar reference, no retrieved snippets, and no tools.

**Syntax-Constrained Prompting.** Since most of the LLMs we evaluate have seen little Cangjie at training time, a common engineering response is to ship a small "language pack", a syntax cheat-sheet injected into every prompt, and we prepend such a reference to the direct-generation template.

**Retrieval-Augmented Generation.** A more involved response gives the assistant access to a Cangjie corpus at inference time and pastes a few retrieved snippets into context. We evaluate two variants matching the two corpora a typical assistant would index, official documentation (RAG-Docs) and crawled code (RAG-Code), and for an emerging language both corpus and retrieval signal are weaker than for Python, so whether this pays off is an open question.

**Agent-based Workflow.** A more open-ended response, similar to how a new developer learns an unfamiliar language, lets the assistant read documentation, write code, run the compiler, and revise its output across several turns, and we want to know what such a loop costs in tokens and buys in pass rate on a language with thin pre-training coverage.

## 4.2 Configuration

**Syntax reference.** The grammar reference used by Syntax-Constrained Prompting covers 20 categories: program structure, variables, numeric types, strings and characters, the boolean type, arrays and dynamic arrays, hash maps, hash sets, sorting, tuples, conditional statements, loop statements, the option type, match expressions, lambda expressions, input and output, functions, classes, interfaces, and reserved keywords. It totals 2,146 GPT-5 tokens, well below every model's context limit.

**RAG corpora and retriever.** Both RAG variants use Okapi BM25 with top-$k = 3$. The *Docs* corpus is the Cangjie Developer Manual and standard-library API reference from the official repository, with HTML stripped and text split on section headers, and because problem statements and API reference rarely share surface vocabulary, we add a query-transformation step in which the model first extracts technical keywords such as library and API method names, which we issue to BM25 in place of the raw description. The *Code* corpus is Cangjie source crawled from public GitCode repositories before 10 November 2025, filtered to files at least 80 % Cangjie, parsed with the Cangjie AST tool, and split into 30,341 functions and 31,483 class definitions, and here we issue the prompt directly to BM25 because it already contains code-shaped material such as signatures and type hints.

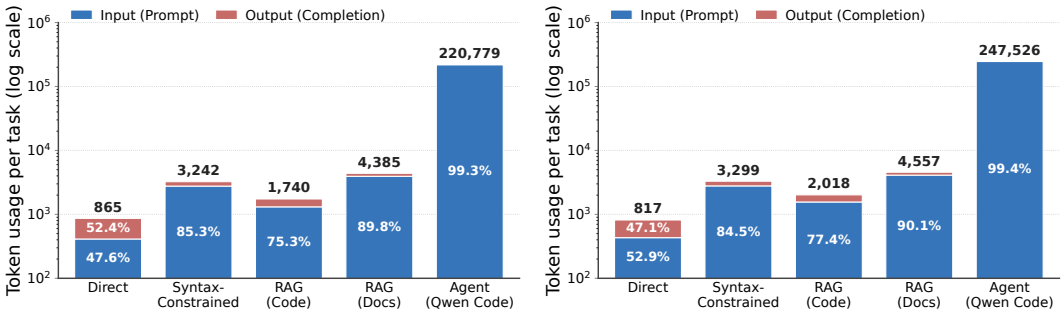
**Agent harnesses.** We use three CLI agent harnesses without modification: **Codex CLI** version 0.63.0, **Qwen Code CLI** version 0.2.3, and **iFlow CLI** version 0.4.8. All three can read files, execute shell commands, and inspect shell output, and their built-in retrieval differs, itself a method-level variable. Each agent receives the problem description, the direct-generation template, and read access to the same Cangjie documentation tree used by RAG-Docs, kept under Git and rolled back after every interaction step, and terminates when its harness reports completion or hits the step budget.

# 5 Results

## 5.1 Experimental Setup

**Subjects.** The open-weights subjects are DeepSeek-V3 (671B parameters), ERNIE-4.5 (300B), Kimi-K2-0905 (1T), Qwen3-235B-A22B-Instruct-2507 (235B), and Qwen3-Coder-480B, and the closed-source subject is GPT-5. We restrict the selection to models above 200B parameters because smaller models bottomed out at near-zero Pass@1 in pilot runs, leaving no headroom to separate the methods, and the six we keep span two families of general-purpose models and two code-specialised ones, so any method effect we report is not tied to a single training recipe. The four agent configurations are Codex CLI / GPT-5, Qwen Code CLI / Qwen3-Coder, iFlow CLI / Qwen3-Coder, and iFlow CLI / Kimi-K2-0905, using the three CLI harnesses of Section 4.2, chosen because they are the harnesses a Cangjie developer can install and run today.

**Table 2** Pass@1 (%) and Compile rate (%) on CangjieBench. Light gray columns indicate Text-to-Code (T2C), and dark gray columns indicate Code-to-Code (C2C). The best result per method is in **bold**, and the overall best across all methods is **red and underlined**. Avg. averages over HumanEval (164 tasks) and ClassEval (84 tasks) weighted by task count.



| Method | Subject | HumanEval | | | | ClassEval | | | | Avg. | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Pass@1 | | Compile | | Pass@1 | | Compile | | Pass@1 | | Compile | |

**Decoding protocol.** All cells use greedy decoding with `temperature` = 0 and `max_tokens` = 8192, drawing a single sample per task, with open-source models served through the SiliconFlow API and GPT-5 through the OpenAI API. This removes sampling variance from the comparison but forgoes the smoothing of Pass@$k$ with $k > 1$, so we add a Pass@10 robustness check under syntax-constrained prompting in Section 6. For agent runs we cap each task at the harness default step budget and count a run as failed if it exhausts the budget without a compiling submission.

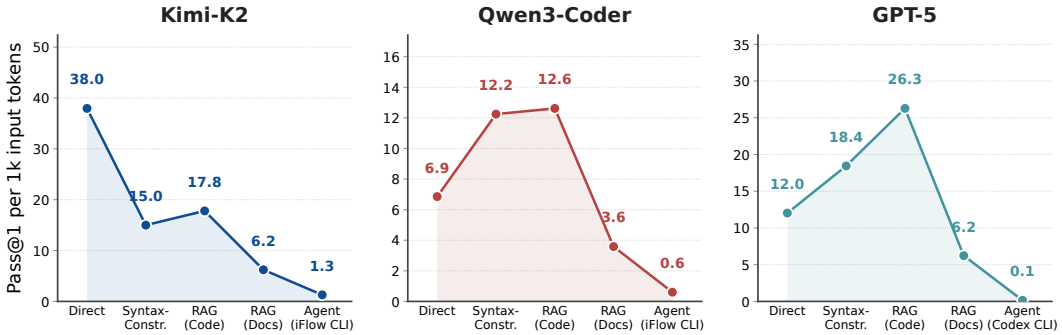
**Metrics.** *Pass@1* is the fraction of tasks whose single sample compiles and passes every test, and *Compile rate* is the fraction that compile regardless of tests, so their gap separates logic-only failures from cases where no compilable Cangjie program was produced. *Token usage* sums input and output tokens over the 248 tasks, aggregating every turn for agent runs, and *Failure category distribution* reports the share of unsuccessful samples in each of the seven failure classes of Section 5.5. We report Pass@1 and Compile rate as percentages weighted by task count across the two subsets, and the per-cell records behind every number are in the replication package (Section 9).

## 5.2 RQ1: How do the four method families compare on pass rate?

In Table 2 the four method families do not order themselves on a single accuracy axis, as the three findings below make precise.

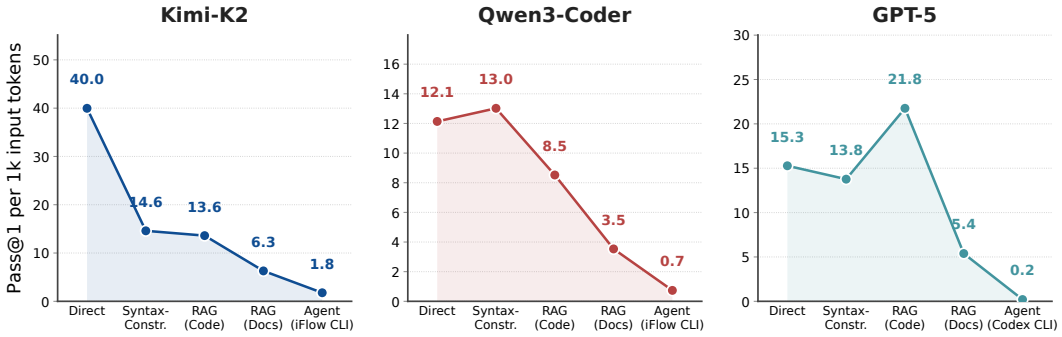
(a) Text-to-Code (b) Code-to-Code

**Figure 3** Per-task token usage of Qwen3-Coder across the five methods on (a) Text-to-Code and (b) Code-to-Code. Total tokens are on a log scale, and each bar is split into Input (Prompt) and Output (Completion) percentages, with the absolute total printed above.



**Direct generation fails at the compile step, not the logic step.** Without Cangjie-specific scaffolding, five of the six base models score under 7 % Pass@1 in either modality, only Kimi-K2 breaks 10 % at 15.3 % T2C and 16.9 % C2C on average, and GPT-5, the strongest model elsewhere, reaches only 4.8 % on Direct T2C. Compile rate sits within about 3 pp of Pass@1 on every Direct cell, so a failing model usually fails before the tests run, unable to produce a program the toolchain accepts.

**Syntax-Constrained Prompting dominates the prompt-based methods.** On T2C average, every base model gains 22–46 pp over Direct once given the grammar reference: GPT-5 climbs from 4.8 % to 50.4 %, Kimi-K2 from 15.3 % to 40.7 %, and Qwen3 from 2.8 % to 39.5 %. Both RAG variants help less, as averaged over T2C and C2C GPT-5 reaches 33.7 % under RAG-Code, 25.2 % under RAG-Docs, and 44.2 % under Syntax-Constrained, with the same ordering on the open-weights subjects. That a 2,146-token grammar reference outperforms BM25 retrieval over megabytes of Cangjie source shows that **fixing the syntax model matters more than supplying example code**, since retrieved examples cannot fix syntax the model has not yet seen.



**Agent reaches the highest pass rate, but only with a strong backbone.** Codex CLI on GPT-5 averages 66.9 % T2C and 77.0 % C2C, the best on every subset and modality and the only Agent configuration that dominates Syntax-Constrained on its own backbone, while the other three sit in the 18–40 % range, comparable to or below Syntax-Constrained on the same backbones. The agentic loop amplifies what the backbone can already do, but does not lift a weak backbone past a stronger one running with the syntax reference.

## 5.3 RQ2: How much does each method cost in tokens?

Figure 3 reports Qwen3-Coder's per-task token usage across all five methods, spanning two orders of magnitude. Direct generation consumes roughly 1k tokens per task, Syntax-Constrained about 3.3k once the 2,146-token grammar header is added, and the two RAG variants between about 1.7k and 4.6k, while Agent under iFlow CLI jumps to 34–36k and Agent under Qwen Code CLI to 221–248k, roughly 220–250x Direct. Output share falls from about half of Direct's tokens to below 3 % for both agent runs, so the assistant spends almost all of its budget reading documentation and prior turns rather than writing code.

(a) Text-to-Code

(b) Code-to-Code

**Figure 4** Pass@1 per 1,000 input tokens for Kimi-K2, Qwen3-Coder, and GPT-5 on (a) Text-to-Code and (b) Code-to-Code. Pass@1 and input tokens are task-count-weighted over HumanEval (164) and ClassEval (84), matching Table 2. Higher is better.

**Cost reverses the accuracy ranking.** Figure 4 plots Pass@1 per 1,000 input tokens, on which a method that doubles accuracy at tenfold the tokens loses. On Kimi-K2, Direct is the most efficient cell at around 40 Pass@1 per 1k tokens on both modalities despite scoring only 15–17 % Pass@1, since a single 500-token prompt yields a little correct code very cheaply. On Qwen3-Coder and GPT-5, where Direct yields almost no passing samples, Syntax-Constrained and RAG-Code lead, and GPT-5 RAG-Code on T2C reaches 26.3 Pass@1 per 1k tokens, more than 4x RAG-Docs at 6.2 on the same backbone.

**The Agent ceiling collapses on the per-token axis.** Codex CLI on GPT-5 sets the absolute Pass@1 ceiling, but Figure 4 shows it consumes those gains at 0.14 Pass@1 per 1k tokens on T2C and 0.20 on C2C, tens to nearly two hundred times below the prompt-based methods on the same backbone, and the two iFlow configurations sit at 0.6–1.8. Method choice therefore becomes a question of token budget rather than absolute accuracy: when tokens are unconstrained Codex CLI on GPT-5 is the right choice, but under any practical budget **Syntax-Constrained Prompting is the dominant strategy on every backbone we evaluate**, reaching on Qwen3-Coder 33.9 % T2C and 36.3 % C2C at 10–75x lower cost than the same backbone in either Agent harness.

## 5.4 RQ3: Does a Python reference help or hurt?

**Code-to-Code is not uniformly easier than Text-to-Code.** Averaged across all six base models and all prompt-based methods, C2C and T2C are within about 1 pp on HumanEval and T2C is slightly ahead on ClassEval. The Python reference neither reliably helps nor

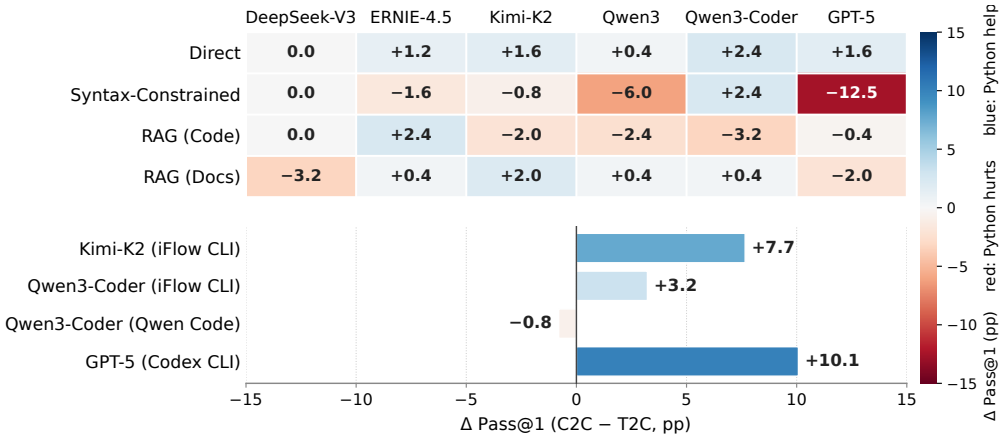


**Figure 5** Δ Pass@1 (C2C − T2C, percentage points), task-count-weighted over HumanEval and ClassEval. Negative (red) means a Python reference hurts on Code-to-Code, and positive (blue) means it helps. Top: prompt-based methods × base models. Bottom: each of the four agent configurations.

hurts, since its direction depends on the method and its effect on the average is small next to the method-level variance in Figure 5, which shows Δ Pass@1 in percentage points, C2C minus T2C, for every cell, with the Cangjie-anchored prompt-based methods on the red side where the reference hurts and Direct, RAG-Docs, and the Agent configurations on the blue side where it helps.

The most striking case is GPT-5 under Syntax-Constrained on HumanEval, where Pass@1 drops from 64.0 % T2C to 44.5 % C2C, a 19.5 pp regression on the same tasks with the Python solution available, and the average column drops 12.5 pp. Compile rate moves with it, from 67.1 % to 45.1 %, so the regression is a syntax issue rather than a logic one, with the reference pulling GPT-5 toward Python idioms that do not survive the Cangjie compiler.

The pattern splits cleanly by method type: under *Syntax-Constrained* and *RAG-Code*, which put Cangjie syntax or code in the prompt, T2C beats C2C on 4 of 6 base models on the average column, so negative transfer concentrates where the model already has Cangjie-shaped material to anchor on. Two apparent exceptions confirm the mechanism rather than break it. Syntax-Constrained on Qwen3-Coder shows a slight positive Δ of about +2.4 pp, the same direction it takes under Direct, because this code-specialised model carries structure over from the Python reference faster than it takes on the Python idioms the compiler rejects. RAG-Docs on GPT-5 shows a negative Δ of about −2.0 pp despite no Cangjie code in the prompt, because retrieved documentation fragments introduce inconsistent Cangjie API calls that the reference compounds. Under *Direct* and *RAG-Docs*, by contrast, the reference helps on most subjects, since with no Cangjie scaffold to anchor on the Python solution at least gives a structural skeleton.

The Agent rows show a sharply different pattern: three of the four configurations score higher under C2C than T2C on the average column, by 10.1 pp for Codex on GPT-5, 7.7 pp for iFlow on Kimi-K2, and 3.2 pp for iFlow on Qwen3-Coder, with only Qwen Code on Qwen3-Coder flat at −0.8 pp, and the gap is largest on ClassEval, where Codex on GPT-5 jumps from 32.1 % to 58.3 %. The multi-turn loop absorbs the negative-transfer pressure, since the extra turns let the agent revise Python-specific syntax that would land verbatim in a single-shot prompt, so **negative transfer is a property of the consuming method, not of the Python reference itself.**

**Table 3** Failure distribution per method and modality, primary annotator glm-5.1. Cells show the share of failed samples in each category. Avg. aggregates failed samples across methods within each modality. The last row gives the total failure count for each column.

| Failure category | Direct | | Syntax-Constrained | | RAG (Code) | | RAG (Docs) | | Agent | | Avg. | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | T2C | C2C | T2C | C2C | T2C | C2C | T2C | C2C | T2C | C2C | T2C | C2C |
| Syntax (foreign) | **83.9** | **82.0** | 30.0 | 27.2 | **56.6** | **59.1** | **60.9** | **61.0** | **46.1** | **50.4** | **58.8** | **58.7** |
| API/library | 12.4 | 14.0 | **34.6** | **42.4** | 32.5 | 30.4 | 26.4 | 26.6 | 30.0 | 30.0 | 26.0 | 27.5 |
| Type/mutability | 2.6 | 3.2 | 16.3 | 16.8 | 8.2 | 8.7 | 4.6 | 6.8 | 13.3 | 13.7 | 7.9 | 8.9 |
| Duplicate def. | 0.0 | 0.1 | 8.9 | 10.2 | 0.0 | 0.0 | 4.5 | 3.7 | 0.0 | 0.0 | 2.6 | 2.7 |
| Runtime exc. | 0.4 | 0.5 | 0.7 | 0.8 | 0.6 | 0.7 | 0.4 | 0.5 | 1.2 | 1.0 | 0.6 | 0.7 |
| Logic error | 0.6 | 0.1 | 9.2 | 2.6 | 2.0 | 1.0 | 3.1 | 1.4 | 9.4 | 4.7 | 4.0 | 1.6 |
| Timeout | 0.0 | 0.0 | 0.2 | 0.0 | 0.1 | 0.0 | 0.1 | 0.0 | 0.0 | 0.2 | 0.1 | 0.0 |
| *Total failures* | 1,414 | 1,396 | 944 | 990 | 1,229 | 1,243 | 1,238 | 1,243 | 647 | 597 | 5,472 | 5,469 |

## 5.5 RQ4: Where do the failures come from?

We labelled every failed sample with one of seven error categories.

**Taxonomy.** The taxonomy was derived through open coding of 788 failed GPT-5 samples on T2C across all five methods. We selected GPT-5 because it reaches the widest range of failure modes, whereas weaker models stall almost entirely on foreign-syntax errors, and we seeded on T2C because the model cannot attribute failures to the Python reference, so each error traces to a gap in its Cangjie knowledge. The first author grouped samples by recurring surface patterns and merged or split categories until no large cluster remained unlabelled, producing six categories, with a seventh, *Timeout*, added for runs that do not finish within the evaluation budget.

**Annotation procedure.** For each failed sample we supplied the LLM annotator with the compiler or runtime error output, the first failing error line, and the category descriptions with one short example each, and instructed it to assign exactly one label, report a confidence level, give a one-sentence rationale, and quote the primary evidence.

**Annotator selection.** We chose glm-5.1 and kimi-k2.6 as annotators because both have strong Chinese-language understanding, which matters as Cangjie documentation and error messages often mix English identifiers with Chinese descriptions, and they come from different organisations, Zhipu AI and Moonshot AI, so agreement across two independently trained models is stronger evidence of label reliability than two runs of one model. Treating glm-5.1 as primary and kimi-k2.6 as a cross-check, applying both to the 788 manually annotated samples reproduced the manual labels on almost every sample, so we extended LLM labelling to the full benchmark.

The seven categories are *Syntax (foreign)* for invalid syntax mirroring another language, *API/library* for nonexistent identifiers or wrong call shapes, *Type/mutability* for type or mutability mismatches, *Duplicate def.* for redeclarations or harness conflicts, *Runtime exception* for uncaught exceptions, *Logic error* for wrong test outputs, and *Timeout* for runs that did not finish. Table 3 reports the failure mix per method and modality.

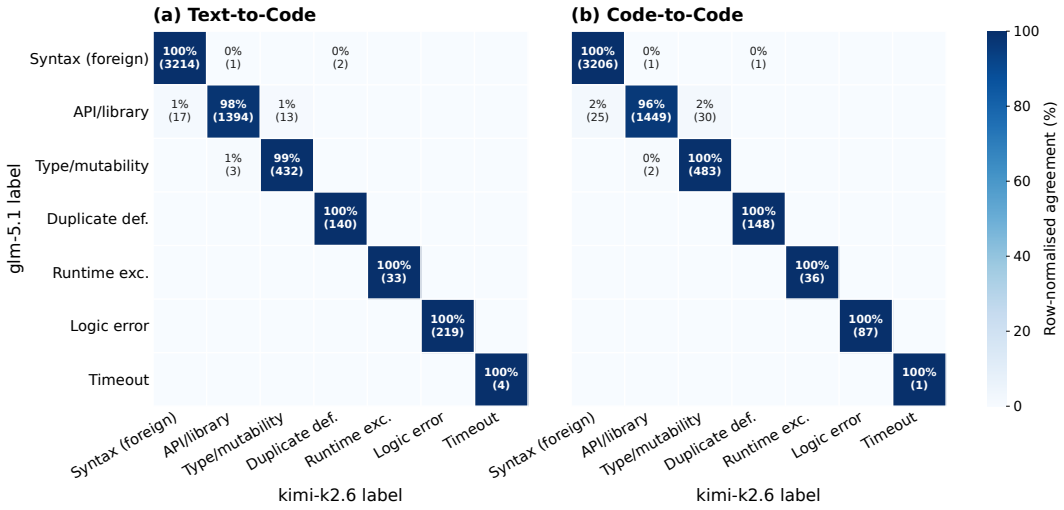

**Figure 6** Inter-annotator confusion matrix between glm-5.1 (rows) and kimi-k2.6 (columns) for (a) T2C and (b) C2C. Each cell shows the row-normalised percentage and the absolute count.

**Foreign-syntax errors dominate, and only the grammar reference cuts them.** Direct generation fails almost entirely on syntax, with about 83 % of its failed samples on both T2C and C2C being *Syntax (foreign)*, code that borrows Python, Rust, Java, or Swift constructs the Cangjie compiler rejects, such as `if x > 0:` written without parentheses, `for i in range(n)` loops, and `|acc, x|` closure syntax, matching the roughly 3 pp Pass@1-to-Compile gap on every Direct cell. The pattern is consistent across the weaker models, which almost never emit a construct Cangjie accepts once it diverges from Python, so their low Pass@1 reflects a parser they cannot satisfy rather than an algorithm they cannot find. The other methods address this with mixed success: Syntax-Constrained cuts foreign-syntax failures to about 28–30 %, but RAG-Code and RAG-Docs still leave 56–61 % despite putting Cangjie tokens in the prompt, because retrieval supplies surface text without overriding the model's syntactic priors, and Agent sits at 46–51 % where the multi-turn loop revises some surface errors.

**Where the rest of the failures shift.** Once Syntax-Constrained removes most foreign syntax, the mass shifts onto API/library at 34–42 % and Type/mutability at around 16 %, because the grammar reference teaches the parser-level shape of Cangjie but not the standard library or type rules, so models write valid Cangjie that calls methods Cangjie lacks or mixes incompatible numeric types. The C2C column spikes at 42.4 % on API/library versus 34.6 % on T2C, consistent with RQ3, as the Python reference seeds Python-style API names Cangjie rejects. About 9–10 % of Syntax-Constrained failures are Duplicate def., where the model declares its own `main` and conflicts with the harness, and Logic error reaches a non-trivial level only under Agent on C2C, at 4.7 %, the only method where many failed samples reach the test phase with code the toolchain accepts.

**Cross-annotator validation.** Figure 6 reports the 7×7 confusion matrix between glm-5.1 and kimi-k2.6. Both matrices are almost entirely diagonal, with raw agreement 99.34 % on T2C ($\kappa = 0.989$) and 98.92 % on C2C ($\kappa = 0.981$) and no off-diagonal pair above 2 % of any row, so the percentages in Table 3 do not depend on the choice of annotator.

**Table 4** Repeated syntax-guided sampling against single-run agents on Text-to-Code. *Syntax* reports task-level Pass@10 from ten Syntax-Constrained samples per task, and *Agent* reports Pass@1 from one CLI run. $^{+N.N}$ shows the pp gain of Syntax Pass@10 over Agent Pass@1. *Tokens* is the input-plus-output sum per task. Same backbone within each row.

| Backbone | Agent harness | HumanEval | | | | ClassEval | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | Syntax | | Agent | | Syntax | | Agent | |
| | | Pass@10 | Tokens | Pass@1 | Tokens | Pass@10 | Tokens | Pass@1 | Tokens |
| Kimi-K2 | iFlow CLI | 84.1 $^{+45.1}$ | 27.1k | 39.0 | 24.2k | 28.6 $^{+10.7}$ | 36.6k | 17.9 | 27.5k |
| Qwen3-Coder | iFlow CLI | 64.0 $^{+34.1}$ | 28.1k | 29.9 | 36.1k | 19.0 $^{+14.2}$ | 42.2k | 4.8 | 36.2k |
| Qwen3-Coder | Qwen Code CLI | 64.0 $^{+39.0}$ | 28.1k | 25.0 | 224.8k | 19.0 $^{+11.9}$ | 42.2k | 7.1 | 212.9k |
| GPT-5 | Codex CLI | 96.3 $^{+11.5}$ | 46.4k | 84.8 | 391.7k | 42.9 $^{+10.8}$ | 82.8k | 32.1 | 618.2k |

# 6 Discussion

For Cangjie, the bottleneck on every task is parser-level rather than reasoning-level, since direct generation fails almost entirely on syntax and the Compile-to-Pass@1 gap is at most about 3 pp on every Direct cell. The model already knows the algorithm but cannot yet write a program the toolchain accepts, so what separates the four method families is how each closes parser distance to Cangjie and at what token cost.

## 6.1 Spending the Agent's Budget on Repeated Syntax Sampling

Section 5.3 shows an agent run costs 10–120x a single Syntax-Constrained call for a single-digit Pass@1 gain, so an obvious alternative is to keep the cheap method and draw several samples instead of one long agent trace. We test this with ten Syntax-Constrained samples per Text-to-Code task, scored under task-level Pass@10, and match it in Table 4 against the Pass@1 of the same backbone wrapped in each agent harness.

**Repeated sampling beats the matched agent in every cell, on both subsets.** On Kimi-K2 the gap is 45.1 pp on HumanEval at roughly iFlow's token cost, and on Qwen3-Coder against Qwen Code CLI it is 39.0 pp on HumanEval at one-eighth of the agent's budget. Even GPT-5 under Codex, the strongest cell in Table 2, gains 11.5 pp on HumanEval and 10.8 pp on ClassEval by switching to parallel syntax-guided samples within roughly one-eighth of Codex's budget.

This is not an unconditional argument against agents. Pass@10 assumes a test harness that can pick the passing sample, and without tests ten samples are ten guesses. With tests, the budget pays off more on alternative implementations than on long tool-use traces, because most failures the agent repairs are surface syntax errors a fresh draft would not have made, and repeated sampling is parallelisable, so its wall-clock cost can be below an agent run that waits on each compiler call. The edit-and-rerun loop thus earns its tokens only when the failure mix rewards serial repair rather than a fresh draft.

## 6.2 Why Retrieval Helps Less Than Expected

Both RAG variants trail Syntax-Constrained Prompting on all base models, and failure analysis sharpens the point, since 56–61% of RAG failures are foreign-syntax failures (Table 3) even with Cangjie tokens in the prompt. Retrieved context is plentiful but rarely corrective.

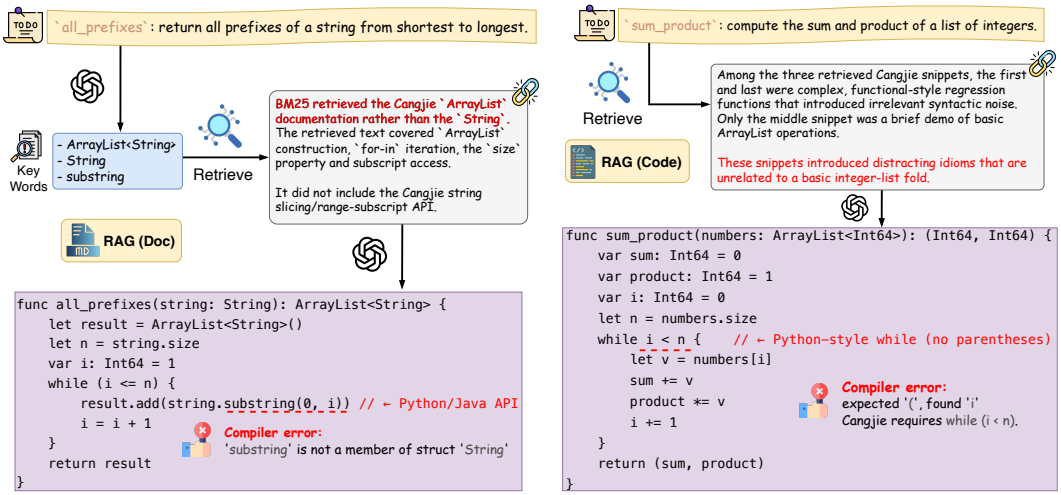

**Figure 7** Two representative RAG failures. On `all_prefixes`, RAG-Docs returns `ArrayList` documentation when the task needs Cangjie string slicing, and the model writes `substring` (an API Cangjie does not expose), which the compiler rejects. On `sum_product`, RAG-Code returns syntactically valid but task-irrelevant snippets, and the model still emits `while i < n` without parentheses.

Figure 7 illustrates two cases where retrieval returns documentation or source unrelated to the task and the model falls back to a foreign API name or a Python-style loop the compiler rejects, so retrieval produces context but not the context that would prevent the failure.

For an emerging language this matters more than for Python, because with a thinner corpus a noisy index can no longer compensate by sheer volume, and two failure modes drive the foreign-syntax share even when the prompt is full of Cangjie text. The first is vocabulary mismatch, where a natural-language description and a Cangjie source file share almost no surface tokens, so a BM25 query for "slice the prefix of a string" rarely surfaces the slicing example a developer would open. The second is the small-corpus problem, where among only a few tens of thousands of crawled functions many APIs appear once or not at all, so the snippet the model needs is often absent. A more useful index would be small and compiler-checked, organised by API signature and paired with short examples for the constructs that most often break, loops, string handling, option types, and mutability, so that retrieval aims at the most likely compiler error rather than enlarging the prompt with plausible but inert text. Until such an index exists, the RAG cells in Table 2 are best read as adding tokens that do not move parser distance, not as a real alternative to the syntax reference.

## 6.3 A Staged Workflow for Emerging-Language Assistants

No single ranking covers both accuracy and token cost, so the practical question is which method to reach for at each stage of a workflow. Direct Generation is best read as a measurement of how much Cangjie a model already knows rather than a deployment choice. Syntax-Constrained Prompting is the appropriate first stage, since it dominates both RAG variants on every base model, addresses the largest failure class, and adds only a 2,146-token header, and when a test harness is available repeated syntax-guided sampling extends it to recover most of the agent's headline accuracy at a fraction of the budget (Section 6.1).

Curated retrieval, indexed by signatures rather than free text, is worth its tokens on API-heavy tasks where the syntax reference leaves API/library failures unaddressed, and only after a Syntax-Constrained attempt has surfaced a concrete API gap. Agents are best reserved for tasks that genuinely require interaction, such as inspecting files, preserving multi-method class structure, or repairing Python-specific drift across turns, where Section 5.4 shows them earning their cost on Code-to-Code. The staging is therefore an escalation triggered by the failure class the previous step cannot fix.

## 7 Threats to Validity

**Construct validity.** Pass@1 and Compile rate measure whether the toolchain accepts the program and whether it passes the tests we wrote, not whether the code is idiomatic or maintainable in a real codebase. We mitigate this by writing the tests against the same reference solutions we translated and reviewing each suite against deliberate perturbations so that obvious wrong answers are rejected. Token cost counts only API tokens rather than wall-clock time, and agent runs that interleave shell calls may incur additional costs, so agent figures are a lower bound on the true gap.

**Internal validity.** Every cell uses greedy decoding with a single sample, so the comparison is sensitive to sampling noise, and we report a ten-sample Pass@10 robustness check under Syntax-Constrained Prompting in Section 6.1. The failure categories are produced by an LLM annotator rather than a human, so we cross-checked them against a second LLM and against 788 manually inspected GPT-5 failures before extending the labels to the rest of the benchmark. The translation rules, taxonomy seed set, and category definitions are themselves methodological choices, so we derived the rules from pilot work rather than post-hoc, seeded the taxonomy on the strongest model across all five methods for coverage, and checked that the categories are jointly exhaustive and mutually exclusive on the inspection set. Our Cangjie reference solutions and tests were written by hand and could contain bugs, so two additional authors reviewed every problem, and we verified that each suite accepts the reference solution and rejects deliberately broken variants.

**External validity.** We evaluate one emerging language, six base models, and three agent harnesses, so any quantitative claim is tied to that subject set. The qualitative pattern, that direct generation fails at the parser before the algorithm and that a small grammar reference closes most of the gap, holds because Cangjie is statically typed with limited public code; we expect it to transfer to other emerging general-purpose languages in the same early-adoption phase, but not to dynamically typed languages or DSLs, where the failure surface is shaped by domain semantics rather than parser distance. Tasks come from HumanEval and ClassEval, which are algorithm-level rather than repository-level, so our results say little about long-context Cangjie work such as multi-file edits or build configuration, where an agent's ability to navigate a project may matter far more than single-file syntax. Pinning the toolchain and CLI versions means absolute pass rates are a snapshot; the ordering across methods is wide enough that it is unlikely to reverse under minor version changes.

## 8 Conclusion

We asked whether current LLM coding assistants can support an emerging programming language, and the answer from CangjieBench is that they can, but only when the method is matched to where the model actually fails. For the six models we evaluated, the failure on

Cangjie is not one of reasoning: direct generation fails almost entirely on syntax, a short syntax reference of about two thousand tokens closes most of that gap, and retrieval helps less than its prompt size suggests because a BM25 index over public Cangjie code rarely returns the snippet that would prevent the next compiler error. The best agent configuration reaches the highest absolute Pass@1, but only at ten to one hundred and twenty times the cost of a single prompt, while weaker agents do not match a Syntax-Constrained call on the same backbone. For a team adopting an emerging language today, the implication is to ship a syntax cheat sheet first, add curated retrieval once it is tailored to the language, and reserve an agent loop for tasks that need file inspection or multi-turn repair. The same staging also guards against the negative transfer we observed under Code-to-Code, where a Python reference pulls a single-shot prompt toward idioms the Cangjie compiler rejects and only the multi-turn loop reliably repairs them. We expect the qualitative pattern, that syntax is the barrier before semantics, to hold for other statically typed languages in their early-adoption phase, with the thresholds shifting as public code and documentation accumulate. We release CangjieBench, the harness, and the failure taxonomy, validated by two LLM annotators with $\kappa \geq 0.98$, so that the same comparison can be repeated as models and tooling evolve.

## 9 Data Availability Statement

All data used in this study are available under the MIT licence at `https://github.com/cjhCoder7/CangjieBench`. The repository contains five components, cross-referenced below to the sections that use them.

1. **CangjieBench dataset** (Section 3.1). The 248-task benchmark ships as two JSONL files, one holding the 164 function-level HumanEval tasks and one the 84 class-level ClassEval tasks, with each entry giving the task identifier, Cangjie prompt, reference solution, and test harness, alongside the per-task Cangjie and Python source files.
2. **Evaluation sandbox** (Section 3.3). A Docker image packaging the Cangjie 1.0 compiler, runtime, standard libraries, and standard extensions (stdx), exposing three REST endpoints (`/evaluate_humaneval`, `/evaluate_classeval`, and `/run_code`) for automated compilation and testing. We used the same image to produce every cell in Table 2.
3. **Per-cell evaluation records** (Sections 5.2–5.4). Per model, method, and task we provide the raw generation, the compile/pass status, compiler and runtime stderr, and the input and output token counts, with per-cell summaries and the Pass@10 data from Section 6.1.
4. **Failure analysis** (Section 5.5). Both annotators, glm-5.1 and kimi-k2.6, labelled every failed sample with one of the seven categories, each record giving the category, annotator confidence, the compiler or runtime evidence, and a short rationale, with per-cell distribution summaries.
5. **Prompt templates and method resources** (Section 4). We provide the four prompt templates for Direct, Syntax-Constrained, RAG-Docs, and RAG-Code together with the agent prompt for both modalities, the 2,146-token Cangjie syntax reference used by Syntax-Constrained Prompting, and the two RAG corpora, namely the official Cangjie documents for RAG-Docs and the crawled GitCode source for RAG-Code.

**Generative AI tool usage.** We used large language models, glm-5.1 and kimi-k2.6, as automated annotators to label failure categories across the full benchmark, as described in Section 5.5. All model-generated labels were cross-validated against each other and against a manually annotated seed set.

## Abstract

**Background.** Smart contract vulnerabilities pose significant security risks in blockchain systems. Automated static auditing tools are commonly used in practice, yet their effectiveness varies across vulnerability categories and at scale. Recently, large language model (LLM)-based tools have been proposed, but their performance is rarely evaluated against real-world contracts and alongside established analyzers.

**Aim.** This paper presents a systematic benchmarking study of smart contract auditing tools under a single, explicitly defined task: identifying smart contract vulnerabilities in Solidity contracts.

**Method.** We evaluate static and LLM-based tools ($n = 7$) on two benchmarks: SmartBugs Curated ($n = 143$) and a filtered FORGE subset of real-world audit-derived contracts ($n = 173$). We use a tool-agnostic evaluation pipeline to normalize heterogeneous tool outputs, reporting accuracy, top-$K$ detection, execution robustness, and cross-dataset performance.

**Results.** Our findings expose systematic trade-offs across auditing approaches. Static tools optimized for broad vulnerability coverage tend to over-report categories, potentially increasing triage burden, while exhibiting stability limitations on real-world contracts. LLM-driven auditors demonstrate strong coverage across many vulnerability categories, but similarly suffer from over-prediction.

**Conclusions.** These results show that current smart contract auditing tools differ less in their ability to identify potential vulnerabilities than in their ability to do so precisely and reliably, motivating future auditing workflows for practical smart contract vulnerability detection.

## 1 Introduction

Smart contracts are a foundational component of modern blockchain ecosystems, underpinning decentralized finance (DeFi), governance protocols, and supply-chain applications [5]. Unlike traditional software, smart contracts are immutable after deployment and operate in adversarial, economically incentivized environments, where vulnerabilities can be actively

exploited for financial gain [50]. As a result, security defects – such as reentrancy, arithmetic errors, and access-control flaws – can lead to irreversible losses and systemic failures [32]. For instance, the Decentralized Autonomous Organization (DAO) exploit in 2016 [33] led to the loss of over $50 million (3.6 M ETH). Subsequent attacks on DeFi protocols further demonstrate smart contract security remains a critical and unresolved challenge [2].

To mitigate these risks, a wide range of automated smart contract analysis tools have been developed and adopted by developers and auditors [9, 15, 41]. These tools rely on different static analysis and symbolic execution techniques – such as rule-based detection, control-flow and data-flow analysis, and constraint solving – to identify vulnerability patterns. Such analyzers are routinely integrated into smart contract development workflows, continuous integration (CI) pipelines, and professional audits [25, 15]. Despite their widespread adoption, static analyzers exhibit fundamental and well-documented limitations. Rule-based and pattern-driven tools tend to over-approximate vulnerability conditions, leading to high false-positive rates and increased manual triage effort [12, 17]. Symbolic execution offers greater expressiveness, but suffers from path explosion, scalability challenges, and brittle behavior on complex or real-world contracts [35]. Large-scale empirical studies show that no static analyzer provides strong coverage across vulnerability classes while maintaining both precision and robustness [13].

Recent research explores the use of large language models (LLMs) for smart contract auditing [22]. Rather than relying on predefined rules or symbolic exploration, LLM-based approaches generate vulnerability predictions directly from contract code based on a corpus of training data, sometimes augmented with structured prompting or post-processing. For example, *Smart-LLaMA*, uses "smart contract-specific continual pre-training" and "explanation-guided fine-tuning" to detect and explain vulnerabilities [49]. While early results suggest such models can detect a broad range of vulnerability categories with high recall [10, 47], existing evaluations are fragmented: they often use custom datasets, inconsistent vulnerability taxonomies, or lack direct comparison against established tools. Thus, **it remains unclear how model-driven auditors perform relative to traditional tools when evaluated on the same contracts, under the same labeling scheme, and with the same metrics.**

Our paper addresses this gap by presenting a systematic study comparing static and LLM-assisted smart contract vulnerability detection tools. We evaluate seven widely used and emerging auditing tools on two benchmarks: SmartBugs Curated ($n = 143$) [11] and a curated FORGE subset of real-world audit-derived contracts ($n = 173$) [6]. This two-dataset design allows us to retain the reproducibility and comparability of SmartBugs while directly evaluating LLM and non-LLM-based approaches – aligning with guidelines for empirical software engineering studies with LLMs [3]. To account for differences in tool capabilities, we normalize outputs into a common vulnerability taxonomy, enabling direct category-level comparison across heterogeneous reporting formats, and report coverage-aware metrics restricted to supported vulnerability categories. Beyond detection accuracy, we also examine operational robustness by measuring crashes, empty outputs, and missing or invalid results when executed across the datasets under consistent execution conditions.

To guide our study, we investigate the following research questions (RQs):

- **RQ1:** How accurately do existing smart contract auditing tools detect SmartBugs vulnerability categories under a unified evaluation protocol?
- **RQ2:** How do auditing tools differ in their effectiveness for ranked vulnerability triage, as measured by top-$K$ detection performance?
- **RQ3:** How robust are smart contract auditing tools when executed at scale across a diverse set of real-world contracts?

- **RQ4:** To what extent does tool performance transfer to newer real-world smart contracts?

Our findings reveal systematic trade-offs across auditing approaches. Tools that emphasize broad detection coverage tend to over-report vulnerability categories, while more expressive analyses improve detection for certain vulnerability classes at the cost of scalability and stability. LLM-driven auditors tend to exhibit similar over-prediction behavior, indicating false positives and robustness remain bottlenecks in automated smart contract auditing [7]. More importantly, our cross-dataset results show that benchmark choice can substantially change tool conclusions – suggesting that strong performance on canonical benchmarks does not necessarily transfer to newer real-world contracts. Our contributions include:

- We conduct a two-dataset empirical benchmark of smart contract auditing tools across SmartBugs Curated and FORGE.
- We propose and apply a unified evaluation protocol that normalizes tool outputs into vulnerability categories.
- We compare seven static and LLM-based tools on detection accuracy, top-$K$ triage effectiveness, coverage-aware performance, and operational robustness.

## 2 Background and Related Work

### Smart Contracts and Vulnerability Classes

Smart contracts are blockchain programs that automatically execute transactions and enforce protocol rules. Because deployed contracts are difficult to modify and operate in adversarial, economically incentivized environments, vulnerabilities can lead to irreversible financial loss, denial of service, or systemic protocol failures [8]. Prior work identifies recurring vulnerability classes, including reentrancy, unchecked low-level calls, access-control flaws, arithmetic errors, timestamp dependence, and insecure randomness [45]. The SmartBugs vulnerability taxonomy has become a widely used benchmark-oriented classification for organizing such vulnerabilities into comparable categories [11]. Prior work also shows that blockchain development is shaped by distinctive software-engineering practices and by the broader cryptocurrency ecosystem [21, 24, 23].

### Automated Smart Contract Analysis Paradigms

To mitigate smart contract security risks, a variety of automated analysis paradigms have been developed. These approaches differ significantly in expressiveness, scalability, robustness, and the form of their reported outputs. Rule-based and linting tools are fast and easy to integrate into development workflows but often over-approximate vulnerability conditions, leading to false positives [51]. Static analyzers based on intermediate representations or control-flow graphs provide deeper structural reasoning, while symbolic execution tools explore possible execution paths but may suffer from path explosion, timeouts, or incomplete exploration on complex contracts [18]. More recently, LLM-based auditors have been proposed to predict vulnerability categories directly from contract code, but their outputs may be weakly ranked, over-predictive, or insufficiently grounded in program semantics [19].

### Challenges in Evaluating Smart Contract Auditing Tools

Fair evaluation of smart contract auditing tools is difficult for three reasons. First, tools produce heterogeneous outputs, ranging from structured detector identifiers to unstructured textual reports, requiring normalization into a common representation [51]. Second, tools support different vulnerability categories, so missed detections must be distinguished from

unsupported categories [12]. Third, robustness and ranking are often under-reported: tools may crash, time out, produce empty outputs, or emit many unranked findings, even when they detect relevant vulnerabilities [37]. These issues motivate evaluation protocols that report accuracy, supported-category performance, ranked triage effectiveness, and execution robustness together.

### Related Work

To enable systematic evaluation of automated analyzers, several benchmark frameworks and datasets have been proposed. SmartBugs introduced a curated dataset of vulnerable Solidity contracts and a unified framework for comparing analyzers under shared ground-truth labels [11]. Building on this infrastructure, Durieux et al. evaluated automated smart contract analysis tools at scale and showed substantial variation in detection accuracy, false positives, and robustness [13]. These studies provide important baselines, but they primarily focus on deterministic tools and canonical benchmarks.

Recent learning-based and LLM-based auditors expand this design space by predicting vulnerabilities directly from contract code, sometimes using domain-specific pretraining, fine-tuning, or program-analysis support [39, 19]. Tools such as Smart-LLaMA, FTSmartAudit, and GPTScan illustrate this shift toward model-driven or hybrid LLM-based auditing [49, 48, 40]. However, existing evaluations often rely on custom datasets, limited baselines, or heterogeneous vulnerability definitions, making it difficult to assess whether strong benchmark performance transfers to newer real-world contracts; for instance, high scores on curated benchmarks can be achieved using only word counts, without detecting any actual vulnerability [36]. In contrast to prior work, our study evaluates deterministic and LLM-based smart contract auditing tools under a unified category-level protocol across two benchmarks: SmartBugs Curated and a filtered FORGE subset.

## 3 Methodology

### Study Design

We conducted a controlled benchmarking study of automated smart contract auditing tools, focusing on the task of *contract-level vulnerability category detection*. Given a Solidity smart contract, a tool reports one or more vulnerability classes present in the contract. This formulation reflects a common first-pass auditing workflow, where automated tools are used to triage contracts and identify likely vulnerability types prior to deeper manual analysis. We evaluate tools across two benchmark settings: a canonical benchmark used widely in prior work and a real-world audit-derived benchmark. This design allows us to assess not only tool effectiveness within a shared taxonomy, but also whether conclusions drawn from canonical benchmarks generalize to newer contracts.

### Dataset

We evaluate tools on two datasets: SmartBugs Curated and a filtered subset of FORGE. **SmartBugs Curated** consists of 143 Solidity smart contracts annotated with known vulnerability categories under a fixed taxonomy. The dataset is widely used in prior empirical studies and provides manually curated ground truth labels. For evaluation, vulnerability labels are extracted from the dataset's annotations and are used without modification for all tools. To evaluate generalization beyond SmartBugs, we also construct a FORGE subset of 173 real-world audit-derived Solidity contracts. **FORGE** provides vulnerability findings

extracted from audit reports and mapped to CWE-style vulnerability descriptions. We filtered FORGE to align with our contract-level category detection task and to enable comparison with SmartBugs-style vulnerability categories. Specifically, we retained only Medium, High, and Critical severity findings; valid Solidity files; findings whose CWE labels could be mapped to our selected SmartBugs-compatible categories; and affected Solidity files with at most 500 lines of code. We excluded Low and Informational findings, non-security CWEs, and files that did not contain analyzable Solidity source code. The final FORGE subset covers seven vulnerability categories: reentrancy, unchecked low-level calls, access control, arithmetic, bad randomness, time manipulation, and denial of service. This subset provides a complementary real-world benchmark for assessing whether tool behavior observed on SmartBugs transfers to newer contracts. We evaluate detection at the category level rather than line-level localization, as the primary goal of this study is to compare tools' ability to correctly identify vulnerability classes rather than pinpoint exact source locations. For both datasets, each contract is represented by the set of ground-truth vulnerability categories associated with that contract. Tool predictions are scored against these category-level labels.

The two datasets also differ substantially in Solidity compiler versions. SmartBugs Curated primarily consists of legacy Solidity contracts, with prior work reporting that over 90% of its contracts use Solidity 0.4+. In contrast, FORGE is more representative of newer smart contract development: the full FORGE dataset reports Solidity 0.8+ as the most prevalent compiler family, accounting for 59.0% of projects. Thus, FORGE provides a useful complementary benchmark for assessing whether tool behavior on legacy canonical contracts transfers to newer real-world contracts. Most contracts in our filtered FORGE subset use Solidity 0.8.x, whereas SmartBugs Curated is dominated by legacy Solidity 0.4.x contracts.

### Tool Selection

We selected a sample of traditional and LLM-based smart contract vulnerability detection tools. A comparison of all the tools observed is provided in Table 1.

- **Relevance:** Tools had to support smart contract vulnerability detection for Ethereum-based smart contracts written in Solidity. We conducted a lightweight literature review of recent academic work on smart contract security. We searched Google Scholar and major software engineering and security venues including ICSE, ISSTA, ASE, CCS, USENIX Security, using terms such as *"smart contract vulnerability detection," "Ethereum security analysis," "Solidity static analysis," "symbolic execution smart contracts,"* and *"LLM-based smart contract auditing."*. We reviewed papers that introduced or evaluated tools for smart contract vulnerability detection, resulting in an initial set of 19 tools spanning various vulnerability detection approaches, including: static analysis ($n = 7$), symbolic execution ($n = 2$), logic-based ($n = 1$), dynamic analysis ($n = 1$), hybrid static/dynamic analysis ($n = 1$), neural networks ($n = 2$), and LLM-based ($n = 5$) approaches. The observed tools are summarized in Table 1. We further filtered selected tools by the following criteria.
- **Reproducibility:** Tools had to be reproducible by the research team. The researchers manually attempted to configure and and execute the tool using publicly available artifacts, documentation, and repositories. Reproducibility was assessed based on the ability to install dependencies, resolve compiler requirements, execute the tool on representative contracts, and obtain interpretable outputs with limited manual intervention.
- **Compatibility:** Tools had to be compatible with Solidity source code analysis and our target benchmark settings. Compatibility was assessed with respect to source-code execution, compiler requirements, output interpretability, and integration into our automated

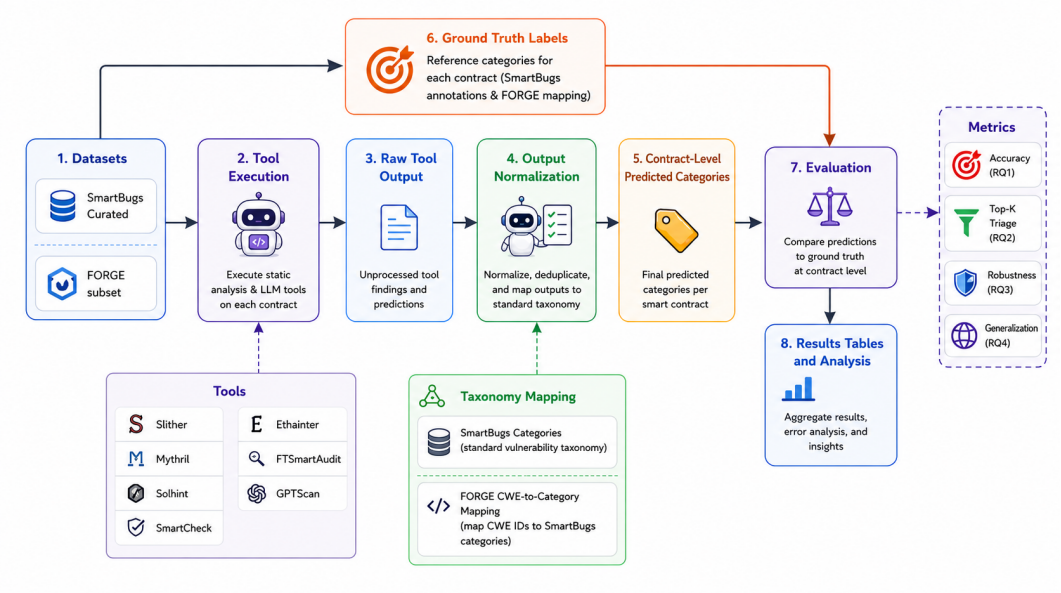

**Figure 1** Benchmarking pipeline for smart contract auditing tools.

pipeline. Tools that require modern compiler pipelines, runtime test harnesses, or analyze solidity versions unsupported by the dataset were excluded. For instance, MANTICORE and CONFUZZIUS require interactive fuzzing environments, failing on a substantial portion of the datasets. These exclusions are based on dataset compatibility rather than tool quality, and follow established practice in prior SmartBugs-based evaluations [13].

**Static and Symbolic Analysis Tools.** We include five static, symbolic, and logic-based analyzers used in prior smart contract security studies and satisfy our selection criteria. Specifically, we benchmark SOLHINT, SMARTCHECK, and SLITHER as rule-based and intermediate-representation–based static analyzers that emphasize scalability, deterministic execution, and fast triage. MYTHRIL is included to represent symbolic execution, enabling deeper semantic reasoning over EVM bytecode at the cost of execution stability. ETHAINTER is included as a logic-based semantic analyzer that applies declarative Datalog rules over Ethereum Virtual Machine (EVM) execution facts, representing a distinct analysis paradigm from both rule-based static analysis and symbolic execution.

**LLM-based Tools.** We include two large language model (LLM)–based auditing tools that represent complementary design choices and satisfy all screening criteria. FTSMARTAUDIT, evaluated using a single fixed foundation model (GPT-4o), represents a free-form LLM auditor that infers vulnerability categories directly from contract text without explicit structure. GPTSCAN, based on GPT-3.5-turbo, represents an LLM-assisted auditing approach that combines LLM-based code understanding with additional analysis to identify smart contract vulnerabilities.

**Table 1** Smart Contract Vulnerability Detection Tool Comparison.

| Tool Name | Type | Input | Output | Reproducible? | Compatible? |
|---|---|---|---|---|---|
| Conkas [44] | Static | .sol, bytecode | Text | ✗ | ✓ |
| ConFuzzius [42] | Static, Dynamic | .sol, JSON | Text | ✓ | ✗ |
| Maian [31] | Static | .sol, bytecode | Text | ✓ | ✗ |
| Mythril [9] | Symbolic Execution | .sol, bytecode | Text, JSON | ✓ | ✓ |
| Ethainter [4] | Logic-based | .sol, bytecode | Text | ✓ | ✓ |
| Oyente [26] | Symbolic Execution | .sol, bytecode | Text | ✗ | ✓ |
| Securify 2.0 [43] | Static | .sol | Text | ✓ | ✗ (^0.5.8) |
| Slither [15] | Static | .sol | Text, JSON | ✓ | ✓ |
| SmartCheck [41] | Static | .sol | Text | ✓ | ✓ |
| SmartEmbed [16] | Static | Text | Text | ✗ | ✓ |
| Solhint | Static | .sol | Text | ✓ | ✓ |
| Manticore [28] | Dynamic | .sol, bytecode | Workspace | ✗ | ✗ (^0.5.12) |

| VulnSense [14] | AI (GNN) | .sol, bytecode | Vector | ✗ | ✗ (^0.5.12) |
| FTSmartAudit [48] | LLM | Text | Text | ✓ | ✓ |
| GPTScan [40] | LLM | Text | JSON | ✓ | ✓ |
| iAudit [27] | LLM | Text | Texte | ✓ | ✗ (^0.8.0) |
| LLMSmartSec [29] | LLM | Text, .sol | Text | ✓ | ✗ |
| SmartLLM [20] | LLM | Text | Text | ✗ | ✗ (^0.8.0) |

Tools that were reproducible and compatible (highlighted) were included in our evaluation. Excluded tools are retained to demonstrate our tool selection process and clarify exclusion decisions.

## 3.1 Evaluation Pipeline

### 3.1.1 Tool Execution

We evaluate a sample of smart contract auditing tools spanning static, logic-based symbolic execution, and LLM–based analysis approaches. Each tool is executed independently on every contract using default or recommended configurations. No manual tuning, contract-specific configuration, or post hoc adjustment is applied, in order to reflect realistic out-of-the-box usage and ensure comparability across tools. All experiments are executed on both SmartBugs Curated and the filtered FORGE subset with automated scripts for tool execution, output collection, normalization, and scoring. Contracts are analyzed individually, and each tool is invoked in isolation to avoid cross-contamination of intermediate artifacts or cached results. When required, Solidity compiler versions are selected automatically using `solc-select` to match the contract's declared pragma, subject to tool compatibility constraints.

For static, symbolic, and logic-based tools, inputs consist of Solidity source code and, where required, compiled EVM bytecode. Static analyzers (e.g., Slither, SmartCheck, Solhint) operate directly on Solidity source code or intermediate representations, while symbolic execution tools (e.g., Mythril) analyze contract behavior through path exploration over the EVM semantics. Logic-based tools (e.g., Ethainter) extract execution facts from compiled bytecode and apply declarative rules to infer vulnerability patterns.

LLM-based tools are evaluated as black-box analyzers using their publicly available implementations. Each tool is executed using its default inference configuration as provided by the authors, without modification of prompts, decoding parameters, or internal reasoning strategies. We do not perform prompt engineering, temperature tuning, or multi-turn interaction; instead, each contract is analyzed exactly once per tool via automated scripts, and only the final reported outputs are collected for evaluation. This setup reflects usage of LLM-based auditing tools as off-the-shelf systems and ensures comparability with deterministic analyzers evaluated under default configurations.

### 3.1.2 Output Normalization

Auditing tools produce heterogeneous outputs, including unstructured textual warnings, semi-structured reports, and structured JSON artifacts. To compare across tools, we normalize all outputs into a unified, tool-agnostic representation at the contract level. For each contract, raw tool outputs are parsed into an intermediate representation that captures individual findings, including any available detector identifiers, warning descriptions, or reported vulnerability names. These findings are then mapped to SmartBugs-compatible vulnerability taxonomy using a tool-specific mapping layer. For tools that provide explicit vulnerability labels or detector identifiers (e.g., Slither, Mythril, SmartCheck), mapping is performed using documented detector-to-category correspondences. For tools that emit free-form or semi-structured text (e.g., LLM-based tools), vulnerability categories are inferred using deterministic keyword and phrase matching based on canonical SmartBugs category names and commonly used synonyms. For FORGE, CWE-style vulnerability labels are mapped to the selected SmartBugs-compatible categories described in the dataset construction step, enabling category-level comparison across both benchmarks. When a tool reports multiple findings for a contract, individual alerts are first mapped to vulnerability categories. For micro-averaged accuracy computation, duplicate findings within the same contract-category pair are collapsed, yielding a binary indication of whether each category is detected for that contract. For ranked top-$K$ evaluation, however, we retain category-level frequency counts so that repeatedly reported categories can be treated as stronger tool signals when explicit severity or confidence scores are unavailable. Line numbers are not used for scoring because our evaluation focuses on category-level detection rather than localization accuracy. Severity labels, confidence scores, native output order, and duplicate counts are retained only when needed to construct rankings; they do not change whether a category-level prediction is counted as correct or incorrect.

If a tool executes successfully but reports no findings, the result is recorded as an *empty output*. If a tool crashes, times out, or produces output that cannot be parsed by the normalization pipeline, the contract is marked as an *execution failure*. Empty outputs and execution failures are excluded from accuracy metrics, but are reported as part of our robustness analysis (RQ3). All normalized results are stored in a common schema that records detected categories, execution status, and tool metadata, enabling consistent computation of micro-averaged accuracy metrics, ranked top-$K$ performance, and robustness statistics across all evaluated tools.

### 3.1.3 Scoring Procedure

For each tool and contract, the normalization layer produces (i) a set of detected categories and (ii) an execution status. For accuracy scoring, a true positive (TP) occurs when a detected category matches a ground-truth category for the same contract. A false positive (FP) occurs when a tool reports a category that is not present in the ground truth, and a false negative (FN) occurs when a ground-truth category is not reported by the tool. Contracts marked as execution failures are excluded from RQ1/RQ2 accuracy computations, but counted in RQ3 to measure robustness. Contracts with empty outputs are included in RQ1 as empty prediction sets and counted separately in RQ3 as empty outputs. For ranked evaluation (RQ2), category rankings are derived from tool-provided priority signals when available (e.g., severity levels or confidence scores).When tools do not provide an explicit ranking, categories are ranked by the frequency of mapped findings for that category within the contract, with more frequently reported categories treated as stronger tool signals. Ties

are resolved using the tool's native reporting order. If fewer than $K$ categories are emitted, we evaluate using the available categories without padding. The evaluation pipeline scripts for tool execution, output normalization, and scoring, are made available in our supplemental materials to promote the replication of this work (see Section 8).

## 3.2 Evaluation Metrics

### 3.2.1 RQ1: Accuracy

We evaluate tools on the task of contract-level vulnerability category detection. For this task, we compute **micro-averaged precision**, **recall**, and **F1 scores** across all vulnerability instances in the dataset. Micro-averaging treats each detected vulnerability instance equally and reflects realistic auditing workloads, where vulnerability categories are highly imbalanced and frequent classes dominate overall risk exposure. This avoids over-emphasizing rare categories that appear only a small number of times in the benchmark. In addition, we report the number of **true positives (TP)**, **false positives (FP)**, and **false negative (FN)** counts to outline vulnerability detection behavior and error patterns. TPs correspond to instances where detected vulnerabilities match ground-truth labels, FPs correspond to detected vulnerabilities that do not match ground-truth labels, and FNs capture ground-truth vulnerabilities that were not detected. In addition to aggregate micro-averaged metrics, we report category-level recall to examine how tool behavior varies across vulnerability categories.

Because auditing tools are designed with different detection scopes, not all tools support the same set of vulnerability categories. To account for this, we report coverage-aware metrics that restrict evaluation to categories explicitly supported by each tool. This allows us to separate detection quality from coverage limitations and ensures that tools are not penalized for vulnerabilities they are not designed to detect.

### 3.2.2 RQ2: Effectiveness

Automated auditing tools often produce multiple findings per contract, and developers typically review only a limited subset of these findings in practice [30]. For instance, in our preliminary evaluations we observed several tools emit high volumes of warnings per contract (*e.g.,* 1,485 for Smart Check and 5,205 for Solhint), which are infeasible for manual review in practice. To evaluate models according to this triage process, we compute ranked **top-$K$ metrics** for $K \in \{1, 3, 5, 10\}$, where $K \in \{1, 3, 5, 10\}$ approximates a bounded analyst attention budget. Top-$K$ complements micro-averaged accuracy by measuring whether correct vulnerability categories are surfaced early. Vulnerability categories are ranked using tool-provided severity or confidence signals when available, and evaluation is performed using only the top-$K$ predicted categories per contract. This captures how effectively tools prioritize relevant vulnerability classes under practical review [47].

### 3.2.3 RQ3: Robustness

Detection accuracy alone does not capture the practical usability of auditing tools. We therefore explicitly measure tool robustness by tracking three execution level outcomes: **successful executions**, **execution failures**, and **empty outputs**. A successful execution occurs when a tool is able to complete the analysis and produces a vulnerability report (either correct or incorrect) for given smart contract within the dataset. Execution failures capture cases when a tool terminates (e.g., due to crashes, timeouts, etc.) and is unable to

**Table 2** RQ1/RQ4: Micro-averaged category-level detection accuracy across SmartBugs Curated and FORGE. "Scored' ' excludes contracts with missing/invalid outputs.

| Tool | Type | SmartBugs Curated | | | FORGE | | |
|---|---|---|---|---|---|---|---|
| | | Scored | TP/FP/FN | P/R/F1 | Scored | TP/FP/FN | P/R/F1 |
| Solhint | Static (lint rules) | 139 | 51/85/92 | 0.38/0.36/0.37 | 145 | 26/29/169 | 0.47/0.13/0.21 |
| SmartCheck | Static (rules) | 142 | 58/64/85 | 0.48/0.41/0.44 | 173 | 29/63/204 | 0.32/0.12/0.18 |
| Slither | Static (IR + detectors) | 140 | 120/267/21 | 0.31/0.85/0.45 | 142 | 110/283/81 | 0.28/0.58/0.38 |
| Mythril | Symbolic execution | 141 | 87/130/55 | 0.40/0.61/0.48 | 144 | 8/10/186 | 0.44/0.04/0.08 |
| FTSmartAudit | LLM | 142 | 138/495/5 | 0.22/0.97/0.36 | 145 | 192/891/37 | 0.18/0.84/0.29 |
| GPTScan | LLM | 142 | 141/137/2 | 0.51/0.99/0.67 | 145 | 44/175/151 | 0.20/0.23/0.21 |
| Ethainter | Logic-based (Datalog) | 142 | 85/463/58 | 0.16/0.59/0.25 | N/A | N/A | N/A |

*Note.* Scored excludes contracts with missing, invalid, or non-parsable outputs.

analyze smart contracts within the dataset. Empty outputs correspond to tools that ran successfully, but did not provide any output. These indicators capture operational stability, capturing execution failure modes that affect real-world adoption beyond accuracy metrics.

#### 3.2.4 RQ4: Cross-dataset Transfer

To assess whether conclusions from canonical benchmarks transfer to newer real-world audit-driven contracts, we compare each tool's performance across SmartBugs Curated and FORGE. We report dataset-specific precision, recall, F1, top-$K$ performance, and robustness outcomes, and examine changes in tool behavior across datasets. This analysis focuses on whether tools that perform well on SmartBugs maintain similar performance on FORGE.

## 4 Results

### 4.1 RQ1: Category-Level Detection Accuracy

#### 4.1.1 Overall micro-averaged performance

Table 2 outlines the micro-averaged detection accuracy across tools on the SmartBugs Curated and FORGE benchmarks. Overall, we observed precision-recall trade-offs across tool designs: static analyzers varied between conservative and recall-oriented behavior; symbolic execution balanced precision and recall on scored runs; and LLM-based tools often achieved high recall with varying false-positive burden. Additional insights are provided below.

**Static vs. LLM behavior.** Across tools, the static analyzers illustrated a precision–coverage trade-off: SmartCheck and Solhint were relatively conservative (higher precision, lower recall), while Slither was a recall-oriented static baseline (high recall with substantial over-reporting). For instance, SmartCheck was conservative (P=0.48, R=0.41), Solhint was narrow-scope (R=0.36), and Slither acted as a high-recall static triage baseline (R=0.85). In contrast, the LLM-based auditors behaved as recall amplifiers. FTSmartAudit achieved near-ceiling recall on SmartBugs Curated (R=0.97) but incurred the largest false-positive burden (FP=495), while GPTScan achieved the strongest SmartBugs Curated F1 score (0.67) due to high recall and comparatively lower false positives. These results suggest that static tools are useful for fast first-pass triage, while LLM outputs require explicit calibration through ranking, filtering, or validation to remain usable in analyst workflows.

**Table 3** RQ1/RQ4: Coverage effect of restricting evaluation to supported vulnerability categories.

| Tool | SmartBugs Curated | | FORGE | | Coverage Effect |
|---|---|---|---|---|---|
| | Supported F1 | ΔF1 | Supported F1 | ΔF1 | Interpretation |
| Solhint | N/A | N/A | N/A | N/A | Not emitted |
| SmartCheck | 0.51 | +0.07 | 0.19 | +0.01 | SB coverage-limited; FG minimal |
| Slither | 0.46 | +0.01 | 0.38 | +0.00 | No change |
| Mythril | 0.49 | +0.01 | 0.08 | +0.00 | No change |
| FTSmartAudit | 0.36 | +0.00 | 0.29 | +0.00 | No change |
| GPTScan | 0.67 | +0.00 | 0.21 | +0.00 | No change |
| Ethainter | 0.30 | +0.05 | N/A | N/A | SB coverage-limited; FG TBD |

*Note.* ΔF1 = supported-category F1 − all-category F1 from Table 2. Supported categories are defined by our tool-output-to-taxonomy mapping when emitted by the evaluator. Marked N/A because its evaluator does not emit supported-category metrics.

### 4.1.2 Coverage-aware evaluation (supported categories only)

Because tools do not support all SmartBugs-compatible vulnerability categories equally, all-category scores can mix detection quality with category-coverage limitations. Table 3 reports the effect of restricting evaluation to supported categories only. On SmartBugs Curated, SmartCheck shows the clearest coverage effect: its recall rises from 0.41 to 0.56 and its F1 rises from 0.44 to 0.51 when evaluated only on supported categories. Ethainter also improves from 0.25 to 0.30 F1, suggesting that part of its lower all-category score reflects limited coverage. By contrast, Slither changes only slightly (0.45 to 0.46 F1), while FTSmartAudit, and GPTScan show no change, indicating that their main limitations are not unsupported-category penalties but false positives, missed detections, or calibration. On FORGE, SmartCheck improves only slightly from 0.18 to 0.19 F1, while Slither, Mythril, FTSmartAudit, and GPTScan show no supported-category gain. Solhint is marked N/A because its evaluator does not emit supported-category metrics.

### 4.1.3 Category-level detection: primary-label recall

Aggregate micro metrics can hide sharp category dependencies. Table 4 reports primary-label recall per category across all evaluated tools. These results surface practical strengths and blind spots that are not visible from aggregate micro-F1 alone.

**Category-level patterns.** **Static rule tools have "spiky" recall.** Solhint achieved strong performance on `unchecked_low_level_calls` and `time_manipulation`, but failed to detect interaction-heavy and semantic categories (`reentrancy`, `access_control`, `arithmetic`). SmartCheck was extremely strong on `unchecked_low_level_calls` but nearly blind to `reentrancy`, `bad_randomness`, and `front_running`.

**Slither was the broadest non-LLM tool by recall, except for `front_running` and `short_addresses`.** It hit 1.0 recall on `reentrancy`, `arithmetic`, `bad_randomness`, and `time_manipulation`, and remains high on `unchecked_low_level_calls`. Its main recall gaps were `front_running` and `short_addresses` in this protocol. **Mythril was strong on reentrancy-like semantics but uneven elsewhere.** It performed well on `reentrancy` (0.87) and `unchecked_low_level_calls` (0.88), moderate on `access_control` (0.56), but failed on `arithmetic` and `denial_of_service` under this labeling.

**LLM tools behave like recall amplifiers.** FTSmartAudit reached 1.0 recall on nearly everything, including `short_addresses`, but did not address the ambiguous `other` bucket. GPTScan also showed broad SmartBugs Curated recall, reaching perfect recall on several

**Table 4** RQ1/RQ4: Primary-label recall by category across SmartBugs Curated and FORGE (higher is better).

| Dataset | Category | # | Solhint | SmartCheck | Slither | Mythril | FTSmart | GPTScan | Ethainter |
|---|---|---|---|---|---|---|---|---|---|
| SB | unchecked_low_level_calls | 51 | 0.90 | 1.00 | 0.96 | 0.88 | 1.00 | 1.00 | 0.98 |
| SB | time_manipulation | 5 | 1.00 | 0.20 | 1.00 | 0.40 | 1.00 | 1.00 | 0.00 |
| SB | bad_randomness | 8 | 0.00 | 0.00 | 1.00 | 0.25 | 0.88 | 0.88 | 0.00 |
| SB | denial_of_service | 6 | 0.00 | 0.33 | 0.83 | 0.00 | 1.00 | 1.00 | 0.00 |
| SB | front_running | 4 | 0.00 | 0.00 | 0.00 | 0.25 | 0.75 | 1.00 | 0.00 |
| SB | access_control | 18 | 0.00 | 0.11 | 0.44 | 0.56 | 1.00 | 1.00 | 0.94 |
| SB | short_addresses | 1 | 0.00 | 0.00 | 0.00 | 0.00 | 1.00 | 1.00 | 0.00 |
| SB | reentrancy | 30 | 0.00 | 0.00 | 1.00 | 0.87 | 1.00 | 1.00 | 0.00 |
| SB | arithmetic | 15 | 0.00 | 0.07 | 1.00 | 0.00 | 1.00 | 1.00 | 0.93 |
| SB | other | 3 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.67 | 1.00 |
| FG | time_manipulation | 36 | 0.39 | 0.03 | 0.52 | 0.10 | 0.90 | 0.19 | N/A |
| FG | bad_randomness | 1 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | N/A |
| FG | denial_of_service | 6 | 0.00 | 0.33 | 0.00 | 0.00 | 0.96 | 0.00 | N/A |
| FG | access_control | 16 | 0.00 | 0.19 | 0.27 | 0.00 | 1.00 | 0.75 | N/A |
| FG | reentrancy | 14 | 0.00 | 0.00 | 0.64 | 0.00 | 0.79 | 0.08 | N/A |
| FG | arithmetic | 51 | 0.00 | 0.04 | 0.89 | 0.00 | 0.86 | 0.14 | N/A |

*Note.* SB = SmartBugs Curated; FG = FORGE. Solhint, Slither, and Mythril FORGE recall values are computed on the compile-success-only subset; therefore, their effective category denominators differ from the full FORGE category counts shown in the # column.

major categories while detecting some cases in the `other` bucket. **Ethainter exhibited extreme category dependence: high for explicit dataflow/permission patterns; zero for interaction/temporal vulnerabilities.**

Its near-perfect recall on `unchecked_low_level_calls`, `access_control`, and `arithmetic` suggests that Datalog rules capture certain explicit structural patterns well, while zero recall on `reentrancy`, `time_manipulation`, and `front_running` indicates missing modeling assumptions (e.g., cross-contract call ordering, temporal/transaction semantics, or ranking/heuristics). Notably, high category-level recall does not guarantee low analyst effort, as tools may still generate substantial noise even when they successfully identify the correct vulnerability family.

## 4.2 RQ2: Ranked Triage Effectiveness (top-$K$)

We evaluated ranked triage effectiveness via top-$K$ metrics for $K \in \{1, 3, 5, 10\}$. Because many tools do not provide an explicit severity ordering, we constructed a comparable ranking by sorting predicted categories *within each contract* by the **frequency of mapped findings** for that category (most frequent first). Categories repeatedly triggered by a tool's detectors are treated as its strongest signals for given contracts. Table 5 reports these results.

**First-alert utility (K=1).** First-alert utility signifies the frequency the first reported category is correct. GPTScan provided the strongest first-alert signal on SmartBugs Curated, with P@1=0.887, R@1=0.881, and F1@1=0.884. Among non-LLM tools, Slither provided the strongest first-alert signal, with P@1=0.775 and F1@1=0.600. This indicates that, although Slither's overall micro precision is low (Table 2), the *most frequently triggered category* within each contract is often aligned with the ground truth. In practice, this corresponds to a triage-friendly behavior: analysts who only review the first suggested category are likely to see a relevant vulnerability family early.

**Table 5** RQ2: Ranked triage effectiveness under frequency-based top-$K$ ordering. We report first-alert utility ($K = 1$), deep triage ($K = 10$), and recall gain $\Delta R = \text{R@10} - \text{R@1}$.

| Tool | SmartBugs Curated | | | FORGE | | |
|---|---|---|---|---|---|---|
| | P/R/F1@1 | P/R/F1@10 | $\Delta R$ | P/R/F1@1 | P/R/F1@10 | $\Delta R$ |
| Solhint | N/A | N/A | N/A | N/A | N/A | N/A |
| SmartCheck | 0.604/0.385/0.470 | 0.487/0.406/0.443 | +0.021 | 0.30/0.08/0.13 | 0.32/0.12/0.18 | +0.04 |
| Slither | 0.775/0.489/0.600 | 0.342/0.837/0.486 | +0.348 | 0.125/0.021/0.036 | 0.248/0.157/0.192 | +0.136 |
| Mythril | 0.542/0.275/0.364 | 0.420/0.606/0.496 | +0.331 | 0.385/0.026/0.048 | 0.444/0.041/0.075 | +0.016 |
| FTSmartAudit | 0.577/0.573/0.575 | 0.218/0.965/0.356 | +0.392 | 0.213/0.131/0.162 | 0.178/0.843/0.294 | +0.712 |
| GPTScan | 0.887/0.881/0.884 | 0.507/0.986/0.670 | +0.105 | 0.26/0.13/0.18 | 0.20/0.23/0.21 | +0.10 |
| Ethainter | 0.372/0.357/0.364 | 0.155/0.594/0.246 | +0.237 | N/A | N/A | N/A |

SmartCheck also showed strong first-alert behavior (P@1=0.60, F1@1=0.47), consistent with conservative output volume and detectors that repeatedly fire only on a limited set of patterns. Mythril's P@1 was moderate (0.54), but its R@1 is low (0.27), suggesting that the most frequent reported category is not always the true label; correct categories may appear only after considering multiple reported categories. Among LLM-based systems, GPTScan showed the strongest first-alert behavior, suggesting that its dominant predicted category is often aligned with the ground truth on SmartBugs Curated. FTSmartAudit also performed well at $K = 1$ (P@1=0.577, R@1=0.573), showing that even a highly over-reporting LLM can surface a correct primary category early when ranked by frequency. Ethainter was weakest at $K = 1$ (P@1=0.372, F1@1=0.364), indicating that its most frequent categories are often not well aligned with ground truth.

**Recall gains from deeper triage.** We next examine how much recall improves when analysts inspect more ranked categories, moving from $K = 1$ to $K = 10$. This shows whether relevant categories are *concentrated* among the top-ranked findings or only appear after reviewing deeper ranks. Table 5 summarizes the recall gain. Slither exhibited a large recall gain when increasing $K$ (0.489→0.837), indicating that additional relevant categories are present but not always dominant in frequency. GPTScan showed a smaller recall gain on SmartBugs Curated (0.881→0.986), suggesting that most correct categories were already concentrated near the top rank. Mythril's recall rose steadily (0.27→0.61) while maintaining relatively stable precision compared to high-recall systems, suggesting that useful categories are distributed across several findings rather than concentrated in a single dominant category. SmartCheck showed minimal recall improvement (0.38→0.41), consistent with limited output diversity: if SmartCheck misses a category, inspecting deeper ranks does not help because the tool does not emit many alternative categories per contract.

Ethainter saturated quickly: R@1=0.36 and R@10=0.59, with limited improvement beyond $K = 3$–$K = 5$. This indicates weak ranking calibration under the frequency heuristic and aligns with its category blind spots (Table 4). For several categories Ethainter emitted few or no mapped findings, so increasing $K$ cannot recover the missing true label. Further, while recall typically increases with $K$, we saw precision declined as more categories are reviewed. This decline is steepest for over-reporting tools. For example, FTSmartAudit improved recall dramatically (0.57→0.97) but precision dropped sharply (0.58→0.22), reflecting that the long tail of additional categories is dominated by false positives. Slither's precision also decreased from 0.78 to 0.34.

**Table 6** RQ3/RQ4: Dataset-scale execution robustness.

| Tool | SmartBugs Curated | | | FORGE | | | Notes |
|---|---|---|---|---|---|---|---|
| | Succ. | Empty | Crash | Succ. | Empty | Crash | |
| Solhint | 140 | 0 | 3 | 145 | 0 | 0 | FG compile-success subset |
| SmartCheck | 142 | 1 | 0 | 145 | 0 | 0 | FG compile-success subset |
| Slither | 141 | 0 | 2 | 142 | 0 | 3 | FG analyzer failures |
| Mythril | 100 | 42 | 1 | 108 | 0 | 37 | FG: 36 crashes + 1 timeout |
| FTSmartAudit | 143 | 0 | 0 | 145 | 0 | 0 | Full FG completion |
| GPTScan | 143 | 0 | 0 | 101 | 44 | 0 | FG: many empty outputs |
| Ethainter | 138 | 0 | 5 | N/A | N/A | N/A | FG not evaluated |

*Note.* Succ. = successful non-empty output. FORGE values are reported on the 145-contract compile-success subset. Crash includes invalid outputs, analyzer crashes, and timeouts.

## 4.3 RQ3: Dataset-Scale Execution Robustness

Table 6 reports execution robustness outcomes. Static analyzers exhibited consistently high robustness. On SmartBugs Curated, Solhint produced usable outputs for 140/143 contracts, with three invalid outputs. SmartCheck completed on 142/143 contracts, producing one empty output and no crashes. Slither completed on 141/143 contracts, with only two invalid outputs. On FORGE, Solhint and SmartCheck produced usable outputs for all 145 contracts in the compile-success subset, while Slither produced usable outputs for 142/145 contracts and failed on three contracts. These results indicate that static analyzers generally provide reliable dataset-scale execution, even when their detection accuracy varies across categories.

Symbolic execution showed reduced robustness at dataset scale. Mythril produced usable outputs for 100/143 SmartBugs Curated contracts, with empty outputs for 42 contracts and one crash. On FORGE, Mythril produced usable outputs for 108/145 contracts, while 37 contracts resulted in crashes or timeouts. Although Mythril can provide useful accuracy on scored runs, these failures reduce its effective coverage in large-scale benchmark settings.

Among LLM-based auditors, FTSmartAudit showed the strongest execution robustness, successfully producing usable outputs for all 143 SmartBugs Curated contracts and all 145 FORGE contracts. GPTScan also completed all SmartBugs Curated contracts, but on FORGE it produced usable outputs for only 101/145 contracts and empty outputs for 44 contracts. This suggests that GPTScan is robust on SmartBugs Curated but less reliable on FORGE, where many runs produced no usable vulnerability-category signal. Ethainter exhibited a distinct failure profile on SmartBugs Curated: it produced usable outputs for 138/143 contracts but failed with crash or invalid outcomes on five contracts, the highest crash rate among the evaluated SmartBugs tools.

## 4.4 RQ4: Cross-Dataset Evaluation

Table 2 compares micro-precision, micro-recall, and micro-F1 across SmartBugs Curated and FORGE. These paired results allow us to examine whether performance on the canonical SmartBugs benchmark transfers to newer audit-derived contracts. Overall, we find limited transfer: most completed tools show lower F1 on FORGE than on SmartBugs Curated, although the size of the drop varies substantially by tool (see Table 7).

The smallest cross-dataset F1 drops were observed for Slither and FTSmartAudit, each decreasing by 0.07 F1. However, the two tools transferred in different ways. Slither decreased from 0.45 on SmartBugs Curated to 0.38 on FORGE, suggesting that its detector coverage and intermediate-representation-based analysis remain comparatively stable across the two

**Table 7** RQ4: Cross-dataset transfer from SmartBugs Curated to FORGE using micro-F1.

| Tool | SB F1 | FORGE F1 | ΔF1 | Transfer Pattern |
|---|---|---|---|---|
| Solhint | 0.37 | 0.21 | -0.16 | Partial transfer; narrow scope |
| SmartCheck | 0.44 | 0.18 | -0.26 | Weak transfer |
| Slither | 0.45 | 0.38 | -0.07 | Stable transfer; high FP burden |
| Mythril | 0.48 | 0.08 | -0.40 | Poor transfer |
| GPTScan | 0.67 | 0.21 | -0.46 | Large transfer drop |
| FTSmartAudit | 0.36 | 0.29 | -0.07 | Strong recall transfer; high FP burden |

*Note.* ΔF1 = FORGE F1 − SmartBugs Curated F1.

benchmarks, although its FORGE precision remains low due to substantial false positives. FTSmartAudit also showed a modest F1 drop from 0.36 to 0.29, primarily because its recall remained high on FORGE, but this came with a large false-positive burden.

By contrast, Mythril and GPTScan showed the largest transfer drops. Mythril decreased from 0.48 F1 on SmartBugs Curated to 0.08 on FORGE, indicating that its symbolic-execution strengths on canonical benchmark contracts did not generalize well to the newer FORGE subset. GPTScan decreased from 0.67 to 0.21 F1, showing that its strong SmartBugs Curated performance does not transfer directly to audit-derived contracts. Solhint and SmartCheck also declined on FORGE, but their results reflect narrower rule coverage and lower recall rather than complete execution failure.

***Summary across RQs.*** **Our results show that tool performance depends strongly on evaluation dimension. GPTScan leads on SmartBugs Curated accuracy and first-alert ranking, but transfers weakly to FORGE. Slither shows the strongest non-LLM transfer with broad recall, but many false positives. FTSmartAudit is highly robust and recall-oriented across datasets, but creates substantial triage burden. Mythril, SmartCheck, and Ethainter show useful strengths on specific settings, but are limited by robustness, coverage, or category selectivity. Static and LLM-based tools saw a performance drop across datasets.**

## 5 Discussion and Future Work

Our results suggest no single type of tool dominates across accuracy, effectiveness, and robustness. We also observed substantial differences in tool performance across datasets. Based on these insights, we discuss implications for smart contract auditing in practice, benchmarking smart contract vulnerability detection tools, and future research directions.

### 5.1 Implications for Practice

Our findings provide insights for practitioners considering integrating smart contract vulnerability detection tools in development workflows.

**Static analyzers are reliable scaffolding, but not complete auditors.** Slither and SmartCheck demonstrate that modern static pipelines can execute reliably at dataset scale. However, their utility depends on analyst goals. Slither functions as a high-recall triage engine and shows the strongest cross-dataset transfer among completed FORGE tools, but it produces substantial false positives and requires downstream filtering and prioritization. SmartCheck

behaves more conservatively, achieving high precision on the categories it supports well (especially `unchecked_low_level_calls`) but failing to cover interaction-heavy vulnerabilities (e.g., `reentrancy`). Solhint is best viewed as a specialized rule checker rather than a general security auditor under this evaluation.

**Symbolic execution provides strong accuracy, but suffers from dataset-scale fragility.** Mythril performs reasonably on SmartBugs Curated, but its performance transfers poorly to FORGE. On SmartBugs Curated, its frequent empty outputs (42/143, 29.4%) reveal dataset-scale fragility; on FORGE, it produced 36 crashes and one timeout on the 145-contract compile-success subset. Its FORGE F1 drops to 0.08, suggesting that symbolic-execution signals from canonical benchmarks do not generalize cleanly to newer audit-derived contracts.

**LLM-based auditors behave like "recall amplifiers," not calibrated detectors.** LLM-based tools showed strong recall, but transfer behavior differed across datasets. On SmartBugs Curated, GPTScan achieves the strongest micro-F1, but its FORGE F1 drops sharply to 0.21. FTSmartAudit retains high FORGE recall (0.84), but with a large false-positive burden, indicating that it behaves more like a recall amplifier than a calibrated detector. The top-$K$ results add nuance: on SmartBugs Curated, LLM tools can surface correct categories early, but on FORGE their ranking behavior is weaker and often requires deeper inspection.

**Logic-based semantic analysis is promising, but uneven.** Ethainter's results illustrate both the value and risk of declarative semantic rules: the tool can achieve near-perfect recall for some explicit pattern families (e.g., call/permission/dataflow-related categories) while failing completely on interaction/temporal classes (e.g., `reentrancy`, `time_manipulation`, `front_running`). Even in categories where recall is high, low precision indicates that rule sets and mappings require careful calibration and possibly additional context to avoid spurious matches. Ranking results further show that correct categories are not strongly prioritized early, limiting analyst usability.

**Accuracy alone does not determine usability.** A central observation is that micro recall does not directly translate into practitioner benefit unless correct categories are surfaced early. For instance, GPTScan achieves the strongest first-alert behavior on SmartBugs Curated, while Slither remains a strong ranked static baseline. However, this pattern does not transfer uniformly: on FORGE, Mythril shows little recall gain with larger $K$, while FTSmartAudit gains substantial recall only by exposing analysts to many additional false positives.

SmartCheck changes little with $K$, reflecting low output volume: its strengths are "early and few", but it cannot recover missing categories by deeper inspection. Ethainter's limited gains across $K$ indicate weak prioritization. These differences imply that future evaluations of auditing systems should treat ranking and prioritization as first-class properties, especially for tools that generate many potential issues. In practice, teams often operate under strict time constraints [34], making $K = 1$ behavior particularly important.

## 5.2 Implications for Research

Our findings also suggest several directions for improving tool evaluation frameworks.

**Cross-benchmark evaluations.** Our cross-dataset results demonstrate that benchmark choice can substantially influence tool conclusions. For example, GPTScan achieved the strongest SmartBugs Curated F1 among evaluated tools, but its F1 dropped from 0.67 to 0.21 on the FORGE compile-success subset. Similarly, Mythril dropped from 0.48 to 0.08 F1, while Slither and FTSmartAudit transferred more strongly, dropping only from 0.45 to 0.38 and from 0.36 to 0.29, respectively. Thus, relying on a single benchmark risks producing misleading results on tool performance, potentially leading practitioners to select tools that may not generalize to real-world contracts in production environments. Our results highlight the necessity of evaluating tools across multiple, diverse benchmarks.

**Robustness metrics.** Our results demonstrate robustness should be reported alongside accuracy to provide a comprehensive picture of tool reliability. For example, Mythril performed reasonably on SmartBugs Curated but showed reduced dataset-scale reliability, producing 42 empty outputs on SmartBugs and 36 crashes plus one timeout on the FORGE compile-success subset. Reporting only micro metrics can obscure this limitation. Conversely, FTSmartAudit completed all FORGE runs but produced a large false-positive burden, showing that robustness must be interpreted together with accuracy and alert volume. By incorporating robustness measures into benchmarking methodologies, the research community can provide practitioners with more realistic performance expectations and help identify tools that not only achieve high accuracy but also maintain consistent, predictable behavior across smart contract vulnerability detection tasks.

**Category-dependent evaluation.** Aggregate metrics can mask critical blind spots. For example, our findings indicate Ethainter's failure on reentrancy and temporal categories is not visible from overall recall alone without per-category analysis. Similarly, we observed SmartCheck achieved high performance on low-level calls, but near-zero performance on reentrancy. This suggests that practitioners should pair tools with complementary strengths rather than relying on a single auditor. Future benchmarking frameworks should also incorporate category-level results to enable more meaningful comparisons of vulnerability detection tool capabilities. In addition, the complementary strengths observed across smart contract vulnerability detection approaches motivate the needs for multi-faceted evaluations and pipelines to prevent single approach bias.

## 5.3 Future Work

Future work will extend the evaluation pipeline beyond category-level detection by incorporating runtime cost, alert volume, severity-aware ranking, confidence calibration, and line-level localization when available. Future benchmarks should also explore more semantically grounded normalization strategies for mapping heterogeneous tool outputs into vulnerability categories and should evaluate how developers interpret and act on tool findings in real-world workflows. Our findings motivate the potential for hybrid LLM-static approaches [1]. For example, an LLM proposes candidate smart contract vulnerability categories, and a critic/validator stage filters or confirms them using static analysis, symbolic checks, or rule-based constraints. Future work can explore hybrid auditing workflows in which LLM-based systems generate candidate vulnerability categories and static, symbolic, or logic-based analyzers validate or prioritize them. Such workflows may preserve the high recall of LLM-based tools while reducing false positives and improving robustness through selective invocation, time-bounded analysis, contract slicing, or staged analysis pipelines [38]. Future efforts are needed to investigate developer perceptions and tool effectiveness within smart contract auditing workflows. Finally, similar evaluation pipelines can compare static and LLM-based tools for other tasks.

## 6 Threats to Validity

Several threats should be considered when interpreting our results. First, tool behavior may be affected by implementation versions, dependencies, compiler settings, runtime limits, and LLM model configurations. We mitigate this risk by using default or recommended configurations and recording tool versions, prompts, execution scripts, and normalization logic in the replication artifact. Second, our evaluation focuses on contract-level vulnerability categories rather than line-level localization, exploitability, severity, or report understandability. This abstraction enables comparison across heterogeneous tools, but it may miss details that matter in practical audits. Third, our ground truth relies on SmartBugs annotations and FORGE audit-derived findings mapped into SmartBugs-compatible categories; labeling errors, incomplete audit reports, or imperfect CWE-to-category mappings could affect measured accuracy. Finally, our results are limited to seven Solidity/Ethereum tools and two benchmark datasets. Although SmartBugs supports comparison with prior work and FORGE adds newer audit-derived contracts, results may differ for other smart contract ecosystems, future Solidity versions, newer LLMs, or alternative prompting and orchestration strategies.

## 7 Conclusion

Smart contracts are critical to DeFi protocols on modern blockchain systems, yet prone to vulnerabilities. This work introduces a reproducible evaluation pipeline, and presents a benchmark of seven smart contract vulnerability detection tools across static and LLM-based auditing approaches on the SmartBugs Curated and FORGE datasets. Our results show none of the sampled tools simultaneously achieve high detection accuracy, low false-positive burden, and robust dataset-scale execution – motivating the need for compositional and hybrid pipelines that combine the complementary strengths of varied approaches. Based on our findings, we provide implications for practitioners and researchers, in addition to future research directions to establish a rigorous benchmarking foundation for evaluating next-generation smart contract auditing systems.

## 8 Data Availability Statement

All data and study artifacts, including our evaluation pipeline scripts, prompt templates, etc., are available to support reproducibility and reuse.[1] SmartBugs Curated[2] is made available by Durieux et al. FORGE[3] is made available by Chen et al.

## Abstract

**Background.** Vulnerability-Contributing Commits (VCCs) are the code changes at which a software system turns from safe to unsafe with respect to a specific vulnerability. Accurate VCC identification is crucial for training vulnerability detection models, yet the reliability of existing VCC datasets remains underexplored. If these VCC datasets contain mislabeled commits, models trained on them may learn incorrect patterns.

**Aims.** We present a two-part study of VCC dataset quality: characterizing how VCCs are defined and identified across the literature, and empirically measuring the accuracy of existing VCC datasets.

**Method.** We review 38 papers and, based on their findings, propose an operational VCC definition based on security state transitions and testable through parent commit validation. We apply this definition in an exploit-based validation study on 6 datasets aggregating 3,105 VCC samples, of which 168 (5.41%) have publicly documented exploits enabling empirical validation.

**Results.** We found significant terminological and definitional inconsistencies: 8 distinct terms with varying definitions, 15.8% of papers lacking explicit definitions, and confusion between commits that *contain* versus commits that *introduce* vulnerabilities. Among the 168 validated samples, we observe a 79.2% false positive rate, rising to 88.4% in the subset whose verdicts rest entirely on runtime exploit reproduction, with 47.0% being commits labeled as VCCs although the vulnerability was already exploitable in the parent commit.

**Conclusions.** Existing VCC datasets contain labeling errors detectable through exploit-based parent commit validation. Our findings call for standardized VCC definitions and parent commit validation to distinguish VCC commits from those that merely modify already-vulnerable code.

## 1 Introduction

Software security remains a persistent concern as applications become increasingly integrated into critical infrastructure and daily life [33]. Software vulnerabilities, which are defects that can be exploited to violate security policies [48], can lead to serious consequences ranging from system crashes to sensitive data breaches. Prior works have developed various techniques to address this challenge, including code reviews [22], automated static analysis [60], fuzz testing [6, 29], and machine learning (ML) approaches for vulnerability detection [38, 50].

A promising direction in this field focuses on detecting vulnerabilities at the commit level. A *Vulnerability-Contributing Commit* (VCC) is commonly described as a code change that introduces a vulnerability into a software system [27, 40]. Identifying VCCs when they occur enables developers to address security issues while the code context is still fresh, rather than discovering vulnerabilities months or years later after exploitation [38, 71].

While ML models have shown promise for VCC detection [38, 45, 50], they depend heavily on the *training data quality*. If VCC datasets contain mislabeled commits or samples that cannot be validated due to obsolete dependencies and missing build documentation, models trained on them may learn incorrect patterns, leading to poor real-world performance. Without build documentation to reproduce the project's historical state at the labeled commit, mislabeled samples cannot be empirically detected before entering training, and models risk learning incidental commit features rather than security-relevant changes.

Several challenges complicate VCC dataset construction. First, tracing a vulnerability back to the commit at which it first became exploitable is inherently difficult. The widely used SZZ algorithm [62] and its variants [2, 5, 7, 36, 51, 53, 65] rely on `git blame` heuristics that can produce incorrect results when code has been refactored or when multiple commits contribute to a vulnerability [25, 27]. For example, if a vulnerable function was introduced in commit $A$ and later reformatted in commit $B$, SZZ traces the eventual fix back to $B$, blaming a cosmetic change rather than the commit where the vulnerability first appeared. Second, there is no consensus on what precisely constitutes a VCC: existing literature uses different terminology and definitions [35, 40, 45, 50], making it difficult to compare datasets or combine them. Third, validating whether a vulnerability actually becomes exploitable at a labeled VCC requires reproducing historical software environments, which is often difficult due to missing dependencies and incomplete documentation [27].

These dataset construction challenges create three research gaps. *First*, while prior work has acknowledged that VCC definitions vary [27], this inconsistency has not been systematically characterized, leaving open whether datasets constructed under different definitions are compatible or whether models trained on one generalize to others. *Second*, despite known limitations of labeling approaches (*e.g.*, SZZ), the actual false positive rates in VCC datasets remain unmeasured, so ML models may be trained on data of unknown quality with performance metrics that do not reflect real-world effectiveness. *Third*, although researchers recognize the need to distinguish vulnerability-introducing commits from those that merely modify existing vulnerable code [27], no operational validation methodology exists, so SZZ-style labels are treated as ground truth and over-attribution remains undetected.

To address these gaps, this work includes a two-part study. To address the first gap, we conduct a *systematic literature review (SLR)* to investigate ***how VCCs are defined and termed across the literature***, quantifying the extent of terminological fragmentation, and synthesize a precise VCC definition that provides a standard criterion against which datasets can be compared. To address the second and third gaps, we apply our definition through an ***exploit-based validation study***. Using publicly available exploits from Exploit-DB [47],

we reproduce vulnerabilities in Docker containers that recreate historical software states. For each successfully exploited vulnerability, we perform *parent commit validation*, testing whether the same exploit succeeds on the parent commit. This provides a rigorous verification procedure grounded in runtime analysis and empirically measures false positive rates in existing datasets. Rather than replacing SZZ-based candidate identification, we provide a complementary verification method for filtering candidates and establishing reliable ground truth. Therefore, this work makes the following contributions:

- A systematic literature review of 38 papers (2005–2025) examining VCC terminology, definitions, challenges, and dataset construction practices (**Section 4**).
- An *operational* definition of VCC grounded in security state transitions, together with recommendations for improving dataset construction practices. Through this definition, we developed a novel validation methodology incorporating parent commit testing to verify that the exploitability transition occurs at the labeled commit (**Section 5**).
- An empirical validation of 3,105 VCC samples aggregated from 6 datasets, revealing a 79.2% false positive rate among the 168 samples with documented exploits (5.41% of 3,105; see § 6.2), of which 47.0% are commits labeled as VCCs although the vulnerability was already exploitable in the parent commit (**Section 6**).

# 2 Background & Related Work

## 2.1 Vulnerabilities & Vulnerability Contributing-Commits (VCCs)

**Software vulnerabilities** are caused by defects that can be exploited by attackers to negatively impact the software system's confidentiality, integrity, or availability [41]. These vulnerabilities may be assigned a **CVE ID** (Common Vulnerabilities and Exposures identifier), which uniquely identifies a publicly disclosed vulnerability in the CVE catalog [46]. Since different vulnerabilities can share a similar *root cause*, *consequence*, or *fix pattern* [42], they can also be assigned a vulnerability type, *i.e.*, a **CWE ID** from the Common Weakness Enumeration catalog [41]. These IDs are used as a common vocabulary to refer to a specific security incident (CVE ID) or a group of vulnerabilities (CWE ID).

A **Vulnerability-Contributing Commit (VCC)** is a term used in the literature to refer to a commit that introduces a vulnerability in software, *i.e.*, a defective code change that contributes to the root cause of a vulnerability [8, 27, 40]. These commits may also be referred to as *"vulnerable code changes"* [8,9], *"vulnerability-inducing commits"*, *"vulnerability-introducing commits"*, or *"fix-inducing changes"* [2, 10, 19], although some researchers prefer *"contributing"* over *"inducing"* [39,40]. In this work, we use **VCC** as the umbrella term for the remainder of this paper; characterizing the term precisely is itself an open problem, which we discuss in § 4 and resolve with a formal, operationalizable definition in § 5.

An example of a VCC obtained from the Vulnerability History project [39] is shown in Listing 1. This vulnerability (CVE-2010-4476) is caused by the use of the `Double.parseDouble()` method. This method (in an earlier JRE version) could be exploited by attackers to conduct a denial of service (DoS) attack through a String (*e.g.*, `"2.2250738585072012e-308"`) that triggered an infinite loop while converting this string to a floating point number [46]. This vulnerability was introduced in the first commit of this file (revision **302975**).

## 2.2 Automated VCC Detection

Prior works have studied the characteristics of VCCs [8, 9, 40] and ways to automatically detect them [50]. **Just-in-time (JIT) vulnerability detection** is a term commonly used to refer to approaches that detect vulnerabilities present in a commit being pushed into a code

java/org/apache/catalina/connector/Request.java

```
2455 +            // Extract the quality factor for this entry
2456 +            double quality = 1.0;
2457 +            int semi = entry.indexOf(";q=");
2458 +            if (semi >= 0) {
2459 +                try {
2460 +                    quality = Double.parseDouble(entry.substring(semi + 3));
2461 +                } catch (NumberFormatException e) {
2462 +                    quality = 0.0;
2463 +                }
2464 +                entry = entry.substring(0, semi);
2465 +            }
```

**Listing 1** VCC example from the Apache Tomcat project (CVE-2010-4476).

repository [38, 71]. VCC detection's main advantage is giving developers immediate feedback, helping them consider ways to improve the code's security while having the code change context still fresh in mind [38]. However, there are two main challenges in VCC detection. First, a commit is an *incomplete* part of a program, so VCC detection must reason about its impact on the program as a whole. Second, a commit may include *casualty changes* [59], *i.e.*, unrelated changes that do not affect the security of the program, introducing noise during VCC detection. The difficulty is the entanglement of casualty changes with security-relevant edits in the same diff, *e.g.*, a method rename can touch dozens of lines without changing behavior, while a single deleted check introduces a vulnerability. Distinguishing them requires reasoning about program semantics rather than the surface diff.

## 2.3 VCC Dataset Construction

The SZZ algorithm [62], the primary approach for VCC dataset construction, uses `git blame` to trace fixed lines back to their last-modifying commits. Numerous SZZ variants [2, 5, 7, 36, 51, 53, 65] have been proposed to improve accuracy: Kim *et al.* [31] introduced annotation graphs, and Costa *et al.* [20] developed a framework for systematic evaluation. However, studies reveal limitations in SZZ-based construction. Rosa *et al.* [55, 56] found accuracy variations across implementations, while Hinrichs *et al.* [26] assessed 12 VCC mining techniques for Java, finding none sufficiently accurate.

For security-specific datasets, Perl *et al.* [50] created the VCCFinder dataset by manually linking CVEs to VCCs. Paul *et al.* [49] constructed a Chromium VCC dataset using SZZ-based tracing from security patches. Riom *et al.* [54] revisited VCCFinder with updated methodology, while Coskun *et al.* [19] profiled developer characteristics associated with vulnerability introduction. Recently, Cannavale *et al.* [12] demonstrated that the choice of SZZ variant significantly impacts JIT vulnerability prediction performance, and Cheng *et al.* [17] proposed VERCATION for vulnerable version identification using static analysis and LLMs. However, these datasets rely on either automated SZZ labeling (which may produce false positives) or limited manual verification. Our work provides the first systematic exploit-based validation quantifying the actual false positive rates in these datasets.

## 2.4 Dataset Quality Assessment

Prior work has examined the limitations of SZZ-based bug-inducing commit identification and challenges in VCC datasets. Herbold *et al.* [25] analyzed how tangled commits and feature interactions introduce SZZ errors, while Rosa *et al.* [55] compared SZZ implementations against developer-informed ground truth and reported precision ranging from 48% to 67%. In the vulnerability domain, Lomio *et al.* [38] surveyed JIT vulnerability detection approaches but did not empirically validate the underlying datasets, Bao *et al.* [5] proposed V-SZZ for identifying affected vulnerability version ranges rather than validating VCC accuracy, and

Nguyen *et al.* [43] introduced a unified evaluation framework for JIT vulnerability prediction models while focusing on model comparison instead of dataset validation. Unlike these prior works, we introduce an *exploit-based validation approach*: we reconstruct historical software states and verify whether the vulnerability actually becomes exploitable at labeled VCCs. Specifically, we test parent commits to distinguish commits at which a vulnerability first becomes *exploitable* from those at which it was *already exploitable*, a distinction that prior dataset construction approaches have not systematically operationalized.

## 3 Research Questions (RQs)

**RQ1** ***What terminology and definitions are used in the literature to characterize VCCs?***

Before evaluating VCC datasets or detection techniques, we must understand how prior work conceptualizes VCCs. Inconsistent terminology and definitions can yield incompatible datasets and undermine downstream tools. Thus, we catalog terminology and definition patterns to identify sources of confusion and areas needing standardization.

**RQ2** ***What are the key challenges in identifying and labeling VCCs?***

Accurate VCC identification is crucial for building reliable training data and for understanding vulnerability lifecycles. While prior work [27] has noted challenges in VCC identification, these have not been systematically characterized. Understanding them can help explain errors in existing datasets and guide future methodological improvements.

**RQ3** ***How accurate are existing VCC datasets when subjected to exploit-based validation?***

VCC datasets are widely used to train and evaluate vulnerability detection tools, yet their accuracy is often assumed rather than validated. Mislabeled commits can propagate errors to downstream models. We use exploit-based validation of security state transitions to provide empirical evidence of dataset quality beyond metadata-based heuristics.

Fig. 1 shows an overview of our two-part study, which is detailed in the next sections.

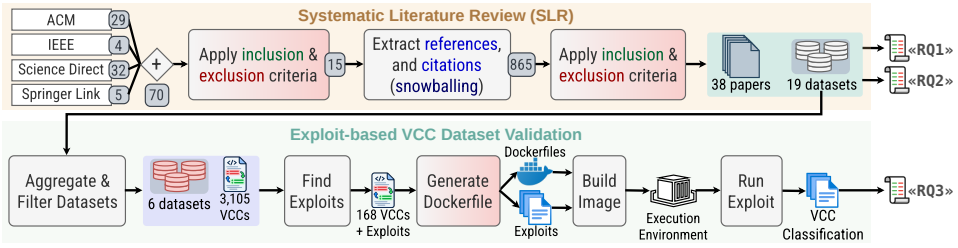

**Figure 1** Overview of our two-part study. **Part 1:** the literature review to answer RQ1 and RQ2. **Part 2:** the exploit-based validation, aggregating 6 datasets into 3,105 samples, screening to the 168 with documented exploits, and testing each labeled commit and its parent to answer RQ3.

## 4 A Systematic Review of VCC-Related Literature

To answer RQ1 & RQ2, we first conducted a systematic review of VCC-related literature following the guidelines of Kitchenham and Charters [32].

### 4.1 Systematic Literature Review Methodology

The review consisted of three phases: planning, conducting, and reporting.

**Planning Phase.** We first established a review protocol defining: (i) the SLR's objectives, (ii) the search string, (iii) the digital libraries to query, and (iv) inclusion and exclusion criteria. The objectives of our SLR are fourfold: (1) to identify papers that describe or apply the concept of VCCs; (2) to analyze how VCCs are defined across different studies; (3) to identify the key challenges researchers face when identifying and labeling VCCs; and (4) to collect and examine the VCC datasets referenced/provided by these papers.

We searched for papers containing any of the following terms (combined with `OR`): *"vulnerability contributing commit," "vulnerability introducing commit," "vulnerability injecting commit," "vulnerability fix inducing commit," "just in time vulnerability detection," "vulnerable commit,"* or *"vulnerable code change."* We applied this query to four major digital libraries (ACM Digital Library, IEEE Xplore, SpringerLink, and ScienceDirect).

**Table 1** Inclusion and Exclusion Criteria for Paper Selection.

| Inclusion Criteria | Exclusion Criteria |
|---|---|
| **I1** Describes a dataset of VCCs | **E1** Duplicate studies |
| **I2** Describes an approach to detect, repair, or test VCCs | **E2** Not written in English |
| **I3** Develops techniques to detect VCCs | **E3** Less than 4 pages of text |
| **I4** Studies the problem of VCC identification | **E4** Secondary studies (*e.g.*, surveys) |
| **I5** Describes techniques to identify VCCs from patches | **E5** Does not provide a VCC-related approach or dataset |

We used Parsifal [24] to organize the review process. For each accepted paper, we extracted: (i) a summary of objectives and research questions, (ii) terminology used for vulnerable code changes, (iii) verbatim definitions of VCCs, (iv) challenges discussed in VCC identification, and (v) dataset availability and access information.

**Conducting Phase.** After collecting 70 papers from all four databases, we removed duplicates and applied the inclusion and exclusion criteria (shown in Table 1) in two stages: first based on titles, abstracts, and keywords, then through a full-text review. This first pass yielded 15 accepted papers. For these 15 papers, we performed one round of *forward* and *backward* snowballing, extracting their cited references and citing papers, which contributed 865 additional candidates. We did not iterate the snowball beyond this single round, since the four digital libraries already provided broad coverage of the relevant venues. We applied a keyword-based pre-filter on titles and abstracts to remove papers clearly outside the scope of VCC research, reducing the snowballed pool to 309 papers requiring detailed screening. Two computer science researchers (2 years of experience) independently screened these 309 papers following the criteria in Table 1. A senior software security researcher (4+ years of experience) verified their decisions, with disagreements resolved through discussion. This screening retained 23 of them, which combined with the 15 from the database search resulted in a final corpus of 38 papers. The Cohen's $\kappa$ [18] between the verifier and each reviewer was 0.71 and 0.65, both indicating *substantial agreement* [34][1], and the 26 disagreements (8.41%) were resolved through discussion. Of these 38 papers, 19 provided VCC datasets.

**Reporting Phase.** We recorded each paper's own term, definition and stated challenges verbatim, then aggregated these records into three categories: *terminology* grouped by morphological variants of the same term (papers using no dedicated term formed a *generic terms* category), *definitions* by the dimension along which they disagreed, and *challenges*

[1] We note that the inter-rater agreement reported here reflects agreement between extractors and a more experienced verifier rather than between equally-trained peers.

by shared underlying cause. The same two researchers coded independently, working from the extraction records and the grouping rules above rather than from a predefined category list, so that the categories emerged from the papers themselves. The senior author verified the coding, and differences were resolved by discussion. Per-paper codes are in Table 3 and Table 4, with the full extraction sheet in the replication package.

## 4.2 RQ1 Results: Terminology and Definitions

As shown in Table 2, our SLR yielded **38 papers** spanning from 2005 to 2025.

**Table 2** Year-wise distribution of accepted papers ($n = 38$).

| Year (#) | Papers |
|---|---|
| 2005–2015 (4) | [8, 40, 50, 62] |
| 2017–2020 (7) | [16, 23, 27, 37, 57, 67, 71] |
| 2021–2022 (10) | [5, 11, 19, 28, 35, 38, 49, 54, 68, 69] |
| 2023–2025 (17) | [1, 4, 12, 13, 15, 17, 26, 30, 43–45, 58, 61, 63, 64, 70, 72] |

**Terminology Usage.** Our analysis revealed **8** distinct terms used in the literature to refer to commits that introduce vulnerabilities. These terminologies are listed in Table 3.

**Table 3** Terminology usage across VCC-related papers ($n = 38$).

| Terminology | Papers | Total |
|---|---|---|
| Vulnerability-Contributing Commits (VCC) | [1, 4, 8, 12, 13, 15, 19, 26, 27, 35, 40, 45, 49, 50, 54, 57, 67, 71] | 18 |
| Just-In-Time (JIT) vulnerability detection | [38, 43, 64] | 3 |
| Vulnerability-Inducing/Introducing Commits (VIC) | [5, 17, 30, 44] | 4 |
| Security patches / Patch commits | [11, 58, 72] | 3 |
| Vulnerability Introduction Detection (VID) | [70] | 1 |
| Vulnerability-relevant / -related commits | [16, 68] | 2 |
| Fix-Inducing Changes (FIC) | [62] | 1 |
| Generic terms (e.g., “vulnerable code”) | [23, 28, 37, 61, 63, 69] | 6 |

**Definition Patterns.** Grouping the verbatim definitions by the dimension along which they disagreed revealed three inconsistency types:

- **Temporal ambiguity**: Some works define VCCs as *“the commit that introduced a vulnerability”* [26, 27, 50, 54] while others specify *“the previous commits which last modify [vulnerable] statements”* [45] or *“the earliest commit that modified the vulnerable lines”* [5].
- **Attribution scope**: Definitions vary between commits that *“contributed to the introduction of a post-release vulnerability”* [40] or *“likely to have contributed to the introduction of a vulnerability”* [38] versus commits that *“contain software vulnerabilities”* [35].
- **Attribution granularity**: Some approaches identify a single VCC per vulnerability, such as *“the earliest commit as the inducing commit”* [5], while others acknowledge that *“forming a vulnerability in a code version could require one or more VCCs over time”* [45].

## 4.3 RQ2 Results: Challenges in VCC Identification

We found five recurring challenges in VCC identification and labeling (Table 4): **21** papers discussed at least one of these challenges, while the remaining **17** [1, 4, 8, 11, 16, 23, 28, 37, 44, 49, 50, 57, 62, 67–69, 72] used existing labeling approaches or raised tangential limitations (*e.g.*, class imbalance, scope) without thorough examination of VCC identification accuracy.

**Table 4** Challenges in VCC identification across VCC-related papers ($n = 38$).

| Challenge | Papers | # | % |
|---|---|---|---|
| C1: SZZ Algorithm Limitations | [5, 12, 17, 19, 26, 27, 35, 45, 61, 64, 70] | 11 | 28.9% |
| C2: Lack of Ground Truth Validation | [12, 15, 27, 30, 35, 40, 63, 64, 70, 71] | 10 | 26.3% |
| C3: External Data Source Unreliability | [5, 19, 30, 58, 63] | 5 | 13.2% |
| C4: Multi-Commit Vulnerability Introduction | [13, 15, 45, 70] | 4 | 10.5% |
| C5: Reproducibility Barriers | [26, 38, 43, 54] | 4 | 10.5% |

*Note: Some papers discuss multiple challenges.*

**C1: SZZ Algorithm Limitations.** We found **11 papers** documented limitations in how SZZ traces and attributes vulnerability-introducing changes. At the *line-tracing* level, SZZ's *"last modified"* heuristic assumes the commit that last touched a line introduced the defect, an assumption that breaks down in several ways. V-SZZ [5] found that over 50% of vulnerabilities were introduced in initial or foundational commits that SZZ cannot trace, because these commits create code rather than modify existing lines. SZZ also cannot handle fixes that consist entirely of added lines, since there are no deleted lines to trace back from [17, 26, 70]. The *"inappropriate patch assumption"*, where prior work assumes patches contain only vulnerability-relevant changes and must include deletion lines, further distorts SZZ-style tracing [61]. Moreover, at the *commit-identification* level, tangled and multi-purpose commits that mix vulnerability-introducing code with unrelated changes cause SZZ to attribute the vulnerability to the entire commit [26,45]. Cosmetic changes (*e.g.*, comments, refactoring, and variable renames) cause SZZ to flag commits that merely touched but did not introduce the vulnerability [19]. In the adjacent setting of non-functional bugs, rather than vulnerabilities, empirical studies of SZZ report false positive rates as high as 79% [52], with mislabeling persisting even after curation [35] (only 85% of automatically mined VCCs were valid after manual verification), making manual validation infeasible at scale. The resulting noise is substantial: Coskun *et al.* [19] report that SZZ-based tracing initially identified 402 candidate inducing commits, which filtering reduced to 187, and Sun *et al.* [64] needed to manually filter mislabeled commits before their data was usable.

**C2: Lack of Ground Truth Validation.** We found **10 papers** highlighting the absence of validated ground truth as a fundamental limitation in VCC research. Manual labeling, the most direct path to validated ground truth, faces practical constraints: it requires "hundreds of man-hours" [40] even for small datasets, and VulDigger [71] noted the lack of VCC ground-truth datasets as a core obstacle. Moreover, when manual verification is attempted, the results expose labeling errors in automatic methods. Le *et al.* [35] reported that only 85% of their automatically mined VCCs were valid after manual verification, meaning 15% were mislabeled from the start. Manual verification is itself imperfect: Meneely *et al.* [40] observed that some vulnerabilities could not be bisected due to missing context, and Charoenwet *et al.* [15] acknowledged that manual CWE mapping introduces human bias into VCC datasets, impacting study results. Despite this evidence, most datasets rely on SZZ-based identification with no manual verification step. Cannavale *et al.* [12] explicitly acknowledged evaluating model performance *"without validating absolute VCC correctness against manual ground truth"*, leaving labeling accuracy unverified. CommitShield [70] pointed to label noise from incomplete commit context, and Sun *et al.* [63] stated directly that *"our ground truth is imperfect"*, noting that vulnerabilities may span multiple repositories and files, with patching commits that are *"incomplete or contradictory"*.

**C3: External Data Source Unreliability.** We found **5 papers** that identified problems with the external data sources (primarily NVD and CVE databases) that VCC identification pipelines depend on as input. V-SZZ [5] found that 99 of 172 NVD entries (57.6%) had incorrect version information, meaning the starting point for many VCC traces is already wrong. Hash4Patch [58] reported that only 28.75% of vulnerabilities in NVD have a link to their patch, limiting the availability of confirmed fixing commits needed as entry points for VCC identification. They also described a "chicken-and-egg problem": building a vulnerability dataset requires patches, but finding patches requires an existing dataset.

The traceability gap extends beyond missing links. Sun *et al.* [63] noted that *"the repository of the vulnerable product is not the mandatory information in the NVD,"* which creates uncertainty when even locating the correct codebase. Jiang *et al.* [30] found no explicit link either from a CVE to its fix commit or from a fix commit onward to the corresponding vulnerability-inducing commit, so the traceability gap compounds across both hops. Coskun *et al.* [19] found that SmartSHARK [66] did not include the vulnerabilities their prediction model required, forcing manual extraction.

**C4: Multi-Commit Vulnerability Introduction.** We found **4 papers** noting that a vulnerability may result from code changes spread across multiple commits, challenging the assumption of a single VCC per vulnerability. Nguyen *et al.* [45] noted that a vulnerability may arise from one or more VCCs over time, yet simplified their approach to focus on single vulnerability-triggering commits, potentially omitting earlier contributing changes. Charoenwet *et al.* [15] and Cao *et al.* [13] both noted that a vulnerability may depend on code changes introduced across multiple commits, which complicates one-to-one VCC labeling and introduces ambiguity in ground truth construction. CommitShield [70] pointed out that the single-VCC assumption underrepresents multi-commit introduction patterns, increasing false negatives. Moreover, Cao *et al.* [13] also observed that the actual vulnerable changes within a VCC are typically small relative to the total set of code changes in the commit, making them difficult to identify even when the correct commit is labeled.

**C5: Reproducibility Barriers.** We observed **4 papers** noting difficulties in reproducing VCC research artifacts or historical software states for validation. Riom *et al.* [54] and Lomio *et al.* [38] reported being unable to fully reproduce VCCFinder [50] due to missing details and artifacts. Hinrichs *et al.* [26] further identified tooling inconsistencies, missing dependencies, and required implementation changes that threatened reproducibility and potentially affected results. Nguyen *et al.* [43] described data curation for VCC research as *"repository-specific, error-prone, and labor-intensive"*, noting that this complexity results in limited experimental scale and inconsistent evaluation across models.

## 5 Exploit-Based Formalization of VCCs

Our SLR revealed inconsistent VCC terminology and definitions. We identified eight distinct terms, often used interchangeably, while 15.8% of papers gave no explicit definition and others reflected differing interpretations. Some adopted ***operational definitions*** describing *how* VCCs are identified rather than *what* they are (*e.g.*, *"a code modification identified through a semi-automatic process using git blame"* [71]). Others relied on ***containment definitions*** (*"commits whose changes contain software vulnerabilities"* [35]) or ***modification definitions*** (*"the previous commits which last modify [vulnerable] statements"* [45]), both of which identify commits that merely touched or contained vulnerable code rather than

commits at which the vulnerability first became exploitable. These inconsistencies have practical consequences. SZZ-based approaches, which dominate dataset construction, trace fixed lines backward, potentially labeling commits that merely reformat, move, or extend pre-existing vulnerable code, even when the vulnerability predates them. This confusion between commits that contain vulnerable code and commits at which it becomes exploitable propagates mislabeled samples into training datasets.

These challenges (§ 4.3) shape the definition and the validation protocol that follow in this section and in § 6. C1 and C2 motivate validation itself, since SZZ mislabels and no validated ground truth exists, and testing the *parent* is what separates introducing from containing; C5 motivates the two-tier fallback, since historical build environments frequently cannot be reproduced. C3 motivates the ban on lineage-based reasoning, since unreliable NVD and CVE metadata means a verdict must rest on direct evidence at the commit, and C4 is why the definition anchors on exploitability rather than on responsibility for the vulnerability.

## 5.1 VCC Formal Definition

Our definition is grounded in the *security state transition* observed across a commit. Intuitively, a VCC is the commit at which the project's security status with respect to a specific vulnerability changes from *safe* to *unsafe*; that is, the precise point where that vulnerability becomes *exploitable*. While the project may contain other unrelated vulnerabilities before or after this commit, the state transition refers only to the vulnerability in question. A vulnerability may also emerge from code changes spread across multiple commits [70], or depend on configuration and on properties of the surrounding execution environment. Rather than apportioning responsibility among such changes, we anchor the definition on a property that can be tested directly: whether the vulnerability is exploitable in a given state. This yields a deterministic criterion that separates VCCs from commits that merely contain or modify existing vulnerable code: **a VCC is the commit at which the vulnerability first becomes *exploitable***, that is, the earliest state in the project's history in which an attacker can compromise the system through that vulnerability, as formally defined below.

▶ **Definition 1 (Vulnerability-Contributing Commit – VCC).** *Let* $\mathbf{P}$ *be a software project,* $\mathbf{v}$ *be a specific vulnerability, and* $\mathbf{c}$ *be a commit with parent commit* $\mathbf{c}^-$*. We define* $\mathbf{c}$ *as a* ***VCC*** *for vulnerability* $\mathbf{v}$ *iff:* $\boldsymbol{VCC}(\mathbf{c}, \mathbf{v}) \iff \boldsymbol{Exploitable}(\mathbf{v}, \mathbf{P}(\mathbf{c})) \wedge \neg \boldsymbol{Exploitable}(\mathbf{v}, \mathbf{P}(\mathbf{c}^-))$*, where* $\mathbf{P}(\mathbf{c})$ *denotes the software state after applying commit* $\mathbf{c}$*.*

A commit is a VCC only if the vulnerability becomes exploitable at that commit and was not exploitable in the previous version. Two edge cases require special treatment:

- **Initial commits**: When $c$ has no parent, the condition on $P(c^-)$ does not apply; any vulnerability present in $P(c)$ is, by construction, first exploitable at $c$.
- **Merge commits**: When $c$ has multiple parents, our validation focuses exclusively on the main branch. We treat the merge commit itself as the single predecessor of the subsequent commit, without tracing into the merged feature branch history. This reduces the multi-parent case to a single-parent comparison.

## 5.2 Operationalization via Parent Commit Validation

Our definition can be operationalized through a parent commit validation procedure. Given a labeled commit $c$, we first reproduce the software state at $P(c)$ and verify whether vulnerability $v$ is exploitable in that version. We then reproduce the parent state $P(c^-)$ and attempt to exploit the same vulnerability in the preceding version. A commit is classified as a **VCC**

if the vulnerability is exploitable in $P(c)$ but not in $P(c^-)$, indicating that the exploitable state first appears at $c$. Conversely, if the vulnerability is exploitable in both versions, the commit is classified as a **false positive** because the vulnerability was already exploitable prior to the labeled commit. Finally, if the vulnerability is not exploitable even in $P(c)$, the label is also considered a **false positive**, indicating incorrect vulnerability attribution.

This methodology directly tests the state-transition criterion. Existing approaches (SZZ-based identification, CVE/NVD mapping, and manual labeling) can serve as *candidate generation* steps, efficiently identifying commits at which a vulnerability may have become exploitable. However, without parent commit validation, these candidates remain unverified. Our definition provides the criterion against which candidates must be tested.

# 6 Exploit-Based Validation of VCC Datasets

VCC datasets are widely used to train and evaluate vulnerability detection tools, yet their accuracy is often assumed rather than validated, allowing mislabeled commits to propagate errors into downstream models. To answer **RQ3**, we apply our exploit-based VCC validation (§ 5.2) to determine whether labeled commits in existing datasets satisfy Definition 1. This section describes our validation methodology (§ 6.1) and presents RQ3 results (§ 6.2).

## 6.1 RQ3 Methodology

Our protocol operationalizes the security-state-transition definition (Section 5): $c$ is a VCC for $v$ iff $v$ is exploitable post-commit and not in its parent. We impose an explicit ban on *lineage-based reasoning*, meaning that a commit's verdict must come from direct evidence at the commit itself, never from its position in version history (e.g., date relative to a fix release). Each commit enters with a CVE identifier, commit hash, repository URL, and reference to a public exploit. The protocol is a two-tier cascade: **Tier 1** attempts ***runtime*** exploit reproduction, and **Tier 2** (***static***) runs only when Tier 1 cannot produce a runnable artifact. We restrict Tier 2 to the fallback role because static matching establishes pattern presence, not exploitability. Commits with an `EXPLOITABLE` child verdict are re-evaluated at the parent under the same protocol, and the joint (child, parent) pair determines the final classification. Since the two sides of a pair can be resolved at different tiers, we record the tier separately for the child and the parent verdict, and refer to a commit as *Tier-1-pure* when every side that was tested reached its verdict dynamically.

### 6.1.1 Dataset Aggregation and Exploit Retrieval

We applied the following inclusion criteria to the 19 datasets identified in the SLR (§ 4): **(i)** it contains vulnerable code changes (commits) rather than general bugs; **(ii)** it includes metadata (repository URL, commit hash, CVE identifier) needed for exploit validation; **(iii)** it contains commits from Java projects, for a consistent build and exploitation toolchain[2]. After applying these criteria, which are distinct from the paper-selection criteria in Table 1, we discarded 13 datasets. Then, after aggregating the samples in the remaining **6 datasets**, removing duplicated (repository URL, commit hash) pairs and removing samples without resolvable hashes, we obtained **3,105 aggregated VCC samples**. For each of these 3,105 samples, we searched Exploit-DB [47], the most comprehensive public exploit collection [3, 14, 21], to

[2] Cross-language replication (C/C++, Python) is left to future work.

find associated exploits with reproduction steps. Of the 3,105 samples, we found associated exploits for **168 (5.41%)** of them[3]. This rate is consistent with prior findings that only 2–4% of CVEs in NVD correspond to exploits observed in real-world attacks [3].

### 6.1.2 Tier 1: Runtime-based Exploit Analysis (Dynamic)

Tier 1 reproduces the labeled commit's vulnerability by cloning the repository at the target commit, creating a Dockerfile containing the exploit script, building a Docker image, and trying two execution environments in sequence to run the application. We used GPT-4o and Claude Sonnet 4 to draft the initial Dockerfiles and exploit scripts. Before building the execution environment, we determined manually what the reproduction should do for that CVE, checked the Dockerfile's repository URL, commit hash, and build steps against the dataset record, and confirmed that the exploit script exercises the behavior described in the Exploit-DB write-up. Artifacts that diverged were manually corrected.

We then build the Docker image using two execution environments in sequence. The first is an ***at-hash source build*** using the project's native build tool (Maven, Gradle, or Ant). When at-hash dependency resolution fails (common for older projects whose pre-2014 Maven coordinates are no longer hosted on public mirrors), we fall back to a ***release-baseline overlay***: a pre-built release archive from an immutable mirror (*e.g.*, `archive.apache.org`, Maven Central, DockerHub, *etc*) is deployed as the surrounding runtime, and then at-hash `.class` files for the CVE-relevant source files are surgically replaced inside the deployed artifact. What executes at runtime is the commit's own bytecode for the CVE-relevant classes embedded in a release-baseline framework; the baseline is the release closest in date to the labeled commit. We record which execution environment was used for each verdict. If neither environment produces a runnable artifact, the protocol moves to Tier 2.

We execute the exploit on the runnable environment and record HTTP traces, container logs, and filesystem side-effects to identify three possible outcomes: *exploitable*, *not exploitable*, or *inconclusive*. Unambiguous indicators of unsafe behavior (RCE, directory traversal beyond the configured root, privilege escalation) yield `EXPLOITABLE`. A clean failure (sanitized response, blocking exception in framework code) yields `NOT_EXPLOITABLE`. An environment that never reached a runnable state yields `INCONCLUSIVE` with the failure reason recorded. These three verdict categories were uniformly assigned across all commits by a senior author. We also note that errors are self-limiting: a configuration that does not build yields a documented Tier 1 failure rather than a verdict, and an `EXPLOITABLE` verdict requires the exploit to actually execute in the container.

### 6.1.3 Tier 2: Pattern-Based Exploit Analysis (Static)

Tier 2 runs only after Tier 1 fails. The failure is recorded with its *error category* (*e.g.*, unavailable dependencies, build tooling, repositories, binary distributions, or exploit environments). The *error message* is also recorded alongside the Tier 2 verdict to confirm Tier 2 was not invoked as a shortcut. For each Tier 2 commit, we first derive a CVE-specific code pattern from the exploit description, naming concrete methods, classes, or files rather than generic strings. Patterns are derived from three complementary sources: (i) the Exploit-DB proof-of-concept, which identifies the vulnerable sink; (ii) the fixing commit's diff, which reveals

[3] We note that exploit availability is not a dataset-level filtering criterion: it is applied per VCC sample aggregated from the 6 datasets. This is why the datasets start with far more samples than we can ultimately validate.

the mitigation, that is, the call or flag the maintainers added to close the vulnerability, such as a canonical-path check before a file read; and (iii) the CVE advisory, which specifies the affected source files. Initial drafts of the vulnerable and mitigation patterns were generated with GPT-4o and Claude Sonnet 4 from these inputs and manually verified before admission: we inspected the source files named in the CVE advisory to locate the vulnerable construct by hand, and admitted a pattern only when it targeted that same construct, checking the mitigation term the same way against the API introduced by the fixing commit's diff. Patterns that did not match the construct we had located were rewritten or discarded. The labeled commit under evaluation was never shown during pattern construction, so a pattern cannot be tuned to the commit it is later used to judge. Patterns are broad enough to absorb minor refactors but narrow enough to avoid spurious matches. We then search the isolated checkout across documented globs. The verdict is determined by the joint presence of the vulnerable pattern and any recognizable mitigation (*e.g.*, *getCanonicalPath* with *startsWith*, input validation, or hardening flags such as *FEATURE_SECURE_PROCESSING*). Pattern present without co-located mitigation yields `EXPLOITABLE`; pattern absent or mitigated yields `NOT_EXPLOITABLE`; a refactored layout with no recognizable equivalent yields `INCONCLUSIVE`.

### 6.1.4 Parent Commit Analysis Step and VCC Classification

A child commit's verdict alone is insufficient to classify it as a true VCC: the parent must be tested to rule out SZZ over-attribution. We trigger the parent commit analysis step whenever the child commit verdict is `EXPLOITABLE`, regardless of tier. Initial commits (no parent) are classified `TRUE_VCC` by construction, since no prior state exists in which the vulnerability could have been exploitable. Merge commits are reduced to the single-parent case by following the first-parent edge only, since our methodological question concerns the labeled commit as it appears on the main-line history. For every commit with a testable parent, we construct the same validation artifact at the parent commit hash and apply the full Tier 1 then Tier 2 cascade under the same lineage ban and tier discipline. The joint verdicts determine the final classification: an `EXPLOITABLE` child with a `NOT_EXPLOITABLE` parent, or an initial commit with no parent, yields `TRUE_VCC`; an `EXPLOITABLE` parent yields `FP_PARENT_EXPLOITABLE`; a `NOT_EXPLOITABLE` child yields `FP_NOT_EXPLOITABLE` with no parent test; and an `INCONCLUSIVE` verdict on either side leaves the case unresolved rather than promoted to a verdict, excluded from both counts in Section 6.2.

For each commit, we produce standardized validation artifacts: a *Dockerfile* and a *Compose* file building the historical runtime at the commit's hash, a script issuing the proof-of-concept against the running container, and a *result.txt* recording the verdict, its tier, and the supporting evidence. Child commits additionally carry the joint child and parent classification. Before a verdict is made, an automated check confirms that `result.txt` uses only the verdict labels defined in Sections 6.1.2–6.1.3, that the evidence type matches the tier (runtime logs for Tier 1, source patterns for Tier 2), that any Tier 1 build failure is documented before fallback to Tier 2, and that the written justification cites direct evidence at the commit being tested rather than the commit's position in version history.

## 6.2 RQ3 Results: Dataset Accuracy

We applied the methodology to the 168-commit corpus, drawn from 61 CVEs affecting over 30 projects in the Apache ecosystem (*e.g.*, Struts, Tomcat, Commons, Solr, ZooKeeper, Olingo, Tika, ActiveMQ, Geronimo, Syncope), the Spring family (*e.g.*, Framework, Security OAuth, Cloud Config), Jenkins, and others (complete list in the replication package). As shown in

Table 5, we find that 133/168 (79.2%) labeled commits are SZZ false positives under the security-state-transition definition. This rate characterizes the validatable subset defined in § 6.1.1, *i.e.*, the 5.41% of the 3,105 aggregated samples whose CVEs have public exploit infrastructure, and not the aggregate corpus. Tier 1 was attempted against every commit; the 90/168 (53.6%) Tier 2 share reflects forced fallbacks after Tier 1 failed on dependency or build-tool failures (unresolvable Maven coordinates, dead HTTP mirrors, Ant-era classpaths under modern JDKs, broken SNAPSHOT chains), not a methodological choice to bypass dynamic validation. Each failure is documented with the exact build error before falling to Tier 2. Since Tier 2 establishes pattern presence rather than exploitability, Table 5 reports each outcome alongside the count whose verdicts rest entirely on runtime evidence.

**Table 5** Joint child and parent verdict distribution with final classification ($n = 168$). The Tier-1-pure column counts commits for which every tested side reached its verdict through dynamic exploit reproduction ($n = 69$); percentages in that column are relative to 69.

| Child commit verdict | Parent commit verdict | Count (%) | Tier-1-pure (%) | Final classification |
|---|---|---|---|---|
| `EXPLOITABLE` | `EXPLOITABLE` | 79 (47.0%) | 36 (52.2%) | `FP_PARENT_EXPLOITABLE` |
| `EXPLOITABLE` | `NOT_EXPLOITABLE` | 30 (17.9%) | 7 (10.1%) | `TRUE_VCC` |
| `EXPLOITABLE` | (initial, no parent) | 5 (3.0%) | 1 (1.4%) | `TRUE_VCC` |
| `NOT_EXPLOITABLE` | (not tested) | 54 (32.1%) | 25 (36.2%) | `FP_NOT_EXPLOITABLE` |
| `INCONCLUSIVE` | not applicable | 0 (0.0%) | 0 (0.0%) | not applicable |
| **TRUE_VCC total** | | **35 (20.8%)** | **8 (11.6%)** | |
| **False Positive total** | | **133 (79.2%)** | **61 (88.4%)** | |

*Tier breakdown: child step* 78 *Tier 1,* 90 *Tier 2; parent step (n =* 109*)* 43 *Tier 1,* 66 *Tier 2. The* 69 *Tier-1-pure commits comprise* 43 *resolved dynamically on both sides,* 25 *with a dynamic* `NOT_EXPLOITABLE` *child verdict requiring no parent test, and* 1 *initial commit. No commit received a Tier 2 child verdict together with a Tier 1 parent verdict.*

**Interpretation.** The dominant outcome is that the labeled commit does *not* satisfy Definition 1. The 133 false positives split across two failure modes. `FP_PARENT_EXPLOITABLE` (47%): the vulnerability is exploitable at the labeled commit, but it was already exploitable at its parent. The exploit runs, or the vulnerable pattern is present without mitigation, at both sides of the diff, so by construction the labeled commit does not exhibit the exploitability transition; the vulnerable state is inherited from its parent. This is precisely what SZZ-style backward tracing cannot detect, since SZZ traces from a fixing commit to the last commit that modified the fixed lines without testing whether the predecessor was already exploitable. At 47%, this is the most common labeling error in our corpus, not an edge case. `FP_NOT_EXPLOITABLE` (32.1%): the vulnerability is not exploitable at the labeled commit. Recurring patterns include commits touching a file or symbol whose name overlaps with the vulnerable artifact in a later refactor, fixing commits for one CVE misattributed to a different CVE, and merge commits SZZ blamed in place of the originating branch change. Only 35/168 (20.8%) commits validate as `TRUE_VCC` (5 initial commits plus 30 with `NOT_EXPLOITABLE` parents). The `INCONCLUSIVE` buckets are empty: every Tier 1 failure was resolved by Tier 2.

**Sensitivity to evidential strength.** The false positive rate is *higher* in the subset supported by runtime evidence alone (88.4%, 95% Wilson CI 78.8–94.0%) than in the full corpus (79.2%, 95% Wilson CI 72.4–84.6%), and the difference between the two strata corresponds to $p = 0.020$ under Fisher's exact test. Since the 168 commits derive from only 61 CVEs, several commits often share a CVE and are not independent observations, so we read this contrast as descriptive of the two strata rather than as an inferential test. Thus, the combined

79.2% rate is conservative with respect to the tier question: restricting attention to the strongest evidence strengthens rather than weakens the finding. The most likely mechanism is that Tier 2 under-detects `FP_PARENT_EXPLOITABLE`. A parent whose file layout was later refactored may not match the CVE-specific pattern even though the vulnerable path is present, yielding a `NOT_EXPLOITABLE` parent verdict and promoting the pair to `TRUE_VCC`; commits involving a Tier 2 verdict validate as true VCCs at 27.3% against 11.6% in the Tier-1-pure subset. Combining the two tiers thus biases the corpus toward appearing *cleaner* than the dynamic evidence indicates, so conclusions drawn from the combined rate understate rather than overstate the labeling problem.

## 7 Discussion

Our findings have several implications for the state of the art in VCC research.

**Terminology and Definition Standardization.** The 8 different terminologies and 3 definition patterns found in RQ1 lead to practical challenges: when different papers operationalize different concepts under the same "VCC" label, cross-study comparisons and dataset aggregation become unreliable. The confusion between *"contributed to"*, *"introduces"* and *"contains"* (attribution scope), and the disagreement over which commit in a chain to blame (temporal ambiguity), also explain the labeling errors observed in RQ3. We recommend that the community adopt "Vulnerability-Contributing Commit (VCC)" as the standard terminology, given its prevalence in the literature (47.4% of the reviewed papers), alongside a state-transition definition, as described in § 5. This definition replaces the temporal ambiguity and the varying attribution wording documented in § 4 with a single testable criterion. We retain the established modifier *"contributing"* for continuity with the existing literature rather than as a claim about causal responsibility: the criterion attached to the term tests where a vulnerability's exploitability status changes, and does not attempt to apportion responsibility among the code changes that jointly enable the vulnerability. We further advocate for parent commit validation as a standard verification methodology for dataset construction, enabling empirically validated ground truth beyond SZZ-based candidate generation.

**Dataset Quality and ML Training.** Only 5.4% of the 3,105 aggregated samples target CVEs with public exploit infrastructure, consistent with prior work showing that only 2-4% of CVEs in NVD correspond to exploits observed in real-world attacks [3]. This bound is set by the datasets rather than our validation steps, so no exploit-based protocol can speak to the labeling accuracy of the remaining 94.6%. Within the validated subset, the 79.2% false positive rate (Table 5) points not to random noise but to systematic confusion: SZZ traces back to commits that *touched* vulnerable lines, not commits at which the vulnerability first became *exploitable*. The 79 `FP_PARENT_EXPLOITABLE` commits (47.0%) demonstrate this directly. Models trained on such data risk learning to detect code modification rather than the transition into an exploitable state, and when training and test sets share this bias, a model can achieve high accuracy while misaligning with the research goal. The practical implication for dataset consumers is therefore conditional: the measured error rate applies to the validated subset, while the correctness of the unvalidated majority rests on the same SZZ heuristics that produced it, with no positive evidence that the majority is cleaner.

**Reproducibility Barriers.** We also observed another structural barrier: 90 (53.6%) out of the 168 validated commits could not be brought to a runnable state under either Tier 1 environments. **Build complexity**, rather than project age, was the main reason: projects

with self-contained build systems reproduced successfully regardless of commit age, while projects with heavy transitive dependency chains and obsolete package mirrors consistently failed, even for relatively recent commits. Any researcher attempting to reproduce these historical states would encounter the same failures. Future dataset construction should address both barriers: prioritizing CVEs with documented exploits and projects with reproducible build systems; this will yield smaller but Tier 1-validated corpora, providing stronger evidence than larger corpora based on unverified heuristics.

## 8 Threats to Validity

**Internal Validity.** Our exploit-based validation depends on the correctness of exploit documentation from Exploit-DB. Errors in exploit guides could cause valid VCCs to be classified as false positives. We mitigated this by manually reviewing failed exploits and consulting multiple sources when available. Moreover, our use of LLMs to draft Dockerfiles, exploit scripts and patterns may have introduced errors. We addressed this through the per-artifact checks described in § 6.1.2 and § 6.1.3. These checks were carried out by a senior author, so they were applied uniformly across commits; all generated artifacts are in the replication package so the checks can be repeated independently. Moreover, the release-baseline overlay described in § 6.1.2 assumes that the framework code surrounding the CVE surface is stable between the labeled commit and the chosen release. Structural changes between the two states could therefore make an overlay verdict diverge from an at-hash source build. We mitigated this by choosing the release closest in date to the labeled commit and by recording the substrate provenance alongside every overlay verdict.

**External Validity.** Our validation covers the 168 samples (5.41% of 3,105) with publicly documented exploits. The remaining 94.6% cannot be validated using publicly documented exploits: their CVEs lack the public exploit infrastructure that runtime validation requires. This limitation is inherent to the underlying datasets, not our methodology, and applies to any exploit-based validation protocol.

Another threat is that the validated subset may be unrepresentative. CVEs with publicly documented exploits may differ from those without them, potentially affecting the accuracy of the underlying VCC labels. However, we have no evidence to determine the direction or magnitude of these differences. We therefore cannot determine whether the false-positive rate for the full population would be higher or lower than 79.2%, and we do not extrapolate beyond the validated subset. What carries beyond the subset is the mechanism rather than the magnitude: `FP_PARENT_EXPLOITABLE`, the most common error, arises from backward tracing without testing whether the predecessor was already exploitable, a limitation independent of exploit availability. Therefore, readers should treat 79.2% as a measurement on the 5.41% that can be checked, and as evidence that prior SZZ-based labeling procedure itself is unreliable, not as an estimate across all 3,105 samples. Moreover, our focus on 6 datasets may not represent all VCC datasets; the Java-only inclusion criterion (§ 6.1.1) means our measured rate characterizes Java VCC datasets rather than the field as a whole.

**Construct Validity.** Tier 1 verdicts come from a runtime exploit attempt against the at-hash bytecode, while Tier 2 establishes only pattern presence, not exploitability. Of the 168 commits, 90 (53.6%) received a Tier 2 child verdict because Tier 1 failed, not because it was not attempted, so we report outcomes stratified by tier (Table 5). The 69 Tier-1-pure commits, whose verdicts rest entirely on runtime evidence, exhibit a higher false positive

rate (88.4%) than the corpus as a whole (79.2%), so the combined 79.2% rate is conservative with respect to this threat: the weaker evidence dampens rather than inflates the reported rate. The residual threat therefore runs opposite to the direction usually assumed, namely that Tier 2 may under-count `FP_PARENT_EXPLOITABLE` at refactored parents and thereby overstate the number of true VCCs.

We further define dataset reliability in terms of exploit reproducibility and parent commit validation. This operationalization may not capture all aspects of reliability, such as completeness (whether datasets include all VCCs for covered projects) or representativeness (whether included VCCs reflect real-world distributions). We also evaluate the protocol without a comparison baseline. Our SLR identified no existing operational validation methodology for VCC labels, so no published technique is available to compare against, and the natural alternative, independent manual expert validation on a representative subset, is the procedure the literature itself reports as infeasible at scale (§ 4.3, C2). Establishing agreement between our verdicts and independent expert judgment on a subset is left for future work and the released artifacts are structured to support it. Lastly, our verdicts also rest on the documented Exploit-DB proof-of-concept for each CVE, so a `NOT_EXPLOITABLE` verdict records that this exploit does not fire rather than that no exploit could. A further exploit succeeding at a parent would move that pair from `TRUE_VCC` to `FP_PARENT_EXPLOITABLE` and never the reverse, so `TRUE_VCC` can only *decrease* as exploit coverage improves.

## 9 Conclusion

We presented a two-part study of vulnerability-contributing commits, combining a systematic literature review of 38 papers (2005–2025) with exploit-based validation of 168 VCC samples from 6 datasets identified in our SLR. The review uncovered terminology inconsistencies in the field (8 distinct terms, 3 conflicting definition patterns) alongside five recurring VCC identification challenges. To resolve this ambiguity, we proposed a formal VCC definition grounded in *security state transitions*: a commit is a true VCC if and only if the vulnerability is exploitable after the commit but not in its parent. Thus, our key methodological contribution, *parent commit validation*, operationalizes this definition by testing whether the exploitability transition occurs at the labeled commit. Applied to the 168 commits (5.41% of 3,105) with documented exploits, it revealed a 79.2% false positive rate: in 47.0% of cases the vulnerability was already exploitable in the parent commit, and in 32.1% it was not exploitable at the labeled commit at all.

# Beyond Heuristics? Rethinking Targeted Unit Test Generation in the Era of LLM Agents

**Jiayu Liu**
Institute of Software, Chinese Academy of Sciences, Beijing, China
University of Chinese Academy of Sciences, Beijing, China

**Yanjun Wu**[1]
Institute of Software, Chinese Academy of Sciences, Beijing, China

## Abstract

**Background.** Targeted unit tests, which aim to reveal a bug at a specific location in the program, are useful for various software development tasks, such as static analysis alarm validation, crash reproduction, or patch testing. While automated unit test generation has progressed significantly, existing approaches remain inefficient for targeted tests due to their reliance on manually-crafted heuristics. To address this shortcoming, Large Language Model (LLM) agents emerge as a potent solution that is free from predefined heuristics, owing to their superior reasoning and tool-use capabilities. Moreover, prior studies have shown that LLM agents can achieve comparable performance across several software engineering tasks with only minor adaptations. However, whether this adaptability extends to targeted unit test generation remains unexplored.

**Aims.** This study aims to investigate the capabilities and limitations of LLM agents in targeted unit test generation under minimal custom setup.

**Method.** We evaluate various combinations of frontier agent scaffolds and models on a benchmark featuring 210 real-world Java runtime exception bugs across 66 software projects. Specifically, LLM agents are tasked with generating a unit test suite that reproduce a target bug given only its location and the corresponding codebase.

**Results.** Our evaluation shows that the top-performing combinations achieve a 89.5% success rate in target bug reproduction, surpassing the state-of-the-art unit test generation tools. Nevertheless, we identify recurring failure modes that illustrate current LLM agents' blind spots.

**Conclusions.** These findings underscore the potential of LLM agents in targeted unit test generation, and provide valuable insights for further research in this area.

## 1 Introduction

As software systems grow increasingly complex, rigorous testing has become more critical than ever. To achieve this, unit testing serves as a foundational practice by validating the correctness of individual units of code, such as methods or classes [15]. Within this practice, there is a specialized need for targeted unit tests, which aim to expose bugs at a specific program location (e.g., line) [13]. Such targeted tests provide benefits for various tasks in software development, such as static analysis alarm validation [8, 17], crash

reproduction [14, 36], or patch testing [5, 28]. To alleviate the burdens of developers on writing unit tests, numerous automated tools have been proposed over the years. Among them, heuristic-based tools, such as EvoSuite [11] and Randoop [33], have emerged as the mainstream approach. While effective in checking the overall correctness of the program under test, these tools lack efficiency in exposing bugs at a given program location, as they employ heuristics that aim to achieve high code coverage, wasting resources exploring unrelated locations. To address this, a recent study proposed UnitCon [13], which introduces specific heuristics to prioritize candidate unit tests that are likely to reach the target location. However, its reliance on heuristics limits its effectiveness in complicated scenarios [13].

Due to the limitations of traditional methods, alternative approaches are needed, and Large Language Models (LLMs) emerge as a promising solution. LLMs have exhibited remarkable proficiency in diverse software engineering tasks without the need for costly fine-tuning [10, 24]. Such adaptability equips LLMs with the potential to address the complex targeted unit test generation scenarios that existing tools could hardly handle.

**But are LLMs a silver bullet for targeted unit test generation?** Prior research has primarily explored LLMs for general unit test generation via prompt engineering [42, 46, 7, 39, 1, 31]. By querying LLMs with fixed prompt templates within hard-coded algorithms, prompt engineering serves as a low-cost application technology in several software engineering tasks [31]. However, these explorations show that prompt engineering is far from a low-cost solution in unit test generation due to the inherent limitations of LLMs. One major limitation is the constraint on context length, posing the challenge of providing concise and precise context in prompts. While recent LLMs support longer context windows, this challenge remains due to economic costs and the lost-in-the-middle effect [23]. Another limitation lies in insufficient validation mechanisms, causing LLMs to frequently generate incorrect tests with compilation or runtime errors. As a result, efficiently repairing these errors becomes a critical challenge. Beyond prompt engineering, LLM agents have recently emerged as a promising paradigm for software engineering automation [6]. Operating as autonomous systems, these agents leverage LLMs to iteratively reason through problems, invoke external tools, and dynamically adapt their actions based on tool-generated feedback [37]. This agentic capability eliminates the need for intricate prompt design. Moreover, some researchers have explored LLM agents for some test-generation tasks with only minor adaptations [30], indicating their potential for targeted unit test generation. Despite this, a comprehensive investigation has yet to be conducted. These emerging possibilities and existing constraints, in combination, directly motivate our research.

**Problem.** The fundamental objective of this study is to investigate the potential of LLM agents in targeted unit test generation. Specifically, we focus on examining whether LLM agents can achieve strong effectiveness in this domain with only minor adaptations. To this end, we structure our study around three concrete goals. First, we aim to quantify the effectiveness of LLM agents in targeted unit test generation. Second, we seek to identify the capabilities that allow LLM agents to outperform existing unit test generation tools. Finally, we conduct a detailed failure analysis to reveal the limitations of LLM agents in this context.

**Methodology.** To achieve the above-mentioned goals, we introduce a comprehensive benchmark by incorporating and refining benchmarks used in prior research on unit test generation [42, 46, 19, 13]. Specifically, LLM agents are tasked with generating a unit test suite that reproduce a target bug given only its location and the corresponding codebase. For reliable

evaluation, we focus on Java runtime exception bugs from a wide range of real-world projects, as whether the generated unit tests trigger these bugs can be objectively verified without subjective judgment. Using this benchmark, we evaluate three state-of-the-art agent scaffolds and three frontier LLMs, both of which include commercial and open-source options from leading companies. Furthermore, we guarantee a fair comparison by aligning the settings of LLM agents, such as provided inputs and time budgets, with those used by existing tools in previous research [13, 12].

**Findings.** Our evaluation reveals that the top-performing combination of agent scaffold and model achieves an 89.5% success rate in target bug reproduction, surpassing traditional tools. Notably, even combinations relying purely on open-source settings outperform all existing tools. Compared to existing tools, LLM agents demonstrate three core capabilities. First, they leverage direct code comprehension to synthesize complex structural inputs. Second, they iteratively refine candidate tests via execution feedback. Third, they dynamically choose between public call paths and Java reflection to reach buggy locations in internal APIs. However, the extent of these advantages varies across agent scaffolds and models. Despite their overall success, current LLM agents still exhibit clear limitations. Our failure analysis identifies four failure modes, with Insufficient Exploration (41.5%) and Inadequate Reasoning (25.5%) together accounting for 67% of failures. These results underscore the potential of LLM agents in targeted unit test generation and provide insights into future improvements in agent scaffolds and models.

In summary, we make the following contributions:

- We bridge the gap between state-of-the-art LLM technology and the urgent need for effective targeted unit test generation, systematically measuring LLM agents' capabilities in this domain.
- We refine existing benchmarks for targeted unit test generation and reveal their potential design flaws. We open-source our benchmark for future research.
- We identify gaps in current LLM agents' capabilities for targeted unit test generation, providing valuable insights for future agent design.

# 2 Background

## 2.1 Targeted Unit Test Generation

Unlike general unit test generation that checks overall correctness [15], targeted unit test generation creates tests to trigger bugs at specific code locations [13].

**Tools.** We focus on tools that generate executable unit tests including sequences of method calls. Heuristic-based tools are the mainstream approach among these tools. For instance, Randoop [33] uses feedback-directed random testing and EvoSuite [11] uses genetic algorithms. However, the heuristics in these tools primarily optimize for general code coverage. In contrast, targeted unit test generation requires not only covering the target location, but also constructing the specific program state needed to trigger the bug. UnitCon [13] addresses this by using static analysis to infer bug-triggering conditions, yet its predefined heuristics still fail on complex patterns such as loops or project-specific states [13].

**Benchmarks.** To evaluate targeted test generation capabilities, empirical studies commonly adopt the task of reproducing known bugs, requiring generated tests to reach the target location and trigger the expected failure. Researchers therefore use real-world bug benchmarks

such as Defects4J [16] and BEARS [27], together with datasets from Genesis, NPEX, and VFix [25, 18, 45]. However, applying these benchmarks to our task raises three challenges: *Subjective Oracles.* Some bugs require human judgment to verify. *Outdated Data.* All bug instances in these benchmarks are published before 2022, risking LLM memorization. *Limited Language Diversity.* Most benchmarks focus on Java, precluding cross-language evaluation. Our study also shares this limitation, as we focus on Java for a fair comparison with existing tools. Section 3 describes how we construct a new benchmark to address the first two challenges.

## 2.2 Capabilities of LLM Agents

Due to the limits of heuristics, LLMs offer a promising alternative by reasoning about code semantics and adapting to bug contexts without manual rules [10, 24]. Prior work has explored LLMs for unit test generation primarily through prompt engineering [42, 46, 7, 39, 31, 1, 41], but this approach is costly for targeted generation: developers must manually select relevant files, craft bug descriptions, and design repair loops for invalid tests [23].

LLM agents address these limitations by autonomously exploring the repository, invoking tools such as code execution and file search, and iteratively revising outputs based on execution feedback [6, 37], which automates precisely the manual effort that prompt engineering demands. Recent work shows that such agents achieve strong results on general software testing tasks with only minor adaptation [30], yet no systematic study has evaluated them for targeted unit test generation. This gap directly motivates our work.

## 2.3 Motivation Example

To illustrate the limitations of existing tools, we examine a real NullPointerException bug in Jackson-databind.[2] Listing 1 shows a simplified view of the relevant code.

**Listing 1** Simplified code from Jackson-databind.

```
// Target NPE trigger condition:
// 1. "stackTrace": null appears BEFORE "message" in JSON input
// 2. Class has Throwable constructor
class ThrowableDeserializer extends BeanDeserializer {
  public Object deserializeFromObject(JsonParser p, DeserializationContext ctxt) {
    // Check Throwable constructor
    boolean hasStringCreator = _valueInstantiator.canCreateFromString();
    if (!hasStringCreator &&
        !_valueInstantiator.canCreateUsingDefault()) return ...;
    ...
    Throwable throwable = null; Object[] pending = null;
    for (...; ; ...) {
      if (/* match "stackTrace": null */) {
        if (throwable == null) // "stackTrace" BEFORE "message": Defer
          pending[pendingIx++] = prop; pending[pendingIx++] = null;
      } else if (PROP_NAME_MESSAGE.equalsIgnoreCase(propName)) {
        throwable = _instantiate(ctxt, hasStringCreator, p.getValueAsString());
        if (pending != null) // Replay deferred properties
          for (int i = 0; i < pendingIx; i += 2)
            // Trigger target NPE!
            ((SettableBeanProperty) pending[i]).set(ctxt, throwable, pending[i+1]);
```

[2] https://github.com/FasterXML/jackson-databind/commit/df12d5cc7fab0085532462307bbf682-afac5f5d1.

```
      ...
class MethodProperty extends SettableBeanProperty {
  public final void set(DeserializationContext ctxt, Object obj, Object value) {
    // Calls Throwable.setStackTrace(null) -> NPE
    _setter.get().invokeExact(obj, value);
   ...
```

The bug is order-sensitive, `"stackTrace": null` must appear before `"message"` in the JSON input. In that order, the deserializer stores `stackTrace` in `pending`, creates the `Throwable` when reading `message`, and then replays the pending property through `prop.set`. This call eventually invokes `Throwable.setStackTrace(null)`, which throws the target exception.

**Why heuristics fall short.** The three tools we compare against each fail for a distinct reason rooted in their reliance on predefined heuristics. EvoSuite [11] optimizes for code coverage, which may reach the parsing loop and the `message` branch, but coverage metrics provide no guidance toward the specific value `null` or the required property order. Randoop [33] explores random call sequences over constructors and parser APIs, but the failing state is encoded in a specific JSON string, a semantic constraint that random sequence generation cannot infer. UnitCon [13] derives heuristics from inferred crash conditions, yet the triggering condition here spans two classes (`ThrowableDeserializer` and `MethodProperty`) and depends on property ordering, making heuristic synthesis brittle.

**The Advantage of LLM Agents.** First, an LLM agent leverages its tool-use capabilities to inspect both classes. Then, it applies its code reasoning capabilities to infer the underlying pending-property mechanism directly from the source code and synthesize valid JSON inputs such as `{"stackTrace":null,"message":"test"}`. Finally, it utilizes its iterative refinement capabilities to continuously improve the generated test using execution feedback. This example concretely illustrates our primary motivation, showing how these combined capabilities of LLM agents effectively address scenarios where heuristic-based tools fail.

# 3 Study Design

This section presents the design of our empirical study. The rest of this section describes the studied agents and models, the compared tools, the benchmark construction process, and the evaluation framework.

## 3.1 Studied Agents and Models

We select the evaluated agent scaffolds and underlying foundation models based on three key principles. First, we prioritize general-purpose software engineering agents over task-specific prototypes to test whether modern agentic systems can handle targeted test generation under minimal adaptation. By minimal adaptation, we mean that each agent receives only the path to the buggy codebase and a raw description of the target bug location in its task prompt, without relying on prompt engineering to introduce manually extracted context, pre-selected relevant files, or repair guidance for invalid tests [42, 46, 31, 6, 37]. Second, we select leading proprietary and open-source options for both scaffolds and models to capture practical trade-offs regarding raw reasoning capabilities, deployment costs, and data privacy. Third, we restrict our selection to models with pre-training knowledge cutoffs prior to October 2025, which enables us to collect a sufficient set of post-cutoff benchmark instances to systematically evaluate potential data contamination risks.

For agent scaffolds, we evaluate Claude Code [3], OpenHands [43], and OpenCode [2]. Claude Code is a proprietary, production-grade coding agent optimized for autonomous, multi-turn repository navigation. OpenHands provides an open-source platform for AI-driven development with multi-agent orchestration capabilities. OpenCode is a lightweight open-source agent focusing on flexible provider integration and transparent action execution. Together, these scaffolds span proprietary production systems and customizable open-source frameworks, covering distinct execution paradigms for general-purpose code repository interaction.

For foundation models, we select GPT-5 [32], Claude-4.5-Sonnet [4], and DeepSeek-V3.2 [9]. GPT-5 and Claude-4.5-Sonnet represent frontier proprietary models with state-of-the-art long-context reasoning and complex tool-use efficiency. DeepSeek-V3.2 represents a leading open-source model that offers competitive coding performance at substantially lower deployment costs [10, 24].

Each scaffold is paired with each model, yielding nine combinations. Across all combinations, we keep the buggy codebase, task specification, execution environment, and time budget fixed. This factorial design helps isolate the contribution of scaffold and model choices.

## 3.2 Compared Tools

We select UnitCon [13], EvoSuite [11], and Randoop [33] as baseline tools. Our selection criteria require baselines to be robust, well-established Java unit test generators that cover both targeted and general-purpose strategies, allowing us to accurately determine whether LLM agents advance state-of-the-art tools. UnitCon serves as our primary and most directly relevant baseline, as it represents the latest specialized technique designed specifically for synthesizing targeted unit tests for Java runtime exceptions. EvoSuite is the most widely used search-based Java unit test generator, and prior work shows it serves as a strong general-purpose baseline when adapted for targeted unit test generation [13]. Randoop complements EvoSuite with a different strategy, namely feedback-directed random generation. Together, these three tools encapsulate the predominant non-agent paradigms for Java test generation, spanning specialized heuristic guidance for target location, search-based optimization, and random test exploration.

## 3.3 Benchmark Construction

To address the key challenges of existing benchmarks identified in Section 2.1, we construct our benchmark by incorporating and refining existing benchmarks.

**Benchmark Incorporating.** To tackle the *Subjective Oracles* challenge, we incorporate Java runtime exception bugs from existing benchmarks, as exception triggering provides an execution-based oracle that can be objectively verified via execution stack traces. Specifically, we first collect candidate bugs from widely used Java bug benchmarks [16, 25, 27, 18, 45, 13], such as Defects4J [16] and BEARS [27]. Then, we identify duplicate instances targeting the same location, and randomly retain a single instance. Furthermore, two authors collaboratively construct containerized execution environments for the buggy codebase of each instance, and filter out any instance whose execution environment fails to build within a 15-minute threshold. This phase yielded a initial benchmark of 169 bugs across 66 software projects, including popular libraries such as Apache Commons IO and Log4j2.

**Benchmark Refining.** To address the *Outdated Data* challenge and mitigate potential data contamination, we refine the initial benchmark by collecting bugs disclosed after the pre-training knowledge cutoffs of all studied models. Following the data collection methodology

established in prior work [16], we gather runtime exception bugs disclosed between October 2025 and May 2026 from the 66 projects covered by initial benchmark. This refinement phase added 41 newly disclosed bugs to our benchmark.

In total, our benchmark contains 210 bugs from 66 projects. Table 1 summarizes the exception categories. `NullPointerException` is the largest category, which reflects the real-world distribution of Java runtime failures rather than a deliberate design choice. The remaining bugs span a broad range of failure modes, including array accesses, illegal states, parsing failures, and user-defined exceptions.

**Table 1** The runtime exception categories covered by our benchmark.

| Type | Total | Type | Total |
|---|---|---|---|
| ArrayIndexOutOfBoundsException | 9 | NumberFormatException | 3 |
| ArrayStoreException | 3 | OutOfMemoryError | 3 |
| ClassCastException | 6 | RuntimeException | 4 |
| IllegalArgumentException | 13 | StackOverflowError | 3 |
| IllegalStateException | 6 | StringIndexOutOfBoundsException | 8 |
| IndexOutOfBoundsException | 2 | UnsupportedOperationException | 3 |
| NullPointerException | 126 | Others (user-defined exceptions) | 21 |

## 3.4 Evaluation Framework

Figure 1 summarizes our evaluation pipeline. For each benchmark instance, an LLM agent or a compared tool receives a buggy codebase along with the target exception type and line-level location information, and output a JUnit test suite. The generated suite is then executed inside a Docker container containing a runnable environment for the buggy codebase and all required dependencies. A task instance is marked as successful if and only if execution triggers the target exception at the specified target line. Following prior studies [19, 13], this execution-based criterion serves as an objective oracle, eliminating the need for subjective human judgment.

**Task Input and Output.** We formalize each task instance as a tuple $\langle P, e, l \rangle$, where $P$ is a buggy program version, $e$ is the target exception type, and $l$ is the target line-level code location. The desired output is a JUnit test suite $T$ such that executing $T$ against $P$ triggers exception $e$ at location $l$. This formulation focuses on bug reproduction rather than broad coverage or assertion generation.

For the compared tools, we adhere to the input formats used in their original studies, as redesigning their interfaces strengthens construct validity. UnitCon receives the buggy program alongside the target exception information expected by its implementation [13]. Tools like EvoSuite and Randoop, which are not intrinsically designed for line-level targeted unit test generation, receive the class containing the target line, following the same adaptation used in prior work [13].

For LLM agents, we convert the target information into a concise task prompt (as illustrated in Figure 1) specifying the buggy codebase path, target exception type, target line, and instructions to generate a reproducing JUnit test suite without altering the codebase. Agents are given access to codebase files and a controlled execution interface to inspect code, run candidate tests, and iteratively revise based on feedback.

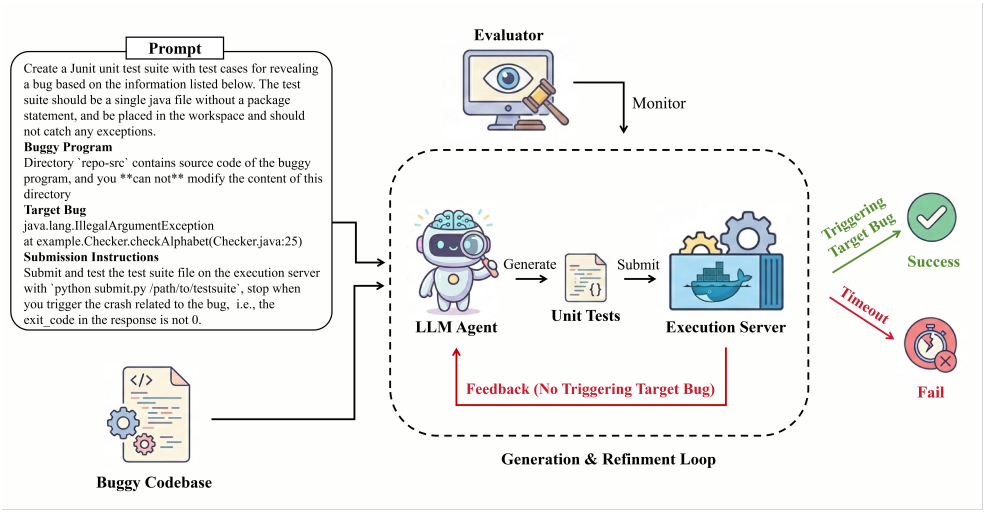

**Figure 1** Overview of the evaluation framework. The sample task prompt given to LLM agents is shown in the figure.

**Evaluation Metrics.** Our primary metric is the bug reproduction success rate, defined as the percentage of benchmark instances where a generated test suite successfully reproduces the target failure. Specifically, a task instance is marked as successful if and only if executing the test suite triggers an exception that matches the target exception type and contains the target location at the top of its execution stack trace. Additionally, we record completion time and monetary cost for agent-based approaches to evaluate economic efficiency.

**Experimental Design Decisions.** All approaches are evaluated in the same Dockerized environment with preinstalled dependencies and a unified compilation script. For LLM agents, we set the temperature to 0 and disable extended reasoning modes by default to ensure deterministic behavior and control API costs. We intentionally adopt a single, minimal prompt template across all agents, as our goal is to evaluate their intrinsic capability to adapt to targeted unit test generation under minimal custom setup, rather than measuring gains from complex prompt engineering. We apply two per-instance resource limits: a 15-minute time budget, following prior time-based test generation evaluations [12], and a $2.00 monetary cap. Compared tools use recommended settings from prior work [13] with the same 15-minute time budget. All experiments were conducted on Linux machines with 512GB RAM and Intel Xeon 2.90GHz processors, repeated five times, and reported as averaged results. Moreover, we discuss whether alternative design decisions could significantly affect our overall conclusions in Section 5.

## 4 Experiment and Results

We structure our evaluation around three research questions.

- **RQ1: How effectively do LLM agents perform in targeted unit test generation?** This question establishes a baseline understanding of what current agents can achieve on this task. We measure success rate, completion time, and monetary cost across all nine scaffold-model combinations, and examine whether open-source models can reach performance levels comparable to proprietary ones.

- **RQ2: How do LLM agents compare to state-of-the-art tools?** Beyond raw success rates, we want to understand *why* agents outperform traditional tools on certain bugs. We compare agents against UnitCon, EvoSuite, and Randoop, and analyze the agent behaviors that explain the performance gap.
- **RQ3: What are the common failure modes of LLM agents in targeted unit test generation?** Even the best-performing agents fail on a non-trivial fraction of cases. Understanding the root causes of these failures is essential for guiding future agent design and identifying where current LLM capabilities fall short.

## 4.1 RQ1: Effectiveness of LLM Agents

To answer RQ1, we evaluate how well state-of-the-art LLM agents perform on targeted unit test generation, assess the associated costs and efficiency, and determine whether open-source alternatives can achieve comparable performance. We evaluate nine combinations of three agent scaffolds (Claude Code, OpenHands, OpenCode) and three models (Claude-4.5-Sonnet, GPT-5, DeepSeek-V3.2) on our benchmark. The overall performance is summarized in Table 2.

**Table 2** Overall performance of LLM agents on targeted unit test generation across different agent scaffolds and models.

| Agent Scaffold | Model | Success Rate (%) | Avg. Time (s) | Avg. Cost ($) |
|---|---|---|---|---|
| Claude Code | Claude-4.5-Sonnet | 83.8 | 263.6 | 1.35 |
| | GPT-5 | 89.5 | 325.8 | 1.09 |
| | DeepSeek-V3.2 | 67.1 | 794.2 | 0.05 |
| OpenHands | Claude-4.5-Sonnet | 81.4 | 230.4 | 1.26 |
| | GPT-5 | 87.6 | 315.8 | 0.98 |
| | DeepSeek-V3.2 | 63.8 | 788.3 | 0.05 |
| OpenCode | Claude-4.5-Sonnet | 82.9 | 279.3 | 1.17 |
| | GPT-5 | 87.1 | 312.5 | 0.93 |
| | DeepSeek-V3.2 | 65.2 | 774.1 | 0.04 |

**Main Results.** As shown in Table 2, The best-performing combination, Claude Code paired with GPT-5, achieves an 89.5% success rate with an average cost of $1.09 per instance. All combinations using proprietary models demonstrate strong effectiveness, consistently exceeding an 81% success rate.

To assess result stability across runs, we repeated each experiment five times. The success rates across runs show no significant variation, with the highest p-value across all nine combinations reaching 0.43 via Fisher's exact test.

> **Finding 1.** Modern LLM agents are highly effective for targeted unit test generation, achieving up to an 89.5% success rate (Claude Code + GPT-5) with high stability across execution runs.

**Agent Scaffold Analysis.** As shown in Table 2, while agent scaffolds differ in capabilities, scaffold choice alone does not yield substantial variance in test generation success rates compared to model capabilities. To uncover the underlying behavioral drivers, we randomly sampled 30 bug instances and manually analyzed the execution trajectories of all nine scaffold-model combinations on each bug. We observed that key behavioral differences primarily

stem from tool invocation strategies, such as distinct mechanisms for file traversal. Moreover, Claude Code employs a multi-agent architecture where a dedicated subagent handles code exploration while the primary agent constructs tests. Although this separation leads to a marked increase in execution cost, it translates into only slight success rate improvements over OpenHands and OpenCode. Fundamentally, test generation across all scaffolds follows a shared behavioral loop: including reading source code to infer exception-triggering conditions, drafting targeted tests, and revising based on execution feedback.

**Finding 2.** Behavioral variations among agent scaffolds, such as distinct tool invocation, do not significantly affect targeted unit test generation success rates. The overall performance is predominantly driven by the capabilities of the underlying models.

**Model Analysis.** Proprietary models significantly outperform the open-source alternative in success rate, whereas the open-source model provides substantial cost advantages. GPT-5 achieves the highest success rate across all scaffolds, outperforming Claude-4.5-Sonnet by 5.7 to 6.2 percentage points. DeepSeek-V3.2 lags behind proprietary models by 16.0 to 24.4 percentage points, yet reduces cost per instance to \$0.04 to \$0.05 compared to \$0.93 to \$1.35 for closed-source models. This performance gap likely stems from limitations in reasoning speed and tool-use efficiency. For instance, when paired with OpenCode, successful test generations using DeepSeek-V3.2 require 774.1 seconds on average, indicating that a large portion of the 15-minute budget may be consumed by reasoning rather than test iteration. A more comprehensive qualitative analysis of model behaviors and failure modes is presented in subsequent sections.

**Finding 3.** Proprietary models demonstrate substantial advantages over open-source models in both success rate and time efficiency, whereas open-source models achieve drastically lower monetary costs.

**Data Contamination Analysis.** Since our studied LLMs are pre-trained on large-scale internet datasets that may include bug instances in our benchmark, we investigate the potential effect of data contamination. To ensure representative coverage, we stratified and randomly sampled 30 pre-cutoff bugs (disclosed before 2022) and 30 post-cutoff bugs (disclosed between October 2025 and May 2026) across exception categories, project domains, and code complexity levels. We evaluated all nine scaffold-model combinations on both subsets and computed the p-values using Fisher's exact test and a Z-test for proportional differences. Across all combinations, the p-values exceed 0.05, indicating no statistically significant difference in success rates between pre- and post-cutoff splits. Due to space constraints, we present the analysis results for OpenCode with all studied models in Table 3.

**Table 3** Success rates and statistical test results for data contamination analysis.

| Model | Pre-cutoff (%) | Post-cutoff (%) | Fisher p-value | Z-test p-value |
|---|---|---|---|---|
| Claude-4.5-Sonnet | 83.3 | 80.0 | 0.74 | 0.74 |
| GPT-5 | 86.7 | 83.3 | 0.71 | 0.72 |
| DeepSeek-V3.2 | 63.3 | 66.7 | 0.77 | 0.79 |

**Finding 4.** There is no statistically significant performance difference between pre-cutoff and post-cutoff bugs for any model. This suggests that the agents' performance reflects genuine reasoning and generalization rather than memorization of training data.

## 4.2 RQ2: Comparison against SOTA Tools

We compare LLM agents with SOTA tools, including UnitCon, EvoSuite, and Randoop, on our benchmark, and examine the scenarios where agents outperform traditional tools. We evaluate the best-performing agent configurations against baselines and manually analyze agent-generated test trajectories to identify the capabilities that explain the performance gap.

**Comparison of Generation Results.** We compare success rates across SOTA tools. Our experiments show that UnitCon achieves a 49.6% success rate, EvoSuite achieves 39.4%, and Randoop achieves 21.3%, consistent with the capability differences among these three tools observed in prior work [13].

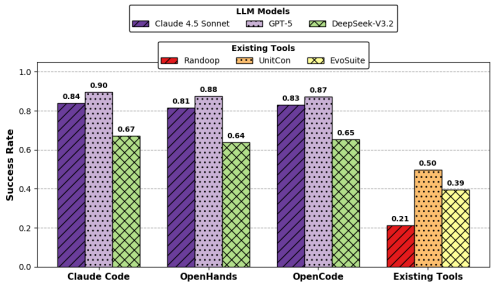

**Figure 2** Generation Success Rate Comparison.

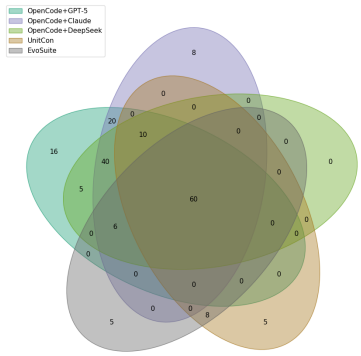

**Figure 3** Venn Plots of Overlapping and Unique Successful Cases.

Figure 2 illustrates the success rate comparison between LLM agents and SOTA tools. The top-performing configuration (Claude Code + GPT-5) achieves an 89.5% success rate, surpassing UnitCon, EvoSuite, and Randoop by 39.9%, 50.1%, and 68.2% in absolute success rate, respectively. Even the lowest-performing open-source configuration (OpenHands + DeepSeek-V3.2, 63.8%) outperforms all SOTA tools by a significant margin.

To evaluate the uniqueness and overlap of successful bug reproductions between LLM agents and SOTA tools, we analyzed the unique successful cases across all scaffold configurations. Since we observed no statistically significant differences in the proportion of unique bugs identified by different agent scaffolds, Figure 3 presents the Venn diagrams for the representative OpenCode scaffold paired with the three studied models alongside SOTA tools. Under this representative setup, 41.8% of the agent's successful cases are unique, whereas only 4.8% of UnitCon successes and 6.0% of EvoSuite successes are not covered by the LLM agent. Qualitative inspection of the small subset where traditional tools succeed but the agent fails reveals a consistent pattern: these cases typically feature shallow execution paths where heuristic-based exploration rapidly hits the target state, whereas the LLM agent occasionally consumes its execution budget on over-analyzing deep call sequences. These

findings demonstrate that while LLM agents substantially expand coverage over complex, semantics-heavy bug scenarios, traditional heuristic-based techniques remain complementary for simple, shallow exploration targets.

> **Finding 5.** LLM agents outperform the most effective SOTA tool UnitCon by a large margin, with an 89.5% versus 49.6% success rate. Agents cover a substantially broader range of bug scenarios, with 41.8% of their successes unreachable by any SOTA tool.

**LLM Agents' Advanced Abilities.** To understand why agents outperform SOTA tools, we randomly sampled 70 successful bug reproduction instances for each model paired with the OpenCode scaffold, yielding 210 analyzed cases in total, and manually inspected their execution trajectories alongside baseline tool logs. This analysis reveals three key capabilities driving the performance gap.

**Advanced Ability 1 – Direct Code Comprehension.** Agents inspect source context around the target location to infer necessary conditions. Moreover, agents integrated with closed source models frequently search the repository for existing test cases that could reach the target location, using these tests as references to accelerate generation. This ability is critical when reproducing bugs that require precise input formats. For example, triggering a target bug requires a JSON string with a specific structural layout. Coverage-guided tools like EvoSuite and Randoop struggle to synthesize structurally valid payload semantics because their reliance on random string generation makes generating such complex formats highly improbable. UnitCon also fails to handle these inputs because its predefined static rules do not cover complex JSON parameter synthesis.

**Advanced Ability 2 – Adaptive Execution-Guided Refinement.** When a generated unit test suite fails to trigger the target exception, agents analyze the execution output to diagnose root causes and iterate. Across successful cases, agents perform at least one refinement round in 74.8% of instances. In contrast, tools like EvoSuite and Randoop adjust generation based on code coverage metrics. If a candidate unit test suite covers the target line without triggering the target exception, these tools pivot to explore uncovered code locations rather than triggering the target exception at the covered target line. Meanwhile, UnitCon employs a static generation pipeline with no execution feedback mechanism.

**Advanced Ability 3 – Flexible Access to Internal APIs.** Many bugs reside in code locations that are not directly accessible via public interfaces, such as private fields, package-private constructors, or protected methods. To reach these target locations, tools like EvoSuite and Randoop apply Java reflection using fixed heuristic rules, whereas UnitCon performs static call graph analysis to discover execution paths starting from public methods. LLM agents demonstrate superior flexibility by adaptively choosing between public interface calls and Java reflection. For example, when agents cannot retrieve any viable test cases or public entry chains in the repository that reach the target location, they dynamically fall back to synthesizing candidate tests via Java reflection. Building upon direct code comprehension and execution-guided refinement, agents produce higher quality reflection logic than the heuristic techniques in EvoSuite or Randoop, thereby achieving a higher success rate in triggering target exceptions.

**Finding 6.** LLM agents demonstrate three core capabilities that SOTA tools lack, namely direct code comprehension for complex structural input synthesis, adaptive refinement driven by execution feedback, and dynamic choice between public call paths and Java reflection. These capabilities explain why agents achieve a clear competitive advantage over heuristic-based SOTA tools.

## 4.3 RQ3: Failure Modes of LLM Agents

To understand the common failure modes of LLM agents in targeted unit test generation, we conduct a root-cause analysis on 200 randomly sampled execution trajectories that fail to generate unit test suites for target bugs across all nine scaffold-model combinations. Two authors independently categorized these failures, achieving an initial agreement rate of 81.5% with a Cohen's kappa of 0.76 that indicates substantial agreement [42]. Disagreements were resolved through qualitative discussion. Through this analysis, we identify four core failure modes.

**Failure Mode 1: Insufficient Exploration.** Accounting for 41.5% of failures, the agent correctly identifies the target location but fails to sufficiently explore the necessary program space, such as repository contexts, input spaces, or runtime execution states, within the allotted time budget. Two representative manifestations illustrate this issue. First, regarding codebase context exploration, open-source models like DeepSeek-V3.2 frequently attempt to parse global directory structures and build configurations to comprehend project context. On large codebases, this exhaustive traversal exhausts the time budget before test synthesis begins. Conversely, frontier closed-source models such as GPT-5 and Claude-4.5-Sonnet extract targeted keywords directly from the target location to perform localized file retrieval, drastically reducing context exploration overhead. Second, regarding test input space exploration, traditional heuristic-based tools like EvoSuite execute thousands of candidate inputs per second, whereas LLM agents can only evaluate a sparse set of inputs under strict time constraints. Although this execution bottleneck can easily lead to insufficient input exploration, stronger code reasoning capabilities can compensate for limited sample volumes. In successful cases, we observe that GPT-5 and Claude-4.5-Sonnet explore significantly fewer test inputs than DeepSeek-V3.2 before triggering the target exception.

**Failure Mode 2: Inadequate Reasoning.** Accounting for 25.5% of failures, the agent establishes an operational test execution environment but fails due to flawed logical deductions regarding program logic, implicit repository context, or runtime system states. Two representative manifestations illustrate this reasoning boundary. First, regarding implicit repository context inference, while target projects exist across multiple versions, our task prompts omit specific version indicators for the buggy codebase. Consequently, agents frequently synthesize method calls corresponding to wrong project versions without first inspecting local buggy codebase specifications. Although execution-guided refinement helps agents correct these failures, initial version misjudgments consume valuable time budgets. Furthermore, frontier closed-source models like GPT-5 mitigate this issue by proactively searching existing test cases in the codebase to confirm correct method signatures prior to generation. Second, regarding deep execution logic and data flow reasoning, agents struggle to trace intricate multi-step dependencies across complex call hierarchies. A representative failure occurs when a bug requires tracing subtle state mutations across multiple classes, such as a case where a key hash code changes between map insertion and subsequent lookup, causing a metadata retrieval to return null.

**Failure Mode 3: Tool Misuse.** Accounting for 14.0% of failures, the agent struggles to correctly interface with external toolsets, encompassing both scaffold-provided tools and system-level execution harnesses. This issue manifests in two primary aspects. On the one hand, agents experience difficulty utilizing scaffold-level tools. Even when agent scaffolds furnish a rich suite of tools, models may struggle to select and use them effectively. For instance, DeepSeek-V3.2 frequently exhausts its entire time budget attempting to locate tools that can help traverse the file structure of the buggy codebase, yet fails to find and invoke them successfully. On the other hand, agents face friction with execution environment harnesses. A representative case is the failure to generate test suites that conform to JUnit specifications. While both open-source models like DeepSeek-V3.2 and proprietary models like GPT-5 and Claude-4.5-Sonnet make initial mistakes regarding harness rules, their self-correction efficiency varies markedly. Closed-source models efficiently leverage execution-guided refinement to correct framework violations within one or two iteration loops, whereas open-source models tend to exhaust their iteration budget on repetitive, superficial syntax modifications without constructing a functional test suite.

**Failure Mode 4: Incorrect Focus.** Accounting for 11.5% of failures, the agent understands the high-level task objective but strays into irrelevant investigation pathways. This behavior manifests in two primary aspects. On the one hand, agents exhibit attention drift by focusing on unrelated exceptions or files. Although agents typically recognize this mistake and attempt self-correction, the time budget consumed during these misdirected investigations prevents them from successfully completing the task. On the other hand, agents exhibit goal confusion where they attempt to patch or fix the target bug instead of generating a unit test suite to reproduce it, which is likely an artifact of pre-training data containing abundant bug-fixing tasks. Crucially, we observe that this tendency to mistake the objective for bug fixing appears randomly across both closed-source models such as GPT-5 and open-source models such as DeepSeek-V3.2. Even though our experiments set the temperature to 0, a configuration commonly expected to ensure relatively consistent trajectories, this random focus drift still persists. We suggest that running the generation task over multiple independent iterations serves as a practical strategy to mitigate the impact of such incorrect focus.

**Finding 7.** Agentic unit test generation is primarily constrained by *Insufficient Exploration* (41.5%) and *Inadequate Reasoning* (25.5%). Proprietary and open-source models exhibit distinct behavioral patterns and self-correction efficiencies across failure modes, highlighting the need for tailored enhancement strategies.

# 5 Discussion

## 5.1 Implications for Research and Practice

**Impact of Experimental Configuration Decisions.** To address whether variations in our experimental design choices could significantly affect our primary conclusions, we analyze the potential impacts of different prompting strategies, reasoning modes, and resource budgets. Incorporating targeted examples into the task prompt could potentially improve performance. For instance, advanced models such as GPT-5 might search the codebase for existing test cases reaching the target location to accelerate test synthesis. However, we intentionally adopt a minimal zero-shot prompt design to evaluate the foundational capabilities of modern agents under minimal adaptation. Extended reasoning modes like test-time compute scaling allow agents to perform deeper chain-of-thought analysis before tool invocation. While

this may help resolve complex multi-class data flow dependencies, it significantly increases per-step latency and monetary cost, which can cause agents to exhaust their budget in time-bounded execution setups. To quantify the effect of time budgets, we conduct an empirical analysis on 30 randomly sampled benchmark instances using OpenCode across the three studied models. Tightening the budget from 15 to 10 minutes decreases the success rates of two closed-source models by approximately 7 percentage points, whereas the open-source DeepSeek-V3.2 experiences a relative success rate drop of over 50% due to inference latency. Relaxing the budget to 20 minutes yields no significant success rate improvement for closed-source models but boosts DeepSeek-V3.2 by about 12 percentage points, and the success rates for all models plateau at 25 minutes. Thus, while resource limits affect open-source models to a larger extent, our 15-minute budget choice does not significantly alter our core conclusions.

**Quality of Generated Tests.** To investigate the quality of agent-generated tests, we randomly sampled 30 successful bug reproduction instances for each model paired with the OpenCode scaffold, yielding 90 analyzed cases in total, and manually inspected the generated tests alongside tests written by project developers. First, regarding bug reproduction validity, our execution oracle checks not only whether target exceptions are thrown but also verifies whether target locations appear precisely at the top of the stack trace, a mechanism that manual analysis confirms completely eliminates accidental paths. Furthermore, only a small minority of cases, specifically 5.6%, exhibit degenerate paths where exceptions are forced via artificial inputs like passing raw `null`s to internal methods, confirming that most generated tests faithfully exercise intended failure scenarios. Second, regarding maintainability, generated tests show structural fragility compared to developer tests. Around 16.7% of agent-generated tests bypass public entry workflows to manipulate private APIs or internal singletons directly, producing overly coupled code vulnerable to internal refactorings. Third, regarding readability, generated tests suffer from low semantic clarity. Over 72.2% of generated tests employ generic method and variable names, such as `testBug` or `boom`, along with cryptic hardcoded parameters like complex JSON strings. This lack of explanatory comments obscures the underlying domain semantics. In contrast, developer-written tests convey clear functional intent through descriptive naming, inline annotations, and structured setup.

**Generalizability to Other Bug Categories and Languages.** While our empirical evaluation focuses on Java runtime exceptions, the core underlying capabilities of LLM agents, such as direct semantic reasoning, iterative execution feedback, and dynamic state manipulation, operate independently of specific bug categories. For assertion failures and logical faults, agents could leverage semantic context from specifications to infer preconditions and synthesize bug-triggering inputs. Conversely, non-deterministic bug categories, such as concurrency races, exhibit structural characteristics distinct from our experimental observations, as reproducing them demands precise temporal control that intersects with observed reasoning limits, necessitating further empirical investigation. Regarding cross-language applicability, the agent capabilities driving performance gains, specifically direct semantic comprehension and execution-guided refinement, are language-agnostic. In dynamically typed languages such as Python or JavaScript, where strict type constraints are absent and traditional heuristic-based methods struggle to infer implicit object structures, the semantic reasoning and dynamic runtime feedback of LLM agents remain equally effective.

**Scaffold and Model Selection in Practice.** Determining the best scaffold and model combination depends on prioritizing target trigger success while considering time and cost trade-offs. Under bug reproduction efficacy as the primary standard, Claude Code consistently emerges as the top-performing scaffold, reaching peak effectiveness when paired with GPT-5. Beyond maximum performance, different deployment settings dictate distinct optimal choices. Claude Code with GPT-5 is ideal for high-precision scenarios demanding maximum effectiveness. OpenHands with GPT-5 strikes a strong balance between high success and lower resource overhead, delivering an 87.6% success rate at 0.98 dollars per instance. Finally, OpenCode with DeepSeek-V3.2 offers the best open-source solution for local or budget-limited deployments, achieving 65.2% success at 0.04 dollars per instance while surpassing all traditional baselines.

## 5.2 Threats to Validity

We systematically analyze threats to validity following established empirical software engineering guidelines [42, 46].

**Internal validity.** Internal validity concerns experimental factors that may introduce systematic bias into observed results. Two threats apply here. First, data contamination may inflate bug reproduction performance if models memorized benchmark instances during pre-training. To mitigate this threat, we incorporated 41 bugs disclosed after all models' knowledge cutoffs, and statistical hypothesis testing confirms no significant performance difference between pre-cutoff and post-cutoff subsets. Second, qualitative failure mode analysis carries potential analyst subjectivity, which could misclassify failure causes. To address this risk, two authors independently categorized sampled failure trajectories using standardized operational guidelines and resolved discrepancies through joint discussion to ensure high annotation consistency.

**External validity.** External validity addresses the generalizability of our empirical conclusions to broader software engineering contexts. Our evaluation dataset focuses exclusively on Java runtime exception bugs from open-source projects. This scope restriction means our quantitative findings may not directly extrapolate to different programming paradigms, bug categories, or complex industrial codebases, such as dynamic languages like Python or non-deterministic concurrency bugs. To address this limitation, our benchmark incorporates diverse software repositories spanning a broad spectrum of runtime exception categories to maximize the diversity of benchmark instances. Moreover, we explicitly analyze the theoretical generalizability of our core findings to other programming languages and bug categories in Section 5.

**Construct validity.** Construct validity concerns whether our operational measurements accurately reflect the true capabilities of agents and baseline tools. Two threats apply here. First, execution oracles may suffer from false positives if a test triggers the target exception at the specified location through an accidental or degenerate path rather than reproducing the genuine failure scenario. To mitigate this threat, our evaluator requires matching both the thrown exception type and stack trace details, and our manual inspection confirms that this mechanism effectively prevents false positive triggering. Second, tool configurations and resource budgets may introduce measurement bias. For instance, search-based baselines like EvoSuite feature extensive configurable parameters, while agents operate under fixed limits like a 15-minute time budget and a zero-temperature setting. To minimize bias, we adopt standard baseline configurations recommended by prior work [13], and our analysis shows that our resource limits provide a stable evaluation platform without altering overall trends.

## 6 Related Work

**Automatic unit test generation.** Automated unit test generation has been studied for decades. Early work established the main technical directions, including symbolic and concolic execution to derive path conditions [44, 40], feedback-directed random testing [33], and search-based generation with genetic algorithms [11]. Subsequent work refines these approaches through better search objectives, seed construction, and analysis-guided exploration [34, 21, 35, 26, 29, 20]. These tools are effective for checking overall program correctness, but their heuristics optimize for code coverage rather than for reaching a specific buggy location, which limits their usefulness for targeted unit tests. UnitCon [13] is the most directly relevant prior work, targeting Java runtime exceptions by leveraging heuristic-based static analysis to infer crash conditions and prioritize candidate tests toward the target location. Our study investigates whether LLM agents can address the cases where such predefined heuristics fall short, using SOTA tools including UnitCon, EvoSuite [11] and Randoop [33] as baselines for comparison.

**LLMs for unit test generation.** Prior research on LLM-based test generation focuses either on model fine-tuning [41] or on prompt engineering techniques such as context selection, execution feedback loops, and intent-guided prompts [42, 46, 7, 39, 38, 31, 22, 1]. While effective for general test generation, these techniques struggled with targeted bug reproduction. Reaching a specified buggy location requires navigating large codebases, constructing complex target states, and repairing failed tests dynamically, tasks that prompt engineering handles poorly due to limited long-context capabilities [23]. Our work addresses this limitation by investigating LLM agents that integrate iterative tool use with dynamic reasoning to handle targeted unit test generation.

**LLM agents for software engineering.** Recent work demonstrates the broader applicability of LLMs to tasks such as code analysis and vulnerability management without domain-specific training [10, 24]. The paradigm shift toward agentic systems, where models iteratively reason, execute tools, and process environment feedback, represents a major advance for software engineering automation [6, 37]. Early evidence indicates that general-purpose agents perform competitively on testing tasks with minimal adaptation [30]. Our work contributes a controlled empirical evaluation of agent capabilities on a prevalent practical task unaddressed by prior work, specifically targeted unit test generation for Java runtime exceptions.

## 7 Conclusion

We present the first empirical evaluation of LLM agents for targeted unit test generation. Using a benchmark of real-world Java runtime exception bugs, our study systematically measures the realistic applicability of LLM agents across diverse agent scaffolds and foundation models. The results demonstrate that LLM agents significantly outperform state-of-the-art traditional tools, driven by capabilities in direct code comprehension, execution-guided refinement, and flexible access to internal APIs. Moreover, we identify four common failure modes of LLM agents during test generation and discuss the implications of our findings for future research and practice in agent scaffolds and models.

## Data Availability Statement

To facilitate future research, we have open-sourced the experimental dataset and evaluation scripts. These artifacts are publicly available on Zenodo at `https://zenodo.org/records/20283766` (DOI: `10.5281/zenodo.20283766`). The repository includes the benchmark of 210 real-world Java bugs from 66 projects, the containerized execution environment setup, and detailed instructions for reproducing our experiments.

# Why Do LLMs Fail at OCL Generation? A Graph Reasoning Perspective

**Hamza Attarwala**
Polytechnique Montréal, Montréal, QC, Canada

**Moataz Chouchen**
Concordia University, Montréal, Canada

**Mohammad Hamdaqa**
Polytechnique Montréal, Montréal, QC, Canada

**Omar Alam**
Trent University, Peterborough, ON, Canada

## Abstract

**Background.** Large Language Models (LLMs) are increasingly used to generate Object Constraint Language (OCL) constraints from natural language specifications and UML class diagrams. However, existing work mainly focuses on improving accuracy, with limited understanding of why these models fail.

**Aims.** This study investigates factors associated with LLM failures in OCL generation by examining the task from a graph-reasoning perspective.

**Method.** We conduct an empirical evaluation using the PathOCL dataset across six LLMs. We analyze the relationship between OCL correctness and UML structural properties (e.g., navigation depth and model complexity), lexical similarity, prompt ordering strategies, and graph-aware prompting.

**Results.** We find that, within the evaluated dataset and models, OCL generation correctness is negatively associated with navigation depth and structural complexity. Lexical similarity provides limited explanatory power, while textual ordering is associated with differences in performance. Graph-based prompting yields partial improvements but does not eliminate errors involving structural navigation.

**Conclusions.** The findings are consistent with structural demands being an important contributor to OCL generation difficulty, while not establishing graph reasoning as the sole or primary cause of failure.

## 1 Introduction

Large Language Models (LLMs) are increasingly used to automate software engineering tasks that translate natural language (NL) specifications into formal representations. One important task is the generation of Object Constraint Language (OCL) expressions from NL specifications and UML class diagrams [25, 1, 6, 8]. Accurate OCL generation could

© Hamza Attarwala, Moataz Chouchen, Mohammad Hamdaqa, and Omar Alam;
licensed under Creative Commons License CC-BY 4.0

reduce manual effort in model-driven engineering and improve specification consistency [9, 7]. However, recent studies show that LLMs frequently generate erroneous OCL constraints even when advanced prompting and fine-tuning techniques are used [1, 28, 21].

Prior work has mainly focused on improving OCL generation through prompt engineering, fine-tuning, and dataset construction [1, 2, 28], with most efforts targeting incremental performance improvements. As a result, they provide limited insight into *why* LLMs fail. In particular, little attention has been given to the role of structural reasoning over UML models, despite its fundamental importance for correct OCL generation [35].

A UML class diagram can naturally be represented as a graph, where classes correspond to nodes and associations correspond to edges [19, 43]. Generating OCL constraints often requires multi-hop navigation across this graph to identify relevant entities and relationships. This suggests that OCL generation is not merely a language translation task, but also a graph reasoning problem.

Recent graph reasoning benchmarks show that LLMs struggle with multi-step reasoning over graph structures, especially as graph depth and complexity increase [37]. These findings motivate the following question: *Do similar structural reasoning limitations explain failures in LLM-based OCL generation using UML models?*

To investigate this question, we study how UML structural properties and non-structural lexical cues influence LLM-generated OCL constraints. Specifically, we address the following research questions:

**RQ1. How do UML structural properties influence LLM-based OCL generation?** More specifically, **RQ1.1** examines how structural navigation depth affects OCL correctness, while **RQ1.2** investigates whether OCL generation degrades as UML structural complexity increases.

**RQ2. To what extent do lexical cues influence LLM-based OCL generation?** Here, **RQ2.1** examines how lexical similarity between natural-language specifications and UML elements influences generated OCL, whereas **RQ2.2** investigates whether the ordering of classes and associations in the textual UML representation affects OCL generation.

**RQ3. How can OCL generation be improved, and which errors persist?** Specifically, **RQ3.1** evaluates whether advanced prompting strategies, such as Chain-of-Thought, Few-shot, and Build-a-Graph, improve OCL generation quality, while **RQ3.2** identifies the types of OCL generation errors that occur across the experimental conditions.

Based on these questions, the core contributions of this paper are fourfold: (1) we conceptualize UML-based OCL generation as a graph reasoning problem and relate observed failures to known LLM limitations in graph reasoning; (2) we empirically evaluate the effects of structural complexity, navigation depth, lexical similarity, and prompt design on OCL generation; (3) we assess advanced prompting strategies, including Chain-of-Thought and Build-a-Graph prompting; and (4) we identify recurring error types, including invalid navigation, incorrect OCL usage, hallucinated content, and syntactically valid but semantically incorrect expressions.

Within the evaluated dataset and models, our results show a negative association between OCL generation correctness and increasing UML structural depth and complexity, consistent with patterns reported in prior graph-reasoning studies. We find limited evidence for a broad lexical-bias explanation: the observed failures cannot be explained by superficial lexical similarity alone, although misleading class-level lexical cues can still be associated with lower correctness in some cases. Advanced prompting strategies provide only partial improvements. Overall, this study shifts the focus from improving OCL generation accuracy toward examining factors associated with LLM failures in model-driven engineering tasks.

## 2 Motivation

Recent work has shown that Large Language Models (LLMs) struggle with reasoning tasks involving graph-structured data, when the graph is expressed entirely in natural language [37, 15, 22, 29]. Across graph reasoning benchmarks, LLMs often generate fluent intermediate explanations while failing to correctly reason about structural relationships such as connectivity, traversal, and path optimization. These findings are particularly relevant to UML-based OCL generation, since generating a valid OCL constraint frequently requires navigating multiple associations and maintaining consistency with the underlying UML graph structure.

Listing 1 shows one representative example is reported in the NLGraph benchmark [37], which evaluates LLMs on graph reasoning tasks formulated in natural language. In this task, an LLM is asked to identify whether a path between two nodes exist.

**Listing 1** Path reasoning failure from [37].

```
Question: "Is there a path, in this undirected graph, that exist
between node 4 and node 5? If yes, give the path."
Graph connections:
0 ⟶ 4, 1 ⟶ 6, 3 ⟶ 5, 2 ⟶ 6, 1 ⟶ 3, 2 ⟶ 5, 5 ⟶ 6, 1 ⟶ 2
Correct path: No path exist that connect Node 4 and Node 5
LLM output: Yes, a path between Node 4 and Node 5 does exisit -
4 ⟶ 0 ⟶ 6 ⟶ 2 ⟶ 5
```

The path generated by the model is not valid. The example illustrates an important limitation: the model fails to correctly captures local graph connectivity, and fails to reason about the graph structure. Other work additionally demonstrates that LLM performance is sensitive to how graph information is presented in text. For example, Ge et al. [15] show that simply reordering graph edges in the prompt can substantially change reasoning accuracy, even when the underlying graph remains identical.

These limitations are directly reflected in OCL generation from UML class diagrams. Although OCL is a formal specification language, producing correct constraints requires reliable navigation over the underlying UML graph, including identifying valid association paths, preserving navigability constraints, and maintaining consistency across multi-step traversals between classes. Listing 2 illustrates this issue through an example generated by *Claude Sonnet 4.5* for the natural language specification: *Only department managers can work less than 5 hours on a project*, based on the UML class diagram in Figure 1, where the resulting OCL expression is incorrect due to failures in maintaining valid structural navigation.

**Listing 2** OCL expression generated by LLM.

```
context WorksOn inv: self.hours < 5 implies
self.employee.department.manager = self.employee
```

The generated constraint incorrectly attempts to navigate through an association named `employee` from the `WorksOn` context class. Similar to the NLGraph example, the model produces syntactically plausible output while failing to preserve the underlying graph structure of the problem domain.

Motivated by these findings, RQ1 investigates whether the structural properties of UML class diagrams are associated with OCL generation performance. Prior graph-reasoning studies report declining LLM performance as reasoning paths become longer and graph structures become larger or more densely connected [37, 31]. We therefore examine whether OCL correctness decreases as UML navigation depth and structural complexity increase.

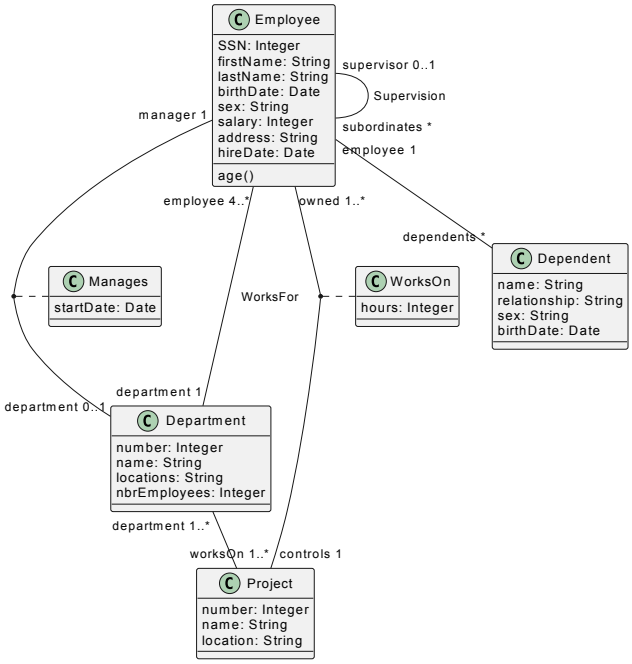

**Figure 1** A class diagram from the EmpoymentAgency Domain.

RQ2 examines two non-semantic characteristics of the model representation that may also be associated with generation performance. Prior studies suggest that LLM outputs can be affected by superficial lexical cues, such as mention frequency, rather than consistently preserving graph structure [17, 37]. Accordingly, we investigate whether lexical similarity between the natural language specification and UML elements is associated with OCL correctness. Since graph-task performance can also vary when the same structural information is presented in a different textual order [15], we additionally investigate whether alternative orderings of UML classes and associations affect the generated constraints. Finally, motivated by evidence that stepwise processing and intermediate graph construction can partially mitigate failures on graph tasks [37], RQ3 evaluates whether graph-aware and other prompting strategies improve OCL generation and identifies the errors that persist.

## 3 Methodology

**Data.** The empirical evaluation conducted in this study uses the dataset introduced in PathOCL [2]. The original dataset consists of 15 UML class models originating from multiple real-world application domains, including airport systems, healthcare, and employment management. For each UML model, the dataset provides three main artifacts: (1) the UML class model itself, represented in PlantUML format, (2) corresponding natural language specifications describing system constraints, and (3) reference gold OCL constraints associated with those specifications.

Since the gold OCL constraints were required for evaluation, two UML models were excluded from the study because they lacked corresponding gold OCL annotations. After filtering, the final dataset comprised 13 UML class models and 115 natural language specifications paired with gold OCL expressions, substantial enough for an empirical study [30, 27, 20]. All UML models were represented in textual form using the PlantUML format [32]. The

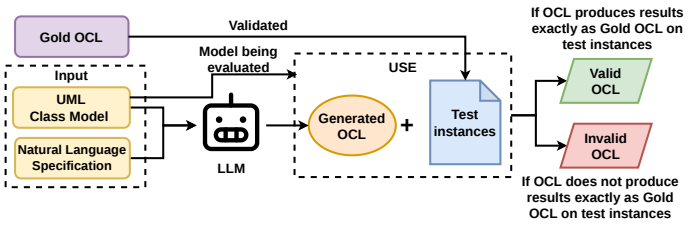

**Figure 2** Process to categorize LLM-generated OCL expressions as valid or invalid.

gold OCL constraints were used as ground truth references during evaluation. In particular, they were used to validate the correctness of the OCL constraints generated by the evaluated LLMs through test-instance-based verification procedures.

**Evaluated Language Models.** This study evaluated six large language models (LLMs), covering both closed and open-source models. The evaluated models included Claude Sonnet 4.5 [5], GPT-5 [26], Llama 4 Scout [24], Gemini 2.5 Pro [12], DeepSeek Chat V3.1 [13], and Grok 4 Fast [38]. For all experiments, the temperature was fixed at 0.1 and the maximum generation length was set to 1500 tokens, allowing sufficient output capacity for OCL generation. Additionally, to account for the stochastic nature of LLM decoding, each input specification was evaluated over 10 independent runs per model under identical prompting and decoding settings. This repeated-sampling protocol was used to reduce variance in generation quality and obtain a more stable estimate of model behaviour.

The 10 generated OCL outputs per specification were aggregated using a deterministic majority-based strategy. The outputs were normalized to remove formatting and whitespace differences, and equivalent expressions were grouped and counted. The most frequent expression, whether valid or invalid, was selected as the final prediction. In case of a frequency tie, tied expressions were considered in run order, and the first syntactically valid expression was selected. If all outputs were invalid, the most frequent invalid expression was retained and categorized as invalid during error analysis.

**OCL Generation and Evaluation Procedure.** The OCL generation and evaluation procedure used in this study is illustrated in Figure 2. For each UML model in the dataset, the model in the text format and its associated natural language specification are provided as inputs to the LLM. Based on these inputs, the LLM generates an OCL expression intended to apply the constraints stated within NL specifications with respect to the provided UML model. The generated OCL expressions are then evaluated using the USE (UML-based Specification Environment) [16] tool.

The evaluation process consists of two stages: syntactic validation and behavioural validation. In the first stage, the generated OCL expressions are checked for syntactic correctness using USE. This step determines whether the generated constraints conform to the grammar and structural rules of OCL. Any generated constraint that cannot be successfully parsed or executed within USE is classified as syntactically invalid.

In the second stage, the generated OCL expressions are evaluated behaviourally to determine whether they correctly capture the intended semantics of the NL specification. For each specification, two manually crafted *object* test instances conforming to the corresponding UML model are created: (1) a positive test instance satisfying the specification, and (2) a counterexample violating the specification. To improve robustness, the test instances include

not only straightforward satisfying and violating cases, but also structurally challenging scenarios designed to expose common OCL generation errors such as incorrect navigation paths, quantifier misuse, cardinality violations, and logical inconsistencies. Prior to evaluation, all test instances are validated against the gold OCL constraints to ensure they correctly represent the intended specification semantics.

Once validated, the same test instances are executed against the LLM-generated OCL expressions using USE. A generated OCL expression is considered behaviourally valid if it produces the same boolean evaluation outcomes as the corresponding gold OCL across all test instances; otherwise, it is classified as behaviourally invalid. This evaluation procedure is applied consistently across invariants, preconditions, and postconditions, enabling uniform comparison between generated and reference OCL constraints.

**Experimental Setup and Graph Construction.** To investigate how structural properties of UML class diagrams influence OCL generation, each UML model was first transformed into a graph-based representation. Since UML class diagrams naturally encode structural relationships between entities, representing the models as graphs enabled systematic analysis of graph-related properties relevant to OCL generation.

The UML models, represented in PlantUML format, were parsed using regular-expression-based extraction procedures. During this process, classes, attributes, operations, and associations were identified and converted into graph components. Specifically, UML classes were represented as graph nodes, while associations between classes were represented as edges. Attributes and operations associated with a class were stored as node-level properties. Additional metadata describing association types, multiplicities, navigability, and association classes were also preserved within the graph representation as edge properties.

This graph transformation enabled the extraction of structural properties required for the empirical analysis. In particular, breadth-first search (BFS) traversal was used to analyze connectivity and navigation relationships between classes. Using the generated graph representation, several structural metrics were computed for each UML model, including: 1) number of classes, 2) number of associations, 3) number of attributes, 4) number of operations, and 5) navigation depth between related classes. These graph-derived metrics were subsequently used as explanatory variables in the statistical analysis to investigate their relationship with OCL generation correctness.

**Statistical Analysis.** To analyze the relationship between UML structural properties and OCL generation correctness, this study employed Generalized Estimating Equations (GEE) [18] model. The dependent variable in the analysis was whether a generated OCL constraint was behaviourally correct according to the evaluation procedure described in Section 3.

A standard logistic regression model was considered, but not used because one of its key assumptions, namely the independence of observations, was violated in the experimental setting. Specifically, multiple natural language specifications were associated with the same UML class model. Since structural features such as the number of classes, associations, attributes, and graph connectivity were extracted at the UML-model level, multiple observations originating from the same UML model shared identical structural characteristics. Consequently, the generated samples were not statistically independent.

Hence, to account for this intra-model correlation, the GEE model was employed. GEE extends generalized linear models by explicitly modelling correlations among grouped observations while still estimating population-level effects. Using GEE allowed us to more reliably estimate the influence of structural UML properties on OCL generation performance while accounting for dependencies between specifications derived from the same UML model.

**Table 1** Effect of navigation depth on OCL correctness.

**(a)** Correctness by navigation depth.

| Navigation depth | Clusters | Generated | Correct | Correctness |
|---|---|---|---|---|
| 0 | 18 | 360 | 277 | 76.9% |
| 1 | 54 | 1080 | 777 | 71.9% |
| 2 | 27 | 486 | 227 | 46.7% |
| 3 | 7 | 126 | 8 | 6.3% |

**(b)** GEE regression results.

| Predictor | Coef. | OR | SE | p-value |
|---|---|---|---|---|
| Navigation depth | -0.937 | 0.392 | 0.218 | 0.0031 |

# 4 Results

## 4.1 RQ1: Effect of UML Structural Properties on OCL Generation

**RQ1.1: Effect of Navigation Depth.** To investigate whether deeper UML navigation affects OCL generation, we operationalize navigation depth from the reference OCL constraints. In OCL, a navigation expression corresponds to a sequence of association traversals starting from the context class of the UML model, where each role access in a `self`-based expression represents one step in the UML graph. Navigation depth is defined as the maximum length of any such navigation chain in the gold OCL, capturing the extent of structural traversal required to express a constraint.

This metric captures the structural traversal required to express a constraint: shallow constraints involve only local attributes or directly associated classes, whereas deeper constraints require navigation across multiple related classes. Although we extract the metric from the OCL expression itself, it directly reflects the underlying UML graph structure, since each role access corresponds to traversal along an association in the class diagram.

To evaluate the association between navigation depth and OCL generation correctness, the navigation-depth feature was incorporated as a predictor variable within the GEE model. Table 1a presents the observed correctness rates across different navigation depths. The results indicate a consistent decline in correctness as navigation depth increases. Constraints with navigation depths of 0 and 1 achieved correctness rates of 76.9% and 71.9%, respectively. In contrast, correctness decreased to 46.7% for depth-2 constraints and further declined to 6.3% for depth-3 constraints. Although this pattern is consistent with longer structural traversals being more difficult, the depth-3 estimate should be interpreted as suggestive because it is based on only seven specification clusters.

The GEE analysis further indicates that this relationship is statistically significant. Navigation depth produced a negative coefficient of $-0.937$, with an odds ratio of 0.392 and a p-value of 0.0031 (Table 1b). Since correctness was used as the binary outcome variable, the negative coefficient indicates that greater navigation depth is associated with a lower probability of generating a behaviourally correct OCL constraint. Interpreted in terms of odds ratios, a one-standard-deviation increase in navigation depth is associated with an approximate 60.8% reduction in the odds of generating a correct OCL expression.

The observed effect remained stable across alternative correlation assumptions. When the GEE model was refitted using an independence correlation structure, navigation depth remained negative and statistically significant, with coefficient $-0.980$, odds ratio 0.375, and $p = 0.0021$. A similar pattern was also observed consistently across all evaluated LLMs, where navigation depth produced negative and statistically significant coefficients for each model individually.

Within the evaluated dataset and models, the results provide evidence of a negative association between navigation depth and LLM-based OCL generation correctness. As the required structural traversal through the UML model increases, the observed likelihood

**Table 2** Effect of UML structural complexity on OCL correctness.

| Structural metric | Coefficient | Odds ratio | 95% CI | p-value |
|---|---|---|---|---|
| Number of classes | -0.514 | 0.598 | [-0.756, -0.272] | $< 0.0012$ |
| Number of associations | -0.523 | 0.593 | [-0.771, -0.274] | $< 0.0024$ |
| Attributes and operations | -0.347 | 0.707 | [-0.779, 0.085] | 0.115 |

of generating a correct OCL constraint decreases. This pattern is consistent with the graph-reasoning perspective motivating this study and suggests that difficulty maintaining longer structural navigation paths may contribute to OCL generation failures. However, the particularly low depth-3 correctness rate remains suggestive rather than conclusive because that category contains only seven specification clusters.

**RQ1.2: Effect of Structural Complexity.** We define UML structural complexity as the size and connectivity of the UML class model that the LLM must reason over when generating an OCL constraint. In graph terms, structurally simple model contains fewer possible classes and navigation alternatives, whereas a structurally complex model contains more classes, more associations, and more model elements that may need to be selected, ignored, or navigated correctly. In this study, we operationalized structural complexity using three model-level metrics: the number of classes, the number of associations, and the total number of attributes and operations.

For each UML model, these metrics were extracted from the graph-based class diagram. Since all specifications belonging to the same UML model share the same structural-complexity values, we evaluated the relationship between each complexity metric and OCL correctness using a logistic GEE model with correctness as the binary outcome. To avoid instability caused by strong correlations among structural metrics, we fitted one GEE model per complexity metric. Each feature was standardized before fitting, so the coefficients represent the effect of a one-standard-deviation increase in the corresponding complexity measure.

Table 2 reports the results. The number of classes has a statistically significant negative association with OCL correctness ($\beta = -0.514$, $p < 0.0012$). The corresponding odds ratio is 0.598, indicating that a one-standard-deviation increase in the number of classes is associated with an approximately 40.2% decrease in the odds of generating a correct OCL expression. Similarly, the number of associations also has a statistically significant negative association with correctness ($\beta = -0.523$, $p < 0.0024$), with an odds ratio of 0.593. This corresponds to an approximately 40.7% decrease in the odds of correctness for a one-standard-deviation increase in associations.

In contrast, the number of attributes and operations does not show a statistically significant independent effect ($\beta = -0.347$, $p = 0.115$). Although the coefficient is negative, the confidence interval crosses zero. This suggests that the amount of local class-level information alone is not sufficient to explain variation in OCL correctness. One possible reason is that attributes and operations are highly correlated with other model-size measures, especially the number of classes and associations, making their independent contribution harder to isolate. Figure 3 further illustrates the relationship between UML structural complexity and OCL generation correctness using class-count bins as a proxy for model size. The observed distributions are consistent with the GEE results, showing a clear decline in correctness as the number of classes increases. UML models containing two to three classes achieve an average correctness of approximately 75.3%, whereas models containing eight or more classes achieve an average correctness of only 38.4%, representing nearly a 49% relative reduction.

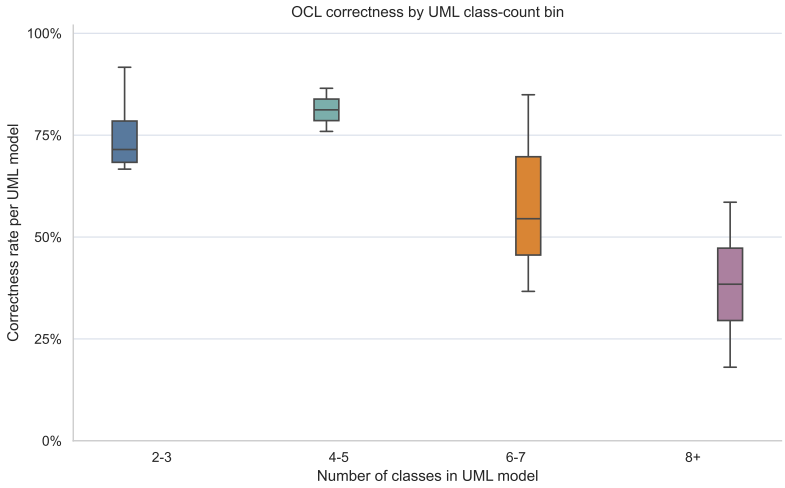

**Figure 3** Distribution of OCL correctness across UML class-count bins.

The box plots further show that smaller UML models (2–4 classes) generally achieve higher median correctness scores, although with greater variability across specifications and prompting configurations. As model size increases, the median correctness decreases consistently across successive bins, while the distributions become increasingly concentrated near lower correctness values. In particular, the largest complexity bins (8+ classes) contain comparatively fewer high-performing observations, indicating lower observed OCL generation correctness for structurally larger models. This descriptive pattern is consistent with the negative associations identified by the regression analysis.

## 4.2 RQ2: Influence of Lexical and Ordering Biases

**RQ2.1: Lexical Similarity Effects.** This research question investigates whether lexical similarity between the natural language specification and UML model elements is associated with the performance of LLM-based OCL generation. To evaluate this hypothesis, we compare the natural language specification against UML elements that appear in the gold OCL constraint and against UML elements that do not appear in the gold OCL constraint. First, we extract the UML elements referenced by the gold OCL constraint, including the context class, referenced classes, terminal attributes, and navigated association roles. These elements form the *gold* element set, representing the UML elements required to express the constraint. All remaining classes, attributes, and roles in the UML model are treated as *non-gold* elements, representing potential distractor elements.

We then compute several lexical similarity features using a token-level Jaccard similarity metric. The gold-alignment features measure how strongly the natural language specification matches the UML elements referenced in the gold OCL constraint. Conversely, the non-gold similarity features measure similarity between the specification and UML elements not used in the gold constraint. We also compute a lexical trap score, defined as the maximum similarity between the specification and any non-gold UML element. Finally, we compute a distance-weighted trap score, which assigns higher weight to lexically similar non-gold classes that are structurally farther from the gold navigation path.

**Table 3** GEE results for lexical-similarity hypothesis features.

| Feature | Expected direction | Coefficient | Odds ratio | p-value |
|---|---|---|---|---|
| Lexical trap score | Negative | 0.610 | 1.841 | 0.1134 |
| Gold alignment | Positive | 0.061 | 1.063 | 0.7681 |
| Distance-weighted trap | Negative | 0.340 | 1.405 | 0.0458 |
| Similarity to non-gold attributes | Negative | -0.514 | 0.598 | 0.0927 |

We hypothesize that if LLM-based OCL generation is influenced by lexical similarity, then higher similarity to gold elements is positively associated with correctness, whereas higher similarity to non-gold elements is negatively associated with correctness. Accordingly, gold-alignment features are expected to have positive coefficients, while lexical trap features are expected to have negative coefficients.

Table 3 summarizes the GEE results for the main lexical-similarity hypothesis features. The overall lexical trap score was not statistically significant ($\beta = 0.610$, $p = 0.1134$), and its coefficient was positive rather than negative. Gold alignment was also not significant ($\beta = 0.061$, $p = 0.7681$). Similarly, the distance-weighted trap score was statistically significant but in the opposite direction from the hypothesis ($\beta = 0.340$, $p = 0.0458$), indicating that it does not support the proposed lexical-trap explanation. Similarity to non-gold attributes showed a negative trend, but it was not statistically significant ($\beta = -0.514$, $p = 0.0927$). These results do not support the broad lexical-bias hypothesis. The expected pattern, where similarity to irrelevant UML elements consistently reduces correctness and similarity to gold elements improves correctness, was not observed. Across the main hypothesis tests, none of the four lexical-similarity features showed the expected statistically significant effect.

However, the broader model reveals a more nuanced result. Similarity to non-gold classes was statistically significant and negative ($\beta = -1.141$, odds ratio $= 0.319$, $p = 0.0006$). This suggests that class-level lexical distractors may still matter. When the natural language specification is lexically similar to classes that are not part of the gold OCL expression, the likelihood of generating a correct constraint decreases. This effect was also stable in the sensitivity analysis using an independence correlation structure ($\beta = -1.132$, odds ratio $= 0.323$, $p = 0.0007$).

Thus, the results provide limited rather than general support for lexical bias. We do not find evidence that LLMs rely primarily on lexical similarity across all UML element types. In particular, gold alignment, lexical trap score, and distance-weighted trap score do not behave as predicted. At the same time, the significant effect of non-gold class similarity indicates that lexical overlap with irrelevant class names can still interfere with OCL generation. This suggests that LLM failures cannot be explained by lexical similarity alone, and instead, lexical cues may interact with structural reasoning, especially when the model must choose among competing candidate classes in the UML graph.

Therefore, for RQ2.1, we conclude that lexical similarity is not a sufficient explanation for OCL generation errors. The results reject the broad lexical-trap hypothesis, but they leave room for a narrower class-level lexical distraction effect. This finding is consistent with the results from several graph reasoning paper [37, 42] where LLMs appear to perform some reasoning over the UML model structure, but their generation can still be affected by misleading textual cues in specific cases.

**RQ2.2: UML Ordering Effects.** To investigate whether the textual ordering of UML elements influences OCL generation, we evaluated five strategies for linearizing UML class diagrams before providing them to the LLM. These include *classes-first*, *associations-first*, *breadth-first search (BFS)*, *depth-first search (DFS)* inspired by graph-reasoning studies [15] and a proposed *leaf-first* traversal. The classes-first and associations-first strategies grouped UML elements by type, whereas BFS, DFS, and leaf-first generated traversal-based ordering over the UML graph structure. The proposed leaf-first strategy begins from terminal classes and progressively moves toward more central classes, motivated by the observation that many OCL constraints ultimately reference terminal attributes or entities located near leaf regions of the UML graph. For BFS and DFS, traversal was performed over the dual graph representation following [15] to ensure that all UML associations were included in the final prompt. These transformations modified only the textual presentation order of the UML model and did not alter its underlying semantics or topology.

Table 4 reports the effect of different textual ordering of the UML class diagram on OCL generation correctness and error distributions across all evaluated LLMs. The results show that LLM performance is sensitive to the textual ordering of UML elements, even though the underlying UML graph remains unchanged. This finding is consistent with prior graph-reasoning studies [15], suggesting that LLMs are influenced not only by structural content itself, but also by how that structure is linearized within the prompt.

Across most evaluated models, no single ordering strategy consistently dominated all others. Nevertheless, several important trends emerge. First, traversal-based orderings such as BFS and DFS often increased the number of navigation and invalid-generation errors relative to simpler serialization strategies. For example, GPT-5 produced 11 navigation errors under the classes-first representation, compared to 14 under DFS ordering. Similarly, Claude Sonnet 4.5 exhibited an increase in invalid outputs from 9 under classes-first ordering

to 14 under DFS ordering. These results suggest that traversal-based serializations may introduce longer or less locally coherent prompt structures, making it more difficult for the model to maintain consistent navigation paths during OCL generation.

Second, the results indicate that textual order can substantially affect syntactic validity. This effect is particularly visible for DeepSeek v3.1. Under the conventional classes-first representation, DeepSeek achieved only 30 correct generations out of 115 evaluated specifications, while producing 64 invalid OCL expressions. In contrast, under associations-first ordering, correctness increased dramatically to 85 correct generations, with invalid outputs decreasing to only 9. Similar improvements were observed for BFS and DFS orderings. Manual inspection revealed that many invalid generations under the classes-first configuration omitted required OCL context declarations entirely. For example:

```
Project.allInstances()->forAll(p | p.department.locations
->includes(p.location))
```

Although structurally plausible, such expressions are not valid OCL invariants because they lack an explicit `context` declaration. One possible explanation is that the classes-first ordering encourages DeepSeek to generate constraints in a more query-like or declarative style rather than following the expected invariant structure. In contrast, traversal-based and associations-first representations may provide stronger relational cues that better align with the model's learned patterns for structured constraint generation. However, because this behaviour was not consistently observed across the other evaluated LLMs, the exact cause remains unclear and requires further investigation.

The proposed leaf-first ordering produced mixed but noteworthy results. For GPT-5 and Gemini 2.5 Pro, leaf-first ordering achieved the highest correctness among all evaluated strategies, reaching 82 and 85 correct generations respectively. This partially supports the intuition underlying the leaf-first design: presenting structurally terminal classes earlier in the prompt may help the model more easily identify terminal attributes and navigation targets frequently referenced in OCL constraints. However, this behaviour was not universal across models. For Llama 4 Scout and Grok-4-Fast, leaf-first ordering did not improve correctness and in some cases increased navigation-related errors. These results suggest that while leaf-first ordering may help certain models prioritize relevant structural regions of the UML graph, its effectiveness likely depends on how individual LLMs internally process long structured contexts.

More broadly, the results indicate that OCL generation is sensitive to prompt serialization structure even when the semantic content of the UML model remains identical. The observed differences across ordering strategies support the hypothesis that LLMs do not reason over UML graphs in a fully structure-invariant manner. Instead, the textual presentation of structural information itself influences how effectively the model can maintain consistent graph navigation and constraint construction during generation.

## 4.3 RQ3: Prompting Strategies and Error Analysis

**RQ3.1: Effectiveness of Prompting Strategies.** To answer RQ3.1, we evaluated four prompting strategies: zero-shot, Chain-of-Thought (CoT), few-shot, and graph-based prompting. The first three follow standard prompting paradigms for code and formal-language generation, while the graph-based variant explicitly instructs the model to reconstruct the UML diagram as a graph before generating OCL, with the aim of improving structural reasoning and navigation consistency, and reduce graph-related reasoning failures during OCL generation.

**Table 5** Distribution of OCL generation errors across prompting strategies and evaluated LLMs.

| Model | Prompting Strategy | Correct | Hal. | Nav. | Log | Inc. | Inv. |
|---|---|---|---|---|---|---|---|
| Claude Sonnet 4.5 | Zero-shot | 82 | 2 | 10 | 4 | 8 | 9 |
| | Few-shot | 73 | 4 | 12 | 7 | 6 | 13 |
| | CoT | 81 | 5 | 9 | 8 | 4 | 8 |
| | Graph-based | 83 | – | 9 | 5 | 6 | 12 |
| GPT-5 | Zero-shot | 80 | 5 | 11 | 8 | 6 | 5 |
| | Few-shot | 82 | 5 | 5 | 8 | 4 | 7 |
| | CoT | 85 | 5 | 5 | 10 | 4 | 6 |
| | Graph-based | 91 | 1 | 4 | 4 | 5 | 10 |
| Llama 4 Scout | Zero-shot | 71 | 3 | 20 | 9 | 4 | 8 |
| | Few-shot | 67 | 1 | 18 | 8 | 3 | 16 |
| | CoT | 69 | 6 | 16 | 11 | 5 | 8 |
| | Graph-based | 60 | 15 | 11 | 5 | 8 | 16 |
| Gemini 2.5 Pro | Zero-shot | 79 | 3 | 12 | 8 | 7 | 6 |
| | Few-shot | 78 | 7 | 9 | 7 | 7 | 7 |
| | CoT | 81 | 4 | 13 | 8 | 5 | 4 |
| | Graph-based | 86 | 4 | 15 | 2 | 4 | 4 |
| DeepSeek v3.1 | Zero-shot | 30 | 2 | 12 | 3 | 4 | 64 |
| | Few-shot | 67 | 11 | 10 | 9 | 5 | 13 |
| | CoT | 41 | 9 | 10 | 8 | 3 | 40 |
| | Graph-based | 80 | 8 | 10 | 3 | 2 | 12 |
| Grok-4-Fast | Zero-shot | 71 | 8 | 8 | 5 | 10 | 13 |
| | Few-shot | 76 | 5 | 11 | 5 | 8 | 10 |

| | Graph-based | 86 | 4 | 12 | 3 | 3 | 7 |

Hal: Hallucination, Nav: Navigation, Log: Logic, Inc: Incorrect Ops, Inv: Invalid Ops

For evaluation, a generated OCL constraint was considered *correct* only if it was both syntactically valid and behaviourally consistent with the corresponding gold OCL according to the test-instance-based evaluation procedure described earlier. Incorrect generations were further categorized into five major error types: hallucinated UML elements, navigation errors, logical inconsistencies, incorrect OCL operation usage, and syntactic invalidity. We use the class-first based textual structure when appending the UML class diagram to the prompts.

Table 5 summarizes the correctness and error distributions across prompting strategies and evaluated LLMs. Graph-based prompting consistently achieved the highest or near-highest correctness across most evaluated models. GPT-5 improved from 80 correct constraints under zero-shot prompting to 91 under graph-based prompting, representing the highest overall performance. Similarly, Grok-4-Fast improved from 71 to 86 correct constraints, while DeepSeek-v3.1 exhibited the largest relative improvement, increasing from only 30 correct constraints under zero-shot prompting to 80 correct constraints using graph-based prompting.

The results further show that graph-based prompting substantially reduced several structural reasoning failures. In particular, GPT-5 reduced navigation-related errors from 11 under zero-shot prompting to 4 under graph-based prompting, while hallucination errors decreased from 5 to 1. Similar reductions in navigation and hallucination errors were observed for Claude Sonnet 4.5 and Grok-4-Fast. These findings suggest that explicitly reconstructing the UML model as a graph may help LLMs better maintain structural consistency during OCL generation.

Compared to graph-based prompting, Chain-of-Thought and few-shot prompting produced mixed results. Although CoT prompting occasionally improved correctness, the gains were generally smaller and less consistent across models. Few-shot prompting similarly showed moderate improvements for some models but occasionally introduced additional invalid or hallucinated outputs. For example, Claude Sonnet 4.5 decreased from 82 correct constraints under zero-shot prompting to 73 under few-shot prompting, while invalid outputs increased from 9 to 13.

Despite the overall improvements, graph-based prompting did not uniformly reduce all error categories. Some models continued to exhibit navigation failures and syntactic invalidity even after explicit graph construction. Furthermore, for Llama 4 Scout, graph-based prompting produced lower correctness than the simpler prompting strategies, suggesting that additional structural reasoning steps may increase reasoning instability for certain models.

In answer to RQ3.1, prompting strategies that explicitly encourage graph construction and structural processing achieved higher observed correctness for several evaluated models, including GPT-5, Gemini 2.5 Pro, DeepSeek v3.1, and Grok-4-Fast. However, graph-based prompting did not improve performance for every model, and its effectiveness varied substantially across LLM families. Explicit structural decomposition therefore provides only a partial and model-dependent improvement and is insufficient by itself to resolve OCL generation failures.

**RQ3.2: Analysis of OCL Generation Errors.** To better understand the limitations of LLM-based OCL generation, we manually analyzed incorrect outputs and categorized the observed failures into five recurring error types: navigation errors, incorrect use of OCL operations, hallucinated model content, logical errors, and invalid or non-OCL constructs. These categories were derived through iterative inspection of generated constraints across all evaluated prompting strategies and models. The results indicate that many failures are closely related to structural reasoning over UML models, rather than purely syntactic generation mistakes. We explain the errors using the class diagram illustrated in Figure 1.

***Navigation Errors.*** Navigation errors occur when a generated OCL expression attempts to access model elements through invalid or nonexistent association paths. Although such expressions are often syntactically valid, they violate the structural relationships defined in the UML model and therefore fail during semantic validation or behavioural evaluation. *Example:* Given the natural language requirement, "The start date of an employee as manager of a department must be greater than his/her hire date," one model generated the following OCL constraint:

```
context Manages inv: self.startDate > self.employee.hireDate
```

However, the class `Manages` contains no association end named `employee`; the correct navigation should use `manager`. Consequently, the navigation path `self.employee` is invalid. This example illustrates how LLMs may incorrectly traverse the UML structure despite producing syntactically plausible OCL.

***Incorrect Use of OCL Operations.*** This category includes errors in which OCL collection or iterator operations are applied incorrectly. Common examples include invoking collection operators on non-collection values, omitting required iterator expressions, or confusing attribute navigation (`.`) with collection navigation (`->`). *Example:* Given the natural language requirement, "The SSN of employees is an identifier (or key)," the following OCL expression was generated:

```
context Employee inv ssnUnique:
Employee.allInstances().SSN->isUnique()
```

The `isUnique()` operation requires an iterator expression specifying the uniqueness criterion for each element in the collection. Since no iterator body is provided, the expression is invalid. This example demonstrates that LLMs frequently struggle with the semantic constraints imposed by OCL collection operators.

***Hallucinated Model Content.*** LLMs occasionally generate associations, attributes, or operations that do not exist in the UML model. These hallucinated elements are often semantically plausible but unsupported by the provided diagram, indicating reliance on learned language priors rather than faithful structural reasoning. *Example:* Given the requirement, "The location of a project must be in one of the locations of its department," the following OCL constraint was produced:

```
context Project inv locationConstraint:
self.controllingDepartment.locations->includes(self.location)
```

In this example, the association `controllingDepartment` does not exist in the UML model and is fabricated by the LLM. The generated expression therefore references a nonexistent navigation path.

***Logic Errors.*** Logic errors arise when a generated OCL expression is syntactically valid and structurally consistent with the UML model, but does not correctly encode the intended semantics of the natural language specification. These errors are typically identified during behavioural evaluation using test instances. *Example:* Given the natural language requirement, "The manager of a department must be an employee of the department," one generated constraint was:

```
context Department inv ManagerIsEmployee: self.manager.department =
self
```

Although the expression is syntactically valid, it does not correctly enforce the intended constraint. Specifically, the generated OCL only checks whether the manager references the current department, rather than verifying that the manager belongs to the department's employee collection. Consequently, invalid instances may still satisfy the constraint.

***Invalid or Non-OCL Constructs.*** Some generated expressions contain operations, symbols, or functions that are not part of the OCL language. These errors typically result in parsing failures and indicate that the model is transferring assumptions from general-purpose programming languages into OCL generation. *Example:* Given the requirement, "The location of a project must be in one of the locations of its department," one model produced the following constraint:

```
context Project inv: self.department.locations.split(',')
->exists(loc | loc.trim() = self.location)
```

In this example, the operation `trim()` is not defined in standard OCL. The generated expression therefore contains non-OCL constructs and cannot be executed by the USE validator.

These observed error categories are consistent with structural demands contributing to some OCL generation failures. In particular, navigation errors and hallucinated associations show that the evaluated LLMs do not always preserve the relationships defined by the underlying UML graph, especially when constraints require multi-step navigation across related classes. While prompting strategies such as graph-based prompting reduce some of these failures, the remaining errors suggest that reliable structural navigation continues to be an important challenge within the evaluated setting.

## 5 Discussion

These results extend prior graph-reasoning findings to a formal software-engineering task: increasing path length and changing graph serialization are reflected not only in lower task accuracy, but also in domain-specific failures such as invalid OCL navigation and hallucinated

UML elements. In particular, the observed relationships involving navigation depth, UML complexity, and textual ordering are consistent with structural task demands contributing to generation difficulty. At the same time, the comparatively weaker and less consistent lexical-similarity effects suggest that the observed failures cannot be explained purely through shallow textual matching or token-level associations. These findings motivate a broader discussion of how structural demands, graph representation, and prompt organization may shape formal specification generation with LLMs.

More broadly, the structural metrics evaluated in this paper represent only a subset of the possible UML properties that may influence OCL generation. While this study focused on navigation depth, class count, association count, and overall model size, many additional graph characteristics may also affect LLM reasoning performance. Examples include node degree distributions, multiplicity constraints, inheritance depth, association types, graph density, centrality measures, and the presence of highly connected hub classes. Similarly, the textual ordering strategies explored in this work represent only a small subset of the possible linearizations of UML graph structures. Since the number of valid serialization strategies grows combinatorially with graph size, exhaustively evaluating all possible orderings is infeasible. Instead, the strategies evaluated here were selected based on prior graph-reasoning literature [15, 17, 42] and to provide representative examples of structurally different prompt organizations.

Consequently, this work should be viewed as an initial empirical investigation into the relationship between UML graph structure and LLM-based OCL generation. Within the evaluated dataset and models, the results identify associations between OCL correctness and structural properties, textual order, and graph-oriented prompting; they do not establish these factors as the sole or primary causes of failure. We therefore view this study as a foundation for future work that can examine these relationships using larger datasets and stronger controls, while providing directions for graph-sensitive prompting, UML structural analysis, and structure-aware evaluation of LLM-based formal specification generation.

## 6 Threats to Validity

**Construct Validity.** OCL correctness was assessed using behavioural agreement with gold constraints on manually constructed test instances. While practical, behavioural equivalence on finite cases does not guarantee full semantic equivalence. Correct formulations may be misclassified and vice versa. To mitigate this, test instances included both satisfying and violating cases, including edge scenarios. Additionally, navigation depth was used as a proxy for structural complexity, but it does not capture all aspects of reasoning difficulty (e.g., branching or predicate complexity). Lexical similarity measures were also limited to surface-level string comparisons.

**Internal Validity.** Observed relationships between UML properties and correctness do not imply causality, as other factors (e.g., logical complexity) may contribute. Model outputs may also vary due to prompting strategies and stochastic decoding, although consistent settings and repeated sampling were used to reduce this effect.

**External Validity.** The study uses the PathOCL dataset (13 models, 115 specifications), which may not represent the full diversity of industrial UML/OCL usage. The focus on class-diagram invariants limits generalizability to more complex or large-scale settings. The small number of models reflects the scarcity of suitable public datasets with aligned UML,

natural language, and OCL. Synthetic datasets were avoided due to potential realism and bias concerns, though this limits scale. Future work should validate findings on larger and more diverse datasets.

**Conclusion Validity.** The use of GEE accounts for correlated observations, but the small number of UML models may limit statistical power. Results were consistent across sensitivity analyses.

## 7 Related Work

Automatically generating OCL constraints from natural language specifications has been studied widely within model-driven engineering research [8]. Early approaches primarily relied on rule-based transformations, template matching, and syntactic parsing techniques to translate restricted forms of natural language into OCL expressions [6, 35]. These approaches typically required carefully structured input specifications and were limited in their ability to generalize across domains and linguistic variations. More recent work has explored the use of Large Language Models (LLMs) for OCL generation [33, 21, 39]. Abukhalaf et al. [1] investigated prompt engineering strategies for Codex-based OCL generation and demonstrated that prompting design significantly influences generation quality. PathOCL [2] further introduced path-based prompt augmentation strategies intended to improve structural navigation during OCL generation. Other recent work has explored dataset construction and fine-tuning approaches for improving LLM-based OCL generation [28, 23, 21]. These studies primarily focus on improving generation accuracy through prompting or training strategies.

Furthermore, recent research has shown that LLMs struggle with graph reasoning tasks when graph structure is represented in natural language form [36, 41, 42, 17, 40]. The NLGraph benchmark [37] demonstrated that LLM performance degrades substantially on tasks such as shortest-path reasoning, connectivity analysis, and Hamiltonian path problems as graph complexity increases. Subsequent work further showed that LLM reasoning is highly sensitive to graph serialization and descriptive ordering [15].

Other studies have proposed methods for improving graph reasoning capabilities [11]. GraphOtter [22] explored graph-evolving reasoning strategies for complex reasoning tasks, while Peng et al. [29] investigated reinforcement-learning-based approaches for improving graph reasoning generalization. These studies collectively suggest that current LLMs often struggle to maintain consistent structural reasoning over multi-hop graph relationships. Additionally, representing UML class diagrams as graphs has been widely studied in model-driven engineering and formal verification research. Prior work has explored transformations from UML models into graph transformation systems for analysis and verification purposes [19, 43, 4]. These graph-based representations enable reasoning about structural relationships, navigability, and model consistency.

OCL validation itself has also been extensively studied [34]. USE [16] provides executable validation support for UML and OCL models, while other work has explored constraint solving and automated test-data generation for OCL specifications [3, 14, 10]. In contrast to prior work, we investigate factors associated with LLM failures in OCL generation by relating them to the structural demands of navigating UML graphs. We show that common errors, such as invalid paths and hallucinated associations, resemble error patterns reported in graph-reasoning tasks, but within a formal software engineering context. Together with the statistical results, these observations suggest that UML structural properties are relevant to LLM performance without establishing them as the exclusive cause of failure.

## 8 Conclusion and Future Work

This paper examined why Large Language Models (LLMs) struggle to generate correct OCL constraints from natural language and UML class diagrams. We approached this problem from a graph-reasoning perspective, analyzing how UML structure influences generation correctness.

Using the PathOCL dataset, we evaluated multiple LLMs and analyzed the relationships between correctness and navigation depth, structural complexity, lexical similarity, and prompting strategies. Within the evaluated dataset and models, correctness declined as navigation depth and UML complexity increased, and constraints involving multi-hop traversal achieved lower observed correctness. These findings are consistent with patterns reported in prior graph-reasoning studies.

The tested lexical factors provided limited explanatory power, indicating that the observed failures cannot be explained by superficial text matching alone. While graph-aware prompting produced modest improvements for several models, common errors persisted, including invalid navigation, hallucinated associations, and logical inconsistencies. These results are consistent with OCL generation involving both linguistic translation and structural navigation demands.

Future work should validate these findings on larger and more diverse UML/OCL datasets using robustness methods such as cluster bootstrap, permutation tests, or mixed-effects models. Multivariable or matched analyses could better isolate the effects of navigation depth and model size from factors such as NL/OCL length, predicate complexity, quantifiers, and collection operations. The semantic oracle could also be strengthened through larger generated test suites, constraint solving, and mutation analysis. Further studies should examine alternative similarity measures, statistically evaluate prompting improvements and their interaction with UML serialization, and explore validity-aware generation, constrained decoding, and iterative repair using parser, type-checker, and behavioural feedback alongside graph-aware and neuro-symbolic approaches.

## Abstract

**Background.** Mutation testing evaluates test-suite adequacy by injecting synthetic faults into program code. However, traditional rule-based tools often generate large numbers of trivial, redundant, or equivalent mutants that limit their practical use for identifying gaps in a test suite. While recent large language model (LLM)-based approaches generate more realistic faults, most remain test-blind: The model sees only the source code and cannot reason about what existing tests already cover. Ignoring such tests means neglecting context that could help generate higher-quality mutants and thus stronger tests to patch the remaining test suite gaps.

**Aims.** We propose *test-aware* mutant generation, in which an LLM receives the problem statement, canonical solution and base tests in a single prompt, and must generate a nontrivial mutant that passes the base unit tests.

**Method.** We evaluate this approach across a set of five LLMs – Gemini 3.1 Pro, Gemini 3 Flash, GPT 5.1 Codex Mini, GPT 4.1 Mini, Qwen3-32B – on the HumanEval and MBPP benchmarks. The extended EvalPlus test suites serve as an automated oracle to verify whether surviving mutants represent genuine bugs.

**Results.** Test-aware prompting yields verified fault rates of 87.7% (HumanEval) and 79.1% (MBPP), meaning these mutants pass all base tests but are caught by the oracle. This vastly outperforms the matched test-blind prompting (which yields only 12.2% and 23.0%, respectively) and the traditional rule-based tool mutmut (4.4% and 5.7%). While fault subtlety (the fraction of extended tests a mutant fails) remains comparable across all three methods, test-awareness minimizes the computational cost per verified fault, compared to test-blind prompting.

**Conclusions.** Exposing an LLM to existing unit tests shifts mutant generation from untargeted bug injection toward effective discovery of weaknesses in an existing test suite. Our work establishes a concrete foundation for future research to scale test-aware mutant generation to production-level environments.

## 1 Introduction

Mutation testing is a well-established technique for evaluating and improving the quality of a software test suite by injecting synthetic faults, called *mutants*, into source code and checking whether existing tests detect them [10, 17]. A surviving mutant is one that passes all tests and reveals a gap in the test coverage [12]. Despite the benefits of mutation testing, its practical adoption remains limited. A key challenge is the equivalent mutant problem: traditional rule-based frameworks like the Python tool mutmut[1] generate many mutants that are syntactically different but semantically identical to the original code. Distinguishing these from genuine faults is generally undecidable [17]. Empirical studies estimate that 5–20% of generated mutants are equivalent [15]. In industrial settings, the computational cost of executing tests against large mutant pools and the manual effort needed to triage them are the main bottlenecks [19]. For example, calculating the mutation score (ratio of "killed" mutants to total mutant count) on the two billion lines of Google code is generally infeasible [18]. Furthermore, even non-equivalent mutants often provide little value, as many are trivially killed by basic assertions rather than exposing concealed logical flaws. This motivates our search for fewer, higher-value mutants that reveal genuine test-suite weaknesses.

Large language models (LLMs) are a promising tool in efficiently generating mutants. Recent work has shown that LLM-generated mutants are more diverse and behaviorally closer to real bugs than those from rule-based tools, having a 1.8× higher real fault detection rate [29]. However, existing LLM-based approaches such as LLMorpheus [27] and BugFarm [9] use *test-blind* prompting where the model is provided only the source code and has no knowledge of what the existing tests already cover. Without this context, the LLM cannot explicitly target gaps in test coverage and may instead produce mutants that are redundant, trivially caught, or semantically equivalent. Instead of improving test quality, these low-quality mutants present unnecessary additional cost either in terms of human review or computational resources required for repeated execution at every future code deployment. In contrast, a *test-aware* model can reason about the behavioral constraints already covered by the tests and focus its mutations on what the suite misses. Although these techniques enhance mutation testing, they require iterative prompting and are computationally expensive. To reduce this overhead, we propose a single-prompt, test-aware mutant generation approach.

More concretely, the LLM is provided with both the source code and the existing test suite in one prompt and asked to generate a subtle logical bug that survives the current tests. This approach isolates the impact of test-awareness in prompting LLMs for mutant generation and investigates whether the reasoning of the model alone (without a feedback loop) is enough to efficiently generate mutants. However, there is a methodological challenge: verifying whether a surviving mutant is a genuine, non-obvious fault, rather than an equivalent program, typically requires manual review. To address this, we use the Python-based EvalPlus

[1] `https://mutmut.readthedocs.io/en/latest/`

benchmark [14], which extends HumanEval [5] and MBPP [3] with 80× and 35× more tests, respectively. The base test suites (7.7 tests on average per HumanEval problem and 3 for MBPP) serve as the developer-written tests the LLM must evade. The extended suites act as an automated oracle, classifying a mutant that passes the base tests but fails at least one extended test as a verified, non-equivalent fault.

Through extensive experiments with five LLMs – Gemini 3.1 Pro, Gemini 3 Flash, GPT 5.1 Codex Mini, GPT 4.1 Mini, Qwen3-32B – we study various aspects of test-aware prompting for mutant generation and provide a comparison to its matched test-blind and exhaustive rule-based alternatives. Crucially, we show that including the existing test cases in the LLM's context yields an increase of up to 7× in the rate of verified fault generations. We then measure how many oracle test cases are triggered to evaluate the subtlety of generated mutants; a subtle mutant fails on fewer oracle tests. Finally, our cost analysis demonstrates that while rule-based techniques remain the cheapest overall, test-aware prompting significantly reduces the amortized token cost per verified fault compared to the test-blind baseline.

## 2 Related Work

Traditional mutation testing tools rely on basic syntactic mutation operations such as altering true/false values or modifying numeric literals. One such tool is the Python library mutmut. Although simple and fast, it produces many low-value candidates that do not compile, are trivially caught by basic tests or are semantically equivalent to the initial code. This motivates our work to focus on mutant quality over quantity by generating fewer yet more informative mutants. Our intuition is that a test-aware LLM can reason about the semantic blind spots in the code to produce targeted non-trivial bugs for important edge cases.

**Test-Blind LLM Mutation.** Several approaches use LLMs to generate mutants from source code without access to existing unit tests. $\mu$BERT [7] generates mutants using the pretrained CodeBERT [8] model to predict masked code replacements. LEAM [25] trains a syntax-guided encoder-decoder on real-world bug-fix patches from GitHub for syntactically correct mutant generation. These methods produce mutants that resemble real faults more closely than semantics-agnostic operators, but they are limited in syntactic accuracy and mutant diversity. LLMorpheus [27] prompts an LLM to fill placeholders in JavaScript code, producing mutants that are more realistic than those from the state-of-the-art (SOTA) rule-based tool StrykerJS[2]. BugFarm [9] uses attention analysis to find the least attended locations in the code and generate hard-to-detect bugs. The main limitation of these approaches is that they are test-blind and do not condition mutant generation on what the current tests already check. LLMut [29] is closest to our work and considers varying levels of contextual information in an LLM prompt. The authors report substantially higher real-bug detection than rule-based mutation, but with a lower compilation rate and higher duplication. Interestingly, while one of their prompts includes existing unit tests, it performs slightly worse than the variant that omits them. We hypothesize that this performance drop occurs because LLMut only appends the tests as passive context. In contrast, our approach succeeds by explicitly structuring the prompt as an adversarial task, instructing the model to bypass the provided tests to produce high-quality, targeted mutants.

[2] `https://github.com/stryker-mutator/stryker-js`

**Adversarial and Iterative LLM Approaches.** AdverTest [4] improves the fault detection on the Defects4J dataset [11] by using two LLM agents in an adversarial loop where one generates mutants to target blind spots, and the other generates tests. MutGen [30] is an iterative mutation-guided LLM-based test generation framework that incorporates mutant feedback (whether it survived or was killed by the tests) into the prompt for improved unit tests. Nafis et al. developed an iterative test generation pipeline where mutant score and test coverage are used as feedback signal for test case refinement [16]. These approaches show that feedback-driven workflows can be effective, but they also require repeated compilation, execution and re-prompting. A related iterative approach on the test-generation side lets the LLM form hypotheses about how to kill specific mutants and refine tests using execution feedback [22]. Compared to these iterative approaches, our proposed test-awareness yields strong results using only a single interaction with the LLM, reducing cost.

**Mutation-Guided and Coverage-Guided Test Generation.** A complementary line of work uses mutation or coverage information to improve LLM-generated tests rather than to generate mutants. MuTAP [6] uses rule-based mutants to iteratively improve LLM-generated tests. Meta's TestGen-LLM provides both source code and existing tests to the model when improving unit tests [1]. CoverUp [2] iteratively targets uncovered code in Python regression test generation, and SymPrompt [21] exploits the multi-step reasoning capability of LLMs and generates test cases in multiple reasoning stages guided by execution path analysis. These approaches do not generate mutants, but they are consistent with our central idea that giving LLMs richer test-related context improves generation quality.

**LLMs for Equivalent Mutant Detection.** Equivalent mutants remain a fundamental challenge for scaling mutation testing. An empirical study on using LLMs for equivalent mutant detection evaluates several strategies such as fine-tuned code embeddings and prompting strategies on Java mutant pairs [26]. The results show that LLM-based techniques outperform prior equivalent mutant detection methods by an average F1 score of 35.69%. This work uses LLMs to filter equivalent mutants after generation, while we aim to reduce low-value mutant generation by giving the model access to the tests.

To the best of our knowledge, no prior work empirically studies the direct impact of test-awareness on LLM-based mutant generation. Test-blind methods cannot directly find test-suite gaps without iterative methods requiring expensive multi-step feedback. Coverage- and mutation-guided test-generation approaches show that test-related context helps LLM reasoning, but they apply that insight to the test side rather than mutant generation.

## 3 Method and Experimental Setup

Our objective is to generate mutants that reveal weaknesses in an existing test suite rather than producing arbitrary bugs. We formulate mutant generation as an adversarial task. Given a problem statement $P$, canonical solution code $C$, and base tests $T_{\text{base}}$, an LLM must produce a mutant $C'$ that preserves the original function signature, passes $T_{\text{base}}$, and fails at least one test on the hidden oracle $T_{\text{oracle}}$. For every problem, model, and prompt configuration, the LLM generates exactly one mutant without compilation feedback, test-execution feedback, or iterative repair (except in the iterative ablation, see Section 4.4). Our single-shot test-aware mutation pipeline is described below and illustrated in Figure 1. Mutants are assigned an outcome label, as described in Table 1.

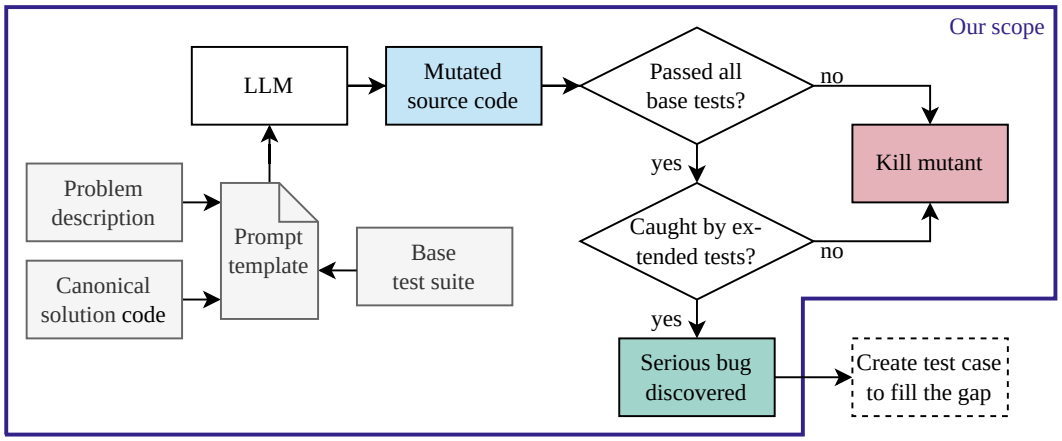

**Figure 1** Our proposed test-aware mutation pipeline. The LLM generates a candidate mutant, which is filtered by the base tests and then validated using the extended EvalPlus oracle, to automatically determine whether the mutant is a serious gap in the test suite or not.

1. **Prompting.** An LLM receives the problem statement, canonical solution and – in the test-aware setting – the base tests. The prompt asks for a subtle logical bug that is executable and passes the provided base tests.
2. **Extraction.** The raw response is parsed to extract the mutant code and discard the surrounding conversational text or markup. If the mutant omits the essential imports, the canonical solution imports are used instead to compile the mutant.
3. **Base-Test Filtering.** The extracted mutant is executed against the base tests and discarded if it throws an error, times out, or fails. This ensures that only eligible mutants are passed to the oracle, which (1) saves cost in running oracle tests on fewer mutants, (2) provides a controlled setting to compare test-awareness vs. test-blindness, and (3) verifies that the mutant is not a trivial bug, but rather has potential to be a genuine fault.
4. **Oracle Evaluation.** Surviving mutants are executed against the EvalPlus extended tests. A mutant that fails at least one oracle test is classified as a verified fault.

**Table 1** Each LLM-generated mutant is assigned one of the four mutually exclusive outcome classes, the meaning of which is explained in this table.

| Mutant Type | Definition |
|---|---|
| Invalid | Mutant does not compile or times out during base-test execution. |
| Rejected | Mutant runs without error, but is killed by at least one base test. |
| Success | Mutant evades the base tests but is detected by the oracle. |
| Undetected | Mutant survives both the base tests and the oracle. |

**Benchmarks and Oracle Design.** We evaluate generated mutants on EvalPlus [14], which extends two Python code-generation benchmarks with substantially stronger test suites for 164 HumanEval problems [5] and 378 MBPP problems [3]. While EvalPlus was designed to benchmark code generation quality, we repurpose it to determine the quality of the LLM-generated mutant. We view the few base tests for each problem as high-quality but incomplete developer-written tests that a good mutant must evade, while the much larger

extended test suite acts as an automated oracle. This design lets us automatically determine the distinction between mutants that are arbitrary syntax modifications vs. those that represent real semantic faults, overlooked by the base tests. We selected EvalPlus over traditional mutation testing benchmarks, such as Defects4J [11], because it enables the automated protocol described above to reliably classify mutants at scale without manual review. Furthermore, the authors of the original EvalPlus study [14] empirically confirm that the base tests in HumanEval and MBPP are often insufficient. By exposing flaws in code solutions that would previously have been accepted, their study provides direct evidence that the extended tests are significantly stronger. While these extended test suites are not perfect either, they serve as a useful tool for evaluating our approach.

**Models and Baselines.** We evaluate five LLMs: Gemini 3.1 Pro, Gemini 3 Flash, GPT 5.1 Codex Mini, GPT 4.1 Mini, and Qwen3-32B. These model choices represent a mix of open-source (Qwen3-32B), frontier SOTA models (Gemini 3.1 Pro) and more computationally efficient versions (Gemini 3 Flash, GPT 5.1 Codex Mini, GPT 4.1 Mini). These specific models have been used in recent software engineering literature for tasks such as vibe-coding benchmark [28], software issue resolving [23], code refactoring [24], and multi-requirement programming tasks [20]. All LLM-based experiments use temperature 0 to evaluate the LLMs in deterministic setting; however, this does not guarantee exact reproducibility because LLMs are non-deterministic by nature and produce stochastic outputs. We compare test-aware prompting against matched test-blind prompting and mutmut.

**Model Prompts.** We use two types of prompts, with two variants each. The design rationale for each variant is described below and summarized in Table 2. The prompt families are dubbed AGENT1 (**A**dversarial **G**eneration of **E**vasive **N**on-equivalent **T**ransformations 1) and AGENT2. Each has a test-aware (TA) and a matched test-blind (TB) variant that differ only in whether the base tests are included in the context. These prompt variants allow for a clean ablation of test-awareness. All prompts (see Table 2 below) share the same task: to generate a single mutant containing a subtle logical bug, given the problem statement and canonical solution. We study two effects: the contribution of test context (TA vs. TB) and the impact of reasoning structure (AGENT1's free-form style vs. AGENT2's template).

**Table 2** Summary of prompt variants used in our study. TA = test-aware; TB = test-blind.

| Prompt | Tests Given? | Reasoning Scaffold |
|---|---|---|
| AGENT1-TA | Yes | Free-form |
| AGENT1-TB | No | Free-form |
| AGENT2-TA | Yes | Structured template |
| AGENT2-TB | No | Structured template |

We now describe the prompts AGENT1 and AGENT2, followed by their full system and user section definitions. Content that appears *only* in the TA variant is marked with a yellow background in the full prompt. Placeholders shown in red are filled at runtime with the problem statement, canonical solution, and base tests.

AGENT1 is the primary prompt. The test-aware variant AGENT1-TA has the base tests along with the source code and instructs the model to (1) analyze the tests for blind spots on valid inputs, (2) plan a minimal mutation, and (3) "mentally dry-run" the mutation against each base test. These reasoning steps are elicited by the LLM inside `<thinking>` tags. The test-blind variant AGENT1-TB uses the same system prompt and output format but omits the base tests from the user message.

**AGENT1 – Test-Aware (TA) and Test-Blind (TB) Variants**

**SYSTEM:**

You are an adversarial software tester and quality-assurance agent. Your goal is to introduce a subtle, realistic logic bug (a "mutant") into the provided Python function.

Your objective is to exploit a semantic blind spot in the Base Tests. The mutated code MUST pass all the provided Base Tests, but it should fail on broader edge cases or uncommon inputs.

Constraints:
1. Preserve the original function signature and all required imports.
2. The modified code must compile successfully without syntax errors.
3. Make the bug subtle and realistic. Do not completely rewrite the function or introduce obvious crashes.
4. The mutated code MUST pass EVERY provided Base Test.
5. The bug MUST manifest on VALID inputs that adhere to the problem description.
6. Do not introduce arbitrary "magic numbers", epsilon values, or floating-point precision hacks.

Format your output EXACTLY as follows:

⟨thinking⟩
1. Analyze the Base Tests to identify a blind spot on VALID inputs.
2. Plan a minimal mutation to exploit this.
3. Perform a mental dry-run against the Base Tests to ensure it passes.
⟨/thinking⟩
⟨mutant⟩
[Insert fully modified Python code here, with no markdown formatting]
⟨/mutant⟩

---

**USER:**

Problem statement:

{problem_statement}

Base Tests:
{base_tests}

Canonical Source Code:
{canonical_solution}

Generate the mutant.

AGENT2 describes the LLM reasoning process in a more structured way. The test-aware variant AGENT2-TA requires the LLM to fill the fields in a fixed template: (1) a short summary of the function's computation, (2) base-test coverage (input types, value ranges, edge cases), (3) a list of two to three identified blind spots, (4) a short mutation plan specifying the exact line and change type, and (5) a per-test trace confirming correctness. This prompt is designed to reduce reasoning shortcuts and force LLM to explicitly analyze gaps in test coverage. Its test-blind counterpart AGENT2-TB only has the function summary and mutation plan fields, because coverage analysis is not possible without tests.

**AGENT2 – Test-Aware (TA) and Test-Blind (TB) Variants**

**SYSTEM:**

You are an adversarial mutation tester. Introduce exactly one subtle logic bug into the given Python function. The mutant MUST pass every base test but fail on other valid inputs.
Reason inside ⟨thinking⟩ tags using this exact structure, keep each field to one or two sentences maximum:

⟨thinking⟩
WHAT IT DOES: [One sentence: the function's core computation and return value]

BASE TEST COVERAGE:
- Input types tested: [e.g. positive ints, non-empty lists]
- Value ranges tested: [e.g. n in [1..10], lists of length 2–5]
- Edge cases tested: [e.g. duplicates, empty input, single element]

BLIND SPOTS: [List 2–3 valid input scenarios the base tests do NOT exercise.]

MUTATION PLAN: [One sentence: exactly what line to change and how.]

BASE TEST TRACE: [For each base test input, confirm the mutant output matches expected]

⟨/thinking⟩

Then output the complete modified function:
⟨mutant⟩
[full function, no markdown]
⟨/mutant⟩

---

**USER:**

Problem statement:
{problem_statement}

Original code:
{canonical_solution}

Base tests to bypass:
{base_tests}

Generate the mutant.

**Evaluation Metrics.** For the quantitative analysis of the efficacy of different prompting approaches, we use "effectiveness" in terms of success rate, "quality" in terms of fault subtlety, and "token cost" for generating a mutant. These metrics are calculated as follows:

**(a) Effectiveness:** We measure the *success rate* as the fraction of generated mutants classified as SUCCESS:

$$M_{\text{eff}} = \frac{|\{\text{mutants classified as SUCCESS}\}|}{|\{\text{all generated mutants}\}|}.$$

A higher $M_{\text{eff}}$ means that the LLM generates more verified, non-equivalent faults.

**(b) Quality:** We measure fault subtlety using the *oracle kill rate*, defined for each SUCCESS mutant $m$ as the fraction of extended oracle tests that detect it:

$$M_{\text{sub}}(m) = \frac{|\{t \in T_{\text{oracle}} \mid t \text{ fails on } m\}|}{|T_{\text{oracle}}|}.$$

A lower $M_{\text{sub}}$ indicates a narrower fault that is triggered by fewer oracle tests and is therefore harder to detect with a randomly chosen assertion. In addition to the mean, we report the distribution of $M_{\text{sub}}$ across all SUCCESS mutants, providing rich information about whether a method produces a long tail of very subtle faults.

**(c) Token Cost:** We report two cost measures, the *raw output tokens* generated by the LLM and *amortized cost per verified fault*. The amortized cost is calculated by normalizing the sum of input, thinking and output tokens by the number of SUCCESS mutants:

$$M_{\text{cost}} = \frac{\text{total tokens (input + output + thinking)}}{|\{\text{mutants classified as SUCCESS}\}|}.$$

A configuration that uses more tokens per prompt but achieves a higher success rate can still have a lower $M_{\text{cost}}$ than a prompt that wastes most of its generations on INVALID or REJECTED outcomes. For the rule-based baseline mutmut, we do not report token cost, since its computational expense lies in execution time rather than API usage; the comparison with mutmut is therefore limited to $M_{\text{eff}}$ and $M_{\text{sub}}(m)$.

## 4 Results

To maximize reproducibility, we evaluate all LLMs with temperature 0. Because this makes the LLM mostly deterministic, we only generate a single mutant per model-prompt-task combination. In contrast, mutmut's exhaustive rule-based generation produces a significantly larger mutant count: around 18 mutants per HumanEval task and 9 mutants per MBPP task on average (see Figure 2 for details). Thus, we present the mutmut results separately in Table 3, showing that the vast majority ends up INVALID or REJECTED.

The LLM-based results in Figure 3 reveal that, as we move from test-blind to test-aware prompting, there is a shift in mutant outcomes from REJECTED to SUCCESS. For example, AGENT1-TB generates predominantly REJECTED mutants: 68% (112) – 87% (143) are executable mutants failing on the base tests for HumanEval and 54% (205) – 78% (295) for MBPP across all LLMs. The proportion of REJECTED and SUCCESS changes drastically for the test-aware AGENT1-TA. For 164 HumanEval problems, the best-performing model, Gemini 3.1 Pro, generates 144 SUCCESS mutants (87.8% SUCCESS rate) and only 4 REJECTED. Except for GPT 4.1 Mini, every test-aware model outperforms all other models (even smaller ones) in the test-blind scenario in terms of success rate. The ranking of model-prompt combinations regarding success rate is similar for MBPP, establishing a clear trend. This confirms that without visibility of the base tests, LLMs introduce changes that existing assertions already cover. We provide the full results in Table 4.

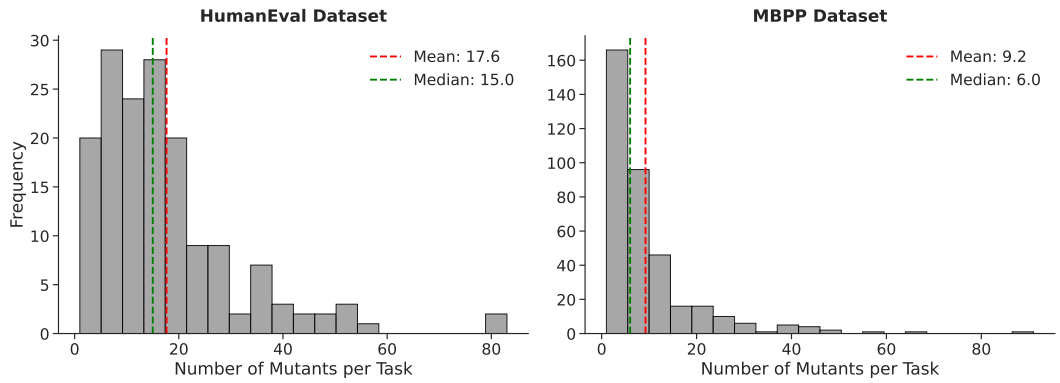

**Figure 2** Mutant counts per task, generated by mutmut. We use the default settings to run mutmut, resulting in varying numbers of mutants per task, depending on the canonical source code.

**Table 3** Status distribution of mutants generated by mutmut. Note that the default setting used for mutmut generates multiple mutants per task, making the total mutant count larger than the number of tasks (2841/164 for HumanEval, 3427/378 for MBPP).

| Dataset | SUCCESS | UNDETECTED | REJECTED | INVALID | Total |
|---|---|---|---|---|---|
| HumanEval | 126 | 179 | 1473 | 1063 | 2841 |
| MBPP | 195 | 197 | 1519 | 1516 | 3427 |

**Table 4** Evaluation of LLM-based mutant generation on 164 HumanEval and 378 MBPP problems under different prompting strategies. For each dataset and model-prompt configuration, we report counts of INVALID (Inv), REJECTED (Rej), SUCCESS (Succ), and UNDETECTED (Und) mutations.

| | qwen3-32b | 378 | 37 | 29 | 219 | 93 | 91 | 31 | 190 | 66 | 26 | 205 | 108 | 39 | 20 | 300 | 41 | 17 |

We also observe that test-aware prompting produces more UNDETECTED mutants than test-blind (e.g., 9 vs. 1 on HumanEval with AGENT1 for Gemini 3.1 Pro). Given the larger number of REJECTED mutants in the test-blind case, this occurs because test-blind models generate many trivial faults caught by the base tests, leaving fewer to reach the oracle. Also, the number of INVALID mutants depends mostly on the LLM used, with smaller models (Qwen3-32B, Gemini 3 Flash, GPT 4.1 Mini) producing more such errors than larger models (GPT 5.1 Codex Mini, Gemini 3.1 Pro). This is likely due to the smaller models' limited capacity to understand the source code and task, weakening the reasoning capabilities required to perform a minimal change that remains executable. Generally, we find that the particular prompt has less effect on the mutant status distribution than the model capability.

## 4.1 Effectiveness of Test-Aware Prompting

Figure 4 compares success rates across the five evaluated models. With mutmut achieving a success rate of only around 4.4% on HumanEval and 5.7% on MBPP (dashed line), this baseline is outperformed by all LLMs, whether prompted in test-aware or test-blind manner, with two exceptions: for AGENT2-TB, Gemini 3.1 Pro has a SUCCESS rate of 4.3% and GPT 4.1 Mini rate is 3.0% on HumanEval. This suggests that even test-blind LLMs are capable of generating higher-value mutants than exhaustive mutmut generation, but test-awareness provides the greatest benefit. In every model, the TA prompt variant outperforms TB. On HumanEval, AGENT1-TA increases the SUCCESS rate for Gemini 3.1 Pro from 12.2% to 87.8% (7.2×) and for GPT 5.1 Codex Mini from 11.6% to 81.1% (7.0×). For AGENT2-TA as well, Gemini 3.1 Pro improves from 4.3% (TB) to 79.3% (TA) and GPT 5.1 Codex Mini improves from 7.9% (TB) to 82.3% (TA). Even for the weakest-performing model, GPT 4.1 Mini, SUCCESS increases from 5.5% to 31.7% (AGENT1) and from 3.0% to 16.5% (AGENT2). On MBPP, the absolute gains are smaller but the trend remains. This consistency across two prompt families and benchmarks for all models shows that test-awareness alone is more crucial for improving mutant generation than the particular prompt phrasing.

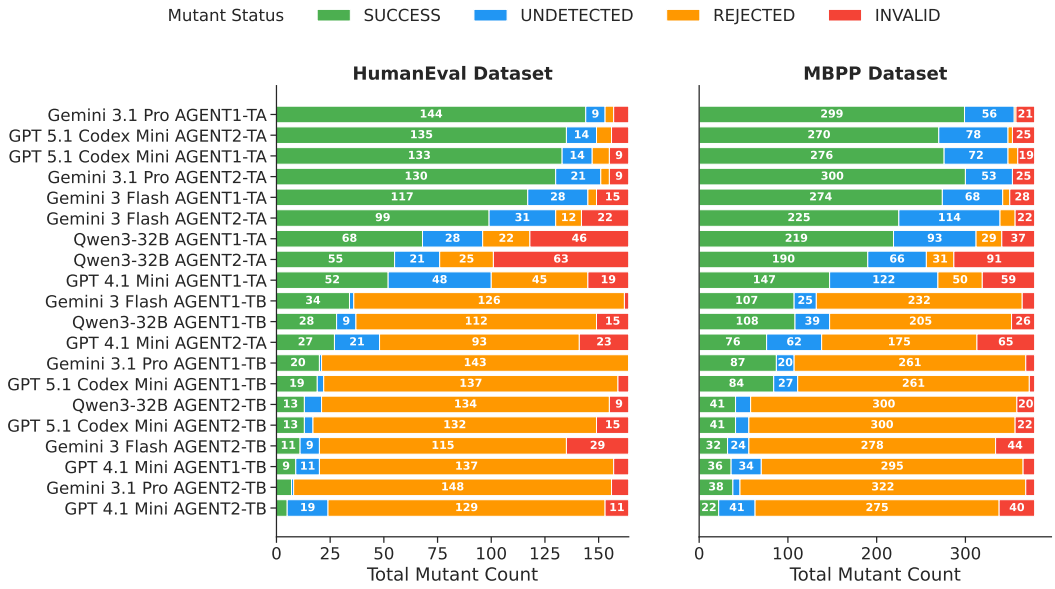

**Figure 3** Distribution of mutant classifications across the HumanEval and MBPP datasets.

Comparing across prompts, our results indicate that the free-form reasoning of AGENT1 generally outperforms the structured template of AGENT2. The rigid constraint of AGENT2-TA to explicitly identify two to three blind spots appears to degrade the model's ability to produce base-test-compliant code, particularly for smaller models. For example, evaluating GPT 4.1 Mini across both prompt variants reveals that AGENT2-TA produces REJECTED mutants on 156 tasks (48 in HumanEval, 108 in MBPP) where AGENT1-TA is able to evade the base tests for the same tasks (SUCCESS or UNDETECTED). This indicates that forcing explicit structural reasoning can hinder the adversarial search space in practice.

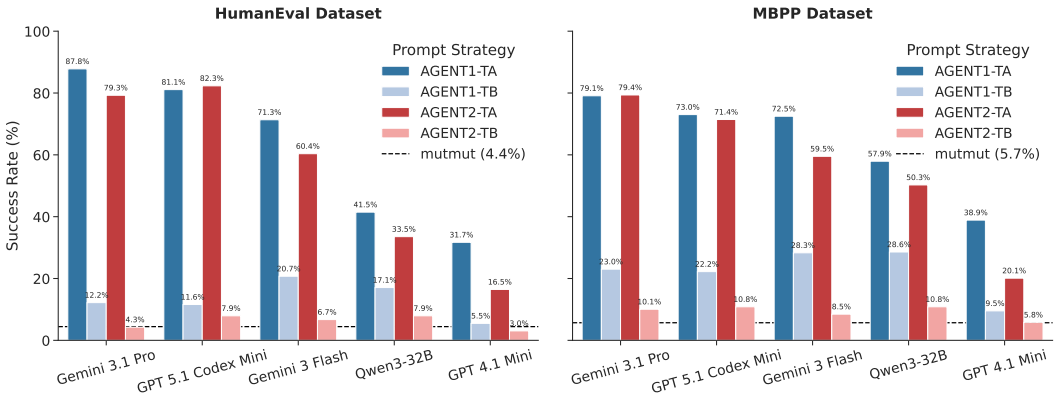

**Figure 4** Comparison of mutant success rates across models and prompting strategies. The dashed lines indicate the success rates of the traditional rule-based baseline (mutmut).

## 4.2 Subtlety and Fault Quality

Figure 5 shows the distribution of oracle kill rates for the generated SUCCESS mutants. We choose this visualization to identify whether certain settings produce more subtle bugs, indicated by a smaller number of extended test cases that catch the mutant. We observe that

although test-aware models have a higher number of successful mutants, the median oracle kill rate for test-aware configurations falls between roughly 10-30%, comparable to those produced by test-blind models. While the dense clustering of points in the lower quartile (e.g., see QWEN3-32B) indicates that test-aware prompting is highly capable of generating narrow, subtle edge-cases rather than catastrophic logical breakages, it is not clear from our experiments that LLMs produce significantly more or less subtle bugs than mutmut.

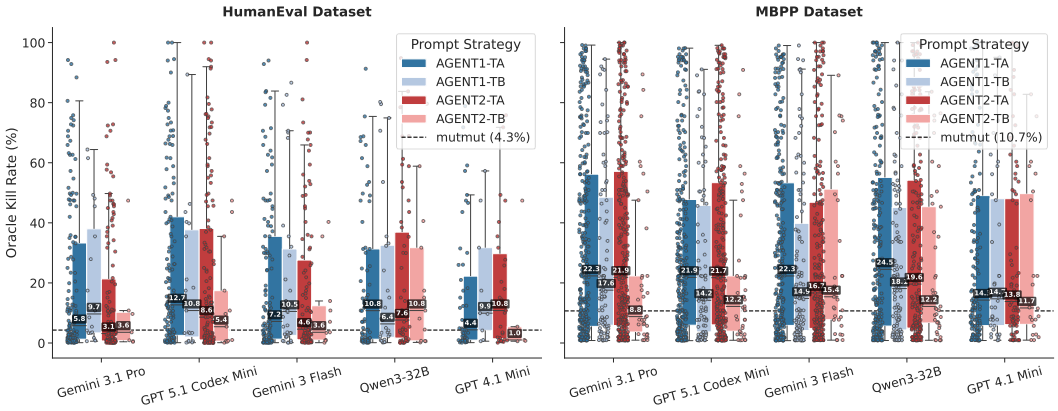

**Figure 5** Fault subtlety as measured by the oracle kill rate. A lower kill rate indicates subtler edge-case bugs that are more difficult for test suites to detect. The horizontal lines in each box and the small numbers above show the *median* value. Thus, mutmut (dashed line) is also presented as the *median* (not mean) in this plot. The whiskers represent 1.5× interquartile range (IQR).

To identify the reason for the substantial number of UNDETECTED mutants in Figure 3, we manually review each such mutant (9 for HumanEval, 56 for MBPP) produced by the best-performing setting, Gemini 3.1 Pro with the AGENT1-TA prompt. We want to know whether undetected mutants represent failures of the generation pipeline (equivalent mutants) or failures of the extended test oracle (genuine but undetected faults). The classification scheme was derived deductively to cover all common mutation testing failures and successes in a non-overlapping manner. Due to resource constraints, the labeling process was conducted by a single author, and therefore inter-rater agreement was not measured. Nonetheless, this qualitative assessment provides valuable insight into the types of edge-case faults that can bypass even extensive automated oracles. Concretely, we establish a hierarchical classification scheme consisting of four equivalency classes and two non-equivalency classes (see Table 5), where equivalent mutants are programs that behave exactly as the original program on all possible inputs, representing a failed attempt to create a program fault.

The four distinctions among equivalent mutants are: (1) Identical code or cosmetic changes such as removing comments or renaming variables, (2) semantic refactoring, i.e., a change in algorithm procedure, but resulting in the same outputs, (3) out-of-specification faults, for example a mutant that produces incorrect results on negative input values even though the task description explicitly restricts inputs to be positive, and (4) dead code, where modifications only occur in unvisited execution branches. Conversely, non-equivalent mutants introduce real faults that the extended oracle failed to catch, which we again divide into two categories: (5) true oracle gaps, representing realistic bugs completely missed by the tests, such as HumanEval#18 which asks how many times a given substring can be found in the original string, but never tests for an empty substring, and finally (6) ambiguous faults, which are bugs that only manifest under poorly defined task specifications, such as MBPP#87, which asks to merge three dictionaries without defining precedence for duplicate

keys. In summary, UNDETECTED mutants of type (1)-(4) represent a failure of the mutant generator, (5) marks a failure in the extended test oracle, and (6) attributes the fault to the underspecified task description.

Out of the 65 UNDETECTED mutants, we found that only 9 (∼13.8%) are equivalent mutants and a vast majority (49/65, ∼75.4%) present serious edge-case bugs that slipped through the extended test cases. This shows that even EvalPlus – the more robust version of HumanEval and MBPP – does not provide guaranteed perfect test cases in these instances. The remaining 7 (∼10.8%) are classified as ambiguous faults, meaning they exploit underspecified edge cases where neither the task description nor the test suite clearly defines the expected behavior. This manual review confirms that rather than representing a failure of the mutation pipeline, the UNDETECTED category highlights the *strength* of test-aware LLMs by showing their ability to act as advanced adversarial testers that even expose flaws in the hidden test oracle, which is significantly stronger than the base tests.

**Table 5** Distribution of UNDETECTED mutants across equivalent and non-equivalent classes. This qualitative analysis was manually performed on the results from Gemini 3.1 Pro with AGENT1-TA.

| Classification | Total | Instances |
|---|---|---|
| *Equivalent Mutants* | | |
| (1) Identical / cosmetic | 1 | HumanEval #114 |
| (2) Semantic refactoring | 5 | MBPP #{103, 235, 463, 578, 765} |
| (3) Out-of-spec fault | 3 | HumanEval #84, MBPP #{124, 445} |
| (4) Dead code | 0 | |

## 4.3 Cost Efficiency

Naturally, LLMs are computationally more demanding than a rule-based mutant generation library like mutmut. We argue this price is worth paying for higher-quality results. Among the LLM-based approaches, we perform a fair cost comparison by considering the *amortized* cost, i.e., the average total tokens consumed to produce a single SUCCESS mutant. This analysis, shown in Figure 6, reveals that test-aware prompting is more token-efficient per verified mutant than test-blind prompting for all models except GPT 4.1 Mini.

We also report the wall-clock time for running these experiments. For mutmut, the full HumanEval run took 6806.5 s and generated 2841 mutants, which is around 2.4 s per generated mutant and 54.0 s per verified SUCCESS mutant. On MBPP, mutmut took 8090.9 s for 3427 mutants, around 2.4 s per generated mutant and 41.9 s per verified mutant. For GPT 5.1 Codex Mini with AGENT1-TA, the total runtime was 29.7 s per problem on HumanEval and 16.4 s on MBPP. This means that a single LLM-generated mutant is roughly 7–12× slower than a single mutmut mutant if we compare one generated candidate to one generated candidate. However, the runtime ranking reverses for cost per useful fault. Because test-aware prompting produces a larger proportion of verified faults, GPT 5.1 Codex Mini requires

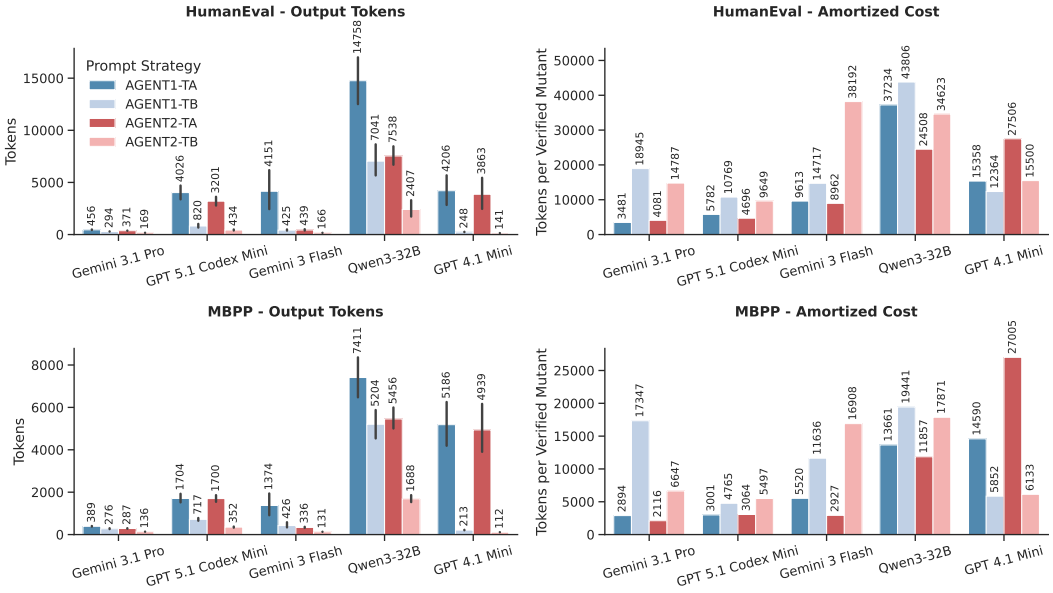

**Figure 6** Distribution of produced output tokens with 95% confidence intervals (left) and amortized computational cost per successful mutant, representing the sum of total tokens (input + thinking + output) used for each mutant, divided by the number of SUCCESS mutants (right).

only 36.6 s per verified mutant on HumanEval and 22.5 s on MBPP, compared with 54.0 s and 41.9 s for mutmut. In other words, LLM-based mutation pays a higher per-candidate premium, but recovers that cost through much higher yield. While LLMs incur higher upfront token and monetary costs, this is offset by the reduction in execution overhead. Executing large suites of trivial mutants is expensive in industrial pipelines; thus, investing compute into high-quality mutants allows for a substantially lower overall cost per verified fault.

## 4.4 Iterative Prompting

While the single-shot results already show that test-awareness leads to subtle and effective mutant generation, a natural question is whether adding execution feedback can close the remaining gap. The answer is a clear yes: Figure 7 shows results for an iterative variant of our pipeline in which the model follows a simple strategy to retry (up to 2 additional times) when a candidate fails the base tests: If a mutant is INVALID, we show the execution error and ask for a syntax fix; if a mutant is REJECTED, we include information on which base-test input failed by revealing the mutant output expected output; finally, if a mutant is UNDETECTED, we encourage the model to take a different approach to avoid semantic equivalence to the original code. Such iterative prompting narrows the TA–TB gap: Gemini 3.1 Pro AGENT1-TB rises from 12.2% in single-shot to 83.5%, approaching the iterative TA rate of 98.2%. We see gains even on the already high-performing TA prompts (e.g., Gemini 3.1 Pro with AGENT2-TA on HumanEval reaches 163 out of 164 verified faults (99.4%), an increase from 130 in the single-shot setting). While the test-blind prompts use around twice the generation cost in the iterative setting, the test-aware iterative configurations require far fewer retries: Gemini 3.1 Pro averages 1.19–1.24 attempts per problem under TA versus 2.27–2.46 under TB. This reinforces the cost-efficiency advantage of test-awareness. These

results suggest that single-shot test-aware prompting captures the majority of the achievable gain and iteration offers diminishing but still meaningful returns, particularly for converting the remaining 10–15% of problems into verified faults.

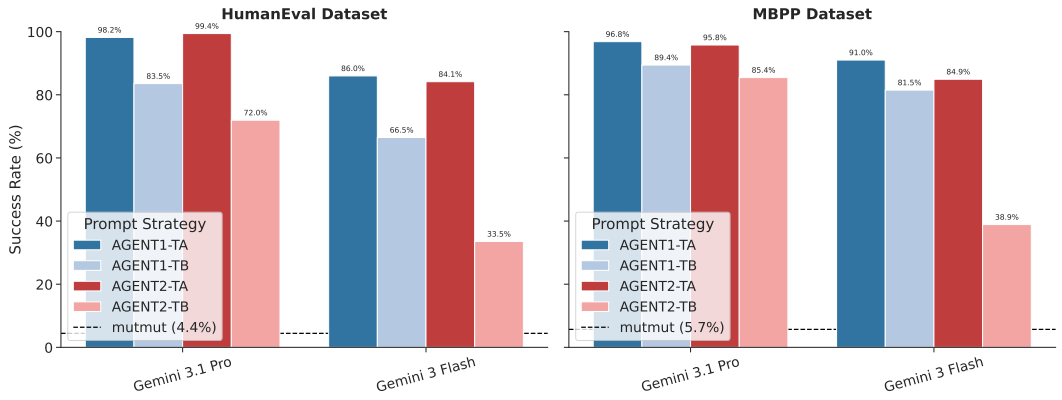

**Figure 7** Success rates under iterative prompting. The TA–TB gap narrows compared with the single-shot results in Figure 4, as repeated execution feedback partially compensates for missing test context (see Table 6).

**Table 6** Iterative prompting results for Gemini 3.1 Pro and Gemini 3 Flash on HumanEval and MBPP. Unlike the single-shot setting, the pipeline retries until the maximum attempt limit (in our case, 3) is reached. For each configuration, we report total generated mutants (Gen), counts of INVALID (Inv), REJECTED (Rej), SUCCESS (Succ), and UNDETECTED (Und) mutants, and the average number of attempts per problem (Att).

## 5 Discussion

Our experiments demonstrate that providing an LLM with test context pushes it to act as an adversarial agent that targets semantic blind spots rather than blindly generating equivalent faults. We further analyze these findings by examining the trade-offs between computational cost and human effort required to find a verified fault, why test-awareness works even in a single non-iterative prompt, how the results improve with an iterative feedback loop, and the limitations of deploying this approach in a real development environment.

**Human Time vs. Compute Time Trade-off.** Generating a few "smart" mutants is more valuable than a large number of low-quality (redundant, equivalent, trivial) mutants. Although the computational cost in generating mutants using mutmut is far lower than LLM-based mutation testing, the human effort required to review these mutants often surpasses the computational efficiency. Petrović et al. [19] perform a cost-benefit analysis of mutation testing in industrial software development applications. They argue that the goal of mutation testing is to provide developers with "productive" mutants (that indicate genuine bugs) rather than achieving mutation adequacy by strengthening the test suite against all "unproductive"

redundant mutants. This supports the intuition behind our *test-aware* approach that a mutant generator becomes more useful when it produces fewer low-value candidates and more mutants that expose meaningful testing gaps. Our results fit this picture well. Test-aware LLM mutation does not win by being cheaper per generated candidate; it wins when cost is measured per useful, verified fault. In this regime, "smart" mutants become practically attractive because less human effort is required in the process.

**Model Selection.** The choice of LLM is an important practical consideration, because the effectiveness of our approach depends on it. For example, one test-aware instance (GPT 4.1 Mini AGENT2-TA) underperforms compared to the test-blind alternative (AGENT1-TB with Gemini 3 Flash and Qwen3-32B). Besides success rate, the fault subtlety and token cost are also affected. Our results suggest practical guidelines for deploying test-aware mutation: When the computational budget is strict, smaller models like GPT 5.1 Codex Mini save token costs. However, to maximize the discovery of subtle edge-case faults, frontier models like Gemini 3.1 Pro are recommended despite the higher API costs.

**Why Single-Prompt Test-Awareness Helps.** The most clear finding in this study is that simply providing the base tests in the prompt only produces more effective, subtle mutants over test-blind generation. This improvement is visible not only in overall success rates, but also in the status distribution: Moving from test-blind to test-aware prompting shifts a substantial portion of outputs from REJECTED to SUCCESS. The interpretation for such a trend is that once the model can see which behaviors are already checked, it becomes better at avoiding trivial mutations that are immediately killed by the base suite. In that sense, the main value of test-awareness is not only that it helps the model generate bugs, but also that it helps it generate bugs specifically aligned with existing test gaps.

**The Dependency on Base Test Quality.** Our results show that even few test cases can provide useful context for LLM-based mutant generation. In EvalPlus, where each problem has only few (7.7 tests on average per HumanEval problem and 3 for MBPP) base tests, access to those tests still substantially improves effectiveness over the test-blind setting. At the same time, this also highlights a limitation of the approach: An LLM can only exploit shortcomings that are actually expressed in the provided tests. Because we did not systematically vary base-test quality or coverage, this study does not establish exactly how performance changes as the initial suite becomes stronger or weaker. That dependency remains an important direction for future work.

**No Oracle in the Real World.** Our evaluation relies on the extended EvalPlus tests as an oracle for determining whether a mutant that survives the base tests is actually non-equivalent. This is useful for controlled benchmarking, but it is not representative of most real-world development settings, where no such oracle is available. In practice, a surviving mutant would not automatically come with a ground-truth label; instead, it would signal that the current test suite may be missing a behavior worth checking. The main value of our setup is therefore methodological: It lets us verify that adding tests to the prompt helps LLMs find faults that the original suite misses. In real workflows, these mutants should be interpreted primarily as concrete suggestions for stronger tests and developer inspection rather than automatically validated defects. Identifying high-quality mutants makes it generally easy to specify an additional high-quality unit test to strengthen the test suite.

**Practical Implications.** Our findings indicate that test-aware LLMs can aid as review assistants in continuous integration (CI), directly improving software engineering workflows. During pull requests, models could analyze modified code and tests to generate targeted mutants, providing developers actionable suggestions for stronger unit tests.

## 6 Threats to Validity

We identify and address the following potential threats to validity in our work:

(a) **Internal Validity: Sparse Base Tests.** Bypassing only a handful of human-written base tests may appear to be a low bar for modern LLMs. However, we view this circumstance as a plausible representation of real-world codebases, where developers often have only basic assertions in place, before moving on to subsequent tasks. The aim of this study is not to show that LLMs are better than humans at generating mutants, but rather that they can achieve what a human developer with abundant time would do: uncover gaps in a test suite to make it stronger.

(b) **Construct Validity: Lack of Human Review.** Our evaluation pipeline is fully autonomous, which raises the question how reliable the mutant classification is. We highlight our careful experimental setup: The four classes are designed to be mutually exclusive and cover all distinct scenarios, with Invalid, Rejected, and Success being clearly defined and automatically verifiable. Only the last category leaves room for error, considering that Undetected mutants can either be fully valid code or contain a bug sneaky enough to go unnoticed by the strong extended test suite. To mitigate this threat, we perform a qualitative analysis, see Section 4.2. We find that most of such undetected cases in the best model-prompt combination are in fact serious faults, revealing that if we had a perfect oracle, this would only further improve the success rates. While EvalPlus serves as a robust automated oracle, we emphasize that it is a proxy rather than a definitive ground-truth measure of mutant quality in industrial settings.

(c) **External Validity: Benchmark Limitations.** Our study evaluates self-contained Python benchmarks rather than complex production systems. We consider this sandbox setting a crucial first step, deliberately using EvalPlus as a controlled pipeline for reliable and transparent results. However, industrial codebases introduce technical complexities such as larger test suites, stateful functions, and multi-file dependencies. This could exceed an LLM's context window and dilute its focus. Scaling to production-level datasets like Defects4J [11] may require iterative prompting to navigate stateful executions and retrieval-augmented generation (RAG) [13] to fetch relevant unit tests.

(d) **External Validity: Model Constraints.** LLM performance inherently varies across models and provider-side policies. We mitigate this threat by evaluating five diverse LLMs, confirming that the benefits of test-aware prompting generally hold across different models. A discussion on the practical trade-offs of model selection is provided in Section 5.

## 7 Conclusion & Future Work

This paper explores whether a test-aware prompting strategy can turn LLMs into targeted mutant generators rather than generic bug injectors. Across HumanEval and MBPP, the answer is yes: Giving the model access to the existing tests substantially improves verified fault generation over both matched test-blind prompting and the rule-based baseline mutmut. Two broader findings stand out. First, the largest gain from test-awareness is not a universal reduction in oracle kill rate, but a significant increase in the number of verified, useful

mutants produced at comparable subtlety. Second, although test-blind prompting can reduce tokens per generation due to less input and thinking tokens, test-aware prompting is more cost-effective per verified mutant because it wastes less computation on outputs that never become useful faults. Overall, our results suggest that test-aware prompting is a practical and lightweight alternative to both exhaustive rule-based mutation and heavier iterative multi-agent systems. More broadly, they indicate that when existing tests are available, LLMs can use them not only as a constraint, but also as a signal for where the test suite is still weak. This finding could substantially improve automated mutant generation, and ultimately lead to stronger test suites.

Our empirical findings pave the way for future work. For example, researchers with access to well-tested industrial code repositories could evaluate our pipeline by splitting their test suite into a handful of base tests and leaving the rest as oracle tests, pretending these are not yet part of the test suite. We hypothesize that this would replicate our finding that test-awareness leads to an increase in success rate. Additionally, as LLMs scale, further research is needed to quantify the computational and environmental trade-offs of this approach. This includes comparing the energy consumption and $CO_2$ emissions of local versus cloud-hosted inference, and analyzing whether next-generation models with extended reasoning capabilities can further optimize the amortized cost per fault.

## Data Availability Statement

We make all code and data publicly available as open artifacts. Our code repository is available at `https://github.com/codingWhale13/test-aware-mutants`. The generated data is available at `https://zenodo.org/records/20195774` under a CC-BY 4.0 license. To reproduce the plots in this paper, rename the unzipped folder to "result", place it at the root of the code repository, and follow the instructions in the repository's README file.

# Does Fixing Break Security? An Empirical Study of Security Degradation in Iterative LLM-Driven Infrastructure-As-Code Repair

**Benjamin Agyekum**
Department of Electrical Engineering, Colorado State University, Fort Collins, CO, USA

**Fabio Santos**
Department of Computer Science, Colorado State University, Fort Collins, CO, USA

## Abstract

**Background.** Iterative feedback loops have become the dominant paradigm for improving LLM-generated Infrastructure-as-Code (IaC): validators such as Checkov and `terraform validate` feed error signals back to the model for successive repair attempts. Prior work reports *cumulative-best* metrics, which are monotonically non-decreasing by construction, so the raw per-iteration security trajectory has never been examined in the IaC domain.

**Aims.** We study *security regression* (a previously-passing CIS Benchmark check that fails after a repair iteration) to determine whether, and how often, iterative LLM repair degrades security while fixing other issues.

**Method.** We analyze 5,968 scenario timelines from the IaC-Eval benchmark, each one scenario run through one configuration for up to 5 repair iterations. The 15 configurations comprise six model-specific RAG and nine model-aggregated non-RAG configurations, three temperatures each, and together they yield 4,440 iteration transitions with Checkov data on both sides. We track 30 individual CIS check IDs and classify regression root causes from code diffs, under two detection modes: *standard* (inclusive) and *strict* (exclusive check failures only).

**Results.** Under standard (inclusive) detection, 13.8% of scenarios (24.8% of transitions) exhibit at least one regression. Under strict detection, which counts only unambiguous, exclusive check failures, the rate falls to 3.3% of scenarios (5.2% of transitions). This gap indicates that most apparent regressions are multi-resource measurement artifacts rather than genuine exclusive failures. Resource restructuring (79.0%) is the dominant root cause. Regression transitions show 2.6× more code churn (Cohen's $d = 0.90$) and 4.9× higher strict-mode check volatility ($d = 1.49$). Of standard-mode regressions, 36.6% self-correct within an average of 1.2 iterations, and iteration 3 is the optimal stopping point.

**Conclusions.** Iterative IaC repair does introduce security regressions, but most *apparent* regressions are multi-resource measurement artifacts. The conservative, defensible rate is approximately 3.3% of scenarios. Our findings motivate security-aware feedback-loop design and provide actionable iteration-budget guidance.

## 1 Introduction

Infrastructure-as-Code (IaC) has become the standard for managing cloud infrastructure, with Terraform serving as the leading declarative provisioning tool [14]. Ensuring security compliance of generated code remains a critical challenge, even after the rise of large language models (LLMs) that are increasingly adopted for automated IaC generation [20, 28]. Studies report that, depending on prompting strategy and validation method, 12–65% of LLM-generated code violates secure coding standards [2]. IaC-specific evaluations find only 7% of generated scripts are secure without explicit security guidance [12].

An increasingly explored approach to improve generated IaC is *iterative feedback*: running static analysis tools (e.g., Checkov [5], terraform validate) on the generated code and feeding error messages back to the LLM for successive repair attempts [20, 28]. Prior work reports promising results from such feedback loops [20, 28]. However, these studies uniformly report *cumulative-best* metrics: the highest compliance achieved across all iterations. These are monotonically non-decreasing by construction and may mask important dynamics in the repair trajectory.

Recent studies on general-purpose code repair have raised alarms about *security degradation*: the phenomenon where iterative LLM repair introduces new vulnerabilities while fixing existing issues. Shukla et al. [25] found a 37.6% vulnerability increase after 5 iterations in C and Java, and Chen et al. [7] demonstrated that 43.7% of GPT-4o iteration chains contain more vulnerabilities than the baseline. Crucially, Chen et al. showed that Static Application Security Testing (SAST)-based gating can *worsen* latent degradation, raising questions about whether Checkov-based feedback in IaC suffers similar effects.

Security regression is a known problem in traditional software evolution. Braz et al. [4] found that regression vulnerabilities in Mozilla are introduced by bug fixes themselves, and security is rarely discussed while the fix is made. Felderer and Fourneret [11] provide a taxonomy of security regression testing approaches. However, no study has investigated security regression specifically in the IaC domain with CIS compliance tracking. IaC differs fundamentally from general code: it is declarative rather than imperative, security checks map to specific configuration properties rather than data/control flow, and validators like Checkov operate at the resource level with enumerable check IDs. This resource-level structure is not a cosmetic difference: because one check can apply to several resources within a single configuration, IaC admits a class of *multi-resource ambiguity* that general-code, CWE-based degradation studies cannot exhibit. As we show, this ambiguity accounts for the majority of apparent regressions. Studying regression in IaC therefore requires a detection methodology without direct analogue in prior general-code work: the *standard/strict* distinction we formalize in Section 4.

This paper presents the first large-scale empirical study of security regression in iterative LLM-driven IaC repair. We analyze 5,968 scenario timelines from the IaC-Eval benchmark [16] across 15 configurations (two RAG models and three non-RAG prompting strategies, each run at three temperatures), tracking 30 individual Checkov check IDs mapped to CIS AWS Foundations Benchmark controls [9] across up to 5 repair iterations. Our study addresses four research questions:

- **RQ1**: Does iterative LLM repair introduce security regressions in IaC?
- **RQ2**: What types of security controls are most vulnerable to regression?
- **RQ3**: How do prompting strategy, model, and temperature affect regression?
- **RQ4**: Is there a security-correctness trade-off in iterative IaC repair?

We make four contributions. This is the first large-scale empirical study of security regression in IaC repair, covering 5,968 scenario timelines, 4,440 transitions, and 30 check IDs across 15 configurations, based on single runs per configuration. From it we derive a taxonomy of regression root causes: in standard mode, resource restructuring accounts for 79.0%, configuration drift 15.5%, argument removal 3.6%, and 1.9% remain unclassified. We quantify the security-correctness trade-off, showing that regression transitions carry 2.6× more code churn and 4.9× higher strict-mode check volatility. Finally, we show that the standard and strict detection modes support qualitatively different conclusions, since the Mistral gap vanishes and RAG reverses between them, and we draw practical guidance from this: stop at iteration 3, expect 36.6% of regressions to correct themselves, and prefer RAG where exclusive regressions matter most.

## 2 Background and Motivation

**CIS Benchmarks and Checkov.** The Center for Internet Security (CIS) AWS Foundations Benchmark v1.5.0 [9] defines security controls for AWS infrastructure. Checkov [5] is a widely-adopted static analysis tool that maps these controls to concrete checks on Terraform configurations. Each Checkov check has a unique ID (e.g., `CKV_AWS_145` for S3 encryption) and can either PASS or FAIL for each resource in a Terraform plan. We map Checkov checks to six security categories: *encryption*, *access control*, *logging*, *networking*, *data protection*, and *other*.

**Iterative LLM-Based IaC Repair.** The standard IaC feedback loop generates Terraform code from a natural-language prompt, validates it (`terraform validate` for syntax, Checkov for security), summarizes any errors back to the LLM for regeneration, and repeats for up to $K$ iterations. Each pair of consecutive iterations (e.g., 0→1) constitutes an *iteration transition*, the unit at which we measure regression. This paradigm is used by TerraFormer [15] and Palavalli et al. [20].

**The Hidden Problem of Cumulative-Best Metrics.** Prior work on iterative IaC repair universally reports *cumulative-best* metrics: the highest compliance rate achieved up to iteration $k$. These are monotonically non-decreasing by construction. The *raw per-iteration trajectory*, however, may contain regressions. Figure 1 illustrates this gap. Across 5,968 scenario timelines the cumulative-best CIS pass rate rises from 73% to 83%, yet the raw trajectory *dips* at iteration 5 (82.6% vs. the 83.4% peak at iteration 4) as previously-passing checks fail.

## 3 Related Work

**Security of AI-Generated Code.** AI-generated code consistently shows security weaknesses: 29.5% of Python Copilot snippets are vulnerable [13], zero-shot security accuracy is only 37.44% [17], and 12–65% of LLM code violates secure-coding standards [2]. Sajadi et al. [23] found LLMs introduce distinctive vulnerability patterns in automated patches, and Yan et al. [29] found that although over 98% of GPT-4o vulnerability explanations are accurate, guided repair does not always eliminate the underlying issue. We instead track security *changes across iterations* rather than static snapshots, in the IaC domain.

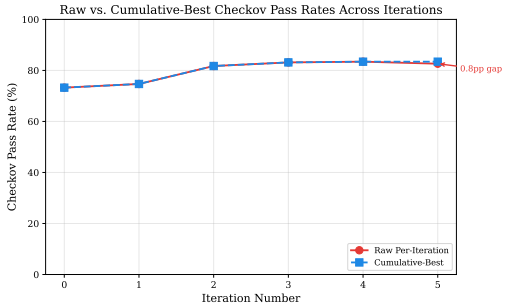

**Figure 1** Raw per-iteration vs. cumulative-best Checkov pass rate (5,968 scenario timelines). The raw trajectory *dips* at iteration 5 (82.6% vs. 83.4%), a regression cost masked by cumulative-best reporting.

**RAG for Secure Code Generation.** RAG improves LLM code security by grounding generation in verified references. Sriram et al. [26] combined RAG with multi-tool feedback (compiler, CodeQL, KLEE) and found retrieval context significantly reduces vulnerabilities, and RESCUE [24] retrieves secure coding patterns at generation time for substantial CWE reduction. Both show RAG's value for *initial* security but not its stability across iterative repair. Our RAG pipeline grounds generation in CIS documentation and Terraform schema chunks. We find this yields more multi-resource outputs (raising standard-mode counts) but fewer exclusive failures (lowering strict-mode regressions).

**IaC-Specific Security and Compliance.** Recent IaC work spans generation, validation, and security. TerraFormer [15] combines fine-tuning with policy-guided verifier feedback (+15.94% on IaC-Eval), and Zhang et al. [30] use DevOps simulation as feedback to improve deployment success. TerraFault [28] uses LLM agents to find bugs in IaC updates via plan-level diffs, complementary to our check-level analysis. Firouzi et al. [12] found only 7% of LLM-generated IaC secure without explicit guidance. GenSIaC [18] and Diaz et al. [10] pursue security-aware generation and self-healing, while Palavalli et al. [20] showed feedback effectiveness decays exponentially to a plateau. To the best of our knowledge, we are the first to analyze the per-iteration security trajectory of IaC repair, tracking individual check regressions rather than aggregate compliance.

**Iterative Code Repair with LLMs.** Iterative LLM feedback is widely applied to code repair. Self-Refine [19] showed ∼20% gains from LLM self-critique. RepairAgent [3] reaches state-of-the-art bug repair on Defects4J via multi-tool orchestration, and LLMLOOP [21] improves functional correctness through generation–test feedback. Tang et al. [27] model repair as an exploration–exploitation trade-off in which LLMs under-explore, and Cheng [8] proposes a Detect-Repair-Verify pipeline that evaluates repair side effects, finding repair can introduce new vulnerabilities. These works target functional correctness. None analyze whether iterative repair preserves security properties in IaC, which is our focus.

**Security Degradation in Iterative LLM Code Generation.** Security regression is well documented in traditional software evolution. Braz et al. [4] studied 78 regression vulnerabilities at Mozilla and found they are introduced by bug fixes themselves. Felderer and Fourneret [11] give a taxonomy of security regression testing. For LLMs, Shukla et al. [25] found a 37.6% vulnerability increase after five iterations of AI code generation, and Chen et al. [7] showed that 43.7% of GPT-4o iteration chains exceed baseline vulnerability counts and that SAST-based gating can *worsen* latent degradation (12.5%→20.8%).

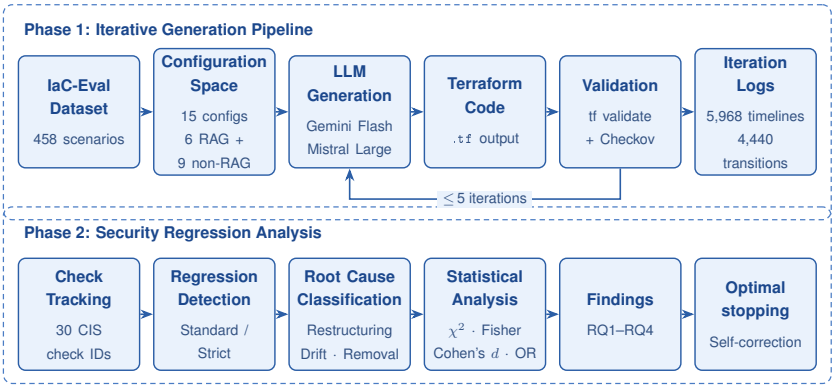

**Figure 2** Study overview. Phase 1 generates Terraform through an iterative feedback loop (up to five iterations) across 15 configurations, yielding 5,968 timelines with 4,440 transitions. Phase 2 tracks 30 CIS check IDs to detect, classify, and quantify regressions under standard and strict modes.

Our study is best read as a conceptual replication and extension of Shukla et al. [25] in the IaC domain. We preserve the core design: iterative LLM repair with security measured after every iteration, making degradation visible inside the repair trajectory. We adapt the measurement apparatus to IaC, from imperative C and Java to declarative Terraform, and from multi-tool static analysis with manual review to Checkov's enumerable check IDs mapped to CIS controls. We extend the design with components absent from the original study: transition-level detection that judges each iteration against its immediate predecessor rather than cumulative vulnerability growth, dual standard/strict detection, a diff-based root-cause taxonomy, self-correction and oscillation analysis, retrieval-augmented configurations, and optimal-stopping analysis.

## 4 Study Design

Figure 2 presents an overview of our two-phase methodology.

### 4.1 Dataset and Configurations

We used the IaC-Eval benchmark [16] containing 458 Terraform generation scenarios spanning various AWS services. Each scenario specifies a natural-language infrastructure requirement to be translated into Terraform code.

We evaluated four prompting strategies at three temperatures, which, with RAG analyzed separately per model, give 15 analysis configurations.

- **Prompting strategies** (4): Zero-Shot, Few-Shot, Chain-of-Thought (CoT), and RAG (Retrieval-Augmented Generation with CIS benchmark context). RAG is analyzed separately for each model, giving two groups, while each of the other three forms a single group, for five groups in total.
- **Temperatures** (3): 0.1, 0.4, and 0.7

These five groups at three temperatures give 15 configurations: six RAG (2 models × 3 temperatures), analyzed per model, and nine non-RAG (3 strategies × 3 temperatures), which are not. Both models were run with all four prompting strategies and neither was discarded. The difference is in what the experiment recorded. Every RAG run is stored together with the model that generated it, whereas the non-RAG runs are not, so an individual non-RAG

run cannot be traced back to Gemini or Mistral. Where a scenario was executed more than once under the same non-RAG strategy and temperature, we keep the most recent execution, so each non-RAG timeline is one run from one model rather than an average of the two. For the 36% of non-RAG timelines whose model can still be determined, the split is 66% Gemini to 34% Mistral (893 and 461 of 1,354), so these groups lean toward Gemini rather than being balanced. We analyze each as a single group whose model composition is estimated rather than known.

Running one scenario under one configuration produces a *timeline*: the ordered sequence of code versions from the initial generation (iteration 0) through up to five repair iterations. A timeline ends early once the code passes all checks or the iteration budget is exhausted, so timelines range from a single generation to six versions.

**Configuration rationale.** The four strategies span the guidance spectrum of prior IaC-generation work: Zero-Shot provides only the task and a security-oriented system prompt. Few-Shot adds three input–output examples. Chain-of-Thought adds an explicit reasoning trace to essentially the same examples. RAG moves to per-query retrieved context from CIS documentation and Terraform schemas. The first three steps each add a single ingredient, permitting descriptive comparison. RAG changes several things at once (its own system-prompt template, no static examples, retrieved context), so we compare it as a paradigm rather than one more increment.

Gemini 2.0 Flash and Mistral Large Latest are production-oriented models from independent vendors, both publicly available at data-collection start (December 2024). Temperatures 0.1, 0.4, and 0.7 cover the lower and middle part of the 0–1 range explored in code-generation evaluations, where low temperatures suit the single-sample setting we use, and higher ones mainly help when many samples are drawn per task [6]. The negligible effect we observe (Cramér's $V = 0.049$) is consistent with reports that sampling temperature has little influence on task accuracy [22].

We excluded agent-based and self-refinement approaches because they replace the validator-in-the-loop paradigm whose per-iteration behavior we measure (Section 2).

We ran each configuration up to five feedback iterations per scenario, validating with Terraform v1.6.0 (`terraform validate`) and Checkov v3.2.392. Versions were locked at data collection start, December 2024, for reproducibility. Every iteration was recorded with its full Terraform code and individual check results. We limited the feedback loop to five iterations, following prior IaC feedback work that found repair effectiveness plateaus after roughly five iterations [20]. Our regression analysis reconstructs timelines from these per-iteration records, which is where the model attribution described above is lost. We therefore analyzed the six RAG configurations at the model level, Gemini and Mistral, and, for each non-RAG strategy and temperature, analyzed one timeline per scenario. This precludes a model-controlled comparison outside the RAG setting (see Section 7).

The three non-RAG strategies shared a single system prompt that instructed the model to generate CIS-compliant Terraform, combining general directives (least-privilege IAM, encryption at rest, logging, restricted network access) with resource-specific guidance (e.g., configuring S3 public-access controls through a separate `aws_s3_bucket_public_access_block` resource). Few-Shot appended three input–output pairs that map a natural-language request to complete HCL (e.g., "Create an AWS RDS instance ... with randomly generated id and password"). Chain-of-Thought appended essentially the same three example scenarios, each preceded by a reasoning trace that enumerated the required resources, filled in their attributes, and then wired the resources together. RAG used a separately maintained system-prompt

template covering the same core security directives, into which the retrieved CIS-control and resource-schema chunks are injected at query time. The complete templates are included in the replication package [1]. Both models were run with all four strategies. As noted above, only the RAG logs record which model produced each iteration.

## 4.2 Regression Detection

We define a *security regression* as follows:

▶ **Definition 1** (Security Regression). *Given consecutive iterations $i$ and $i{+}1$ of a scenario where both have Checkov results, a regression occurs for check $c$ if $c \in PASSED(i)$ and $c \in FAILED(i{+}1)$.*

Transitions are formed only between consecutive iterations with *distinct* indices. Where a scenario has two records sharing an iteration index, that pair is excluded: it reflects a repeated attempt at the same step rather than a repair step. We employed two detection modes. **Standard**: any check ID that is in the passed set at iteration $i$ and in the failed set at iteration $i{+}1$ counts as a regression, regardless of whether it also appears in the passed set (multi-resource scenarios). **Strict**: A check must be *exclusively* passed (not in failed) in iteration $i$ and *exclusively* failed (not in passed) in iteration $i{+}1$. This excludes ambiguous multi-resource cases. Strict detection trades sensitivity for unambiguity: it can miss genuine degradations that affect only a subset of a configuration's resources. For example, suppose two S3 buckets pass CKV_AWS_145 (S3 encryption) at iteration $i$; at $i{+}1$ the LLM restructures the code, and one bucket now fails the check. *Standard* mode counts this as a regression (the check is in both the passed and failed sets). *Strict* mode does not (CKV_AWS_145 is not exclusively failed: it still passes for one bucket). We return to this trade-off in Section 7.

## 4.3 Metrics

Five metrics quantify regression prevalence, the size of the code changes that accompany it, and how often the loop recovers. The *scenario regression rate* is the fraction of scenarios with $\geq$1 regression event, and the *transition regression rate* the fraction of transitions with $\geq$1 regression. *Code churn* covers both lines changed and the text similarity ratio between consecutive iterations, where 0 is completely different and 1 identical. *Check volatility* is $V = |C_{\text{new}}| + |C_{\text{removed}}| + |C_{\text{flipped}}|$, where $C_{\text{new}}$ are checks appearing for the first time at iteration $i{+}1$, $C_{\text{removed}}$ are checks present at iteration $i$ but absent at $i{+}1$, and $C_{\text{flipped}}$ are checks changing status, either pass→fail or fail→pass. The *self-correction rate* is the fraction of regressed checks that return to passing later in the same scenario timeline, reported in Section 6.

For RQ4 we additionally examined two derived transition classes. A *post-syntax-fix transition* is one whose prior iteration was syntactically invalid and whose current iteration is valid for the first time, isolating the effect of syntax repair on security. A *syntax-struggled timeline* is a scenario whose iteration sequence contained at least one invalid-syntax iteration, as opposed to a *clean timeline* that was syntactically valid throughout. We compared regression rates between these two groups.

The self-correction rate, root-cause taxonomy, and temporal patterns are reported as deeper analyses in Section 6.

**Table 1** Dataset Summary.

| Metric | Value |
|---|---|
| IaC-Eval scenarios | 458 |
| Configurations analyzed | 15 |
| Max iterations per scenario | 5 |
| Total iteration log files parsed | 36,736 |
| Unique scenario timelines | 5,968 |
| Transitions with Checkov data | 4,440 |
| Individual Checkov check IDs tracked | 30 |
| CIS security categories | 6 |

## 4.4 Root Cause Classification

For each regression transition, we classify the root cause from the code diff using four mutually exclusive categories, in order of priority. A transition is *resource restructuring* if the number of Terraform resource blocks changes by $\geq$2, or if resource types appear or disappear between iterations. The threshold of 2 separates structural rewrites from single-resource edits, where a $\pm$1 block change is common and would over-trigger the category. Failing that, it is *argument removal* if security-relevant arguments were deleted: the classifier scans removed diff lines for patterns in five groups, covering encryption (`encrypt*`, `kms_key`, `storage_encrypted`, `ssl_policy`), access control (`policy`, `iam_role`, `acl`, `block_public`), logging (`logging`, `flow_log`, `cloudwatch`, `trail`), networking (`security_group`, `cidr_block`, `ingress`, `waf`), and versioning or backup (`versioning`, `backup`, `deletion_protection`). The full regular-expression set is in the replication package [1]. Failing both, it is *configuration drift* if text similarity between iterations exceeds 0.85, meaning small changes flipped a check's status. The 0.85 cutoff separates near-identical edits, such as a single property change, from substantial rewrites, and we treat it as a heuristic (Section 7). Anything left, such as a diff that failed to parse, is *unclassified*.

## 4.5 Statistical Methods

We used chi-squared tests for categorical associations, Mann-Whitney $U$ tests for continuous variables (code churn, volatility), Fisher's exact test for 2$\times$2 tables, and Wilson score intervals for confidence intervals. Effect sizes are reported as Cramér's $V$ (categorical), Cohen's $d$ (continuous, used for interpretability despite non-parametric testing), and odds ratios (binary). All tests used $\alpha = 0.05$. We apply Bonferroni family-wise error rate control within each research question. RQ2 corrects $k = 6$ post-hoc category comparisons ($\alpha_{\text{adj}} = 0.0083$). RQ3 corrects $k = 4$ omnibus configuration-factor tests (model, strategy, RAG vs. non-RAG, temperature) and RQ4 $k = 4$ independent tests, both at $\alpha_{\text{adj}} = 0.0125$. All reported effects remain significant after correction. Detailed test specifications are in the replication package [1].

## 4.6 Scale

Table 1 summarizes our dataset. Of a theoretical maximum of $458 \times 15 = 6{,}870$ scenario-configuration pairs, 902 (13%) are absent due to API rate-limit errors, provider timeouts, or scenarios that produced no parseable output. Applying the deduplication and same-iteration rules (Sections 4.1 and 4.2) leaves 5,968 scenario timelines and 4,440 iteration transitions with Checkov data on both sides.

**Table 2** Regression events by security category (Standard / Strict).

| Category | Standard | | Strict | |
|---|---|---|---|---|
| | Count | % | Count | % |
| Access control | 1,017 | 38.5 | 26 | 9.2 |
| Data protection | 684 | 25.9 | 7 | 2.5 |
| Encryption | 357 | 13.5 | 61 | 21.6 |
| Networking | 375 | 14.2 | 120 | 42.6 |
| Logging | 152 | 5.8 | 38 | 13.5 |
| Other | 54 | 2.0 | 30 | 10.6 |
| **Total** | **2,639** | | **282** | |

# 5 Results

The four research questions build on one another: RQ1 measures how often regressions occur, RQ2 where they concentrate, RQ3 which configurations amplify them, and RQ4 what code-level behavior accompanies them. Section 6 then examines causes, timing, and stopping policy.

## 5.1 RQ1: Does Iterative LLM Repair Introduce Security Regressions?

In the standard analysis, of the 5,968 scenario timelines, 823 (13.8%, 95% CI: [12.9%, 14.7%]) exhibit at least one security regression event. Across the 4,440 transitions with Checkov data on both sides, 1,103 (24.8%, CI: [23.6%, 26.1%]) contain at least one regression, producing 2,639 total regression events.

Under strict detection (excluding ambiguous multi-resource cases), 194 scenarios (3.3%, CI: [2.8%, 3.7%]) exhibit regression, with 282 total events across 231 transitions (5.2% of transitions, CI: [4.6%, 5.9%]). Scenarios fall 4.2×, from 823 to 194. Transitions fall comparably, 1,103 to 231. Approximately 76% of standard-mode-flagged scenarios are not flagged in strict mode, consistent with multi-resource ambiguity rather than exclusive check failures. We use the scenario-level 76% as the headline artifact fraction.

We measure the fraction of scenarios with ≥1 regression event (13.8% standard, 3.3% strict), while Shukla et al. [25] measure cumulative vulnerability growth (37.6% after 5 iterations in C and Java). Metric differences limit direct comparison. The lower IaC rates may reflect its declarative nature and structured validation, but a definitive comparison requires metric alignment across domains.

**Finding:** 13.8% of IaC scenario timelines experience security regression in iterative repair, lower than general code (37.6%) but still substantial. Strict analysis shows 3.3%, indicating most regressions involve multi-resource ambiguity.

## 5.2 RQ2: What Types of Security Controls Are Most Vulnerable?

RQ1 established how often regressions occur. RQ2 asks where they land. Table 2 shows the regression distribution across security categories. Regression events are highly concentrated rather than spread evenly across the six categories: a chi-squared goodness-of-fit test against a uniform reference rejects an even split ($\chi^2 = 1445$, $p < 0.001$, Cramér's $V = 0.33$, medium-to-large effect). We report this test only to quantify the skew (uniformity is not a theoretically motivated null) and use the per-category breakdown below to identify its drivers.

In standard mode, *access control* dominates (38.5%), driven by three IAM-related checks: CKV_AWS_356 (298 events), CKV_AWS_111 (297), and CKV_AWS_109 (291). These checks evaluate IAM policy conditions, wildcard permissions, and role trust boundaries, properties frequently modified during code restructuring.

Strikingly, the category ranking *reverses* in strict mode: *networking* (42.6%) and *encryption* (21.6%) dominate, while access control drops to 9.2%. This reversal indicates that access control regressions are predominantly multi-resource ambiguity, while networking and encryption represent genuine exclusive check failures. The mechanism is structural: IAM scenarios typically generate multiple resources (e.g., `aws_iam_role` and `aws_iam_policy`) where a check like CKV_AWS_356 may pass for one resource but fail for another, creating standard-mode regressions without exclusive failure. In contrast, networking checks (e.g., VPC endpoints) and encryption checks (e.g., KMS key rotation) typically map one-to-one to resources, making multi-resource ambiguity rare.

**Operational impact.** Not all regressing checks carry equal risk. The three most frequently regressing checks all govern IAM privilege boundaries, among the highest-impact misconfigurations operationally: CKV_AWS_356, CKV_AWS_111, and CKV_AWS_109 (886 events, 33.6% of all standard-mode regressions). Aggregating by category, the high-impact categories (access control, encryption, networking) account for 1,749 events (66.3%), while advisory logging checks account for only 5.8%. This coarse lens indicates that regressions concentrate in the controls practitioners care about most, not in low-stakes advisory checks. A full severity- or exploitability-weighted analysis is future work.

**Finding:** Access control dominates standard regressions (38.5%) but drops to 9.2% in strict mode. Networking and encryption represent the most genuine regression risks, and the most frequent regressing checks (886 events, 33.6%) all govern IAM privilege.

## 5.3 RQ3: How Do Configuration Factors Affect Regression?

Knowing how often (RQ1) and where (RQ2) regressions strike, we next ask which configurations amplify them, examining four factors: model, prompting strategy, retrieval augmentation, and temperature. One caveat applies throughout. The logs record the generation model only for RAG runs, so non-RAG results aggregate over an unidentified model and may partly reflect model behavior rather than the named factor. We flag this in each affected result and return to it in Section 7.

In standard mode, the model effect is dramatic: Gemini's scenario regression rates range from 1.9% to 4.7% across temperatures, while Mistral ranges from 32.6% to 41.2%. Mistral scenarios are over 17 times more likely to regress (OR = 17.29, $p < 0.001$). However, this gap **vanishes entirely** in strict mode: neither RAG+Gemini nor RAG+Mistral produces a single strict-mode scenario regression (0 of 1,297 and 0 of 929 respectively), indicating that Mistral's elevated standard-mode rate stems from multi-resource ambiguity rather than exclusive check failures. RAG+Mistral transitions also exhibit substantially larger code changes than RAG+Gemini (median 32 vs. 8 lines changed), consistent with Mistral regenerating whole resource blocks and thus producing more multi-resource configurations.

Regression rates differ significantly across the five strategy/model groups. A 5×2 test of the five strategy/model groups in Table 3 against regressed vs. non-regressed scenario counts gives $\chi^2 = 596$, dof = 4, $p < 0.001$, Cramér's $V = 0.32$ (medium effect). Among non-RAG strategies, Chain-of-Thought achieves the lowest regression rates (8.2–9.6%), followed by Few-Shot (11.6–12.9%) and Zero-Shot (11.6–15.5%), which would suggest that more structured

**Table 3** Scenario regression rates by configuration and temperature. $N$ = scenarios analyzed. Reg = scenarios with ≥1 regression. RAG rows are reported per model. Non-RAG rows are not split by model (Section 4).

| | $t = 0.1$ | | | $t = 0.4$ | | | $t = 0.7$ | | |
|---|---|---|---|---|---|---|---|---|---|
| **Configuration** | $N$ | Reg | Rate | $N$ | Reg | Rate | $N$ | Reg | Rate |
| RAG + Gemini | 413 | 8 | 1.9% | 447 | 21 | 4.7% | 437 | 15 | 3.4% |
| RAG + Mistral | 138 | 45 | 32.6% | 439 | 161 | 36.7% | 352 | 145 | 41.2% |
| Zero-Shot | 354 | 55 | 15.5% | 458 | 53 | 11.6% | 458 | 62 | 13.5% |
| Few-Shot | 419 | 54 | 12.9% | 336 | 39 | 11.6% | 458 | 53 | 11.6% |
| Chain-of-Thought | 453 | 37 | 8.2% | 369 | 33 | 8.9% | 437 | 42 | 9.6% |

prompting reduces regression risk. That reading does not survive the model composition of these groups. Among the non-RAG timelines whose model can be determined (Section 4), Chain-of-Thought is 79% Gemini, Few-Shot 73%, and Zero-Shot only 46%, the same order as the regression ranking. Because Gemini regresses far less often than Mistral under RAG (1.9–4.7% vs. 32.6–41.2%), a ranking of this shape is what differing model mixes alone would produce. We therefore report the ordering as descriptive of the non-RAG configurations as deployed and draw no causal conclusion about prompting strategy.

The RAG effect *reverses* between modes. In standard mode, RAG has a *higher* regression rate: a 2×2 test of RAG vs. non-RAG scenarios against regressed-vs-non-regressed counts gives OR = 1.67, $p < 0.001$. In strict mode, however, RAG records *zero* scenario regressions, versus 4–6% for the non-RAG strategies. This means RAG produces *fewer exclusive regressions* but generates more multi-resource code structures that inflate the standard count (see Section 7 for the retrieval mechanism explanation). Note that this comparison is not controlled for model: the non-RAG timelines are not attributable to a specific model in our logs, whereas RAG includes both Gemini and Mistral.

Temperature has a statistically significant but practically negligible effect (a 3×2 contingency test over the three temperatures: $\chi^2 = 14.3$, $p < 0.001$, Cramér's $V = 0.049$). Higher temperatures show slightly elevated regression rates, but the effect size is minimal.

**Finding:** The model gap (Mistral 17× worse than Gemini in standard mode) vanishes entirely in strict mode (neither RAG model produces a single strict regression), revealing it as a multi-resource artifact. RAG reverses from worse to better between standard and strict analysis.

## 5.4 RQ4: The Security-Correctness Trade-off

The remaining question is mechanism: RQ4 tests whether fixing correctness comes at a security cost, from four angles: the code churn and check volatility of regressing transitions, the regression rate of transitions that immediately follow a syntax fix, and the regression rate of timelines that struggled with syntax.

We compare code churn between all Checkov-bearing transitions that contain a regression and those that do not, pooled across every strategy, model, and temperature. Transitions with regressions show significantly more code modification than those without: the average number of lines changed between consecutive iterations is 140.1 vs. 53.8, a 2.6× difference. The text similarity ratio between iterations also drops from 0.847 to 0.791, indicating that regression transitions involve more extensive rewrites. Mann-Whitney $U$ tests confirm significance ($p < 0.001$, Cohen's $d = 0.90$ for lines changed, large effect).

Check volatility measures the total number of check-level changes between consecutive iterations (Section 4). It is strongly elevated in regression transitions. In standard mode, average volatility is 5.17 with regression vs. 2.09 without, a 2.5× difference. In strict mode

**Table 4** Root cause classification of regression transitions.

| Root Cause | Standard | | Strict | |
|---|---|---|---|---|
| | Count | % | Count | % |
| Resource restructuring | 871 | 79.0 | 158 | 68.4 |
| Configuration drift | 171 | 15.5 | 46 | 19.9 |
| Argument removal | 40 | 3.6 | 19 | 8.2 |
| Unclassified | 21 | 1.9 | 8 | 3.5 |

it is even stronger: 11.55 vs. 2.38 (4.9×), with Cohen's $d = 1.49$, a very large effect and the single strongest signal in our study, making check volatility the strongest indicator of security regression.

In transitions immediately following a syntax fix, the prior iteration had invalid syntax, and the current iteration first achieves validity. These show a 21% higher regression rate than transitions between two already-valid iterations (28.1% vs. 23.3%, OR = 1.29, $p < 0.001$). The two groups partition the 4,440-transition universe: 1,449 and 2,991 transitions. Their regression counts, 407 and 696, sum to 1,103, the count underlying the 24.8% aggregate rate. This effect is not significant in strict mode after Bonferroni correction ($p = 0.045$, above the adjusted $\alpha = 0.0125$), suggesting that post-fix regressions are predominantly multi-resource ambiguity introduced when the LLM restructures code to achieve validity.

Finally, we analyze the syntax struggle paradox. Counter-intuitively, scenarios that *always* had valid syntax ("clean" timelines) show a *higher* regression rate than those that struggled with syntax errors: clean timelines regress in 20.8% of cases versus 12.1% for syntax-struggled timelines. A 2×2 test (clean vs. syntax-struggled timelines × scenarios with ≥1 regression vs. none) gives OR = 1.90 ($p < 0.001$). We discuss two candidate mechanisms for this counter-intuitive result in Section 7.

**Finding:** Larger code changes strongly predict regression (2.6× more churn, $d = 0.90$). Check volatility is the strongest predictor ($d = 1.49$ strict). Syntax-fixing transitions carry 21% higher regression risk.

# 6 Deep Dive Analysis

This section reports analyses that extend the four research questions rather than introducing new ones: the root-cause taxonomy and temporal patterns deepen RQ1 and RQ2 by characterizing *how* and *when* regressions arise, while the optimal-stopping analysis operationalizes the RQ4 security-correctness trade-off into a concrete iteration budget.

## 6.1 Root Cause Taxonomy

We classified the root cause of every regression transition (1,103 standard and 231 strict) from the code diff between consecutive iterations, using resource-block changes, text similarity, and deleted security arguments (Section 4). Table 4 shows the distribution.

**Resource restructuring.** (79.0%) is the dominant cause. The LLM adds, removes, or renames resource blocks while fixing validation errors, and the restructured code loses security configurations from the prior iteration. This is especially common in access control, reflecting how tightly IAM policies are coupled to resource structure.

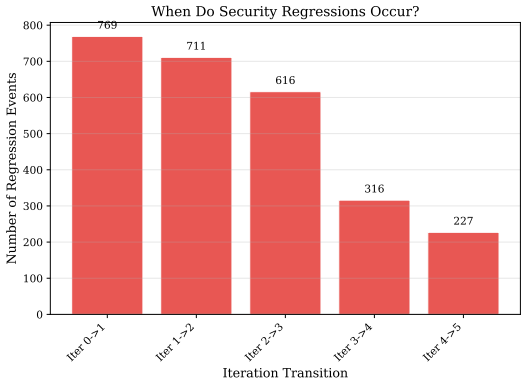

**Figure 3** Regression events by iteration transition: counts peak in early-to-middle transitions, then decline as code stabilizes.

**Configuration drift.** (15.5%) involves small modifications that flip a check's status, typically changing a single property value or adding/removing an attribute. It most often affects networking and encryption checks, where small changes to security-group rules or KMS key references can fail specific checks.

**Argument removal.** (3.6% standard, 8.2% strict) represents explicit deletion of security-relevant Terraform arguments. Its proportion more than doubles in strict mode, indicating these are genuine security regressions rather than ambiguous multi-resource artifacts.

**Temporal Patterns.** Beyond *which* checks regress, we examine *when* regressions occur across the iteration sequence, whether they are subsequently undone, and how often checks flip repeatedly.

**When Do Regressions Occur?** Figure 3 shows the distribution of regression events across iteration transitions. The highest counts occur early (0→1: 769 events, 1→2: 711, 2→3: 616), reflecting the larger number of scenarios still iterating. Normalized by per-slot transition counts, however, the per-transition *rate* peaks at 2→3 (29.5%) and 1→2 (26.6%), while 0→1 is lower (22.8%), consistent with the 24.8% aggregate rate. One plausible explanation, unconfirmed without per-transition modification analysis, is that early iterations make conservative fixes while middle iterations restructure more aggressively. Late iterations (4→5: 20.8%) show lower rates, possibly reflecting code stabilization.

**Self-Correction.** Of 2,639 standard-mode regressions, 967 (36.6%) self-correct in a subsequent iteration, meaning the regressed check returns to passing status later in the same scenario's repair timeline. On average, self-correction takes 1.2 iterations after the regression occurs (median: exactly 1), with 80.4% correcting within a single step (i.e., at the next repair iteration). This indicates that the feedback loop often catches and reverses its own mistakes. Self-correction is at least as common in strict mode (44.0%, mean 1.2 iterations). We report the standard-mode 36.6% as the headline figure because its far larger event pool (2,639 vs. 282 events) gives a more reliable estimate.

**Check Oscillation.** 28.5% of all scenarios (1,698 of 5,968) exhibit *oscillating* checks, i.e., checks that pass, then fail, then pass again (or vice versa) across iterations. The rate is identical under strict detection, as oscillation is a timeline property independent of the

**Table 5** Compliance vs. regression trade-off by iteration (standard mode). N varies as scenarios terminate upon full compliance or budget exhaustion. Average cumulative regressions may decrease when high-regression scenarios terminate earlier, leaving a lower-regression survivor pool.

| Iter | N | Avg Pass | Avg Cum. Reg | % w/ Reg |
|---|---|---|---|---|
| 0 | 2,649 | 73.2% | 0.00 | 0.0% |
| 1 | 3,151 | 74.7% | 0.28 | 13.0% |
| 2 | 2,726 | 81.7% | 0.49 | 17.8% |
| 3 | 1,878 | 83.1% | 0.68 | 20.8% |
| 4 | 1,393 | 83.4% | 0.64 | 18.8% |
| 5 | 1,029 | 82.6% | 0.94 | 23.3% |

multi-resource threshold. The three most oscillation-prone checks are all IAM-related: CKV_AWS_356 (925 timelines), CKV_AWS_111 (922), and CKV_AWS_109 (832), suggesting the LLM lacks stable strategies for complex IAM configurations and cycles between implementations satisfying different subsets of checks.

**Optimal Stopping Point.** Table 5 combines average pass rate and cumulative regression data to identify the optimal stopping point. The "N" column counts timelines with Checkov data at each iteration: it rises from iteration 0 to 1 (2,649 → 3,151) as initially invalid scenarios become checkable, then falls as scenarios reach full compliance or exhaust their budget.

Iteration 3 offers the best trade-off. We anchor this recommendation on the pass-rate trajectory, which is the more reliable of the two signals: the pass rate reaches 83.1% at iteration 3, within 0.3pp of the 83.4% maximum at iteration 4, and then *decreases* to 82.6% at iteration 5. If we define marginal gains as <0.5pp (with ∼30 tracked checks, 0.5pp ≈ 0.15 checks), the iteration 3→4 gain falls below this threshold, so iteration 3 captures essentially all attainable improvement.

The average cumulative-regression column tells a consistent but weaker story, and we treat it as secondary because it is *not monotone*: it rises 0.00→0.68 through iteration 3, dips to 0.64 at iteration 4, then rises to 0.94 at iteration 5. The dip is a survivor-bias artifact, since high-regression scenarios disproportionately terminate by iteration 3 and leave a lower-regression survivor pool, so the column alone cannot serve as a stopping criterion. It does show that regressions keep accumulating past iteration 3. This matches Palavalli et al.'s [20] finding of exponential feedback decay and suggests that adaptive stopping policies (e.g., halt when $\Delta$pass_rate $<$ 0.5pp for two consecutive iterations) could optimize the compliance-regression trade-off per scenario.

## 7 Discussion

Our results tell a single story. Iterative repair does break previously-passing checks (RQ1), concentrated in IAM, networking, and encryption controls (RQ2). The damage tracks how much code is rewritten far more than any configuration knob (RQ3–RQ4). Much of what standard detection flags is multi-resource bookkeeping rather than exclusive failure. The implications below follow from this reading. The following design hypotheses for IaC tooling are motivated by our observations. None has been implemented or evaluated in this study. We offer them as directions for future tooling rather than validated solutions.

**Security anchoring.** The dominant root cause, resource restructuring (79.0%), suggests that LLMs should be constrained to make *minimal modifications* during repair rather than regenerating entire resource blocks. A "security anchor" mechanism could lock passing checks and only modify failing ones.

**Check-aware feedback.** Current feedback loops report all errors without distinguishing new failures from pre-existing ones. Explicitly flagging regressions ("Warning: CKV_AWS_145 was passing but now fails") could prevent the LLM from unknowingly degrading security.

**Iteration budgets.** Our finding that iteration 3 is the optimal stopping point supports a conservative iteration budget. Tools should not blindly iterate to convergence. Three iterations capture most of the compliance improvement while keeping regression risk manageable.

**Choosing a configuration.** Our results support cost- and risk-differentiated guidance rather than a single recommendation. Where retrieval infrastructure is unavailable or too costly, Chain-of-Thought showed the lowest non-RAG regression rates (8.2–9.6%) at no infrastructure cost beyond a longer prompt. That ranking tracks the model mix of the non-RAG groups rather than the strategies themselves (Section 5), so it is descriptive rather than causal. Where stability of individual security properties is paramount, RAG is preferable, since it produced zero strict-mode regressions. Its price is maintaining a retrieval index and triaging the standard-mode alerts that its multi-resource output generates. In either case the iteration budget above applies. Check volatility is cheap to compute online and is the strongest regression signal in our data ($d = 1.49$, strict mode). Halting or flagging a repair loop when volatility spikes offers regression protection at negligible cost. A single regression event, by contrast, is a premature halting signal: 36.6% of regressions self-correct within the loop.

**Standard vs. Strict: Two Valid Perspectives.** The dramatic differences between standard and strict analysis (13.8% vs. 3.3% scenario rate, Mistral 17× worse in standard mode vs. zero RAG regressions in strict) reflect a fundamental tension in how regression is defined for multi-resource IaC. Standard mode captures the practitioner view: any degradation of a check for *any* resource counts, while strict mode captures the analyst view: only unambiguous, exclusive regressions count. Strict mode's exclusivity requirement carries a security cost: a check that fails for several resources while still passing for one is invisible to strict detection, so a transition that degrades most, but not all, instances of a control is not counted. Strict mode is thus a measurement-validity device, not an operational security criterion: it isolates regressions that cannot be explained by multi-resource bookkeeping, at the deliberate price of under-counting genuine partial degradations. We therefore recommend reporting both modes in distinct roles: the strict figures anchor the conservative point estimate we defend as our headline result, while the standard figures give the inclusive outer bound an operator should act on: production monitoring should triage standard-mode alerts precisely because strict detection can miss partial degradations, whereas research comparison and cross-study benchmarking should use strict mode.

**How Real Is the Phenomenon?** A skeptical reading must confront the gap between our standard and strict figures. The standard-mode rates (13.8% of scenarios, 24.8% of transitions) are an *inclusive upper bound*: roughly three quarters (76% of standard-mode regression scenarios, a comparable 79.1% reduction at the transition level) are multi-resource bookkeeping artifacts rather than exclusive check failures (Section 5). The conservative, defensible claim is the strict rate: approximately 3.3% of scenarios (5.2% of transitions) exhibit an unambiguous, exclusive regression.

Three caveats compound around even the strict rate. We ran each configuration once rather than repeating the experiment, so run-to-run variance is unquantified. The root-cause taxonomy is automated diff-classifier output, never validated against human judgment. Some timelines may mix iterations from separate executions. Together these mean the strict 3.3% should be read as an order-of-magnitude estimate rather than a precise point value. What the data *does* support robustly is the qualitative claim: iterative IaC repair sometimes degrades a previously-passing security check, the effect is not negligible, and cumulative-best reporting hides it entirely.

**Self-Correction and Oscillation.** The 36.6% self-correction rate implies that single-iteration regression is an imperfect halting signal: roughly one-third of regressions are transient, resolved by the same feedback mechanism that caused them. The 28.5% oscillation rate, however, shows many corrections are themselves unstable. A check may regress, recover, and regress again, so not all self-corrections are stable recoveries. The three most oscillation-prone checks (CKV_AWS_356, CKV_AWS_111, CKV_AWS_109) are all IAM policy checks, suggesting the LLM cycles between implementations satisfying different subsets of IAM constraints. Stabilizing them needs more structured retrieval context or constrained generation.

**RAG Reversal and Temperature Effects.** The RAG reversal effect (RAG appears *worse* in standard mode but *better* in strict mode) reveals that RAG generates more multi-resource configurations while producing fewer exclusive regressions. We attribute this to retrieval: a query mentioning "VPC with logging" retrieves schema chunks for `aws_vpc`, `aws_flow_log`, and related log-storage resources. That context encourages comprehensive multi-resource solutions, increasing the opportunity for check ambiguity in standard mode. However, the same contextual grounding provides stability for individual security properties, explaining why RAG achieves fewer exclusive regressions in strict mode. The negligible temperature effect (Cramér's $V = 0.049$) likewise suggests regression is driven by structural generation patterns rather than sampling randomness.

**Why Clean Timelines Regress More.** A counter-intuitive RQ4 result is that scenarios with consistently valid syntax ("clean" timelines) regress *more* often than those that struggled with syntax errors (OR = 1.90). We identify two non-mutually-exclusive explanations. First, an *opportunity effect*: clean timelines have more consecutive valid-to-valid transitions, providing more opportunities for Checkov-level regressions to occur, since only syntactically valid code undergoes security evaluation. Second, a *feedback purity effect*: when the LLM receives only security feedback (no syntax errors), it aggressively restructures already-valid code in pursuit of compliance, inadvertently breaking passing checks. Disentangling these mechanisms would require an ablation study varying feedback types, which we leave to future work.

**What Generalizes Beyond Terraform and Checkov?** Which findings are specific to Terraform and Checkov, and which plausibly characterize iterative LLM repair at large? Multi-resource ambiguity, and with it the standard/strict gap and the mode-dependent reversals of RQ3, arises because one check can apply to several resources in a configuration. We expect it to transfer to other IaC ecosystems (CloudFormation, Ansible, tfsec, Terrascan), which likewise evaluate checks per resource, but not to general-purpose code, where findings are not multiplied across resource instances. By contrast, three observations are candidates for domain-general behavior: large rewrites are strongly associated with regressions, restructuring

rather than minimal editing dominates, and repair gains diminish across iterations. The first two are consistent with the degradation Shukla et al. [25] and Chen et al. [7] observe in general-purpose code, and the third is replicated within IaC by Palavalli et al.'s feedback plateau [20]. Whether self-correction and oscillation recur outside IaC is unexamined. These are hypotheses: confirming them requires replications that vary domain and validator while holding the repair loop fixed.

From a human-factors perspective, the contrast is instructive. Braz et al. [4] found that developers focus on the complexity of the bug at hand and work under community pressure to deliver, while security goes undiscussed during the fix. The mechanism we observe differs: LLM regressions arise within a single repair step, when the model rewrites structure wholesale rather than editing minimally. The blind spot, however, is shared. Just as security went unexamined during Mozilla's bug fixes, current feedback loops never tell the model which checks its previous iteration was already passing.

### Threats to Validity

**Internal.** Our root-cause classification relies on automated diff analysis: it was not validated against human labels, may misclassify boundary cases (e.g., resource renaming), and its thresholds ($>0.85$ similarity for drift, $\geq 2$ resource-count change for restructuring) were chosen conservatively rather than empirically tuned. Alternatives could shift the distributions. We mitigate this with the dual standard/strict framework, but manual validation of a stratified sample remains future work. The per-iteration logs record the generation model for RAG runs but not non-RAG runs, precluding a model-controlled RAG-vs-non-RAG comparison and the isolation of retrieval-augmentation effects from model behavior. We partially mitigate this by reporting RAG+Gemini and RAG+Mistral separately (Table 3). Where a scenario ran more than once we keep the later execution and drop same-iteration transitions, yet consecutive iterations in such a timeline may still come from different attempts. The 902 absent scenario-configuration pairs (13%) stem from API errors, timeouts, and unparseable outputs, and are unlikely to bias our estimates. We use single runs per configuration for computational reasons, since repeated trials (e.g., $n = 3$) would require roughly 1.3M additional API calls, and although the negligible temperature effect ($V = 0.049$) suggests stability, point estimates may vary $\pm$2–5pp. Finally, we treat transitions as independent for Mann-Whitney tests despite possible within-timeline autocorrelation, our iteration-3 stopping point rests on a subjective $<0.5$pp threshold, and the post-hoc root-cause taxonomy and exploratory subgroup analyses were not pre-registered.

**External.** Our results are specific to Terraform and Checkov. Other IaC tools (Ansible, CloudFormation) and validators (tfsec, Terrascan) may exhibit different regression patterns. Our dataset (IaC-Eval v1.0, 458 scenarios, accessed December 2024) covers AWS only. We ran 24 experiments in total, all four strategies on both models at three temperatures. Only the six RAG experiments record which model produced each run, so the eighteen non-RAG experiments aggregate into nine model-aggregated configurations, giving the 15 we analyze (Section 4). Attributing all 24 would enable cleaner causal inference. Our findings may also partly reflect the repair capability of the two studied models. More recent or reasoning-oriented models may restructure less aggressively or preserve passing checks more reliably. Replication with newer models is needed to separate paradigm-level from model-level effects.

**Construct.** Checkov provides a proxy for security. Real security assessment requires deployment-time evaluation (`terraform plan`, sandbox testing). We use static validation rather than deployment for scalability (5,968 deployments would incur substantial cost),

reproducibility (outcomes vary by account state), and safety (some scenarios create production resources). Some Checkov checks may be overly strict or context-dependent. Our study also compares RAG holistically without isolating individual components (CIS docs vs. Terraform schema vs. retrieval depth). Future ablation studies should test these variants separately.

## 8 Conclusion

We presented the first large-scale empirical study of security regression in iterative LLM-driven IaC repair, analyzing 5,968 scenario timelines across 15 configurations with up to 5 repair iterations each. Six findings emerge. (1) **Regression is real:** 13.8% of scenarios regress in standard mode, 3.3% in strict mode. (2) **Detection mode changes conclusions:** access control dominates standard mode while networking and encryption are the genuine strict-mode risks, the 17× Mistral-vs-Gemini gap vanishes, and RAG reverses from worst to best. Multi-resource ambiguity drives standard-mode differences. (3) **Resource restructuring** is the dominant root cause (79.0%), ahead of configuration drift (15.5%). (4) **Code churn and check volatility are indicators of regressions**, with strict-mode volatility the strongest signal ($d = 1.49$). (5) **Self-correction is common but unstable:** 36.6% of standard-mode regressions self-correct, yet 28.5% of scenarios oscillate. (6) **Iteration 3 is the optimal stopping point**, balancing an 83.1% pass rate against manageable regression risk. Together, these findings provide actionable guidance for designing security-aware IaC feedback loops.

## Data Availability Statement

Our replication package is openly available [1]. It contains the analysis scripts, the derived results that reproduce every table, figure, and statistic reported here, the complete prompt templates, a `README` documenting the pipeline, and a slimmed subset of the raw per-iteration logs so the pipeline can be exercised end to end.

## Abstract

**Background.** Regression testing has traditionally focused on source-code changes and well-specified software dependencies such as compiler versions, library versions, and operating-system platforms. However, LLM-enabled code-generation systems also depend on non-code artifacts (the model, the prompt template, and the retrieval corpus) that can change independently of the application code. Updates to any of these artifacts can silently regress previously passing tasks, and the lightweight partial-test oracles commonly used in continuous evaluation may not detect such failures. Despite the practical relevance, paired regression rates, measurement validity, and escaped-failure rates under controlled non-code dependency changes have received little empirical attention.

**Aims.** This work empirically analyzes how changes to models, prompts, and retrieval data affect the behavior of LLM-enabled code-generation systems, framing the problem as dependency-aware regression testing rather than a model or retrieval comparison. The questions addressed are failure-rate sensitivity, paired-regression frequency under the answer-bearing canonical retrieval condition, the measurement-validity decomposition of canonical regression signals (answer-bearing baseline rescue vs. non-canonical retrieval sensitivity), and how often generations pass a lightweight oracle yet fail a stronger oracle, reported over all generations and, conditionally, among stronger-oracle failures.

**Method.** We designed a controlled empirical study that treats models, prompts, and retrieval data as software dependencies of an LLM-enabled code-generation pipeline. Starting from a fixed baseline, we varied one dependency dimension at a time across three open-weight 7B-class code LLMs, three prompt templates, and four retrieval-data conditions (one being a synthetic stress test), evaluated on 120 CodeRAG-Bench HumanEval tasks under three random seeds (2,880 generations across eight conditions). For each (task, condition, seed) triple, we recorded syntactic validity and per-assertion execution outcomes to derive failure rate, paired regression rate, escaped-failure rate, and across-seed flakiness, and compared each changed condition to the baseline using paired McNemar tests.

**Results.** In the answer-bearing canonical benchmark condition, removing the retrieved document regressed 11.67% of previously passing tasks ($D_1$, $p = 1.22 \times 10^{-4}$, stable under task-level Bonferroni correction). Replacing it with a different-task mismatched document regressed 9.17% ($D_2$, $p = 9.77 \times 10^{-4}$, significant before correction but not after; reported as an auxiliary stressor). A copy-template audit showed that the $M_0$ baseline output was a normalized byte-level copy of the canonical retrieved document in 331 of 360 generations, and 12 of 14 $D_1$-regressed tasks exhibited this property. A title-based self-excluded BM25 proxy and an answer-stripped $D_0$ check showed that most of this canonical signal was due to answer-bearing baseline rescue (BM25 $D_1$: 3 regressions / 3 recoveries; $D_2$: 3 / 4); thus, harmful non-canonical retrieval degradation was not established in this sample. The intentionally permissive $O_1$ probe let 36/360 $D_1$ and 26/360 $D_2$ generations pass despite failing $O_2$; an order-dependent first-three-substantive variant reduced these counts to 8/360 and 3/360. Model and prompt perturbations are reported as framework coverage checks rather than causal claims.

**Conclusions.** The strongest apparent regression signal arose from the answer-bearing canonical retrieval condition, but validity analyses showed that this signal primarily reflected a benchmark-induced copy-template dependency rather than an established deployment retrieval risk. These findings support dependency-aware paired regression testing and layered oracles, while cautioning that canonical answer-bearing retrieval regression rates should be interpreted as benchmark-specific stress signals rather than deployment-risk estimates.

## 1 Introduction

Regression testing asks whether a change after a known baseline breaks behavior that previously passed [39]. In conventional software, the changed artifact is usually application source code or a pinned dependency such as a compiler, library, runtime, or operating-system version. LLM-enabled code-generation systems add less visible dependencies: model checkpoints, prompt templates, retrieval indexes, retrieval corpora, and oracle definitions. Any of these artifacts can change while the application code that invokes the generator remains unchanged. Prior work on hidden technical debt and software engineering for machine learning showed that ML behavior depends on data, configuration, and pipeline choices that are not always visible in source code [34, 2]. In code generation, these dependencies also appear at inference time and can become sources of silent behavioral regression.

This paper studies that problem for retrieval-augmented code generation (RACG). Existing code-generation evaluations usually report aggregate pass rates such as pass@k on fixed benchmark configurations, including HumanEval and extended-oracle variants such as EvalPlus [9, 26]. RACG benchmarks and systems further evaluate whether retrieved context improves generated code quality [24, 35]. These evaluations are valuable, but fixed-configuration scores do not show which previously passing tasks fail after one dependency changes, whether an observed retrieval effect is a deployment-relevant dependency or a benchmark artifact, or how often a weak oracle accepts a generation that a stronger oracle rejects. We therefore frame the study as dependency-aware regression testing rather than as a model leaderboard or a generic retrieval comparison.

The key measurement-validity issue is that the benchmark retrieval context can contain the answer. In the CodeRAG-Bench HumanEval setting used here, the canonical $D_0$ document contains the target entry-point definition and canonical solution body for all 120 selected tasks. Thus, $D_0$ is not a deployment-realistic retrieval condition; it is an answer-bearing canonical benchmark condition. If a model copies that document, removing or replacing it can create an apparent paired regression by removing the answer template rather than by

revealing harmful non-canonical retrieval-corpus sensitivity. For this reason, we interpret canonical retrieval numbers as benchmark-specific stress signals and decompose them with answer-stripped and self-excluded retrieval baselines.

We represent an LLM-enabled code-generation pipeline as a configuration $C = (M, P, D)$ and change one component at a time. The main experiment varies three open-weight 7B-class code models, three prompt templates, and four retrieval-data conditions over 120 CodeRAG-Bench HumanEval tasks and three seeds. Each generation is evaluated under a permissive partial visible oracle ($O_1$), the full HumanEval visible oracle ($O_2$), and an EvalPlus-derived extended oracle ($O_3$). We report generation-level failure rates, task-level paired regressions and recoveries, escaped failures between oracle tiers, and across-seed flakiness, using paired McNemar tests as the main inferential analysis.

Removing or replacing the answer-bearing canonical document regresses 14/120 and 11/120 tasks, respectively, but the baseline copies that document in 331/360 generations. A title-based self-excluded BM25 proxy yields small, bidirectional changes (3/3 and 3/4 regressions/recoveries), while removing only the canonical solution body reproduces 11/14 removal regressions. Thus, the strongest signal is a benchmark-induced copy-template dependency; harmful non-canonical retrieval degradation is not established in this sample.

This study makes three contributions.

- **Measurement-validity decomposition of answer-bearing retrieval.** We show how an answer-bearing canonical retrieval context can inflate apparent retrieval-regression rates, and we decompose the effect using a copy-template audit, BM25 self-excluded retrieval, and an answer-stripped $D_0$ mechanism check.
- **Dependency-aware paired regression-testing framework.** We formulate model checkpoints, prompt templates, retrieval contexts, retrieval corpora, and oracle tiers as versioned behavioral dependencies, and we evaluate one-factor-at-a-time changes with task-level paired regressions and recoveries.
- **Oracle-tier visibility analysis.** We quantify when dependency-induced failures pass a permissive partial oracle but fail a full visible oracle, and when visible-test-passing generations fail an EvalPlus-derived extended oracle.

The remainder of the paper reviews background (Section 2), formalizes the framework and analysis plan (Section 3), reports the experiments and validity decomposition (Section 4), discusses implications and threats to validity (Section 5), positions the work relative to related work (Section 6), and concludes (Section 7).

## 2 Background

### 2.1 LLM-Enabled Code-Generation Pipelines

A typical LLM-enabled code-generation system can be decomposed into three artifacts that jointly determine its behavior.

1. **Model** $M$: an instruction-tuned code LLM, for example Qwen2.5-Coder-7B [15], CodeLlama-7B [33], or DeepSeek-Coder-6.7B [13].
2. **Prompt template** $P$: a system-plus-user prompt format that typically includes a retrieval-context block, a task description, and instructions such as "return only executable Python code."
3. **Retrieval context** $D$: usually the top-$k$ documents returned by a retriever over a corpus. In CodeRAG-Bench HumanEval, $k = 1$ and the document is a code snippet semantically related to the task.

Fixing a task, seed, sampling configuration, and the versions of $M$, $P$, and $D$ improves repeatability but does not make generation deterministic: runtime versions, batching, kernels, and stochastic sampling can still produce cross-run drift. Unlike a pinned compiler or library, these dependencies are probabilistic and can interact: a change in $M$ can alter how a $P$ or $D$ change manifests, so their effects are not guaranteed to be separable, and we observe one such large model $\times$ data interaction empirically. Any of $M$, $P$, or $D$ can change between deployments without modifying the application code that invokes the generator.

## 2.2 Traditional Regression-Testing Assumptions

Regression testing in classical software engineering [39] checks that code changes do not break previously passing behavior. The unit of change is typically a commit, the artifact under test is the application code, and dependencies (libraries, runtimes, and build configurations) are pinned to specific versions specified in a lockfile. LLM-enabled systems violate the first two assumptions: application-code changes are often absent, and the unit of behavioral perturbation becomes a model or retrieval-corpus update, with documented practical consequences such as the security regressions in GitHub Copilot output reported by Pearce et al. [30].

## 2.3 Retrieval-Augmented Code Generation and Retrieval Quality

Retrieval-augmented generation [24] augments LLMs with documents retrieved by a sparse retriever such as BM25 or by a dense retriever such as ColBERT [21] or DPR [20]. CodeRAG-Bench [35] provides task-specific retrieval documents (`docs[0]...docs[k]`) drawn from multiple corpora. The HumanEval split of this benchmark uses the `programming-solutions` corpus, in which each document is a candidate solution. The top-1 retrieved document for a HumanEval task is therefore a *canonical tier* document, which our audit confirms for the selected subset (Section 4.1). This raises a methodological concern: retrieval-perturbation experiments based on the canonical-tier `docs[0]` can overestimate the magnitude of retrieval-data dependency. This property motivates the main validity analysis in Section 4.4, which uses a BM25 self-excluded retrieval baseline to decompose the canonical RQ2 retrieval-perturbation effect.

We refer to $D_0$ consistently as the *answer-bearing canonical retrieval context*; it is a measurement setting that preserves a known property of CodeRAG-Bench HumanEval rather than a simulation of realistic deployment retrieval. The paper does not refer to $D_0$ as a "realistic retrieval baseline" or as "deployment-realistic retrieval."

Our $D_0$ canonical condition departs from CodeRAG-Bench's published RACG protocol, which excludes the canonical solution document from the retrieval corpus [35]; we deliberately retain the raw programming-solution document as an answer-bearing stress-test context. We therefore do not report the $D_0 \rightarrow D_1/D_2$ contrast as a standard leaderboard number or as evidence that the published protocol is flawed. Our contribution is to quantify, in this raw canonical setup, how much of the apparent retrieval regression signal is due to answer-bearing baseline rescue and how much remains as residual non-canonical sensitivity under a BM25 self-excluded retrieval proxy, via task-level paired regressions and recoveries.

## 2.4 A Three-Tier Oracle Scheme

The oracle problem in software testing [5] is particularly acute for generated code because multiple correct implementations can exist and the visible test suite can be incomplete; complementary approaches such as metamorphic testing [10] attempt to alleviate this gap via input-output relations. For HumanEval and HumanEval+, we can clearly define three oracles of increasing strictness.

**Table 1** Oracle-tier definitions.

| Tier | Definition | Source |
|---|---|---|
| **O1** (permissive partial visible oracle) | Passes syntactically and passes at least one assertion executed inside the HumanEval `check(candidate)` routine. | This work |
| **O2** (benchmark-provided full visible assertion oracle) | Passes syntactically and the full HumanEval `check(candidate)` completes without assertion failures, exceptions, or timeouts. The shorthand "full visible test" refers to the visible test set provided by the benchmark and does not claim absolute oracle completeness; the $O_3$/EvalPlus extended oracle tier addresses that gap. | Equivalent to standard pass@1 |
| **O3** (EvalPlus extended oracle) | Passes syntactically and passes all visible, base, and plus inputs from HumanEval+ that are included in the provided denominator. | EvalPlus [26] |

The $O_1$ tier is intentionally permissive and is used as a low-strength oracle-sensitivity probe. This is not a claim that production smoke tests run every assertion and accept the program if any one of them passes. The $O_1 \rightarrow O_2$ gap captures *permissive partial-oracle escaped failures*, while the $O_2 \rightarrow O_3$ gap captures *visible-test escaped failures*. Section 4.3 reports both, and we treat the $O_2 \rightarrow O_3$ gap as the more direct evidence of oracle insufficiency.

# 3 Framework and Methodology

## 3.1 Research Questions and Analysis Plan

The empirical analysis is organized around four research questions.

1. **RQ1:** How do dependency-change conditions affect the failure rate?
2. **RQ2:** Under the answer-bearing canonical retrieval condition, how often do dependency changes cause tasks that previously passed under the fixed baseline to regress in a paired sense?
3. **RQ3:** How much of the canonical retrieval regression signal is attributable to answer-bearing baseline rescue, and how much remains as non-canonical retrieval sensitivity?
4. **RQ4:** How often do generations pass a permissive oracle but fail a stronger full-assertion oracle, measured over all generations and conditional on stronger-oracle failure?

RQ3 is the main empirical contribution and is answered in Section 4.4. Model- and prompt-replacement contrasts and the cross-model/GEE/scaling analyses are framework-robustness checks, not evidence for deployment-wide causal claims.

## 3.2 A Dependency-Aware Regression-Testing Framework

Let the *generation configuration* be $C = (M, P, D)$ and the *measurement configuration* be $E = (C, O_k)$. We fix a baseline $C_0 = (M_0, P_0, D_0)$ and a task set $T$. For each $t \in T$ and seed $s \in S$, the system produces $G(t, C, s)$, which oracle $O_k$ maps to {pass, fail} for $k \in \{1, 2, 3\}$.

A *changed* configuration $C'$ perturbs exactly one component of $C_0$; that is, we change one factor at a time. Comparing $C_0$ and $C'$ over $(t, s)$ yields the following behavioral metrics, which are re-defined per oracle tier where applicable.

For each ($C_0$ vs. $C_x$) comparison, we compute the failure rate (per generation), the multi-seed paired regression rate (tasks passing all baseline seeds and failing the changed condition in at least one seed), the paired recovery rate, the signed paired change $(c - b)$, the escaped-failure rate ($O_1$-pass-but-$O_2$-fail, analogously for $O_2 \to O_3$), and across-seed flakiness. We treat $M$, $P$, and $D$ as testable dependencies for versioning, provenance, and paired comparison; $O_k$ is the measurement layer rather than a perturbed generation dependency. The paired regression metric captures whether a change induces at least one failed generation in the evaluated seed set and is not the probability that a single deployment run will fail.

## 3.3 One-Factor-at-a-Time Condition Design

We define eight conditions on a single baseline ($M_0$, $P_0$, $D_0$).

**Table 2** One-factor-at-a-time condition design.

| ID | Model | Prompt | Data | Perturbed dimension |
|---|---|---|---|---|
| $C_0$ baseline | $M_0$ | $P_0$ | $D_0$ answer-bearing canonical | reference |
| $C_1$ model | $M_1$ | $P_0$ | $D_0$ | model |
| $C_2$ model | $M_2$ | $P_0$ | $D_0$ | model |
| $C_3$ prompt | $M_0$ | $P_1$ (strict grounding) | $D_0$ | prompt |
| $C_4$ prompt | $M_0$ | $P_2$ (test-aware) | $D_0$ | prompt |
| $C_5$ retrieval | $M_0$ | $P_0$ | $D_1$ (top document removed) | retrieval data |
| $C_6$ retrieval | $M_0$ | $P_0$ | $D_2$ (top document replaced with the offset-7 different-task mismatched document) | retrieval data |
| $C_7$ retrieval (stress) | $M_0$ | $P_0$ | $D_3$ (synthetic outdated-API memo prepended) | retrieval data |

We designate $C_7$ as a stress-test condition and exclude it from claims about non-canonical retrieval-data changes.

We additionally audit the 120 HumanEval replacement contexts used for $D_2$. The replacement source task is never the same as the target task, the source entry point is never the same as the target entry point, and the target entry point appears 0 out of 120 times in the $D_2$ context. The median token Jaccard overlap between $D_0$ and $D_2$ is 0.187 (IQR 0.147–0.219). Therefore $D_2$ is a deterministic different-task replacement stressor and is not a semantic-irrelevance control: the replacement document can still share general Python patterns with the target, and offset 7 is a deterministic but arbitrary construction choice. $D_2$ is therefore used only as a directional auxiliary stressor that supports $D_1$ and the Section 4.4 decomposition, not as the basis for any main retrieval claim.

## 3.4 Statistical Analysis

We report Wilson 95% confidence intervals [36] for each rate. The primary inferential unit is the task, and the McNemar test treats each task as one paired observation. At the task level, $b$ counts a regression when the baseline passes every seed but the changed condition does not; $c$ counts a recovery when the baseline does not pass every seed but the changed condition passes every seed. The primary estimands have distinct denominators: task-level paired regression (tasks passing the baseline), generation-level failure and $O_1 \to O_2$ escape rates (all rows), and conditional $O_2 \to O_3$ escaped failures ($O_2$-passing rows).

The analysis comprises four tiers: (1) the main analysis ($M_0$ HumanEval $D_1$ paired regression under $O_2$, with $D_2$ as an auxiliary stressor); (2) the central validity analysis ($C_0$ copy audit, BM25 self-excluded retrieval, answer-stripped $D_0$); (3) oracle-sensitivity ($O_1 \to O_2$ and $O_2 \to O_3$ escaped failures); and (4) robustness/exploratory checks (MBPP, cross-model, GEE, bootstrap).

For each ($C_0$ vs. $C_x$, oracle $k$) comparison, we use a paired McNemar test [29]; with fewer than 25 discordant pairs we use an exact binomial test, otherwise a continuity-corrected $\chi^2$. We define the multiple-comparison family as all 66 McNemar-style contrasts reported in the paper and companion package (14 main + 8 model × data interactions + 16 scaling + 10 MBPP + 10 BM25 self-excluded + 8 family-expansion), and we report both the uncorrected test and a conservative Bonferroni-equivalent threshold $\alpha/66 = 7.6 \times 10^{-4}$ (with $\alpha = 0.05$). Alternative step-down or FDR procedures [14, 6] could be less conservative, but we adopt Bonferroni as a strict upper bound. Only contrasts that pass this corrected threshold are interpreted as primary inferential results; the model-interaction, scaling, MBPP, and family-expansion contrasts are exploratory. As a sensitivity analysis, we also fit a binomial GEE model [25] with a logit link and an exchangeable working correlation structure clustered on `task_id` to confirm the direction of the retrieval-data effect under a population-average model.

## 3.5 Evaluation Pipeline

Each generation is evaluated under the three oracle tiers by an isolated subprocess runner with per-task wall-clock timeouts (30s for HumanEval visible tests, 20s for each side of the EvalPlus base/plus split). $O_3$ pre-computes expected outputs once by running the canonical solution on the HumanEval+ inputs; the provided denominator excludes 78 very-large-integer plus-output cells, leaving 1,570 base and 122,605 plus outputs, against which generations are compared by parallel worker processes (the released reproduction command uses 16; the worker count affects runtime only, not the recorded outcomes). $O_2$ runs the full `check(candidate)` routine inside an isolated subprocess; $O_1$ instruments every `assert` inside `check(candidate)` and counts whether at least one passes. Two early evaluator

errors (removal of generated import/helper definitions; consideration of only top-level visible assertions in $O_2$) were corrected: the final evaluator preserves top-level imports, helper functions/classes, and the prompt preamble, and runs the full visible-test check. Section 4.5 summarizes the sensitivity analysis. All quantitative tables in this paper were recomputed after the evaluator fixes.

# 4 Experiments

Sections 4.2 (RQ2) and 4.3 (RQ4) report the main analyses of failure rates, paired regressions, and oracle escaped failures. These should be read together with the Section 4.4 decomposition (RQ3), which determines how the RQ2 retrieval-perturbation rate should be interpreted. Section 4.5 presents robustness and exploratory analyses in compact form.

## 4.1 Experimental Setup

**Experimental setup summary.** The primary dataset is 120 CodeRAG-Bench HumanEval tasks (an evenly spaced subsample of 164), and the auxiliary dataset is 50 MBPP tasks. The primary models are Qwen2.5-Coder-7B ($M_0$) [15], DeepSeek-Coder-6.7B ($M_1$) [13], and CodeLlama-7B ($M_2$) [33]; the scaling analysis additionally includes Phi-3.5-mini (3.8B) [1], CodeLlama-13B, and SWE-agent-LM-32B [38]. The configured sampling parameters are temperature 0.2, top-p 0.95, and max_new_tokens 1024. Contemporaneous logs record vLLM 0.15.0 for the 2,880-row primary family. The disjoint five-seed extension used vLLM 0.20.0 with a public model identifier, making the combined eight-seed analysis a compound runtime-and-seed sensitivity; direct engine-version logs were not retained for the BM25 and stripped-$D_0$ families. The EvalPlus $O_3$ coverage spans 14,760 HumanEval generations and 2,160 BM25-proxy rows.

Model weights were loaded from the local paths or public identifiers recorded per run family (see the run-family provenance record in the replication package), and no model was fine-tuned in this study. The cited model and HumanEval/MBPP benchmark references ([15, 13, 33, 1, 9, 4]) are technical reports without a peer-reviewed venue; the citations are used only as a primary-source pointer for model and benchmark identification.

The HumanEval sample size was fixed prior to analysis by an evenly spaced deterministic rule to keep the full $O_1/O_2/O_3$ multi-seed pipeline tractable. The selected 120 and omitted 44 tasks differ by more than $|\text{SMD}| = 0.20$ on 2 of 17 locked static features (entry-point parts and AST loop count); this characterizes the subset but does not establish equivalent generation outcomes for omitted tasks. All selected tasks and seeds are retained in the reported analysis. The MBPP 50-task sample is a deterministic auxiliary replication rather than a cross-benchmark estimate, and it is interpreted under the same canonical-tier retrieval caveat as HumanEval.

On the selected 120 HumanEval tasks, $D_0$ contains the target entry-point definition and the canonical solution body for 120 of 120 tasks. Table 3 should therefore not be read as an estimate of deployment retrieval failure rates; its purpose is to quantify the benchmark-induced dependency signal that Section 4.4 decomposes against a BM25 self-excluded baseline.

## 4.2 Main Experiment: One Factor at a Time

We ran each of the eight conditions defined in Section 3.3 over 120 HumanEval tasks and three seeds, yielding 2,880 generations. Per-condition failure rates and paired-regression results under the $O_2$ full visible-test oracle are summarized in Table 3. These are results for the canonical answer-bearing stress-test setup rather than estimates of deployment retrieval risk.

**Table 3** Canonical answer-bearing stress-test results. Not an estimate of deployment retrieval risk and not a standard CodeRAG-Bench RACG leaderboard. Per-condition full visible-test oracle ($O_2$) results from the main experiment. Paired-regression rates, paired-regression confidence intervals, and McNemar $p$-values are computed at the task level; seed-level tests are descriptive. Boldface indicates a result that is stable under task-level Bonferroni correction. The dagger (†) indicates significance before correction but not stability under the 66-comparison threshold. How much of the $D_1/D_2$ effect is answer-bearing baseline rescue versus residual non-canonical retrieval sensitivity is decomposed in Section 4.4 (Tables 5–7).

| Condition | $n$ | strong_fail | 95% CI | Paired regression (task 95% CI, %) | McNemar $p$ | Direction |
|---|---|---|---|---|---|---|
| $C_0$ baseline | 360 | 0.000 | [0.000, 0.011] | reference | reference | reference |
| $C_1$ model $M_1$ (DeepSeek) | 360 | 0.011 | [0.004, 0.028] | 1.67% (2/120; [0.46, 5.87]) | 0.500 | not significant |
| $C_2$ model $M_2$ (CodeL-lama) | 360 | 0.081 | [0.057, 0.113] | 12.50% (15/120; [7.72, 19.60]) | $6.10 \times 10^{-5}$ | regression |
| $C_3$ prompt $P_1$ (strict) | 360 | 0.000 | [0.000, 0.011] | 0% (0/120; [0.00, 3.10]) | 1.000 | no effect |
| $C_4$ prompt $P_2$ (test-aware) | 360 | 0.025 | [0.013, 0.047] | 2.50% (3/120; [0.85, 7.09]) | 0.250 | not significant |
| $C_5$ data $D_1$ (no document) | 360 | 0.100 | [0.073, 0.135] | 11.67% (14/120; [7.08, 18.63]) | $1.22 \times 10^{-4}$ | regression |
| $C_6$ data $D_2$ (different-task mis-matched docu-ment)† | 360 | 0.075 | [0.052, 0.107] | 9.17% (11/120; [5.20, 15.67]) | $9.77 \times 10^{-4}$ | regression† |
| $C_7$ data $D_3$ (stress) | 360 | 0.000 | [0.000, 0.011] | 0% (0/120; [0.00, 3.10]) | 1.000 | no effect (consistent with stress-test framing) |

Because canonical $C_0$ passes all three seeds for all 120 tasks, $c = 0$ is structural in its contrasts and does not imply that recoveries are generally absent. Task-level McNemar gives $b = 14$, $p = 1.22 \times 10^{-4}$ for $D_1$ (Bonferroni-stable) and $b = 11$, $p = 9.77 \times 10^{-4}$ for $D_2$ (an auxiliary stressor that narrowly misses $\alpha/66 = 7.6 \times 10^{-4}$). Table 3 must be read with the Section 4.4 decomposition, not as independent evidence of deployment degradation.

In seed-aggregation sensitivity checks, the $D_1$ effect persists across the arbitrary-seed (14/120, 11.67%), majority-seed (12/120, 10.00%), and all-seed (10/120, 8.33%) aggregations. $D_2$ is directionally consistent but smaller (11, 9, 7/120).

## 4.3 EvalPlus-Derived Extended Oracle Re-evaluation and Oracle Sensitivity

We re-evaluated 14,760 HumanEval generations under the EvalPlus-derived HumanEval+ extended oracle (this is not an official leaderboard score). $O_3$ is computed after excluding 78 very-large-integer plus-output cells from HumanEval/83 and HumanEval/139. Expected outputs are pre-computed by running the canonical solution and then cached (1,570 base entries; 122,605 plus entries). Verification: the pre-computed cache matches the official EvalPlus ground truth, and the custom runner passes the canonical solution on every evaluated input. Section 4.4 separately reports a 2,160-row BM25 self-excluded $O_3$ check.

**Table 4** $M_0$ oracle results for the main experiment. $O_3$ is the EvalPlus-derived extended oracle (`strong_pass AND evalplus_all_passed`) over the non-excluded HumanEval+ denominator and is not an official leaderboard score. The $O_1 \to O_2$ column reports all-generation escape rates; $O_2 \to O_3$ is conditional on $O_2$ passing. $O_1$ is an intentionally permissive sensitivity probe, not a production smoke-test model. The $C_7$ synthetic stress condition equals $C_0$ and is omitted.

| Condition ($M_0$) | $n$ | $O_2$ pass | $O_3$ pass | $O_2 \to O_3$ escaped | $O_1$ permissive $\to O_2$ escaped |
|---|---|---|---|---|---|
| $C_0$ baseline | 360 | 100.0% | 88.3% | 11.67% (42/360) | 0.00% (0/360) |
| $C_5$ data $D_1$ | 360 | 90.0% | 87.2% | 3.09% (10/324) | 10.00% (36/360) |
| $C_6$ data $D_2$ | 360 | 92.5% | 87.5% | 5.41% (18/333) | 7.22% (26/360) |

RQ4 is an oracle-tier *visibility* analysis rather than a one-sided claim about extended-oracle degradation. The $O_2 \to O_3$ escaped-failure rate (11.67% at baseline) reflects baseline-level visible-test insufficiency; the conditional rates of 3–5% under $D_1/D_2$ are not evidence that retrieval perturbations reduce extended-oracle escaped failures but are a denominator effect.

*$O_1$ variants.* The intentionally permissive arbitrary-assertion probe produces all-generation escape counts of 36/360 under $D_1$ and 26/360 under $D_2$; conditional on $O_1$ passing, the escape rates are 36/360 and 26/359 (one $D_2$ generation fails $O_1$); and among $O_2$ failures, the corresponding failure-conditioned miss counts are 36/36 and 26/27. A less-permissive but order-dependent first-three-substantive variant yields 8/360 (2.22%) and 3/360 (0.83%), respectively; here a *substantive* assertion site is an executable assertion outside comments and docstrings, the first three are taken in source order, and generations with fewer than three such sites follow the released oracle script's documented pass rule. These variants are sensitivity probes rather than models of a production smoke test.

Paired $O_3$ transitions are mixed: in the canonical setup, degradations and recoveries are of similar magnitude (22↓/18↑, 20↓/17↑), and in the BM25 self-excluded setup, recoveries dominate (8↓/20↑, 7↓/19↑). From the pooled $O_3$ robustness perspective, the absolute $O_3$ pass rate drops from 87.9% at baseline to 78.0% under $D_1$ and 79.4% under $D_2$, but this does not replace the primary paired-$M_0$ transition analysis.

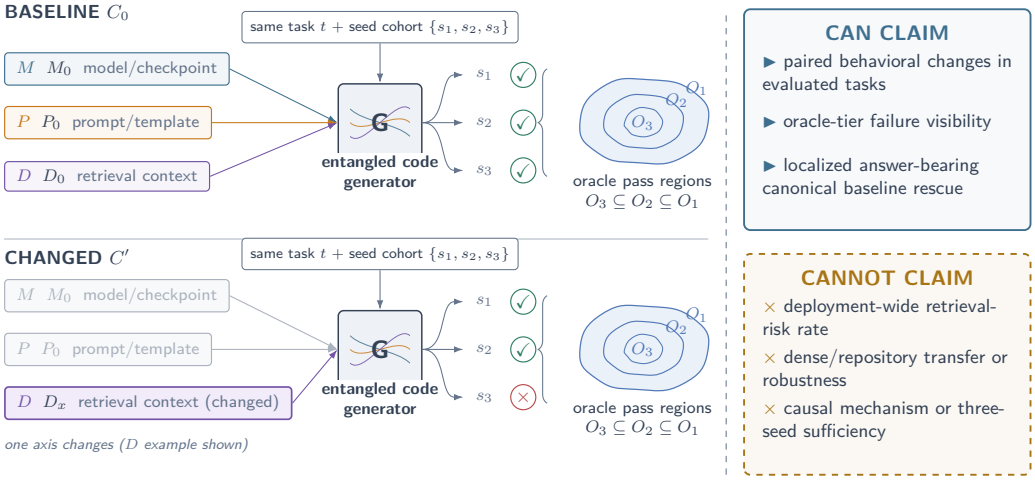

**Figure 1** Dependency axes, paired comparison, and claim boundary. $D$ illustrates the one-factor change; $M/P$ use the same pairing as framework-coverage checks. Check/cross marks depict primary $O_2$ outcomes. At task level, $b$ is baseline all-seed-pass → changed not-all-seed-pass; $c$ reverses this transition. For jointly eligible generations, pass($O_3$) ⊆ pass($O_2$) ⊆ pass($O_1$).

## 4.4 Main Empirical Contribution (RQ3): Measurement-Validity Decomposition of Answer-Bearing Canonical Retrieval Regressions

RQ3 decomposes how much of the Section 4.2 effect is answer-bearing baseline rescue rather than non-canonical retrieval sensitivity; Figure 1 summarizes the dependency axes and the resulting claim boundary. CodeRAG-Bench HumanEval `docs[0]` is a canonical tier; in our subset, $D_0$ contains the target entry-point definition and solution body for all 120 tasks. The central result is therefore the decomposition, not the 11.67% canonical stress rate alone.

**Copy-template baseline audit.** After NFKC normalization and whitespace removal, the $M_0$ baseline is byte-identical to canonical $D_0$ in 331/360 (91.9%) generations and all three seeds for 108/120 tasks. This holds for all three baseline seeds in 12/14 canonical $D_1$ regression tasks and at least two seeds in 13/14. Thus, removing $D_0$ usually removes a copied answer template; the headline contrast is a benchmark-induced dependency stress test, motivating the BM25 proxy and answer-stripped mechanism check below.

To address the canonical answer-bearing setup, we construct a title-based self-excluded BM25 proxy; title exclusion is not equivalent to answer exclusion.

1. Index the entire `programming-solutions` corpus (1,128 documents) with BM25Okapi [32], using regex word tokenization (`[A-Za-z0-9_]+`, discarding single-character tokens) and lowercasing.
2. For each of the 120 HumanEval tasks, query with the task prompt and select the top-1 retrieval document whose title is not the same as the task's own `entry_point`. For 120 of 120 tasks, the self-inclusive top-1 is the canonical solution itself (with an average BM25 score 124.5 higher than the self-excluded top-1), consistent with the answer-bearing $D_0$ audit.
3. Re-run $M_0$ with the same $D_1/D_2/D_3$ perturbation rules over this BM25 self-excluded $D_0$, yielding 2,160 generations, and re-evaluate these rows under EvalPlus $O_3$ as an additional non-canonical oracle check.

No retrieved proxy context contains an exact or NFKC/whitespace-normalized canonical body, but three contain a target-named function and four tasks trigger the predefined overlap review. Excluding all four leaves the task-level $D_1$ and $D_2$ discordances unchanged (3/3 and 3/4), so flagged overlap does not drive the aggregate result; nevertheless, title exclusion does not guarantee answer exclusion.

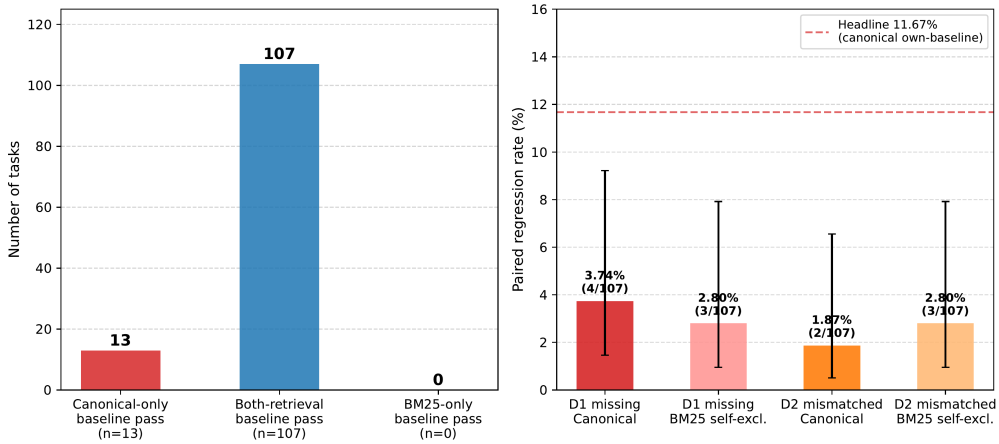

**Figure 2** Task-level decomposition on the common intersection and $D_1/D_2$ regression rates.

Figure 2 decomposes the canonical-tier effect into baseline-rescue and marginal-retrieval components. A naive comparison of paired regression rates between the canonical and BM25 self-excluded setups would use *different* baseline-pass sets and would ignore paired recoveries. We therefore report task-level McNemar $b/c$ counts, where $b$ counts regressions (the baseline passes under every seed and the changed condition fails under at least one seed) and $c$ counts recoveries (the baseline does not pass under every seed but the changed condition passes under every seed).

**Table 5** Self-baseline paired regression, paired recovery, and signed task-level change. *b/c (c-b)* compresses regression, recovery, and net change into a single column.

| Setup | Condition | Baseline-pass $n$ | b / c (c-b) | McNemar $p$ | Interpretation |
|---|---|---|---|---|---|
| Canonical $D_0$ | $D_1$ none | 120 | 14 / 0 (-14) | $1.22 \times 10^{-4}$ | Bonferroni-stable canonical stress |
| Canonical $D_0$ | $D_2$ different-task | 120 | 11 / 0 (-11) | $9.77 \times 10^{-4}$ | directional auxiliary stress |
| BM25 self-excluded $D_0$ | $D_1$ none | 107 | 3 / 3 (0) | 1.000 | inconclusive / bidirectional |
| BM25 self-excluded $D_0$ | $D_2$ different-task | 107 | 3 / 4 (+1) | 1.000 | inconclusive / bidirectional |

**Cross-run drift audit for $D_1$ none.** Because $D_1$ none is a no-context anchor with identical rendered prompts between the canonical main run and the BM25 self-excluded re-run, we audit cross-run drift directly: 360/360 prompt hashes match, 340/360 generations are

byte-identical under NFKC, and 358/360 $O_2$ outcomes agree (only HumanEval/142 changes all-seed-pass status). Re-pairing moves the BM25 paired counts from $b = 3$, $c = 3$ only to $b = 4$, $c = 3$; harmful non-canonical retrieval degradation remains unestablished and bidirectional at this scale.

**BM25 self-excluded prompt sensitivity.** Because the $M_0$ baseline copies the answer-bearing $D_0$ on most tasks, the small canonical prompt effects in Table 3 could in principle be attenuated by the copy-template behavior. Under the BM25 self-excluded $D_0$, the strict-grounding prompt yields $b = 4$, $c = 4$ and the test-aware prompt yields $b = 2$, $c = 2$ at the task level. Neither produces a directional degradation under either retrieval-source setup, which protects the prompt-effect interpretation from this alternative explanation.

**Influence versus non-necessity.** Across 360 same-task, same-seed BM25 $C_0/D_1$ pairs, 122 generations are code-invariant, 203 differ while both pass, 11 pass only with context, 8 pass only without it, and 16 fail in both conditions; task-level $b/c$ remains 3/3. Thus, the null net contrast mixes invariance, functional non-necessity, help, and harm – it is not general retrieval robustness. HumanEval/39 is an illustrative counterexample: all three contextual outputs contain the retrieved context yet fail, while all no-context outputs pass; this demonstrates influence in one task, not a population-level causal effect.

**Table 6** Baseline-rescue decomposition of the canonical regression.

| Task set | $n$ | $D_1$ canonical regression | $D_2$ canonical regression | BM25 regression on the same set |
|---|---|---|---|---|
| Canonical-only baseline-rescue tasks | 13 | 10/13 | 9/13 | not defined |
| Common baseline-pass intersection | 107 | 4/107 | 2/107 | 3/107 for both $D_1$ and $D_2$ |

The 11.67% canonical $D_1$ effect is concentrated on the 13 baseline-rescue tasks: 10/13 regress under canonical $D_1$ and 9/13 under $D_2$. In the common 107-task baseline-pass intersection, canonical regressions are only 4/107 and 2/107, while BM25-proxy changes are small and bidirectional (3/3 for $D_1$, 3/4 for $D_2$). Of the 14 canonical $D_1$ regressions, 10 are baseline-rescue cases and 4 lie in the common intersection; all 14 are visible-assertion failures rather than syntax errors, exceptions, or timeouts.

**Answer-stripped $D_0$ direct validity test.** As a more direct check than the BM25 proxy, we add an $M_0$ condition that preserves the canonical-tier document structure but removes only the canonical solution body: $D_0^{\text{stripped}}$ retains the task's function header, imports, and docstring, with no implementation body. This fixes the same answer-bearing-tier *document slot* and changes only the canonical answer body within the rendered document. We re-ran $M_0$ over 120 tasks $\times$ 3 seeds = 360 generations under the same $O_2$ oracle.

**Table 7** Answer-stripped $D_0$ paired contrast ($M_0$, $O_2$ full visible test). $b/c$ is the count of regression and recovery tasks.

| Baseline | Changed condition | $n$ | b / c | McNemar $p$ | Interpretation |
|---|---|---|---|---|---|
| $D_0$ canonical (body present) | $D_0^{\text{stripped}}$ (no body) | 120 | 11 / 0 | $9.77 \times 10^{-4}$ | direct rescue contribution of the solution body |
| $D_1$ none | $D_0^{\text{stripped}}$ | 106 | 0 / 3 | 0.250 | header/docstring provides only a small additional rescue |
| title-excluded BM25 proxy | $D_0^{\text{stripped}}$ | 107 | 2 / 4 | 0.688 | task-level agreement with the retriever-independent control |

The answer-stripped contrast is a mechanism check, not a separate correction-stable claim: $p = 9.77 \times 10^{-4}$ exceeds $\alpha/66 = 7.6 \times 10^{-4}$. Removing only the solution body reproduces 11/14 (78.6%) canonical $D_1$ regressions; removing the entire document adds three recoveries relative to stripped $D_0$ ($b = 0, c = 3$), indicating little additional rescue from the header/docstring. The retriever-independent stripped control and BM25 proxy are similar at task level ($b = 2, c = 4, p = 0.69$), but the latter is not guaranteed answer-excluded. Together, these contrasts are consistent with the solution body being the operative element of the canonical-tier dependency; because direct engine-version logs were not retained for the stripped-$D_0$ family, we read this as strong supporting evidence rather than a fully isolated causal mechanism.

Accordingly, 11.67% is a canonical-tier stress rate, removing the solution body reproduces most of it (11 of 14 regressions), and the small bidirectional BM25-proxy changes do not establish harmful non-canonical degradation. This negative decomposition prevents a deployment-wide interpretation of the headline rate.

**BM25 $O_3$ check.** Re-evaluating the 2,160 BM25 self-excluded rows under EvalPlus reveals no additional $O_3$ degradation under $D_1/D_2$. The strict $O_3$ pass rate is 83.89% for BM25 $C_0$ and 87.22% for both BM25 $D_1$ and $D_2$. The conditional $O_2 \rightarrow O_3$ escaped-failure rate is 7.65% at $C_0$, 3.09% under $D_1$, and 5.14% under $D_2$. This result should not be over-interpreted as a retrieval benefit; instead, it strengthens the main validity argument that removing the self document does not reproduce the large canonical $D_1/D_2$ effect at a stronger extended-oracle layer.

## 4.5 Robustness and Artifact Checks

The remaining analyses are auxiliary checks rather than separate claims. In the disjoint five-seed rerun, the $D_1$ and $D_2$ regression task sets recur exactly (14/14 and 11/11); 8 and 6 tasks, respectively, have no passing seed in the combined record. Because the extension changed vLLM version and model-loading path, this is compound rerun persistence, not evidence that three seeds are sufficient. Cross-model, MBPP, GEE [25], bootstrap/permutation [12], scaling, and pooled EvalPlus analyses remain exploratory because benchmark exposure and answer-bearing retrieval are major confounders.

# 5 Discussion

## 5.1 Dependency Sensitivity Depends on the Retrieval Source and Model Recipe

The Section 4.4 decomposition is the central empirical finding. The large canonical model × data interaction also attenuates under the BM25 self-excluded setup ($M_1/M_2$ paired regression rates fall from 24.58–57.14% to 6.17–19.51%). The cross-model results are exploratory heterogeneity evidence; the main contribution is separating canonical-retrieval inflation from inconclusive non-canonical retrieval change.

## 5.2 Implications of Canonical vs. BM25 Self-Excluded Retrieval

The residual non-canonical retrieval sensitivity (common 107-task intersection: canonical $D_1$ 3.74% vs. BM25 2.80%) is small and comparable across the two retrieval sources. Future benchmark designs should use retrieval corpora whose top-1 documents are not the canonical solution (for example, `online-tutorials` or `stackoverflow-posts`) or use an explicit answer-stripping variant. Reviewers and practitioners should read effect sizes from canonical-tier RACG benchmarks as benchmark-specific stress-test numbers rather than as deployment retrieval-risk estimates.

## 5.3 Extended and Permissive Oracles Reveal Different Blind Spots

The $O_2 \rightarrow O_3$ escaped-failure rate (11.67% at baseline) reflects visible-test insufficiency, and paired $O_3$ transitions are mixed. The all-generation permissive $O_1 \rightarrow O_2$ gap grows from 0/360 at baseline to 36/360 under $D_1$ and 26/360 under $D_2$; the order-dependent first-three-substantive variant yields 8/360 and 3/360, so the measured escape magnitude is itself a function of the visibility rule. Dependency updates therefore should not be evaluated with permissive probes alone but must be tested with layered oracles.

## 5.4 Practical Implications for LLM-Enabled Software Testing

The practical implications concern benchmark design and evaluation governance rather than quantifying deployment retrieval risk. RACG benchmarks should pair answer-bearing results with answer-stripped or self-excluded controls. A minimal CI record should version model/checkpoint, prompt, retriever/corpus, runtime, sampling configuration, and seeds; report task-level $b/c$ by oracle tier; and escalate correction-stable or security-relevant escaped failures for review.

## 5.5 Threats to Validity

This section follows the four-type validity-threat classification of Wohlin et al. [37]: construct, internal, external, and conclusion validity, framed within the broader measurement-validation guidance of Kitchenham et al. [22].

**Construct validity.** Model replacement is entangled with capability differences and is not a causal estimate of deployment-relevant model-update risk. The paired-regression design partially controls for capability on the easier subset but cannot achieve full separation. $O_1$ is an intentionally permissive sensitivity probe and is not a model of any production smoke test. $D_1/D_2$ are controlled stress conditions rather than direct simulations of every real corpus update.

**Internal validity.** The primary analysis uses three seeds. Although the same $D_1/D_2$ regression task sets recur in the five-seed extension, its different vLLM version and model-loading path prevent interpreting this as a pure seed-count study or as proof that three seeds are sufficient. Two evaluator errors (the removal of import/helper definitions and consideration of only top-level visible assertions in $O_2$) were discovered and corrected; Section 4.5 summarizes the sensitivity analysis. The CodeRAG-Bench HumanEval top-1 canonical tier is a known benchmark property rather than a newly discovered defect [35].

**External validity.** The primary results use 120 HumanEval Python function-level tasks under answer-bearing canonical retrieval, with auxiliary checks on 50 MBPP tasks and the sparse BM25 proxy. Static comparison of the selected 120 and omitted 44 tasks does not establish outcome equivalence, so absolute rates should not be generalized to all 164 tasks. Generalization to closed-weight or multilingual models, dense retrieval, repository-level or multi-turn agents, and non-functional outcomes such as security, performance, and maintainability remains future work. Benchmark contamination and memorization particularly limit cross-model interpretation [28, 8].

**Conclusion validity.** The Bonferroni-equivalent threshold for 66 comparisons ($\alpha/66 = 7.6 \times 10^{-4}$) is a strict upper bound. $D_1$ ($p = 1.22 \times 10^{-4}$) passes this threshold, whereas $D_2$ ($p = 9.77 \times 10^{-4}$) does not. The GEE robustness check supports the direction but is not a condition-specific proof and should be interpreted together with the task-level McNemar results.

# 6 Related Work

This work sits at the intersection of the four areas reviewed below: on top of a task-level *paired regression* design, we treat model, prompt, retrieval, and oracle changes as *controlled non-code dependency perturbations* and combine an *answer-bearing retrieval measurement-validity decomposition* with an *oracle-tier visibility* analysis. To our knowledge, prior work has not combined these four axes.

## 6.1 Evaluation of LLM-Based Code Generation

HumanEval [9] and MBPP [4] are foundational benchmarks for Python function-level code generation, and EvalPlus [26] extends them with automatically generated additional inputs. BigCodeBench [42], LiveCodeBench [16], and SWE-bench [18] extend evaluation toward realistic library use, contamination avoidance, and repository-level tasks, respectively. Beyond pass@$k$ leaderboards, LLM-augmented test generation such as CodaMosa [23] uses pre-trained models to escape coverage plateaus on Java fault databases like Defects4J [19]. All of these benchmarks report aggregate pass rates under a fixed configuration; none measure paired regression under controlled non-code dependency changes, which is the methodological focus of our work.

## 6.2 Defects and Quality in Retrieval-Augmented Generation

Retrieval-augmented generation [24] and dense passage retrieval [20] form the basis of the broader RAG literature, which has since scaled to trillion-token corpora through retrieval-time pretraining such as RETRO [7]. Repository-level extensions such as RepoCoder [40] shifted from QA-style to code-specific retrieval, and Self-RAG [3] adds self-reflective adaptive retrieval.

CodeRAG-Bench [35] characterizes failure modes (irrelevant retrieval, contradictions, retrieval-induced hallucinations) and provides the retrieval-context infrastructure we use. Our work is complementary: we treat the retrieval corpus as a *software dependency*, quantify paired regression under controlled perturbations, and audit how answer-bearing canonical-tier retrieval can inflate the apparent dependency effect, which links retrieval evaluation to benchmark-contamination concerns when the context closely encodes the answer.

### 6.3 Regression Testing for ML and LLM Systems

Sculley et al. [34] argue that ML systems acquire dependencies not visible in source code; Amershi et al. [2] and Zhang et al. [41] document how ML practices differ from classical SE assumptions; DeepXplore [31] exposes DNN defects through differential whitebox testing; and D'Amour et al. [11] show that small perturbations change behavior in ways that traditional evaluation hides. Our work extends this lineage to LLM-enabled code generation by treating prompt templates, retrieval corpora, retriever-exclusion policies, and oracle tiers as versioned dependencies and by showing that answer-bearing retrieval can create a hidden dependency. Flakiness studies in classical testing [27] also support multi-seed evaluation.

### 6.4 Test Oracles and Silent Failures

Test-oracle insufficiency has long been studied in mutation testing [17] and surveyed under the *oracle problem* [5]. The extended test set of EvalPlus [26] targets this for LLM-generated code via automatically generated edge-case inputs. We use EvalPlus as the $O_3$ tier inside a dependency-regression design rather than as an aggregate leaderboard, and our two-stage escaped-failure metrics ($O_1 \to O_2$ and $O_2 \to O_3$) use *non-code dependency changes* as the source of behavioral perturbation instead of mutations.

## 7 Conclusion

Answer-bearing canonical-tier retrieval can create a hidden copy-template dependency in LLM code-generation benchmarks: under answer-stripped and BM25 self-excluded decompositions, the apparent canonical regression signal is largely localized to the solution body and baseline rescue. *Reporting paired regression rates without such decompositions measures a benchmark-induced stress signal rather than deployment-wide risk.* These results motivate dependency-aware regression testing, layered oracles, and replication on answer-excluded corpora.

## Data Availability Statement

In accordance with the ESEM 2026 Open Science Policy, the replication package is archived at `https://doi.org/10.5281/zenodo.21988303`. It contains the configurations, selected tasks and conditions, raw generations, $O_1/O_2/O_3$ results, evaluator pre-fix snapshots, tables, figures, and analysis pipeline. The README maps claims to CPU-only reproduction commands that do not require rerunning inference. Model weights are not redistributed. Original primary rows record local model paths but not checkpoint revisions; public identifiers and cache-resolved commits are post-hoc provenance aids, and the run-family provenance matrix distinguishes these limitations from directly observed engine metadata. The artifact code is released under the MIT license and the derived data under CC BY 4.0, while HumanEval, MBPP, CodeRAG-Bench, and EvalPlus remain subject to their upstream licenses.

## Abstract

Code comprehension is an inevitable part of the software development process and a frequent target of empirical research. However, the field lacks a shared definition of the construct. Studies operationalize code comprehension in diverse ways, often without explicitly stating what aspect of understanding they measure. As a result, researchers design study-specific tasks and measures, limiting comparability across studies and hindering cumulative knowledge building.

To initiate a coordinated approach to assess code comprehension, we introduce a facet-based perspective that distinguishes between analytical skills, abstraction, and critical evaluation. We demonstrate the benefit of explicitly stating the targeted facet(s) of code comprehension and aligning task design accordingly. Building on this perspective, we propose a method to guide researchers from research goals to concrete tasks and study design, including considerations for question formulation and response formats. Rather than immediately prescribing a single standardized instrument, our approach takes a first step toward this long-term goal by enabling researchers to design adaptable yet conceptually grounded measurements. By making operationalizations explicit and tasks reusable, we initiate a cumulative process through which the community can iteratively converge on standardized instruments and, ultimately, a shared understanding of code comprehension.

## 1 Introduction

Code comprehension is a core activity in software development and a recurring focus of empirical software engineering research. Developers spend a substantial portion of their working time understanding existing code rather than writing new code [56]. Nevertheless, code comprehension remains a loosely defined construct [53]. Studies operationalize it in various ways, and no generally accepted definition or measurement approach exists [54, 30]. As a consequence, empirical results are often difficult to compare [55], and it is unclear which aspects of "understanding code" are captured by specific tasks [53, 54].

Beyond this conceptual ambiguity, researchers face concrete methodological challenges when selecting or designing code comprehension tasks. Code comprehension studies use a wide range of tasks – such as output prediction, bug detection, or code reproduction [54] – often

without explicitly stating which cognitive demands these tasks are intended to elicit. Task choices are often guided by prior work or practical considerations, while the alignment between research goals and the cognitive demands induced by a task is rarely made explicit [54].

We argue that this problem is partly caused by treating code comprehension as a monolithic construct. In practice, however, empirical studies implicitly target different aspects of understanding depending on their research goals. These aspects can be understood as different facets of code comprehension, which correspond to distinct cognitive activities involved in understanding code. For instance, a study may focus on analytical skills, that is, decomposing a program into smaller functional units and understanding their behavior [40]; on the ability to abstract, that is, integrating these elements into a coherent mental model of program behavior [50]; or on critical thinking, that is, evaluating code with respect to code quality or correctness [9]. These facets reflect qualitatively different cognitive demands, which in turn require different task designs to be appropriately operationalized.

However, because these distinctions are rarely made explicit, it remains unclear why a particular task is suitable for a given empirical context or which aspect of code comprehension it is actually intended to measure. This lack of explicit grounding complicates systematic task selection and contributes to the variability observed in empirical study designs.

To support systematic task-selection decisions, we introduce a pragmatic distinction between three facets of code comprehension that we derive from the literature: analytical skills (decomposing code into functional units), the skill to abstract (integrating these units into a coherent mental model), and critical thinking (evaluating the correctness, efficiency, or comprehensibility of code). These facets can be seen as a common denominator and are not intended as a comprehensive theory of code comprehension, but as an empirically grounded lens that reflects how code comprehension is treated in current research through combinations of bottom-up, top-down, and integrated comprehension models [53]. They are used here to make task design decisions explicit and to link empirical tasks to the specific cognitive demands they are intended to elicit.

Building on this distinction, we propose a method for the systematic construction of code comprehension tasks in empirical research. The method guides researchers from a use case through the selection of relevant facets, appropriate task types, and concrete design choices, such as question formulation and response formats. We illustrate our approach with an empirical use case in which we measure code comprehension in a controlled study with graduate students. The goal of this evaluation is not to validate the proposed facets as psychological constructs, but to examine how different task designs perform in practice and which design choices affect key quality criteria, such as validity, reliability, and feasibility in empirical settings. Rather than proposing a standardized measurement instrument, we provide task templates and study-design considerations that allow for adaptation to specific experimental contexts, for example, when introducing treatments or manipulating program characteristics. In doing so, we support more transparent, comparable, and systematically designed code comprehension studies without constraining experimental flexibility.

In summary, we contribute (1) a pragmatic, facet-based perspective on code comprehension, (2) a structured method for deriving task designs from research goals, and (3) an empirical illustration highlighting effective practices and common pitfalls in designing code comprehension tasks. Furthermore, we provide supplementary materials on the following Web site: `https://doi.org/10.5281/zenodo.21490313`.

## 2 Code Comprehension and its Heterogeneous Operationalization

Research on code comprehension dates back several decades, with early work distinguishing between top-down and bottom-up comprehension strategies. Top-down comprehension describes a hypothesis-driven process in which developers use prior knowledge to understand

source code. They form expectations about the program's purpose (e.g., sorting a list of names) and iteratively test these expectations against observed behavior [7, 48]. This approach is effective when relevant domain knowledge is available.

In contrast, when such prior knowledge is lacking, developers rely on bottom-up comprehension, in which understanding is constructed from the code itself. Developers analyze code line by line and progressively group statements into meaningful semantic chunks that represent coherent functionality [34, 43]. Higher-level understanding emerges through the iterative integration of these chunks. Developers can switch between these strategies as needed, which is described by integrated models [41, 50].

These theoretical models are the base for measuring code comprehension. For a valid measurement, researchers must make design decisions regarding which aspect of comprehension they intend to evaluate; that is, they must *operationalize* the construct [6]. Despite the theoretical models, measuring code comprehension in a valid way remains challenging, as comprehension strategies depend on multiple factors, including the underlying code base, task framing, prior experience, and domain familiarity [46].

The quality of operationalizations is typically discussed in terms of *construct validity*, that is, the extent to which a measurement reflects the intended theoretical construct [8, 47]. Awareness of construct validity has considerably increased in the software engineering research community [47, 36], and several studies devote substantial effort to justifying their operationalization of code comprehension, reflecting the importance of careful measurement design (e.g., as in [52, 44]).

In empirical practice, researchers operationalize code comprehension through a combination of *tasks* and *measures*. Tasks vary widely, but, according to a previous literature survey, can broadly be grouped into four categories [54]: First, information-providing tasks require participants to answer questions about code or predict program output and have historically been the most common type. Variants include code summarization or reproduction tasks (e.g., [37, 14, 29]). Second, subjective assessment tasks ask participants to rate aspects such as perceived code comprehensibility, their own understanding, or task difficulty (e.g., [26, 38, 9]). Third, debugging tasks require participants to identify, fix, or evaluate defects in code (e.g., [49, 28, 10]). Finally, maintenance tasks involve modifying code, such as filling in missing fragments, extending functionality, or refactoring existing code (e.g., [29, 5, 16]).

The corresponding *measures* used to assess performance are often largely independent of task type [54]. The most common measures are correctness and time, frequently used individually or in combination, followed by subjective ratings. To observe the comprehension and reasoning process itself during task execution, researchers sometimes use think-aloud protocols. More recently, neurophysiological and behavioral measures, such as eye tracking, EEG, and fMRI, have been introduced to study cognitive aspects of code comprehension in greater detail [54, 45, 33, 32].

The diversity of operationalizations and the increasing awareness of construct validity also reveal an issue: The software engineering community lacks a shared theoretical definition of code comprehension.

In practice, definitions of code comprehension are typically implicit and context-dependent, with many empirical studies that measure code comprehension not explicitly defining the construct at all [54, 30, 53]. Instead, the construct is implicitly defined through the chosen combination of tasks and measures. For example, studies on the effect of code smells often claim to investigate code comprehension, but operationalize it through time and accuracy in information-providing or maintenance tasks without specifying which code comprehension

strategy is expected or possible [1, 35, 20]. Similarly, studies on large-scale systems sometimes refer to *top-down* or *bottom-up* comprehension without further clarifying which cognitive process is actually being measured [42].

Given the large number of possible task types, measures, and their combinations, this practice makes it difficult to compare results across studies [55]. Put simply, it remains unclear whether the many ways of measuring code comprehension actually capture the same underlying construct. This lack of conceptual grounding motivates the need for a clearer link between the kind of understanding a study investigates and the tasks used to operationalize it – an issue addressed by the facet-based perspective introduced in the following section.

## 3 A Facet-Based Perspective on Code Comprehension

The variety of operationalizations and (implicit) underlying definitions of code comprehension indicate the research community's diverse view on code comprehension. One contribution of this paper is to provide a unifying umbrella of the research community's current view of code comprehension, as can be deduced from the existing studies on code comprehension.

Distilling the underlying assumptions about what code comprehension is, we derive a multi-faceted view of code comprehension that comprises three facets: analytical, abstract, and critical. To arrive at these facets, our starting point is the systematic mapping study by Wyrich and others [54], which provides an overview of established tasks used in code comprehension studies. Based on these tasks, we can infer the cognitive skills required to solve them, which we group into the three key facets. We analyzed the tasks regarding the cognitive operations required to solve them at a fundamental level, focusing on the skills participants must use to complete them successfully. For example, tasks such as tracing code execution or recalling code elements require participants to focus on individual statements and their effects. This corresponds to analytical or bottom-up thinking. In contrast, tasks such as summarizing code or matching code to higher-level representations (e.g., flowcharts or diagrams) require forming an overall understanding of the program and interpreting details in view of that understanding. This reflects abstract or top-down thinking. Finally, tasks such as debugging, assessing correctness, or rating code quality require participants to evaluate the code, linking comprehension with judgment, which we categorize as critical thinking. By systematically mapping recurring task types to the underlying cognitive skills they require, we observe that the variety of task forms can be reduced to combinations of three key facets.

**Analytical thinking** is the skill to focus on individual parts of code to understand their functionality and, as a result, gradually develop an understanding of the entire program. It maps to the strategy of bottom-up comprehension [34, 43]. Several studies include this view. For example, Huang and others describe a tool to support students in acquiring programming skills, for which they provide different views on code [21]. One of those views focuses on detailed parts of the code to understand the effect of individual statements on the overall program, which is in line with the analytical skill. Barke and others found that programmers focus on details of the code to decide whether to accept or reject generated code [3]. Similarly, during code reviews, Gonçalves and others found that, as part of the code review process, developers understand code in a bottom-up way [13]. Benjamini and others let participants understand and modify functions, in which variable names were replaced with single-letter names, enforcing a bottom-up comprehension process [5]. Izu and Mirolo evaluated students' skill to compare the equivalence of two small programs that had only single-letter identifiers, thereby enforcing bottom-up comprehension [23]. Several studies using eye-tracking and

neuro-imaging methods assess the analytical thinking skill. For example, Abid and others found that developers examine specific code elements, such as call terms, when asked to summarize Java methods [2]. Siegmund and others, followed by Peitek and others, let participants predict the outcome of source code with obfuscated identifier names, enforcing that participants focus on details of code, while being observed in an fMRI study [44, 31]. These examples highlight the relevance of analytical skills in code comprehension studies.

**Abstract thinking** describes the skill to understand individual code elements in the context of an overarching understanding of a program. It is in line with top-down comprehension, which requires knowledge of the domain and the skill to recognize code elements as beacons [7, 48]. Several studies focus on this facet. For example, Kang and others assessed the effect of readability rules on top-down comprehension by giving participants a natural-language description of what a subsequent code snippet is supposed to do [22]. Similarly, Kallia gave students a natural-language description to observe the extent to which students can employ a top-down process [24]. Hassan and others evaluated how to enable students to employ a top-down comprehension strategy when understanding code to explain it in plain English [19]. Sedano indirectly promotes an abstract, overarching understanding by encouraging readers to gain an overview of the code functionality during think-aloud sessions and to interpret individual code elements within this context [39]. The program comprehension tasks used in the study of Konopka and others [25] promote abstract or top-down thinking indirectly, as they require participants to interpret local code elements in the context of a global understanding of the program and the data flow.

**Critical thinking** is the skill to evaluate code in terms of its correctness, efficiency, and comprehensibility. This evaluation of code does not take place after a program has been fully understood, but takes place in parallel to the understanding process and is a fundamental part of code comprehension. In the context of debugging, Gilmore [12] shows that evaluating code takes place parallel to the comprehension process and not, as assumed in earlier models, only after a complete understanding of the program [17]. Votipka and others demonstrate that reverse engineers evaluate code during security evaluations [51]. Basili and Mills [4] also report from observations of programmers that they simultaneously attempt to evaluate the correctness of code while reading it, thus providing early evidence that understanding and evaluation are closely linked.

## 4 Our Vision

The task landscape described in the previous section suggests that many existing code comprehension tasks can be interpreted as instantiations of a smaller set of underlying cognitive demands. In particular, the three facets – analytical thinking, abstract thinking, and critical thinking – provide a way to systematically relate these tasks to the cognitive skills they are intended to elicit. Importantly, this perspective does not require replacing existing tasks; instead, it provides a structure for interpreting and organizing them.

Based on this perspective, we argue that code comprehension tasks can serve as reusable building blocks across empirical studies, provided that their intended cognitive focus is made explicit. Rather than designing study-specific instruments from scratch, researchers could select tasks based on the facet(s) they aim to investigate while adapting the underlying code content to their specific experimental context. This would allow tasks to remain flexible regarding treatments while still being anchored in a shared conceptual framework.

Our long-term vision is to gradually develop a shared pool of empirically grounded and validated code comprehension tasks, organized by facet. In such a setting, researchers would explicitly specify which facet(s) of code comprehension they target in a study and select corresponding tasks from this pool. This would substantially reduce the overhead of designing and justifying bespoken tasks for each individual study, while at the same time improving comparability across studies by enabling the reuse of task structures across contexts.

This vision intentionally builds on existing literature and established task design practices to provide a concrete and actionable starting point. Rather than aiming to fully capture the nature of code comprehension, the proposed facets reflect how the construct is currently operationalized in empirical research. As such, they are intended as a foundation that can be refined, extended, or revised, as further empirical evidence and alternative perspectives emerge. We therefore see this work as a starting point for a broader community discussion on how to conceptualize code comprehension. In what follows, we take initial steps toward this long-term vision by outlining a structured process for designing code comprehension tasks and illustrating the considerations that influence design decisions through a controlled experiment that we conducted for demonstration purposes.

## 5 From Research Question to Reusable Code Comprehension Tasks

Measuring (facets) of code comprehension requires careful design choices regarding tasks, participants, and materials to ensure valid and interpretable results. Feitelson [11] frames experiments on code comprehension as a "challenge–response game", where understanding is demonstrated through task performance, and shows that different task types probe different aspects of comprehension. He also argues that combining multiple tasks can improve validity and reveal otherwise hidden effects.

We build on this perspective and treat it as a starting point. In particular, we agree that task choice strongly shapes what aspect of comprehension is measured. At the same time, we add that these considerations benefit from a more explicit and structured link between cognitive targets, study goals, and practical constraints.

To make this concrete, we move from a set of abstract considerations to a step-by-step walkthrough: from research question to construct definition, to task design, to an instrument ready to be used in a study. The proposed process was developed through careful reflection within the author team, including perspectives from empirical software engineering and psychology, to ensure that the considerations align with established principles of measurement and test design [27]. We illustrate each step with our own case to show how design decisions are made in practice and what their consequences are.

### Step 1: Clarify the Measurement Goal

The first step is to define what exactly should be measured in a given study. In our case, this starts from a typical empirical research question, for example, assessing whether a treatment (such as AI programming support or a teaching intervention) affects code comprehension. However, instead of treating code comprehension as a single construct, we explicitly specify which facet(s) are of interest.

Using a facet-based perspective, we identify whether the study targets analytical thinking, abstract thinking, critical thinking, or a combination of these. This decision directly determines what kind of cognitive processes tasks need to elicit. In our example, we deliberately include all three facets to demonstrate how the full design space can be operationalized within a single set of tasks.

This step results in an explicit and structured definition of the construct that guides all subsequent design decisions. Additionally, it makes studies comparable, because the concrete definition is provided explicitly, so researchers can directly understand what studies measure the same facet(s).

## Step 2: Define Context Constraints

After defining the measurement goal, the next step is to specify the context in which the tasks will be used. This includes both the **use case** of the measurement and the **characteristics of the participant population**, as both strongly constrain task design decisions.

Different use cases impose different requirements on how tasks should be constructed and interpreted. In controlled experiments, for example, the primary goal is typically to detect the effect of a treatment while maintaining controlled conditions and clear evaluation criteria. In contrast, educational settings, such as exams or training, introduce additional requirements, such as fairness, prevention of guessing, and efficient grading. In self-assessment or professional contexts, aspects like feedback value, time constraints, and robustness against strategic cheating behavior become more important.

In our case, we consider a typical empirical study setting in which code comprehension is measured as an outcome variable (e.g., to assess the effect of an intervention such as LLM support or a teaching approach). This implies that tasks need to be sensitive to differences in the targeted facet(s) while still being sufficiently controlled to allow meaningful comparison between conditions.

The participant population further constrains task design. We focus on graduate students with basic Python programming experience. This sets a medium level of expected proficiency: tasks that are too simple would not discriminate between participants, while overly complex tasks (e.g., large-scale real-world systems) would exceed reasonable cognitive limits.

These constraints together define the boundary conditions for task design. They determine what level of complexity is appropriate and how tasks should be framed to align with both the intended facet(s) of code comprehension and the practical realities of the study context. In other words, Step 2 is necessary to understanding the confounding factors that might bias the results. Explicitly defining them ensures a suitable task selection.

## Step 3: Design Tasks Based on Facet Alignment

Given the construct definition (Step 1) and the constraints of the study context (Step 2), the next step is to design concrete tasks that operationalize the selected facet(s) of code comprehension. In our case, this means translating analytical, abstract, and critical thinking skills into observable task requirements.

Each facet implies different cognitive demands. To operationalize all three facets, we design a set of tasks that combines closed and free-text formats. Closed formats allow for controlled and comparable measurement, while free-text formats provide insight into participants' reasoning and help verify whether the intended facet is actually elicited. Free-text formats can potentially reveal the most details about the level of code comprehension of participants, as they require participants to actively recall and apply knowledge. However, they are also the most difficult to analyze and interpret. A combination of these formats enables internal consistency checks between selected answers and explanations.

We further select a familiar programming context based on standard algorithms typically covered in undergraduate courses. This reduces unnecessary domain-specific difficulty while still requiring genuine code comprehension. At the same time, we avoid overly familiar or

trivial examples to ensure that participants engage in actual reasoning rather than recall. In general, contextualization can be an important aspect. A real scenario, perhaps even one to which participants can relate, could improve the participants' motivation. A fictitious scenario is especially useful when working with young participants.

Finally, we design tasks with potential reuse in mind by keeping the underlying task and cognitive demand stable while allowing researchers to adapt the code content, for example, to introduce experimental treatments such as different code formatting or naming styles.

In practice, this step results in a set of tasks, and each task can be traced back to a specific facet (or a combination) and a specific cognitive demand.

## Step 4: Construct the Task Set

In this step, the individual tasks are assembled into a coherent test instrument. The main goal is to ensure that the selected tasks jointly cover the intended facet(s) while remaining balanced regarding difficulty, complexity, and time requirements.

We start by ensuring facet coverage: each selected task is explicitly linked to at least one of the selected facets. This mapping is not only conceptual but also guides practical decisions such as wording, expected reasoning steps, and response format. Where multiple facets are included, we ensure that they are not conflated within a single task unless explicitly intended so that their effects remain distinguishable.

Second, we consider task diversity and redundancy. Tasks targeting the same facet should differ in surface structure (e.g., code context, formulation, or response type) to avoid training or repetition effects while still probing the same underlying cognitive demand. At the same time, the overall set should not become redundant or overly long, especially in time-constrained experimental settings.

Third, we balance difficulty and coverage. Tasks are arranged so that no single facet is systematically easier or more difficult than others, as this would bias comparisons across conditions. In our case, we iteratively adjusted task complexity based on pilot solving to ensure that participants could engage with all tasks within the available time while still exhibiting meaningful variation in performance.

Finally, we ensure that the task set remains adaptable to the experimental context. This includes keeping code snippets modular and avoiding overly context-specific dependencies, so that tasks can be reused across studies or modified to include experimental manipulations (e.g., different code representations or annotations) without changing the underlying facet.

In practice, this step results in a structured collection of tasks where each task can be traced back to a specific facet and a specific cognitive demand, while the full set provides balanced coverage of all facets of code comprehension.

We give an overview of all tasks, including what cognitive process they require, the answer format, and the targeted facet, in Table 1. In total, we defined twelve tasks that cover fundamental programming concepts common within an academic setting, such as arrays, loops, conditionals, and simple algorithmic structures. Tasks were summarized into five groups, with each group using the same source code. They require students to trace and understand code step by step, recognize underlying patterns, and transfer these into more abstract representations. In addition, later tasks address evaluation and improvement of code, thereby assessing students' critical thinking with regard to code quality and readability.

Due to space constraints, we focus on three tasks (see the project Web site for details). The first task covered a loop with non-descriptive identifiers, requiring step-by-step tracing (analytical) while also allowing pattern recognition (abstract). It used a multiple-choice format in which the correct answer could only be determined by understanding the code;

**Table 1** Code comprehension tasks. All task types that are not free-text formats are different variants of closed formats. Rows with the same background denote tasks with the same source code.

| Activity | Task Type | Skills Tested |
|---|---|---|
| Loop & Index Understanding | Multiple Choice | Analytical, Abstraction |
| Edge Case Handling | Multiple Choice | Abstraction |
| Flowchart Comparison | Dichotomous Task | Analytical, Abstraction |
| Detect Output | Multiple Choice | Analytical, Abstraction |
| Assigning Inputs to Outputs | Matching Task | Analytical, Abstraction |
| Detecting Correct Statements on Behavior | Multiple Choice | Analytical, Abstraction |
| Method Naming | Free-text format | Analytical, Abstraction |
| Error Detection | Multiple Choice | Analytical, Abstraction, Critical Thinking |
| Code Snippet Comparison | Multiple Choice | Analytical, Abstraction, Critical Thinking |
| Functionality Check | Multiple Choice | Analytical, Abstraction, Critical Thinking |
| Code Evaluation | Free-text format | Critical Thinking |
| Code Improvement | Free-text format | Critical Thinking |

participants also explained their choice to assess the required thinking processes. The final two tasks required students to evaluate the quality and readability of the code, and based on that, suggest improvements, targeting critical thinking through free-text responses.

## Step 5: Check What the Tasks Actually Measured

After constructing the task set, it is essential to examine what the instrument actually measures in practice. This step should be guided by established quality criteria from psychometrics, in particular *validity*, *reliability*, and *objectivity* [18, 27]. Validity concerns whether tasks measure the intended facet(s) of code comprehension; reliability refers to the consistency of measurement; and objectivity captures the extent to which results are independent of subjective interpretation. Secondary criteria such as fairness, economy, or robustness can further inform design decisions depending on the use case.

To assess these criteria, we applied our tasks in a controlled setting with 34 participants and complemented the results with a qualitative debriefing to collect feedback on the tasks. This revealed several important issues. Most notably, many tasks did not measure the intended facets; although designed to target multiple facets, they often elicited primarily analytical behavior. In some cases, participants focused on low-level details instead of the intended higher-level reasoning, directly threatening construct validity. In addition, certain response formats (especially free-text answers) introduced ambiguity and reduced objectivity, as we had not anticipated the range of valid responses.

For illustration, we discuss the results for the three tasks described in the previous step. For the first task, participants reported that it was clearly phrased and matched their skill level. However, looking at the free-text responses, participants often confused the loop index with the array element and struggled with list construction, suggesting a mismatch between skill level and task complexity. Moreover, participants focused on individual code elements rather than higher-level patterns, indicating that the task did not capture abstract

thinking as intended. For the two final tasks, the responses indicated the they indeed require critical thinking, such that students evaluated readability and correctness and also made useful suggestions for improvements. However, we noticed that students had difficulties separating the two tasks (which were based on the same source code), such that they suggested improvements already in the evaluation task. Thus, the improvement task does not add anything to the measurement of the construct and may not fulfill the validity criterion.

In this light, evaluating reliability of the tasks does not make much sense, as it does not matter how accurate the tasks measure something that we do not know. If it is unclear what a task measures, consistency metrics, such as internal agreement provide limited insight. However, once validity is reasonably ensured, reliability analyses (e.g., internal consistency) can help identify tasks that do not align well with the overall instrument.

Regarding objectivity, evaluating multiple-choice responses is straightforward, as only one option is correct. For free-text responses, objectivity is lower. To improve it, the first author evaluated the responses, and two other authors reviewed the evaluation. For essay-based tasks, we defined possible solutions in advance. However, some tasks were phrased imprecisely, and unexpected responses emerged, threatening objectivity. To mitigate this, 3 of the 4 authors reviewed the responses. Thus, objectivity could be improved by phrasing the questions more precisely and clarifying how unexpected responses should be evaluated.

Overall, the evaluation showed that 10 out of 12 tasks required revision. Importantly, the explicit mapping between tasks and facets allowed us to detect these issues directly. Without such transparency, we might have drawn incorrect conclusions about the absence of effects in a study when, in reality, the targeted facet was not measured at all. If, for example, we had evaluated a teaching method to improve abstraction during code comprehension, and the results did not show any improvement in abstract thinking skills, we would assume that the teaching method had no effect, when in reality, we just did not *measure* abstraction with our tasks. Thus, we would draw incorrect conclusions, and nobody would even notice.

Based on these results, we iteratively improved the instrument: we removed or adapted overly complex or ambiguous tasks, refined response formats to improve objectivity, incorporated unexpected but valid answers, and rebalanced the task set across facets. A second application with a comparable group of eight participants indicated clear improvements.

Such iterative refinement of tasks is still rare in code comprehension research, where instruments are often used only once. However, as our experience shows, it is a necessary step for developing robust measurement instruments and aligns with standard practice in test development [15]. This also includes continuous evaluation of secondary quality criteria, such as fairness (i.e., that there is no systematic discrimination of demographic groups) or scaling (i.e., that scores reflect the actual skill level).

## Step 6: Make Your Instrument Openly Available

The final step is to make the tasks and their design rationale openly accessible, including their descriptions, mapping to intended facets, design decisions, and observed empirical behavior.

Open availability is a prerequisite for building a shared and reusable pool of code comprehension tasks. Without access to concrete instruments and their documented properties, it remains difficult for other researchers to reuse, compare, or systematically improve existing tasks. In contrast, making tasks and their associated metadata publicly available enables incremental refinement across studies.

In line with our long-term vision, such a shared repository allows researchers to explicitly specify the facet(s) of code comprehension they aim to investigate and select corresponding validated tasks from a growing pool. In our case, we therefore provide all tasks, code snippets,

and response formats on the project's Web site, together with documentation of their intended facet alignment and empirical observations. This is a first step toward a community-driven infrastructure for more systematic and transparent measurement of code comprehension.

## 6 Conclusion

In this vision paper, we introduce a facet-based perspective on code comprehension and a structured process for designing corresponding tasks. Together, both provide a practical foundation for making task design more explicit, systematic, and aligned with what researchers intend to measure. Our case illustrates both the challenges and the value of this approach: Even carefully designed tasks may fail to capture the intended facets, but making assumptions explicit enables targeted improvement through iteration. In this sense, task design should be understood as instrument development rather than a one-off activity.

This vision paper does not aim to provide a final definition or a complete measurement framework for code comprehension. Instead, it provides a starting point for a more systematic and cumulative approach to designing and evaluating code comprehension tasks. The proposed process builds on established principles of test construction in psychology, but it should be refined and extended through future empirical work and community discussion. In particular, future research can explore how the facet-based perspective applies to more realistic software engineering activities, such as maintenance tasks involving larger code bases, documentation, and incomplete information, as well as to emerging development contexts involving AI-based tools and assistance.

Our long-term vision is a shared pool of empirically grounded and validated code comprehension tasks, organized by facets and reusable across studies. The process outlined in this paper is a step toward this goal, as it supports transparent design decisions, facilitates comparison and reuse, and enables the community to iteratively improve how code comprehension is measured. We hope that future work adopts and extends this perspective by making task design and validation more explicit, contributing to a cumulative and more reliable measurement practice in code comprehension research.

# PQC-Readiness of Open-Source Software: An Empirical Study

**Lukas Mehl**
Washburn University, Topeka, KS, USA

## Abstract

Migrating open-source systems to post-quantum cryptography requires knowing where classical public-key primitives still appear in code, yet much empirical work has targeted dependency graphs or *misuse* of APIs rather than primitive-level, multi-language usage at scale. This paper describes a static analyzer that scans Python, Java, and Go repositories using syntax-aware parsing, classifies cryptographic calls and imports as post-quantum-vulnerable, quantum-safe, or PQC-ready, and aggregates findings for ecosystem-level measurement.

Applied to a stratified sample of about fourteen and a half thousand GitHub repositories, vulnerable primitives are found to be widespread at the level of explicit calls and imports, with strongly language-dependent rates shaped in part by how transport and certificate stacks are treated in static analysis. Evidence of PQC-ready APIs is exceedingly rare by comparison, underscoring a stark adoption gap relative to migration goals. Methodological limitations are stated so the baseline can be interpreted, reproduced, and extended.

## 1 Introduction

Much of today's deployed *public-key* cryptography (RSA, (EC)DSA, finite-field and elliptic-curve Diffie–Hellman, and related schemes) rests on the hardness of integer factorization or discrete logarithms. Cryptographically relevant quantum computers are widely expected to break those assumptions (e.g., using Shor's algorithms), so such primitives are called *post-quantum-vulnerable*: confidential data or signatures that rely on them could later be forged or decrypted by a sufficiently capable adversary. Symmetric ciphers and cryptographic hashes behave differently under generic quantum search (typically quadratic speedups); they are not overturned in the same way and are often retained with conservative parameters during migration. The practical risk is therefore uneven: long-lived public-key material is especially sensitive, including TLS and software-signing keys and the "harvest now, decrypt later" scenario in which ciphertext recorded today is broken once quantum hardware matures.

Standardization bodies have begun to define the post-quantum migration path. NIST published the first PQC standards in 2024 [8, 9, 10]: **ML-KEM** (a key-encapsulation mechanism, i.e. a replacement for RSA/Diffie–Hellman key exchange, formerly known as Kyber), **ML-DSA** (a digital-signature scheme, formerly Dilithium), and **SLH-DSA** (a

hash-based signature scheme, formerly SPHINCS+). Together with **NTRU**, an earlier lattice-based encryption scheme still used in some libraries, these form what this paper calls *PQC-ready* primitives – algorithms designed to remain secure against quantum attackers. Authorities such as the BSI recommend early transition and hybrid deployment (running a classical and a post-quantum primitive side by side during migration) [2]. For vendors and open-source maintainers, a central engineering question is *where* vulnerable public-key primitives still appear in code so that migration can be prioritized and progress tracked.

**Why this needs source-level, multi-language measurement.** Existing empirical work on cryptography in software has focused on dependency- and package-level analysis [18] or on *misuse* of cryptographic APIs in single languages [26, 17, 7]. Dependency manifests (e.g. a Maven or PyPI entry for a crypto library) say that a project *could* use RSA or AES somewhere; they do not say whether it actually calls a key-generation routine, an import used only in a test file, or a PQC binding. Misuse detectors, symmetrically, assume the algorithm choice itself (e.g. RSA) is acceptable and only check whether it is invoked correctly. Neither view answers the question this paper asks: *which cryptographic algorithms – classical or post-quantum – are open-source projects actually calling in their source code, at what prevalence, and how far is that from the post-quantum migration target?* A gap remains for **multi-language**, **primitive-level** measurement of *which* algorithms are used (classical vs. post-quantum) rather than merely which libraries are declared or whether an API is called correctly. Without such a baseline, it is unclear how far the open-source ecosystem is from the migration targets those standards envision, and maintainers and funders have no empirical basis for prioritizing migration effort.

This paper addresses that gap by asking three concrete research questions:

- **RQ1 (Prevalence).** How common is source-level usage of post-quantum-vulnerable cryptographic primitives in popular, actively maintained open-source repositories?
- **RQ2 (Language dependence).** Does that prevalence differ systematically across programming languages/ecosystems (Python, Java, Go), and if so, is the difference a genuine usage pattern or an artifact of what static analysis can observe per language (Section 6)?
- **RQ3 (Adoption gap).** How common is source-level evidence of PQC-ready primitives (e.g. ML-KEM/Kyber, ML-DSA/Dilithium, SLH-DSA/SPHINCS+) today, i.e. how far has the migration NIST and the BSI call for actually progressed in practice?

To answer these questions, a static analysis tool is presented that scans Python, Java, and Go repositories for cryptographic API usage and imports, classifies each finding as post-quantum-vulnerable, quantum-safe, or PQC-ready, and aggregates results for empirical study. **Syntax-aware parsing** means the tool reads each file into an abstract syntax tree (AST) – the same structural representation a compiler builds – rather than searching raw text with regular expressions; this lets it tell an actual function call (`RSA.generate(...)`) apart from a mention in a comment, a string, or an unrelated identifier that happens to contain the word "rsa". Section 3 gives the concrete classification mapping and states the caveats that follow from this design (e.g., TLS/X.509 import heuristics, dynamic calls). The implementation and methodology are documented together with limitations so that aggregate statistics can be interpreted and reproduced; headline empirical outcomes answering RQ1–RQ3 are reported in Section 5.

**Contributions.** This paper contributes:

1. **A multi-language scanner** for Python, Java, and Go that classifies cryptographic API calls and imports as post-quantum-vulnerable, quantum-safe, or PQC-ready, released as open-source software (Section 3).

2. **A documented sampling and aggregation methodology** for repository-scale measurement, including an explicit test-vs.-production heuristic and a precision/recall check against a curated reference set (Sections 3–4).
3. **An empirical baseline on 14,508 stratified GitHub repositories** quantifying the prevalence of vulnerable primitives, its variation by language, and the PQC-ready adoption gap (Section 5).
4. **A transparent discussion of what the measurement can and cannot support**, including a sensitivity analysis isolating how much of the language difference in RQ2 is attributable to a single import-level heuristic rather than genuine usage differences (Section 6).

**Long-term objectives and intended impact.** This submission reports an initial, reproducible baseline (tool, evaluation, large-sample measurement) rather than a finished longitudinal study; that scope matches the Emerging Results track's purpose of sharing early results for community feedback. The longer-term research agenda this baseline is meant to seed includes: (1) *longitudinal rescans* of the same repository population to track migration progress over time as ML-KEM/ML-DSA library support matures; (2) *broader language and library coverage* (JavaScript/TypeScript, C/C++, additional crypto libraries per language) to reduce the detection gaps discussed in Section 3.9; and (3) *refining the TLS/X.509 signal* (Section 6) so that transport-layer usage can be distinguished from direct key-material handling. For the open-source software engineering community, the intended contribution is a reusable, extensible measurement instrument and an open dataset that other researchers and maintainer communities can rescan, audit, and build on – rather than a one-off number – so that PQC migration progress becomes something the community can track empirically instead of anecdotally.

The remainder of the paper is structured as follows. Section 2 reviews related work, including empirical repository-mining methodology; Section 3 describes detection, classification, and sampling; Section 4 reports a reference-set spot check; Section 5 presents empirical results answering RQ1–RQ3; Section 6 discusses implications, threats to validity, and closes.

## 2 Related Work

### 2.1 Post-Quantum Standards and Migration

NIST's 2024 standards (ML-KEM, ML-DSA, SLH-DSA) [8, 9, 10] and hybrid transition guidance from authorities such as the BSI [2] define migration targets; this work measures *where* source code still relies on quantum-vulnerable public-key primitives rather than prescribing how to migrate.

### 2.2 Empirical Studies on Cryptographic Usage

Prior work has studied the use of cryptography in software at different levels. Dependency- and package-level analyses track which crypto libraries or versions are declared in manifests (e.g. Maven, PyPI, Go modules) and have been used to study vulnerability propagation and supply-chain risk [18]. Such studies are valuable for supply-chain and vulnerability management but do not reveal *which primitives* are actually invoked in source code, e.g. whether a project uses RSA, ECDSA, or both, or whether it has already adopted PQC APIs. Source-code-based studies exist for single languages or specific libraries; for example, Wickert et al. analyze cryptographic API *misuse* in 895 Python projects from GitHub [26]. A gap remains for **multi-language**, **primitive-level** measurement of classical vs. post-quantum *usage* (rather than misuse) at scale, which the present scanner and dataset aim to provide.

## 2.3 Static Analysis for Cryptography

Static analysis tools for cryptography have largely focused on **misuse detection**: finding incorrect or insecure *usage* of cryptographic APIs (e.g. weak modes, hardcoded keys, improper randomness). CryptoGuard [17] and CogniCrypt/CrySL [7] are prominent examples that use AST- or pattern-based analysis to flag such issues. They assume that the *algorithm* in use is an accepted choice; their goal is to ensure it is used correctly.

The contribution addresses a **complementary but orthogonal** question. Existing tools such as CryptoGuard and CogniCrypt address incorrect usage of cryptographic primitives; the focus here is the *algorithm-level* quantum vulnerability of open-source software, independent of implementation correctness. A correctly implemented RSA-2048 is a non-issue for prior tools but a critical migration target under NIST's post-quantum standards. Thus, this work does not replace misuse detectors; it answers a different, policy-relevant question: how far is the ecosystem from the post-quantum migration path, and where are classical primitives still in use?

Technically, the approach shares with prior work the use of syntax-aware parsing to reduce false positives from comments and string literals and to distinguish direct API calls from imports: rather than matching raw text, the scanner walks each file's abstract syntax tree – for Python via the standard-library `ast` module, for Java and Go via tree-sitter [24], an incremental parser-generator that produces a concrete syntax tree independent of a full language toolchain – and inspects import statements and call-expression nodes directly (see Section 3 for the exact node patterns per language). CryptoGuard and CogniCrypt/CrySL apply the same AST-based principle to misuse detection [17, 7]; this work reuses it for a different classification task (primitive identity rather than usage correctness). Limitations such as dynamic or reflective invocation (e.g. algorithm names from configuration) apply equally [17, 7] and are discussed in the Methodology and Limitations sections.

## 2.4 Empirical Methods for Repository Mining

Because the study's evidence comes from mining a large, unlabeled population of GitHub repositories, its design choices are checked here against established guidance from the mining-software-repositories (MSR) literature rather than treating GitHub as a neutral, representative corpus. Combining a large-scale analysis of GitHub metadata with a manual inspection of 434 repositories, Kalliamvakou et al. document nine "perils" of using GitHub data for research, including that most projects are inactive, that a large share of repositories are not used for software development at all (experimentation, storage, personal websites), and that roughly two-thirds are personal, effectively single-committer projects rather than collaborative software efforts [6]. This motivates treating "a GitHub repository" as a noisy, non-representative unit rather than a de facto software project. The sampling design (Section 3) is consistent with that concern: it stratifies by star-count range rather than taking a flat top-$N$ sample, and applies a minimum popularity threshold intended to bias the sample away from personal or abandoned repositories. This is a partial mitigation, not one derived from Kalliamvakou et al. or a solved problem: Section 6 reports the threshold explicitly and notes that popularity alone does not guarantee the properties they describe. Vidoni's systematic literature review of MSR studies finds that most do not follow or report an explicit, systematic protocol for repository selection and data extraction, and recommends making such choices explicit so they can be scrutinized [25]; the per-repository JSON output, the aggregation CSV, and the CLI report pipeline (Section 3), together with the Limitations and Threats to Validity discussion (Sections 3.9 and 6), are structured in that spirit. Finally,

Gold and Krinke argue that MSR research is, in an important sense, human-subjects research: the repositories studied here reflect real developers' work and choices, and those developers did not consent to having their code analyzed for this specific purpose [4]. Consistent with the ethical caution they call for, the scanner only inspects already-public repositories, records no personal data about individual contributors, and the paper's per-repository discussion (Section 5) reports only externally observable facts about code (which cryptographic APIs are imported or called) rather than characterizing the people who wrote it.

# 3 Methodology

## 3.1 Overview

The study uses a static analysis tool that scans source code repositories for uses of cryptographic primitives and classifies each finding as **post-quantum-vulnerable**, **quantum-safe**, or **PQC-ready**. The tool targets three languages (Python, Java, and Go) and produces per-repository summaries plus an aggregated dataset suitable for empirical analysis of PQC adoption in open-source software.

## 3.2 Detection Approach

**Syntax-aware parsing** is used rather than plain text or regex search. This reduces false positives from comments, string literals, and documentation, and allows direct API usage (e.g. key generation) to be distinguished from mere imports. For **Python**, the standard library `ast` module is used; for **Java** and **Go**, **tree-sitter** [24] with language-specific grammars. The tool does not execute code; therefore dynamic or reflective invocations (e.g. algorithm names passed via configuration) may be missed and are a known limitation.

## 3.3 Per-Language Detection

- **Python.** Each `.py` file is parsed for (1) imports of 11 known crypto libraries (`cryptography`, PyCryptodome, `ssl`, `hashlib`, `hmac`, `rsa`, `ecdsa`, `oqs`, etc.) and (2) 14 API call patterns (e.g. `RSA.generate`, `ECC.generate`, `load_pem_private_key`). Each finding is associated with a primitive name and a confidence level (high for direct calls, medium for imports).
- **Java.** `.java` files are parsed with tree-sitter; the detector collects (1) imports from `javax.crypto`, `java.security`, or `org.bouncycastle` (including `org.bouncycastle.pqc`), and (2) invocations of `getInstance(...)` with a string argument. The implementation recognizes 24+ algorithm strings (classical: RSA, EC, ECDH, DSA, AES, SHA-256; PQC: Kyber, Dilithium, ML-KEM, ML-DSA, SPHINCS+) and 6 PQC import-path patterns.
- **Go.** `.go` files are parsed with tree-sitter; the detector collects (1) imports from 10 paths (`crypto/rsa`, `crypto/ecdsa`, `crypto/elliptic`, `crypto/dh`, `crypto/tls`, `crypto/x509`, `golang.org/x/crypto`, liboqs-go) and (2) 11 call signatures (e.g. `rsa.GenerateKey`, `ecdsa.GenerateKey`, `elliptic.P256`). Imports of `crypto/tls` and `crypto/x509` are classified as post-quantum-vulnerable (medium confidence), since TLS and X.509 usage in practice implies classical RSA/ECDSA certificates; this is an *import-level* signal, not a claim about the actual certificates in use (see Limitations and Discussion).

## 3.4 Classification of Primitives

Section 1 motivated the split between public-key schemes whose standard hardness assumptions fall to quantum algorithms (hence migration targets) and symmetric-style primitives that remain comparatively robust under known quantum attacks and are grouped here as *quantum-safe* for measurement purposes. The categories below instantiate that split for concrete API names and library paths; edge cases (e.g., elliptic-curve key agreement used ephemerally in TLS) are flagged where they affect interpretation.

Each detected primitive name is mapped to one of four categories:

- **Post-quantum-vulnerable:** RSA, ECDSA, ECDH, DH, DSA, ElGamal, classic curves (e.g. P-256), and **X25519/Ed25519** (counted as vulnerable for transparent reporting; ephemeral TLS use is discussed in Section 3.9) [2].
- **Quantum-safe:** Symmetric and hash primitives (AES, SHA-2, SHA-3, ChaCha20, HMAC, PBKDF2) that are not broken by known quantum algorithms in the same way as public-key schemes.
- **PQC-ready:** Algorithms standardized or in wide use for post-quantum cryptography: KyberML-KEM, DilithiumML-DSA, SPHINCS+, NTRU, and usage of the Open Quantum Safe library (liboqs/oqs) [20].
- **Unknown:** Any primitive name not in the mapping table; such names are not counted as vulnerable or PQC-ready in the aggregate metrics.

The mapping table is extensible and documented in the tool's source (see repository).

## 3.5 Test vs. Production Code

Repositories often contain test code or third-party code (e.g. under `test/`, `tests/`, `vendor/`, `node_modules`, `third_party`). Each finding is tagged with a boolean **is_test_file** if the file path (relative to the repo root) contains any of these segments. Code under `vendor/` is thus counted as non-production. The paper reports both: (1) vulnerability metrics over **all** findings, and (2) metrics restricted to **production** code only, so that the share of vulnerable findings in test code can be clearly communicated. Many cryptographic libraries ship their own tests; if a repository is primarily such a library, a large fraction of vulnerable findings may fall in test paths. That pattern is treated as a valid empirical outcome; test detection is **path-based only** (no semantic analysis), as noted in the Limitations subsection.

## 3.6 Dataset and Sampling

The dataset uses **stratified sampling** over Python, Java, and Go (roughly equal shares), and **star-range strata** (e.g. $\geq$10k down to lower ranges) to diversify beyond the GitHub Search API's per-query result cap, rather than a flat top-$N$ query that would only capture already-famous projects. A fixed repo list is built once (`build-repo-list` or snapshot; `docs/SCALING.md`) for reproducibility. As Section 2.4 discusses, popularity-based filtering is a mitigation against, not a guarantee against, the kind of unrepresentative repositories documented in the MSR literature [6]; the sample retained in the final 14,508-repository run has no repository below **92 stars** (median 946, maximum 408,536 – see Section 5 for the exact per-language breakdown), which excludes toy or single-commit repositories but still skews toward already-popular projects, a limitation carried through to Section 6.

## 3.7 Output and Aggregation

The scanner writes a JSON result per repository (list of findings, summary counts, vulnerability score) and appends one row per repo to an aggregated CSV. Detectors emit raw primitive names (e.g. `RSA`, `ECDSA`, `crypto/rsa`, `rsa.GenerateKey`, or language-specific spellings). For aggregation, these labels are **normalized** to a **canonical key** per logical primitive (e.g. all RSA variants and Go `crypto/rsa` / `rsa.GenerateKey` are merged into one entry), so that the top-primitives tables are not split by spelling or language. A CLI report command produces paper-ready statistics: fraction of repos with $\geq$1 vulnerable primitive, fraction with $\geq$1 PQC-ready primitive, breakdown by language, top primitives (aggregated), and criticality (vulnerable in production vs. test).

## 3.8 Evaluation of the Scanner (Precision and Recall)

Before large-scale use, repo-level labels in a CSV (cited README or official docs, not a line-by-line audit) are compared to scanner output on `has_vulnerable` and `has_pqc_ready` as a deterministic **sanity check** (Section 4); broader threats are in Section 3.9.

## 3.9 Limitations

The following limitations are stated explicitly so that reviewers and readers can judge the generalizability of the results:

- **Dynamic and reflective usage:** The scanner relies on static analysis only. Algorithm names or library choices that are determined at runtime (e.g. from configuration, reflection, or string concatenation) are not detected. This may lead to **false negatives** in projects that use such patterns.
- **Unsupported libraries and patterns:** Only a fixed set of libraries and API patterns per language is recognized. Use of other crypto libraries or custom wrappers is not captured and may be underreported.
- **Languages omitted:** JavaScript/TypeScript and other ecosystems are out of scope; extending the tree-sitter approach would require new pattern libraries comparable to adding a fourth language.
- **Path-based test heuristic:** The distinction between "test" and "production" code is based on path heuristics (e.g. `test/`, `tests/`, `vendor/`). Misclassification (e.g. production code under a test path, or tests outside these paths) can affect the criticality breakdown; both "all" and "production-only" metrics are reported to reduce reliance on this heuristic.
- **TLS and X.509 (Go):** Imports of `crypto/tls` or `crypto/x509` count as vulnerable (import-level signal; actual certificates are not inspected). Top-primitive tables and Section 6 discuss interpreting rates with and without these signals.

These limitations are also reflected in the Discussion and Threats to Validity where appropriate.

# 4 Evaluation

Section 3.8 sketched a **reference-set spot check** ($n = 19$). Labels tie `has_vulnerable`/`has_pqc_ready` to **citable docs** (README, official API text), not a line-by-line audit; entries skew to mainstream crypto libraries and PQC bindings, so the set is **transparent but coverage-biased** and does not estimate ecosystem-wide error rates. Nineteen repositories are enough to sanity-check that the detectors fire on well-known crypto

**Table 1** Agreement with the curated reference set ($n = 19$); spot check, not ecosystem-wide validation.

| Task | Precision | Recall | F1 |
|---|---|---|---|
| has_vulnerable | 1.00 | 0.93 | 0.97 |
| has_pqc_ready | 1.00 | 0.88 | 0.93 |

and PQC libraries and to surface concrete failure modes (below), but they are far too few to estimate precision/recall with any statistical confidence across the full 14,508-repository sample, or across less mainstream libraries and wrapper patterns that this reference set does not include. Growing this reference set – more repositories per language, more non-mainstream and wrapper libraries, and ideally multiple independent annotators with an agreement statistic – is the most direct way to strengthen this evaluation and is left as immediate follow-up work rather than attempted within this Emerging Results submission.

Labels group into **vulnerable-only** exemplars (`pyca/cryptography` [15], `golang/crypto` [21], `paramiko/paramiko` [14], `jpadilla/pyjwt` [16], `golang/go` [22], `square/go-jose` [19], and others), **PQC-ready-only** liboqs bindings [20, 13, 12, 11], and **mixed** stacks (`bcgit/bc-java` [1], `cloudflare/circl` [3], `tink-crypto/tink` [5, 23]); the CSV in the replication package lists all 19 with cited sources. For Tink, PQC-ready labels depend on which subtree is scanned [5]. The pipeline clones each repo, runs the scanner, and compares predictions to the CSV; Table 1 gives precision/recall as **regression-style** checks, not calibrated ecosystem-wide error.

*Replication.* Table 1 reflects a full run of `evaluation/run_evaluation.py` on the CSV with the scanner version documented in the replication package; verification output ships with that package (see Data Availability).

Recall is 0.93 (`has_vulnerable`) and 0.88 (`has_pqc_ready`); precision is 1.0 on both tasks. The two false negatives illustrate coverage limits rather than label errors. `square/go-jose` implements RSA/ECDSA JOSE operations via `github.com/square/go-jose`, which is outside the Go detector's fixed stdlib-oriented import and call patterns [19]. `tink-crypto/tink` is a multi-module monorepo: PQC-ready APIs appear in language-specific trees (e.g. `tink-go/v2` ML-DSA/SLH-DSA paths), while the ground-truth label follows roadmap-level PQC support [5]; a root-level scan can miss sparse submodule imports.

## 5 Results

**Headline outcomes.** Across a stratified sample of 14,508 repositories (sampling procedure below), three patterns dominate: (1) **19.38 %** of repositories exhibit at least one post-quantum-vulnerable primitive at the level of explicit API calls and imports, with strong variation by language (**Go 40.7 %**, Java 12.6 %, Python 4.8 %), driven in part by import-level TLS/X.509 coverage in Go; (2) a pronounced **adoption gap**, with only **0.08 %** (11 of 14,508) showing any PQC-ready usage; and (3) vulnerable findings split almost evenly between production and test/example paths, suggesting that classical primitives remain the default across both.

### 5.1 Sample

A stratified sample of $N = 14{,}508$ repositories was scanned (Python, Java, and Go in roughly equal shares: 4,986 / 4,635 / 4,884 per GitHub primary language metadata, with three repos lacking language metadata), drawn by star-range strata and a minimum star count to ensure

**Table 2** Repositories and vulnerability by language.

| Language | Repos | With vuln. | % w. vuln. | PQC-ready | % PQC-ready |
|---|---|---|---|---|---|
| Go | 4,884 | 1,987 | 40.7% | 5 | 0.10 % |
| Java | 4,635 | 584 | 12.6% | 5 | 0.11 % |
| Python | 4,986 | 239 | 4.8% | 1 | 0.02 % |

diversity and exclude toy projects. Concretely, every repository in the final sample has **at least 92 GitHub stars** (median 946; maximum 408,536), which is the empirical minimum enforced by the star-range strata used to build the list rather than a single global cutoff applied afterward. The aggregate data and exact stratification parameters are documented in the replication package (`docs/SCALING.md`). The summary statistics reported below come from a full scan using the scanner's `report` command; raw aggregates and per-repo outputs from large runs are supplied there rather than in a public VCS snapshot (see Data Availability).

## 5.2 Overall Vulnerability Rate

The *PQC vulnerability rate* is defined as the fraction of repositories that contain at least one finding classified as post-quantum-vulnerable (RSA, ECDSA, ECDH, classical curves, or, for Go, imports of `crypto/tls` or `crypto/x509`). In this sample, **19.38 %** of repositories (2,811 of 14,508) have at least one such finding, for a total of 79,802 vulnerable findings (and 3,948 quantum-safe findings). This rate is methodologically conservative in the sense of *detection*: the scanner only counts *explicit* API calls and imports; indirect use through frameworks or configuration is not detected. At the same time, import-level TLS/X.509 signals (especially in Go) can substantially increase the number of repositories flagged compared to patterns that omit those imports; interpretation is discussed in Section 6.

## 5.3 By Language

The vulnerability rate varies sharply by language (Table 2). With the updated detectors and aggregation pipeline, **Go** shows the largest share of repositories with at least one vulnerable finding (1,987 of 4,884, 40.7 %), followed by **Java** (584 of 4,635, 12.6 %) and **Python** (239 of 4,986, 4.8 %). The Go result is consistent with import-based classification of `crypto/tls` and `crypto/x509` (Section 3.9) and with those primitives dominating the top of the frequency table (Section 5, Top primitives). Java projects often use cryptographic infrastructure directly (e.g., Bouncy Castle, JCA `getInstance`) [17]; Python code frequently relies on higher-level libraries that abstract crypto and may not surface as direct primitive usage in the implemented patterns [26]. Repositories with PQC-ready findings are split across languages (Table 2), reflecting bindings and libraries in more than one ecosystem [20].

*Note.* Three repositories lack GitHub language metadata; they are omitted from Table 2 (one of them has a vulnerable finding).

**Sensitivity: is Go actually less secure, or does it just import more visibly?** Because `crypto/tls`/`crypto/x509` imports are counted as vulnerable at import level and are Go-specific labels in the mapping table (Section 3), part of Go's lead in Table 2 could be

**Table 3** Vulnerability rate with vs. without `tls`/`x509`-labeled findings.

| Language | % w. vuln. (all) | % w. vuln. (excl. `tls`/`x509`) |
|---|---|---|
| Go | 40.7% | 21.4% |
| Java | 12.6% | 7.0% |
| Python | 4.8% | 4.6% |

an artifact of that single heuristic rather than a genuine difference in cryptographic usage. Table 3 recomputes the per-language vulnerability rate after dropping findings labeled exactly `tls` or `x509`. Go's rate falls from 40.7 % to **21.4 %** – roughly half of its repositories with a vulnerable finding owe that finding solely to a `crypto/tls`/`crypto/x509` import – while Java falls from 12.6 % to 7.0 % and Python is almost unchanged (4.8 % to 4.6 %, since its `cryptography.x509` and `ssl.PROTOCOL_TLS*` labels are spelled differently and are not removed by this filter). Two things follow: (1) a non-trivial share of the Go vulnerability rate is indeed a transparency effect of one import-level heuristic, so the headline **40.7 %** should not be read as "40.7 % of Go repositories call classical key-generation APIs"; but (2) even after removing that heuristic, Go's residual rate (21.4 %) remains roughly three times Java's and more than four times Python's, so the language gap is not *purely* an artifact – Go repositories in this sample also more often contain direct calls such as `rsa.GenerateKey` or `ecdsa.GenerateKey` than their Java or Python counterparts. Both readings are reported so that neither the raw rate nor the sensitivity-adjusted rate is mistaken for the whole picture; Section 6 returns to the interpretive consequences.

## 5.4 PQC Adoption

The clearest result regarding **PQC adoption** is that only **0.08 %** of repositories (11 of 14,508) exhibit at least one PQC-ready finding (Kyber, Dilithium, SPHINCS+, NTRU, or liboqs/oqs usage [20]). In total there are 947 PQC-ready findings across these repositories; the most frequent labels include NTRU, SPHINCS+, Dilithium, ML-DSA, ML-KEM, and Kyber (consistent with the aggregated primitive frequencies from the same reporting pipeline). This quantifies a clear gap between current open-source practice and the post-quantum migration target [8, 9, 10, 2] and constitutes a central finding of the study. The scanner also reports quantum-safe primitives (AES, SHA-2, ChaCha20, HMAC); with 3,948 findings they are omitted from the vulnerability rate but kept in the aggregate pipeline for context.

**Who are the 11 adopters?** Inspecting the 11 repositories individually (they are not part of the curated evaluation set) and cross-referencing each PQC-ready finding's file path against the test/vendor path heuristic (Section 3) refines the headline number further. Two repositories owe their PQC-ready label entirely to a *vendored third-party dependency* rather than their own code: `GhostTroops/scan4all`'s 22 findings and `darkweak/souin`'s single finding both resolve to a bundled copy of Cloudflare's CIRCL library under a `vendor/` path – the host project itself does not call these APIs. Several more show PQC-ready evidence concentrated in *test code for library features still under development*: `openjdk/jdk` (21 of 22 findings in tests, consistent with the JDK's ML-KEM/ML-DSA support landing first as tested library internals) and `pyca/cryptography` (20 of 22 in tests) follow this pattern, and `apache/camel`'s dedicated `camel-pqc` component is mostly test code (33 of 41) with a small non-test core. The remaining repositories show PQC-ready primitives in *non-test, non-vendor code*: `bcgit/bc-java` (Bouncy Castle; 523 of 823 findings outside test paths, by far the

**Table 4** Top five post-quantum-vulnerable primitive labels (finding counts).

| Label | Findings |
|---|---|
| `tls` | 20,275 |
| `x509` | 18,603 |
| `rsa` | 13,681 |
| `ecdsa` | 11,201 |
| `ec` | 5,513 |

largest genuine contributor via its `org.bouncycastle.pqc` packages), `Keyfactor/ejbca-ce` (a certificate-authority product), `XTLS/Xray-core`, `XTLS/REALITY`, `ivpn/desktop-app`, and `i2p/i2p.i2p` – all networking, VPN, or anonymity tools with production-path post-quantum key-exchange or signature code. This breakdown (informal, derived from inspecting these 11 repositories rather than a systematic classification) suggests that even the already-tiny 0.08 % adoption figure overstates *deployed* PQC usage: at least 2 of the 11 repositories show no adoption of their own, several more show it only in test/development code for not-yet-released features, and clearly production-path adoption today is effectively confined to cryptography-library internals (Bouncy Castle) and a handful of privacy/networking early adopters.

## 5.5 Criticality (Test vs. Production)

Path heuristics (`test/`, `tests/`, `vendor/`, etc.) tag each finding. Among vulnerable findings, **39,807** fall in test or example code and **39,995** in production paths (roughly even). Classical primitives therefore appear at scale in both settings; reporting production-only and all-findings metrics (as here) helps readers judge criticality.

## 5.6 Top Primitives

Table 4 lists the five most frequent vulnerable labels; `tls` and `x509` dominate, reflecting Go import-level `crypto/tls`/`crypto/x509` classification together with TLS/X.509 usage elsewhere. These are import-level signals where applicable: importing `crypto/tls` for HTTPS counts as vulnerable without inspecting certificates or cipher suites (Section 6).

# 6 Discussion

The near-even split of vulnerable findings across production and test paths shows classical primitives remain the default in both settings; when developers write tests or demos involving cryptography, they still reach for classical APIs because PQC alternatives are not yet part of the default toolkit.

### Is Go actually less secure, or just more transparent to the scanner (RQ2)?

Table 3 (Section 5) gives a direct, data-backed answer rather than a purely qualitative caveat: roughly half of Go's headline gap over Java and Python is a transparency effect of the `crypto/tls`/`crypto/x509` import heuristic (40.7 % falls to 21.4 % once those two labels are excluded), but the other half is not – Go's residual rate remains about three times Java's and more than four times Python's even on a like-for-like comparison that excludes the heuristic entirely. A plausible reading is that Go's standard library exposes

`crypto/rsa`, `crypto/ecdsa`, and `crypto/elliptic` as commonly-used, low-ceremony stdlib calls for everyday networking code, where equivalent Java code more often goes through a higher-level provider abstraction (`getInstance`) that this detector also tracks, and Python code more often goes through libraries this detector's Python patterns do not cover as exhaustively [26]. In other words, *both* things are true: the scanner is more "transparent" to Go's import style than to Python's, *and* Go code in this sample does call classical key-generation and signing APIs directly more often. Consumers of the **19.38 %** repository-level rate and the Go-specific share in Table 2 should read both numbers in Table 3 together, not the 40.7 % figure in isolation (Section 3.9).

The headline statistics are a **readiness signal**, not a quantum timeline forecast: they inventory where classical APIs and TLS paths remain default and how rarely PQC-ready calls appear (**0.08 %** of repos, and rarer still once vendored dependencies and test-only usage are excluded, Section 5). That gap suggests **limited embodied PQC practice** at scale before policy, certificates, and library defaults converge, while *harvest now, decrypt later* still motivates long-lived confidentiality planning. Dependency upgrades alone seldom remove vulnerable signals without application-level algorithm changes.

### Threats to validity

**Construct validity:** labels reflect static API/import patterns, not runtime cipher suites or certificate contents (especially for Go TLS/X.509); the sensitivity analysis in Table 3 bounds, rather than eliminates, this threat for the language-comparison claim (RQ2). **Internal validity:** the $n = 19$ reference set is a documentation-backed regression check, not a calibrated sample for ecosystem-wide precision; false negatives on wrapper libraries (Section 4) bound recall on curated exemplars only, and growing this set is planned follow-up work rather than a solved problem. **External validity:** results apply to popular GitHub repositories (all above 92 stars in this sample, Section 5) in Python, Java, and Go; popularity filtering only partially mitigates the risks documented in the MSR literature [6], and JavaScript/TypeScript and unstarred code are out of scope. Main claims rest on transparent rules, the large sample, and the sensitivity analysis for RQ2.

### Contribution to the open-source software engineering community

Beyond the headline numbers, this work's practical contribution is a reusable measurement instrument: the scanner, its per-language pattern tables, and the aggregation/report pipeline are released as open-source software so that maintainer communities and other researchers can point it at their own repositories rather than this paper's specific sample. Because the classification mapping (Section 3) is an explicit, editable table rather than logic buried in the parser, extending it to a new library, algorithm, or language is a scoped engineering task, not a re-implementation. The intended impact is turning "is our project PQC-ready?" from a manual, ad-hoc audit into a repeatable measurement that maintainers, security teams, and standardization bodies can rerun over time.

For maintainers, low PQC adoption and pervasive classical usage suggest underused migration guidance [2, 8, 9, 10]. For researchers, the scanner and dataset support longitudinal rescans and extensions (more languages, dependency-level views [18]), building on the MSR guidance in Section 2.4 [6, 25, 4]. This complements misuse-centric studies [17, 7] by measuring algorithm-level distance to the post-quantum path at scale.

## Data Availability Statement

Replication materials – scanner source code, the per-language detection patterns, the classification mapping table, the 14,508-repository aggregate CSV and per-repository raw JSON outputs, the evaluation reference set and its CSV of cited labels, and the scripts used to produce the tables in this paper – are archived on Zenodo at `https://doi.org/10.5281/zenodo.19634475`. Any material that cannot be shared (e.g. full clones of the scanned repositories, which remain available from GitHub directly) is noted in the replication package's README.

The author used large language models for grammar and phrasing support during manuscript preparation; all claims, analyses, and citations were verified by the author.

## Abstract

Repository-level configuration artifacts allow developers to provide guidance for agentic AI coding tools, e.g., Claude Code, Gemini. Although prior research has examined repository-shared context files that capture project-level instructions and conventions (e.g., `AGENTS.md` files), little is known about more task-oriented artifacts such as *Agent Plans*. We present an exploratory study of Agent Plans in open-source software repositories, examining how plan files are preserved, which development activities they support, and what information they provide to guide agent execution. We screened 36,710 GitHub repositories belonging to engineered software projects and identified 85 Markdown plan files from 10 repositories. Within this concentrated corpus, Agent Plans supported several kinds of software engineering work, including maintenance, design, construction, quality-related work, and process support. They also provided task-oriented execution guidance, most commonly through implementation steps, concrete files and locations, and testing and validation information. Overall, repository-preserved Agent Plans in these tool-specific directories appear to be a narrow but informative artifact for studying task intent and execution guidance in human-agent workflows.

## 1 Introduction

Repository-level configuration artifacts allow developers to guide agentic AI coding tools, such as Claude Code [13, 21]. Prior work has shown that artifacts such as `AGENTS.md` files capture project knowledge, development conventions, and workflow-related guidance that is versioned and inspectable within repositories [13, 21, 8]. This means that interactions with agentic AI coding tools are shaped not only by prompts, but also by persistent repository-level artifacts. Prior work has identified *configuration mechanisms* for such tools, that is,

general ways of tailoring tool or agent behavior to a project or workflow; examples include Context Files, Skills, Subagents, etc. [13]. *Context files* are one particularly prominent type of configuration mechanism whose artifacts are Markdown files, such as `AGENTS.md`, `CLAUDE.md`, or `copilot-instructions.md`. These files provide persistent project-level instructions, conventions, and contextual guidance for agentic AI coding tools. Such guidance may include build and run commands, test procedures, architectural information, coding conventions, and project-specific workflow rules [13, 8]. Thus, interactions with agentic AI coding tools are shaped not only by prompts, but also by persistent repository-level guidance. Earlier research has largely examined context files at a *coarse-grained level*, asking whether such files exist, how they are adopted, and whether they improve tool performance [13, 8, 21, 15, 19]. However, *task-oriented* planning artifacts remain underexplored.

In this study, *Agent Plans* refer to task-oriented Markdown artifacts that describe a concrete unit of intended work for an agentic AI coding tool. Plan files are used with tools such as Cursor, where the agent can inspect the codebase, identify relevant files, and produce a plan file for the developer to review, edit, or approve the plan files before implementation [9]. Agent Plans are therefore hybrid human-agent artifacts: they may be drafted by the agent, reviewed or revised by the developer, and then used to guide execution. When saved as Markdown files in a repository, they become accessible to other developers or future agents. For example, the *travis-php85-gha-migration* plan in `boldgrid/w3-total-cache` [5] describes a staged migration from Travis CI to GitHub Actions and later Argo Workflows, identifies migration-related files such as `.travis.yml`, `composer.json`, `phpunit.xml`, and planned GitHub Actions workflows, and specifies validation work such as running PHPUnit and proving the replacement CI workflow before retiring the Travis CI workflow. Unlike general-purpose context files such as `AGENTS.md`, which typically provide persistent project knowledge or behavioral instructions, Agent Plans are explicitly oriented toward concrete development tasks and ongoing implementation activity. We therefore treat Agent Plans as a distinct form of repository-based configuration artifact. Importantly, not all Agent Plans are preserved in public repository history; some may remain local artifacts on a developer's machine. To characterize how Agent Plans manifest as repository artifacts and what role they play in developer-agent collaboration, this study investigates three research questions in the context of open-source software (OSS) systems:

**RQ1: How are Agent Plans preserved as repository artifacts in OSS?**
**RQ2: What tasks and developer activities do Agent Plans support?**
**RQ3: What information do Agent Plans provide to guide task execution?**

These questions are important because Agent Plans sit between a developer's task request and the agent's execution. In the planning workflow, the agent may draft a plan file in response to the developer's request, the developer can then read, revise, or approve it before the agent proceeds with the work. When plan files are saved in a repository, they become visible records of human-agent collaboration rather than remaining local or transient interaction artifacts. By focusing on these repository-preserved Agent Plans, this paper examines how development work is organized for agentic AI coding tools beyond broader repository-level context artifacts. When committed, they provide observable evidence of how a development task was framed, structured, and prepared for execution by agents. We focus on this directly inspectable subset of Agent Plans while excluding plans that remained local or were stored outside the searched directories. This paper makes three contributions:

- First, it provides an exploratory empirical study of Agent Plans as repository-preserved artifacts in OSS development.

- Second, it shows that Agent Plans in the observed corpus support activities including maintenance, design, construction, quality-related work, and process support; requirements clarification and design exploration were not observed in this corpus.
- Third, it shows that Agent Plans mostly specify implementation steps, files and locations, and testing and validation information.

Together, these contributions help clarify what Agent Plans are as observable repository artifacts, what kinds of work they capture, and how they differ from project-level context files. The remainder of this paper is organized as follows. Section 2 reviews background and related work on agentic AI coding tools and repository-level context artifacts. Section 3 describes the data collection and analysis procedures. Section 4 presents the results for the three research questions. Section 5 discusses the implications of the study and its threats to validity. Finally, Section 6 concludes the paper.

## 2 Background and Related Work

Studies of GitHub repositories and pull requests report a growing use of agentic AI coding tools and agent-generated contributions across activities such as bug fixing, feature implementation, and documentation updates [25, 18, 28]. Related work also shows that LLM-based coding tools can favor popular technology choices even when they are not well suited to the task [27], highlighting the need for project-specific guidance. A second line of research examines how developers incorporate coding agents into collaborative practice. Cynthia et al. [11] show that agent use differs between developer roles: peripheral contributors rely more heavily on agents for implementation, whereas core developers use them more selectively and focus on review and validation. This shifts attention from whether agents are adopted to how agentic coding is coordinated. A third line of research studies repository-level artifacts that guide agentic AI coding tools. Galster et al. [13] identify mechanisms for configuring such tools, including prompts, instruction files, and repository-level context files. Related studies examine context files and agent-facing repository documentation in more detail, including `AGENTS.md` files and other files that encode conventions, architecture, build commands, test execution, setup, and workflow guidance [8, 21]. Experimental studies report mixed evidence about their effects: context files can improve agent performance in some settings, but their impact depends on the model, task, and evaluation setting [15, 19].

This body of work shows that agentic AI coding tools are becoming part of OSS development and that repository-level files can influence how these tools operate. Also, prior work has mainly focused on broad project-level context files or agent-generated code contributions. Less is known about task-oriented plan files that describe concrete units of intended work. Agent Plans capture how a task is framed before or during execution, including the intended changes, relevant files or locations, and checks used to assess completion. This study addresses this gap. Agent Plans follow a hybrid human-agent workflow. Support for this workflow has emerged in major tools including Cursor, Gemini, and Claude Code. When developers commit plan files to a repository, typically under directories such as `.cursor/plans` or `.claude/plans`, they become inspectable by other developers and agents, functioning as a lightweight record of intended work alongside the resulting code.

## 3 Data Collection and Analysis

### 3.1 Data Collection

Figure 1 summarizes the data collection process. The repository scan was conducted on May 14, 2026. The results therefore describe the plan files present on the repository's default branches at that point in time. The set of repositories screened in this study was derived

from the repository processing pipeline introduced by Baltes et al. [12]. The pipeline began with a metadata-filtered set of 40,585 GitHub repositories and subsequently classified 36,710 of them as belonging to engineered software projects (i.e., repositories of sufficient size, age, activity, and with indicators that point to the use of software engineering practices) [22].

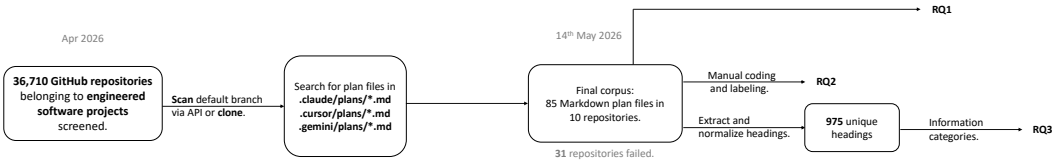

**Figure 1** Process for identifying Agent Plan Markdown files in GitHub repositories.

To identify Agent Plan artifacts, we scanned the default branches of these repositories using the GitHub API. The search targeted Markdown files stored under tool-specific plan directories: `.claude/plans/*.md`, `.cursor/plans/*.md`, and `.gemini/plans/*.md`. A repository could contain more than one such file, and each individual Markdown file was treated as a separate unit of collection and analysis. The documentation for Cursor and Claude Code establishes the existence of planning workflows, but does not provide a complete convention for storing plan files in the repository [10, 3]. We therefore used the observed tool-specific plan-directory patterns as conservative search locations for repository-preserved planning artifacts, while recognizing that plan files stored under other paths would not be captured. This directory-based strategy increases precision by focusing on explicit tool-plan locations, but it can miss plan-like artifacts stored under general paths such as `docs/`, `tasks/`, `specs/`, or issue and pull-request bodies. The `.gemini/plans/*.md` pattern was included to keep the search strategy symmetric across the agentic coding tools considered in the study. It returned no files among the 36,710 repositories screened. We therefore treat this as a null result for the search, not as evidence that Gemini-based planning artifacts are absent or that Gemini users do not create plans. Repositories without matching plan files were excluded.

During processing, 31 repositories could not be retrieved or processed successfully and were recorded as failed repositories. For repositories with candidate plan files, the files were retrieved along with repository- and file-level metadata. After retrieval, candidate files were manually inspected to confirm that they were, in fact, plan files, that is, task-oriented Markdown documents describing the intended development work for an agentic AI coding tool. This validation step was a file-inclusion check rather than the qualitative coding used for RQ2 and RQ3. Because all retrieved files came from highly specific tool-plan directories and all met the inclusion criterion, no candidate files were removed at this stage. All candidate files met this criterion, which was expected given the specificity of the tool-specific directory patterns used in the search. Thus, because the search was restricted to predefined tool-specific directory conventions, plan-like artifacts stored under other names or locations may have been missed. After validation, the collected files were assembled into a local corpus while preserving their repository context.

The final corpus consisted of 85 Markdown plan files drawn from 10 repositories. These files formed the empirical basis for the subsequent analysis. Individual plan files ranged from 14 to 901 lines ($M = 178$) and 116 to 5,227 words ($M = 876$), with 1 to 41 section headings to structure plan files ($M = 13.5$), totaling 1,145 heading occurrences.

## 3.2 Data Analysis

To address **RQ1**, we examined how Agent Plans were preserved in the repository history. We counted repositories that contain plans, plan files per repository, and associated repository- and file-level metadata, including commit counts and contributor summaries.

To address **RQ2**, we used iterative qualitative coding to identify the tasks and developer activities reflected in the 85 plan files [26, 20]. The coding unit was one complete plan file. For each file, coders first inspected the file name, title, and opening material, such as summaries, goals, or problem statements, where present. They then checked this interpretation against the remaining content, including implementation notes, file lists, verification steps, and to-do items. This procedure was used to avoid assigning labels based only on a single heading or isolated section. The coding framework had three levels. The `Task`-level captured the concrete task described in the plan file. The `Task-group`-level grouped related tasks into recurring activities, such as refactoring or testing. The `SWEBOK`-level mapped task groups to SWEBOK knowledge areas as higher-level representations of software engineering practices and technical, operational, and managerial activities [6]. The final coding was bottom-up: each plan file was assigned a `Task`-level label, then a `Task-group`-level label, and finally one `SWEBOK` category. When a plan file contained multiple possible activities, coders assigned the label that best captured the plan's primary task based on the plan title, stated goal, and dominant implementation content. We used a primary-task label rather than multi-label coding to keep each plan file as a comparable unit in the SWEBOK and task-group distributions; this reduces double-counting but may underrepresent secondary activities. We therefore interpret the RQ2 results as distributions of primary plan purposes rather than exhaustive lists of every activity mentioned in the files.

The final coding involved two researchers. One researcher developed the initial coding framework and coded the full corpus; a second researcher independently coded the same 85 plan files at the `Task`, `Task-group`, and `SWEBOK` levels using the coding guide. The two coding sets were matched by plan file link, and all 85 plans were present in both sets. For `SWEBOK`-level labels, the coders achieved Cohen's $\kappa = 0.7586$ with 80.0% raw agreement. For `Task-group`-level labels, after applying a predefined mapping between equivalent label names, they achieved Cohen's $\kappa = 0.8002$ with 82.4% raw agreement. Both correspond to substantial agreement [17]. Disagreements were discussed and resolved to produce the final coding used in the results.

To address **RQ3**, we extracted all Markdown section headings from the 85 plan files, normalized them by lowercasing, removing special characters, lemmatizing, and conservatively merging lexical variants with the same meaning. All 85 plan files included headings. In total, we observed 1,145 heading occurrences and 975 distinct representative headings. Following related work on `AGENTS.md` and `README` files [21, 14], we limited the information-category analysis to level-1 and level-2 headings, which comprised 592 occurrences: 126 at level 1 and 466 at level 2. The coding unit was a level-1 or level-2 section, consisting of the heading and its section content, including prose, bullet points, file paths, commands, code snippets, tables, and nested lower-level subsections where present. Headings were used to locate and group recurring sections, but information categories were assigned by reading the corresponding section content. We developed an initial coding guide from six representative headings that appeared in at least three repositories and at least three times at levels 1 or 2, then applied it to 23 representative headings that appeared in at least two repositories and at least twice. The resulting coding guide covered nine information categories, which are reported in Table 3 and discussed in Section 4.3. One researcher developed the initial category mapping, and a second researcher independently coded the 472 representative level-1

and level-2 headings using the coding guide. Equivalent category names were mapped before calculating agreement. The heading-level coding achieved Cohen's $\kappa = 0.7359$ with 77.1% raw agreement, corresponding to substantial agreement [17]. Ambiguous cases and category names were discussed and resolved by returning to the corresponding section content.

# 4 Results

## 4.1 RQ1: How are Agent Plans Preserved as Repository Artifacts?

Agent Plans were rarely found under canonical tool-specific directories in public repository history. This is consistent with plan preservation being an emerging practice: Cursor introduced Plan Mode only in early October 2025. Among 36,710 GitHub repositories, we found 85 plan Markdown files across ten repositories (Table 1), stored under `.cursor/plans` ($n = 72$) and `.claude/plans` ($n = 13$). One possible reason for committing such files is to make implementation decisions visible to collaborators and code reviewers, preserving task reasoning alongside the code.

**Table 1** Distribution of Agent Plan files with selected repository-level characteristics.

| Repository | #Plan files | Created | #Contrib. | #Commits | Size (KB) |
|---|---|---|---|---|---|
| `forcedotcom/salesforcedx-vscode` | 66 | 2017 | 119 | 5,013 | 906,966 |
| `youtrackdb/youtrackdb` | 8 | 2024 | 143 | 24,278 | 262,502 |
| `forcedotcom/sfdx-core` | 3 | 2018 | 57 | 3,553 | 79,282 |
| `adobe/spectrum-design-data` | 2 | 2022 | 14 | 1,337 | 46,196 |
| `hubtype/botonic` | 1 | 2018 | 34 | 3,297 | 49,664 |
| `nam20485/OdbDesign` | 1 | 2023 | 6 | 2,230 | 10,459 |
| `natemcmaster/commandlineutils` | 1 | 2017 | 99 | 1,030 | 18,073 |
| `nomadkaraoke/python-audio-separator` | 1 | 2023 | 26 | 353 | 150,754 |
| `boldgrid/w3-total-cache` | 1 | 2018 | 49 | 1,203 | 23,632 |
| `input-output-hk/daedalus` | 1 | 2016 | 62 | 11,099 | 255,858 |

The corpus was strongly concentrated. `forcedotcom/salesforcedx-vscode` accounted for 66 of the 85 plan files. We report sensitivity checks for RQ2 and RQ3, excluding this repository. Plan-file preservation was also contributor-concentrated: `mshanemc` contributed 64 of the 66 plan files in `forcedotcom/salesforcedx-vscode` and all three in `forcedotcom/sfdx-core`; `andrii0lomakin` contributed all eight in `youtrackdb/youtrackdb`; and `GarthDB` contributed both files in `adobe/spectrum-design-data`.

The remaining repositories likewise had a single contributor for preserved plan files, except `input-output-hk/daedalus`, where the single plan file involved two contributors. However, committing Agent Plans was not a routine practice among these contributors across their repositories. Instead, contributors who committed plan files in one repository did not necessarily do so in others. To distinguish intentional sharing from incidental preservation, we checked whether each plan file was revised, referenced in repository issues or pull requests, or followed by adding the plan directory to `.gitignore`. Most plan files ($n = 78$) appeared in one single commit, and 73 of these had no observed issue or pull-request reference. Only seven files were revised across multiple commits, and only two of those were also externally referenced. No repository later added the plan-file directory to `.gitignore`. Overall, most committed plan files are therefore better characterized as ephemeral task records than as intentionally maintained project artifacts.

To assess AI tool co-authorship, we examined 72 unique commits that touched plan files and for which complete GitHub metadata were available. Of these, 31 commits contained explicit AI co-authorship signals, affecting 27 of the 85 plan files. We counted only explicit `Co-authored-by` lines naming Claude or Cursor; tool-name mentions in commit messages were not treated as authorship evidence. Thus, we distinguish plan files associated with explicit AI-co-authored commits from those with no explicit AI co-authorship signal, without treating the latter as confirmed human-authored. These signals are conservative commit-level evidence: repository metadata does not show whether a plan was drafted by an agent, edited by a developer, used during implementation, or committed incidentally.

Revision behavior was similar across the two groups. Only 2 of the 27 AI-co-authored plan files and 5 of the 58 files without explicit AI co-authorship signals were revised after their first plan-file commit. Issue or pull-request references appeared in plan-file commit messages for 23 of the 27 AI-co-authored files and 54 of the 58 files without explicit AI co-authorship signals. Thus, AI co-authorship affects how the corpus should be interpreted, but it did not correspond to a distinct revision pattern.

## 4.2 RQ2: What Developer Activities do Agent Plan Files Support?

Using the three-level coding framework described in Section 3.2, we coded each of the 85 Agent Plan files with one concrete `Task`-level label, one `Task-group` level label, and one `SWEBOK` knowledge area. Figure 2 shows the SWEBOK distribution for the full corpus and, as a sensitivity check, the distribution after excluding the dominant repository, `forcedotcom/salesforcedx-vscode`.

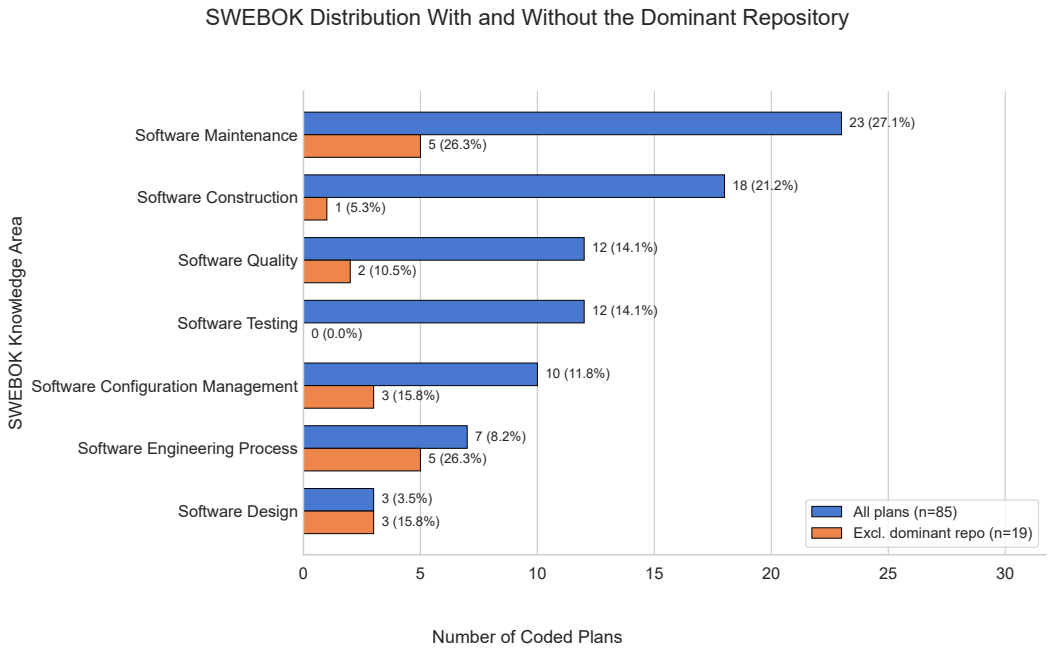

**Figure 2** Distribution of Agent Plans across SWEBOK knowledge areas.

In the full corpus, the most frequent SWEBOK areas were *Software Maintenance* ($n = 23$) and *Software Construction* ($n = 18$), followed by *Software Testing* and *Software Quality* ($n = 12$ each). Thus, the observed plan files were not limited to new-feature implementa-

tion; they also supported refactoring, migration, bug fixing, test creation, test repair, and quality enforcement. Figure 2 also reports the distribution after excluding the dominant `forcedotcom/salesforcedx-vscode` repository. The remaining 19 plans still covered several SWEBOK areas, but the distribution changed substantially: *Software Testing* was not observed among the 19 plan files outside the dominant repository, *Software Construction* dropped to one plan file, and *Software Engineering Process* and *Software Design* became more prominent relative to the smaller remaining corpus. Therefore, the aggregate RQ2 findings should be interpreted as describing the observed corpus rather than as population-level evidence about all Agent Plans in open-source repositories. Because only 19 plan files remain after excluding the dominant repository, the sensitivity analysis should be read as a robustness check to assess whether categories still appear outside that repository, rather than as a representative cross-repository estimate.

We also split the RQ2 labels by explicit AI co-authorship signal, distinguishing plan files associated with commits containing such signals from those without. Both groups covered multiple SWEBOK areas. Plan files associated with AI-co-authored commits were most frequent in *Software Maintenance* and *Software Construction* ($n = 7$ each), followed by *Software Testing* and *Software Configuration Management* ($n = 4$ each), *Software Design* ($n = 3$), *Software Quality* and *Software Engineering Process* ($n = 1$ each). Plan files without explicit AI co-authorship signals were also concentrated in *Software Maintenance* ($n = 16$) and *Software Construction* ($n = 11$), followed by *Software Quality* ($n = 11$) and *Software Testing* ($n = 8$), *Software Configuration Management* and *Software Engineering Process* ($n = 6$ each). Thus, this split does not suggest that AI-co-authored plan files supported a separate type of software engineering work.

At the task-group level, the most frequent category was *refactoring and migration* ($n = 20$, after harmonizing capitalization and equivalent labels), followed by *testing and validation* ($n = 12$), *feature development* ($n = 12$), *build and CI/CD workflow* ($n = 10$), *code quality* ($n = 8$), *developer tooling* ($n = 7$), and *bug fixing* ($n = 6$). Outside the dominant repository, *testing and validation* was not observed, while *developer tooling* ($n = 5$), *build and CI/CD workflow* ($n = 3$), and *refactoring and migration* ($n = 3$) remained visible. Overall, the observed plan files supported both implementation work and surrounding engineering activities, but their relative emphasis was shaped by the dominant repository.

Table 2 illustrates how concrete tasks in plan files were mapped to task groups and SWEBOK categories.

## 4.3 RQ3: What Information do Agent Plans Provide?

Using the heading and section-content analysis described in Section 3.2, we examined the information categories that Agent Plans provide to guide the tools. Table 3 summarizes the resulting information categories.

Sections that mainly stated the goal, problem, topic, or scope of the plan file were coded as *Plan overview and scope*. We retained this label in the coding output for traceability, but excluded it from Table 3 because it describes what the plan file is about, rather than how the agent is guided to carry it out. *Implementation steps* sections typically describe actions such as updating files, removing obsolete code, migrating behavior, or implementing planned changes [29]. *Files and locations* sections narrow the technical scope by identifying packages, modules, tests, schemas, traces, or other artifacts to inspect or modify. *Testing and validation* sections describe checks, tests, success criteria, or expected behavior used to determine whether the task is complete [16]. The remaining categories provide supporting guidance for execution. *Architecture and design* captures architectural context, data flow,

**Table 2** Examples of coded plan file purposes from the most frequent SWEBOK areas.

| Repository | Plan file name | Task-level | Task-group level | SWEBOK |
|---|---|---|---|---|
| `forcedotcom/salesforcedx-vscode` | *Enable Naming Convention ESLint Rules* | ESLint enforcement of naming conventions. | Code quality | Software Quality |
| `boldgrid/w3-total-cache` | *travis-php85-gha-migration* | Migration of PHP and WordPress test automation from Travis to GitHub Actions and Argo. | Build and CI/CD workflow | Software Configuration Management |
| `forcedotcom/sfdx-core` | *Update Features from Salesforce Docs* | Synchronization of feature metadata from Salesforce documentation. | Developer tooling | Software Engineering Process |
| `adobe/spectrum-design-data` | *Size Property Analysis Across Component Schemas* | Analysis of size-option patterns across component schemas. | Design system standardization | Software Design |

**Table 3** Information categories in Agent Plans by corpus and AI co-authorship signal. **All repos**: full corpus ($n = 85$ plan files, 10 repos). **Excl. SF**: excluding `forcedotcom/salesforcedx-vscode` ($n = 19$ plan files, 9 repos). Occ. = heading occurrences; Files = distinct plan files; Repos = distinct repositories.

| | All repos | | | Excl. SF repo | | AI co-authorship | |
|---|---|---|---|---|---|---|---|
| **Category** | **Occ.** | **Files** | **Repos** | **Occ.** | **Repos** | **AI** | **No signal** |
| Implementation steps | 82 | 54 | 8 | 20 | 7 | 19 | 63 |
| Files and locations | 68 | 46 | 7 | 11 | 6 | 21 | 47 |
| Testing and validation | 57 | 40 | 6 | 9 | 5 | 22 | 35 |
| Architecture and design | 39 | 26 | 6 | 11 | 5 | 24 | 19 |
| Analysis and findings | 30 | 18 | 4 | 8 | 3 | 14 | 16 |
| Project context | 29 | 29 | 6 | 7 | 5 | 13 | 16 |
| Task breakdown | 28 | 13 | 4 | 5 | 3 | 7 | 19 |
| Tooling and build configuration | 24 | 20 | 5 | 10 | 4 | 8 | 16 |
| Design constraints and decisions | 23 | 21 | 7 | 7 | 6 | 8 | 15 |

and design choices [2]. *Analysis and findings* records observations, root causes, or patterns from failures and previous runs [23]. *Project context* describes the current system state, dependencies, workflow, or environment. *Task breakdown*, *Tooling and build configuration*, and *Design constraints and decisions* organize the work, identify tools and workflows to use, and define boundaries the agent should preserve [5].

The most common category was *Implementation steps*, followed by *Files and locations* and *Testing and validation*. These categories show that plan files commonly specify what actions to perform, where to perform them, and how to check whether the work is complete. To account for the concentration of plan files in `forcedotcom/salesforcedx-vscode`, the table also reports heading occurrences and repository coverage, excluding that repository. The same broad information categories remained visible after excluding the dominant repository, although their relative ordering changed. *Implementation steps* remained the most frequent category, while *Files and locations*, *Architecture and design*, and *Tooling and*

*build configuration* were also common in the remaining repositories. This suggests that the broad structure of Agent Plans was not limited to `salesforcedx-vscode`, but the exact ranking of categories should be interpreted with caution, as only 19 plan files remained after excluding the dominant repository.

We also compared information categories by explicit AI co-authorship signal. This split separates plan files associated with commits that contain explicit AI co-authorship signals from those with no such signal. The split showed that AI-co-authored plan files and plan files without a clear signal used the same broad kinds of execution guidance. The file-level counts show that the main categories were not only produced by a few highly structured files. *Implementation steps*, *Files and locations*, and *Testing and validation* appeared in 54, 46, and 40 distinct plan files, respectively. In the heading-occurrence split by explicit AI co-authorship signal, plan files associated with AI-co-authored commits most often contained headings related to architecture and design, testing and validation, files and locations, and implementation steps. Plan files without explicit AI co-authorship signals often contained headings related to implementation steps, files and locations, and testing and validation. The main plan file structure was similar across the two groups, although the relative emphasis differed.

Overall, Agent Plans translate the planned task into actionable information about changes, locations, validation, context, tools, and constraints. This distinguishes them from repository-level context files, which typically provide standing project-level guidance. Comparing the nine Agent Plan categories with the `AGENTS.md` content categories reported by Mohsenimofidi et al. [21] further illustrates this distinction (Table 4). Three categories, namely *Implementation steps*, *Files and locations*, and *Task breakdown*, have no direct counterpart in `AGENTS.md`. The remaining categories partially overlap with the `AGENTS.md` categories but differ in scope, as Agent Plans encode task-specific knowledge rather than general repository guidance.

**Table 4** Comparison of Agent Plan information categories against `AGENTS.md` categories [21].

| Agent Plan Category | Closest `AGENTS.md` Category | Relationship |
|---|---|---|
| Implementation steps | None | Plan-specific |
| Files and locations | None | Plan-specific |
| Task breakdown | None | Plan-specific |
| Analysis and findings | Troubleshooting | Scope differs |
| Design constraints and decisions | Conventions | Scope differs |
| Architecture and design | Architecture/structure | Scope differs |
| Testing and validation | Test execution, Test strategy | Scope differs |
| Tooling and build configuration | Build commands, References | Scope differs |
| Project context | Goals/purposes, Setup, Tech stack | Scope differs |

# 5 Discussion

## 5.1 Implications for Research and Future Work

Agent Plans make intended work explicit so that it can be revised and preserved alongside code. Although public preservation is uncommon, the practice is actively discussed in developer communities [7, 24], suggesting that local, uncommitted use is likely more widespread than repository traces indicate. Below we list several implications of our findings.

- **For tool builders:** The three most frequent categories: *Implementation steps*, *Files and locations*, and *Testing and validation*, form a minimum viable plan file schema covering what the agent should do, where, and how to verify completion; tools should scaffold these three sections by default. We did not observe any files in `.gemini/plans/` across the screened repositories, suggesting that future work should examine whether Gemini-related planning artifacts are stored elsewhere or remain local.
- **For practitioners:** A plan file lacking any of these three categories is likely under-specified as operational guidance, giving teams a lightweight readiness check; explicit conventions for naming, structuring, and committing plan files are still needed.
- **For researchers:** The mining pipeline [4] can be extended to broader directory patterns (e.g., `docs/plans/`) and complemented by surveys to capture local plan files. The most pressing open question is whether plan files affect outcomes: comparing PR merge time and revert rate for `forcedotcom/salesforcedx-vscode` commits with and without an associated plan file, controlling for author identity, file and line count, would provide direct evidence of whether planning artifacts improve work. A key open question is whether planning workflows could be extended to cover requirements clarification and design exploration, activities not observed in this corpus, enabling agents to participate earlier in the software lifecycle. Finally, going beyond the *emerging results* in this paper, researchers could explore how developer activities in plan files (RQ2) are supported by the information in plan files (RQ3).

## 5.2 Threats to Validity

- **Construct validity.** The analysis is restricted to repository-preserved Markdown files found in tool-specific plan directories; plan files that remained local, transient, or stored under other naming schemes are not captured. The directory-pattern search may introduce selection bias. By searching only tool-specific plan directories, we likely missed plan-like artifacts stored under other paths or retained only in local tool state, issues, pull requests, or external planning documents. The reported prevalence should therefore be interpreted as prevalence under the searched repository-directory conventions. Authorship attribution is also uncertain: of the 72 unique plan-file commits for which we retrieved complete metadata, 31 (43.1%) showed explicit AI co-authorship signals, affecting 27 of the 85 plan files. The remaining plan files should not be interpreted as definitively human-authored, as the absence of an explicit co-authorship signal does not constitute evidence of human authorship.
- **Internal validity.** The coding for RQ2 and RQ3 relied on manual interpretation, and alternative category assignments remain possible, particularly for overlapping SWEBOK areas and section-level information categories. Two researchers independently coded all plan files and resolved disagreements through discussion before producing the final coding scheme. Some plan filenames were also insufficiently descriptive, complicating traceability during analysis.
- **External validity.** The corpus is small (85 files from 10 repositories) and heavily concentrated: 66 plan files (77.6%) originate from a single repository, and approximately 78.8% were contributed by one developer across two related Salesforce repositories, making corpus concentration a stronger threat than small size alone. Sensitivity analyses show that several activity and information categories also appear outside the dominant repository, but generalization beyond the Salesforce ecosystem is limited, and plan files stored under other directory conventions are not represented. A further concern is survivor bias: plan files deleted, added to `.gitignore`, squashed, or rebased before the scan are invisible to this study.

## 6 Conclusion

This *Emerging Results* paper identifies 85 Agent Plan files from 10 repositories across 36,710 screened GitHub projects, showing that public preservation is uncommon and heavily concentrated (77.6% from one repository), while sensitivity analyses show that several activity and information categories also appear outside the dominant repository. Plan files supported a range of activities and exhibited recurring information structures, most prominently implementation steps, files and locations, and testing and validation. Most plan files appeared in only a single commit, which means that they function as task-specific records rather than documents that are repeatedly maintained over time. These findings position repository-preserved Agent Plan files under tool-specific directories as a narrow but informative repository artifact that surfaces a task-oriented layer of human-agent coordination beyond coarse-grained context files, and point to directions for different audiences as agentic AI coding tool adoption continues to grow.

## Data Availability Statement

The repository-processing pipeline used to derive the set of screened repositories, along with the study data and analysis artifacts is available on Zenodo [4, 1].

# Tools for Detecting Security Issues in Infrastructure-As-Code: A Focused Literature Review

**Mohamed Haady Tiemtore**
Université d'Orléans, INSA CVL, LIFO UR 4022, Orléans, France

**Frédéric Loulergue**
Université d'Orléans, INSA CVL, LIFO UR 4022, Orléans, France

## Abstract

Infrastructure-as-Code (IaC) artefacts such as Puppet manifests, Ansible playbooks, Kubernetes manifests, Helm charts, Terraform configurations, and CloudFormation templates are increasingly used to manage critical infrastructures. Security defects in these artefacts may therefore be propagated rapidly through automated deployment pipelines. This paper reports emerging results from a focused literature review of tools for detecting security issues in IaC artefacts. The current review protocol covers the ACM Digital Library and IEEE Xplore and includes 23 primary studies. We identify the main families of tools captured by this protocol, classify their detection approaches, and analyse how they are evaluated. The review corpus includes rule-based linters, deeper static analyses, graph- and model-based approaches, comparative scanner studies, deployment-oriented analyses, and recent machine-learning and LLM techniques.

## 1 Introduction

Infrastructure-as-Code (IaC) is the practice of managing and provisioning infrastructure through machine-readable artefacts. In such an approach, infrastructure descriptions are versioned, reviewed, tested, and maintained similarly to software source code. IaC artefacts include Puppet manifests, Ansible playbooks, and Chef recipes for configuration management; Terraform and CloudFormation templates for cloud provisioning; and Kubernetes manifests and Helm charts for container orchestration.

The increasing adoption of IaC is motivated by automation, reproducibility, and scalability. However, these same characteristics also amplify the consequences of defects. A security weakness may be propagated quickly through deployment pipelines and replicated over many machines, clusters, or cloud resources. In practice, such weaknesses include insecure defaults, over-permissive access-control rules, exposed services, embedded secrets, and unsafe scripting constructs. The security of IaC artefacts is therefore an important concern.

Over the last decade, a growing body of research has addressed this concern. The literature includes rule-based detectors, static analyses, graph-based and model-based approaches, and more recently machine-learning and LLM based techniques. These studies target different IaC

© Mohamed Haady Tiemtore and Frédéric Loulergue;
licensed under Creative Commons License CC-BY 4.0

ecosystems and different classes of security issues. However, the landscape is fragmented. It is therefore difficult to obtain a structured view of the existing tools, the technical approaches they rely on, and the evaluations reported for them.

Previous secondary studies provide a broad map of IaC research [15], survey static analysis for both security and reliability defects [3], or examine artificial intelligence across the full IaC lifecycle [13]. Our review is narrower: it focuses on security *detection* tools across analysis families and, in particular, on the empirical evidence used to evaluate them. This focus helps researchers identify comparable evaluation designs and helps practitioners judge what kind of evidence supports a tool family in a given IaC setting.

We present emerging results from a focused literature review of tools for detecting security issues in IaC artefacts. The goal is to establish a structured first map of the reported research landscape captured by the current review protocol. This first iteration covers the ACM Digital Library and IEEE Xplore, and it is intended to be extended with additional digital libraries and backward and forward snowballing. This scope is focused on detection. Topics such as automated repair, prevention, or runtime enforcement are adjacent and relevant, but require a broader study. More specifically, the contributions are:

- an overview of the tools and methods proposed for detecting security issues in IaC;
- a taxonomy of these studies according to the targeted artefacts, the security issues considered, the core detection mechanisms, and the evaluation methods;
- a discussion of the reported evaluations, with implications for empirical software engineering research on IaC security tooling.

In the remainder of the paper, Section 2 describes the review methodology. Section 3 presents the results with respect to the research questions. Section 4 introduces the proposed taxonomy. Section 5 discusses challenges. Section 6 summarizes threats to validity. Section 7 concludes and gives future research directions.

## 2 Research Methodology

The SLR carried out by the authors of this work adhered to established literature guidelines [14]. It consisted of three main steps: *(i) planning*, which involves protocol creation with research questions, search strategy, selection criteria, and data extraction and synthesis methods; *(ii) execution*, which entails the identification, selection, and analysis of studies; and *(iii) reporting*, which aggregates the information extracted from relevant studies in relation to the research questions, synthesizing the findings to draw conclusions.

**Research Goal.** The research goal is to establish a focused overview of the tools and methods for detecting security issues in IaC.

**Research Questions.** To guide this study, we formulated three research questions (RQs) aimed at identifying primary studies on security tools and methods for IaC.

> RQ1. What tools and methods have been proposed to detect security issues in Infrastructure-as-Code artefacts?

*RQ1 Rationale*: IaC security tooling has evolved rapidly over the past decade, with a growing number of tools targeting different technologies, threat models, and stages of the development lifecycle. However, no consolidated inventory of these tools and methods exists to date. Answering RQ1 provides practitioners and researchers with a structured overview of the current tooling landscape for IaC security detection, enabling informed decisions about tool adoption and identifying areas where tooling is still lacking.

RQ2. What technical approaches are used by existing IaC security tools?

*RQ2 Rationale*: Understanding the technical approaches of IaC security tools is essential to assess their capabilities and limitations. Different approaches offer varying trade-offs in terms of coverage, precision, and applicability. Answering RQ2 provides a deeper understanding of how these tools work, facilitating comparisons between approaches and helping researchers identify promising directions for future work.

RQ3. What empirical evidence supports the effectiveness of existing IaC security tools?

*RQ3 Rationale*: Proposing a tool is not sufficient to establish its practical value. Experimental validation is necessary to assess whether a tool effectively detects security issues in real-world IaC scripts. However, the rigour and reproducibility of evaluations vary significantly across the literature. Answering RQ3 provides an overview of how existing tools have been evaluated, and to what extent their effectiveness has been empirically demonstrated.

### Search strategy

We carried out an automated search process over two electronic publication databases to retrieve relevant studies to answer the posed RQs: ACM Digital Library and IEEE Xplore. They are among the most popular publication databases in Computer Science and Engineering, and have good coverage.

Based on the defined RQs, two main groups of terms were identified. The first group covers security-related concepts, while the second targets IaC technologies and frameworks. The following search string was built considering synonyms and alternative terms to increase coverage of the literature. Security-related terms were searched in the document title only, ensuring that security is the primary focus of retrieved studies.

IaC related terms were searched in both the title and abstract, in order to capture studies where the IaC context is described in the abstract without being explicitly mentioned in the title. The named technologies operationalize three families in the review goal – configuration management, cloud provisioning, and container orchestration – and complement rather than replace the generic "Infrastructure as Code" and "IaC" terms. Restricting security terms to titles favours precision and feasible manual screening. The search was limited to publications from 2016 to 2026, covering the last decade:

```
(Title:(Security OR DevSecOps OR Secure OR Detection OR Scanning OR Check
  OR Identification) ) AND
(Title:("Infrastructure as Code" OR IaC OR Ansible OR Puppet OR Chef OR Terraform
  OR Kubernetes OR Pulumi OR CloudFormation OR SaltStack) OR
 Abstract:("Infrastructure as Code" OR IaC OR Ansible OR Puppet OR Chef OR Terraform
  OR Kubernetes OR Pulumi OR CloudFormation OR SaltStack) )
```

This search design intentionally favours focus and traceability over maximal recall. We restricted the automated search to the ACM Digital Library and IEEE Xplore because these databases provide strong coverage of software engineering and security venues while keeping a first review iteration manageable for full manual screening. We also relied on title and abstract metadata for automated retrieval, which is common in systematic searches but may miss studies whose security contribution is expressed only through body text, keywords, or alternative terminology. We therefore treat the present study as a focused first-pass review of IaC security *detection* tooling, rather than as an exhaustive census of all work touching IaC security. A natural next step is to extend the protocol with additional libraries and citation snowballing to assess the stability of the trends reported here under broader coverage.

### Eligibility Criteria

We included primary studies published in peer-reviewed venues that propose, implement, evaluate, or systematically compare a concrete tool, prototype, or technically specified method for detecting security issues in Infrastructure-as-Code artefacts. To be eligible, a study had to focus either on the analysis of IaC artefacts themselves or on the security effects of configurations that remain explicitly traceable to IaC level artefacts and policies. We also retained studies that use a concrete security checker to assess policy violations in generated IaC artefacts when this contributes direct empirical evidence on IaC security tooling. In all cases, the study had to provide sufficient technical detail to allow classification of the underlying detection approach. Only full-text studies written in English were considered. Empirical evaluation was not required as an inclusion criterion, because excluding unevaluated studies would have biased the corpus against technically relevant tools and methods needed to answer RQ1 and RQ2. Instead, the presence, type, and strength of empirical evidence were extracted and summarized separately to address RQ3.

We excluded studies that did not address the detection of security issues in IaC artefacts or in their directly traceable deployment effects, studies concerned only with non-security properties of IaC, and studies that discussed security at the cloud or infrastructure level without an explicit link back to IaC artefacts or configuration policies. We also excluded papers that lacked sufficient technical detail to classify the detection approach, papers published outside the review window, and duplicate reports of the same study or tool, in which case only the most complete version was retained.

For borderline studies, we considered detection as a technically specified method that produces a security finding from an IaC artefact, an explicit configuration policy, or a deployment effect traceable to such an artefact. Repair- or prevention-centred work was excluded unless it exposed a separable detection component. Compliance and generated-IaC studies were retained only when they applied a concrete checker, while deployment-oriented studies were retained only when the reported violations remained traceable to IaC configurations.

For transparency, the operational eligibility criteria are summarized below.

#### Inclusion Criteria.

- **IC1:** The study is a primary peer-reviewed study published between January 2016 and April 2026.
- **IC2:** The study focuses on detecting security issues in IaC artefacts or deployments.
- **IC3:** The study proposes, implements, evaluates, or systematically compares a concrete detection tool, prototype, or technically specified method.
- **IC4:** The study provides sufficient technical detail to classify the detection approach.
- **IC5:** The study is presented in a full text available in English.

#### Exclusion Criteria.

- **EC1:** The study is not a primary peer-reviewed study.
- **EC2:** The study does not address the detection of security issues in IaC.
- **EC3:** The study addresses only non-security properties of IaC or only general cloud, infrastructure, or runtime security without an explicit link back to IaC artefacts.
- **EC4:** The study lacks sufficient technical detail to classify the detection approach.
- **EC5:** The study was published outside the review window.
- **EC6:** The full text is unavailable, or the study is not written in English.
- **EC7:** The study is a duplicate report of the same tool or study.

### Selection process

The selection process is divided into five phases: (i) exclusion of duplicates, (ii) selection based on title, (iii) selection based on abstract, (iv) entry into full-text screening, and (v) final full-text inclusion or exclusion. The automated search retrieved 343 results (77 from ACM Digital Library and 266 from IEEE Xplore). After removing 6 duplicates, 337 studies remained. In Phase 2, 276 studies were excluded based on title screening, leaving 61 studies. In Phase 3, 30 additional studies were excluded based on abstract reading, leaving 31 studies for full-text screening. Finally, full-text reading retained 23 studies in the review corpus and excluded 8 studies. Figure 1 depicts the complete selection process, from the initial set of retrieved studies to the final set of relevant primary studies.

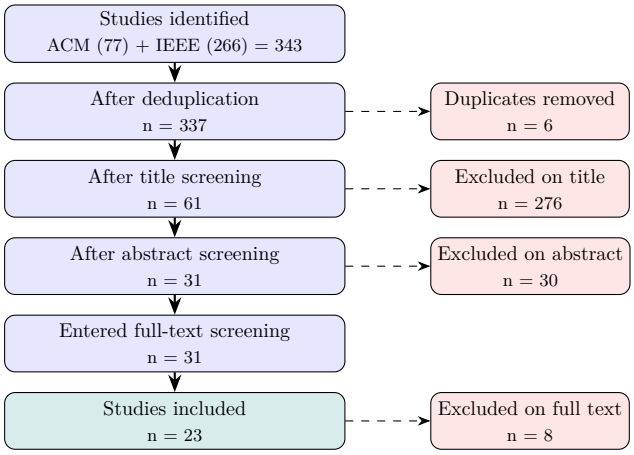

**Figure 1** Process for selecting the relevant primary studies.

### Data extraction and synthesis

For each included study, we extracted bibliographic data, the tool or method, target artefacts, technical approach, reported empirical results, evaluation basis, and a scope note. These fields directly support RQ1–RQ3 and are available in the replication package. For synthesis, the extracted descriptions were coded into non-exclusive categories for ecosystem, security target, primary reasoning mechanism, and evaluation design. A study may therefore contribute to several evaluation categories, for example by combining a mined corpus, a baseline comparison, and practitioner feedback. We kept study role (new detector, refinement, comparison, or pipeline) distinct from detection mechanism, and used the resulting study-to-category mapping to derive the taxonomy and the counts reported below.

## 3 Results and Discussion

### 3.1 RQ1. What tools and methods have been proposed to detect security issues in Infrastructure-as-Code artefacts?

The reviewed studies cover several families of IaC security detectors. A first family targets configuration-management languages such as Puppet, Ansible, and Chef. In this part of the literature, security issues are often expressed as *security smells* or insecure coding patterns. Representative examples include SLIC for Puppet [17], SLAC for Ansible and Chef [18],

GLITCH as a cross-language smell detector [21], GASEL for Ansible [12], TaintPup for Puppet [16], and SecureCode for risky embedded scripts in Ansible playbooks [4]. Recent work in the same ecosystem also studies the detection of secret-sensitive Ansible parameters with machine-learning and language-model based classifiers, which extends the earlier smell-oriented literature toward more targeted semantic classification tasks [11].

A second family targets container-orchestration artefacts in the Kubernetes ecosystem, mainly Kubernetes manifests and Helm charts. Some studies propose dedicated detectors such as SLI-KUBE [19]. Others study the behaviour of existing analysers or compare several tools on Kubernetes and Helm artefacts, either directly on manifests and charts or indirectly through deployed configuration effects [23, 7, 8, 22, 6]. These comparative and deployment oriented studies bring concrete tools such as KubeLinter, Kubesec, Kubescape, Trivy, kube-bench, Terrascan, and Checkov into the corpus, even when the paper contribution lies more in the evaluation setting than in the proposal of a new detector. The literature in this family also includes work that reasons about deployment topology or structural conformance in order to identify security exposures [1, 10].

A third family concerns cloud-provisioning artefacts such as Terraform and CloudFormation. The reviewed studies include threat-model reconstruction from Terraform configurations [26], comparisons of Terraform-oriented scanners [24], an evaluation of security policy compliance in LLM-generated IaC [5], and a recent workflow combining LLM based agents for vulnerability detection and remediation in CloudFormation templates [25]. A smaller set of studies targets cross-ecosystem validation workflows, for example design-time IaC scanning combined with runtime anomaly detection through the IaC Scan Runner/LOMOS combination [2] and LLM-augmented policy validation across Kubernetes, IAM, and Terraform [9]. Finally, a few recent papers revisit detection across several IaC ecosystems with machine-learning or LLM based approaches, e.g. SecLLM for Ansible, Puppet, and Chef [27]. Taken together, these studies show that the area is no longer limited to language-specific linters, even if ecosystem-specific tools still dominate the corpus.

Overall, the literature shows that IaC security detection is supported by a variety of tools and methods. However, the coverage of ecosystems remains unbalanced. Puppet and Ansible are well represented in the smell-detection literature, Kubernetes and Helm are increasingly studied through both direct and deployment-oriented analyses, while CloudFormation and other industrial ecosystems remain much less covered.

## 3.2 RQ2. What technical approaches are used by existing IaC security tools?

Rule-based static analysis is the most common approach in the reviewed literature. In this family, detectors rely on handcrafted rules, smells, or best-practice checks over parsed IaC artefacts [17, 18, 19, 20, 23]. These approaches are attractive because they are usually lightweight, interpretable, and easy to integrate into development pipelines. They also underpin a large part of the comparative literature, where tools such as Checkov, Tfsec, Tflint, KubeLinter, Kubesec, or Kubescape are evaluated as representatives of current practice rather than as research prototypes in their own right.

Several studies go beyond simple rule matching by introducing richer static analyses. GASEL uses program dependence graphs and graph queries to analyse Ansible scripts [12]. TaintPup reasons about the propagation of weaknesses in Puppet manifests through taint-style data-dependence analysis [16]. SLI-KUBE tracks information flow across Kubernetes configurations through def-use style reasoning [19], while SecureCode analyses embedded scripting fragments inside IaC code using structured intermediate trees [4]. These approaches aim at capturing interactions that are difficult to express with local syntactic rules only.

Another family of approaches relies on intermediate representations or structural abstractions. GLITCH translates several IaC languages into a common representation in order to support reusable cross-language detectors [21]. Other studies build graphs, architectural models, or threat abstractions before applying security reasoning [1, 10, 26]. In this group, the technical core is not merely parsing but the construction of a model on which further reasoning is performed, for example topological graphs enriched with ATT&CK-inspired features, architecture-conformance models, or data-flow diagrams consumed by threat-modelling engines. Such approaches are particularly useful when the relevant security property depends on interactions among several resources or components.

The most recent studies introduce learning-based techniques. SecLLM uses large language models for smell detection across configuration languages [27]. Opdebeeck et al. predict secret-sensitive Ansible parameters with machine-learning and language models [11]. Toprani and Madisetti combine retrieval-augmented generation with specialized agents for CloudFormation vulnerability detection and remediation [25]. Mittal and Venkatesan augment pipeline-level policy validation with an LLM ensemble [9]. These methods add contextual interpretation, cross-language reuse, and explanatory or remediation output beyond fixed syntactic rules. By contrast, Hase et al. use the deterministic Checkov policy checker to measure violations in IaC generated by a LLM [5]: the LLM produces the input but is not the detector. The evidence does not establish general superiority of learning-based detection because evaluations use different tasks, datasets, baselines, and model settings.

The corpus also includes hybrid or deployment-oriented approaches. IaC Scan Runner combines design-time scanning across several IaC languages with runtime anomaly detection in logs [2]. Other studies evaluate dynamic application security testing (DAST) tools or workload scanners against configuration violations observed after deployment [22, 6]. In these papers, the observation point moves from the artefact alone to the effects of that artefact once deployed, typically through cluster queries, workload scans, or compliance checks over running resources. These papers broaden the technical landscape by connecting artefact-level properties to their operational manifestations.

The answer to RQ2 is therefore that the field is technically diverse, but still dominated by interpretable static analyses. Rule-based checks are lightweight, reproducible, and easy to integrate, but cover only encoded policies and may miss contextual or indirect flows. Data-flow and graph-based analyses capture richer relations at the cost of greater ecosystem-specific engineering. LLM-based methods offer flexible semantic reasoning but add nondeterminism, model drift, and cost. They also remain less uniformly evaluated than deterministic static analyses.

## 3.3 RQ3. What empirical evidence supports the effectiveness of existing IaC security tools?

Most reviewed studies provide some form of empirical evaluation, but the evaluation settings differ sharply. Some papers evaluate their approaches on mined open-source corpora, report standard detection metrics, and compare against baselines or prior tools [21, 12, 16, 27, 11]. Others complement quantitative results with practitioner feedback, accepted bug reports, or qualitative analyses [17, 18, 20, 19]. Large mined-repository evaluations dominate Puppet, Ansible, and Kubernetes studies, whereas recent LLM-based and pipeline-level papers often rely on smaller synthetic or case-study settings. As a result, strong metric values in one paper are not directly commensurable with strong metric values in another.

**Table 1** Quantitative synthesis of reported evaluation evidence ($N = 23$). Dataset bases are exhaustive; other categories are non-exclusive.

| Dimension | Category | $n$ |
|---|---|---|
| Dataset | Large mined repository corpus | 12 |
| Dataset | Controlled benchmark, case, or deployment | 8 |
| Dataset | Synthetic or small template set | 3 |
| Comparison | Explicit baseline or oracle | 17 |
| External validation | Practitioner/maintainer feedback or bug reports | 10 |
| Metric | Detection quality (e.g., precision, recall, F1, FP/FN) | 16 |
| Metric | Runtime, resource use, latency, or cost | 11 |

Table 1 makes this heterogeneity explicit. Baseline or oracle evidence is reported by 17 studies, but practitioner or maintainer evidence occurs in 10 and runtime, resource, latency, or cost evidence in 11. Accuracy-oriented metrics are common, but their denominators and ground truths differ. Consequently, the table summarizes evaluation designs rather than pooling reported precision or recall values. The study-level audit, mapping, and operational definitions are included in the replication package.

Comparability is particularly limited across ecosystems and evaluation settings. In studies of Kubernetes and Helm analysers, tools targeting similar artefacts may implement different policies and produce different outputs [8, 7]. Deployment studies introduce a further distinction by observing IaC security through running systems rather than through direct artefact inspection [22, 6]. A similar issue arises in studies of Terraform and generated IaC: one paper may benchmark scanners on intentionally vulnerable infrastructures, whereas another uses them as measurement instruments to evaluate LLM-generated configurations [24, 5]. Cross-study comparisons may therefore reflect differences in artefacts, policies, and observation points as much as differences in detector effectiveness.

The realism of the evaluations also varies. Some studies rely on large repositories of publicly available IaC artefacts [21, 18, 19, 16]. Others rely on smaller case studies, benchmark suites, intentionally vulnerable artefacts, deployment-specific observations, or synthetic templates [7, 24, 25, 2, 22, 6, 5, 9]. The benchmarked settings themselves also differ: some studies use curated honeypot or challenge environments such as TerraGoat, others use real Helm-chart repositories, and others use synthetic IaC cases or LLM-generated templates. Such evaluations are useful for controlled experimentation, but they do not necessarily reflect the complexity of industrial deployment pipelines or organization specific policies.

The main conclusion for RQ3 is twofold. First, the area is empirically active: most papers do not stop at proposing a detector, but also attempt to evaluate it. Second, the reported evaluations remain uneven in scope, rigour, and realism. This limits cumulative knowledge building and makes it difficult to compare approaches fairly across ecosystems and detector families.

For practitioners, the current evidence supports deterministic rule-based scanners as a first-line CI check, with data-flow or graph analyses added when security depends on indirect resource interactions. Deployment checks complement rather than replace source analysis. LLM-based detectors should presently augment a deterministic baseline and human review rather than act as the sole deployment gate.

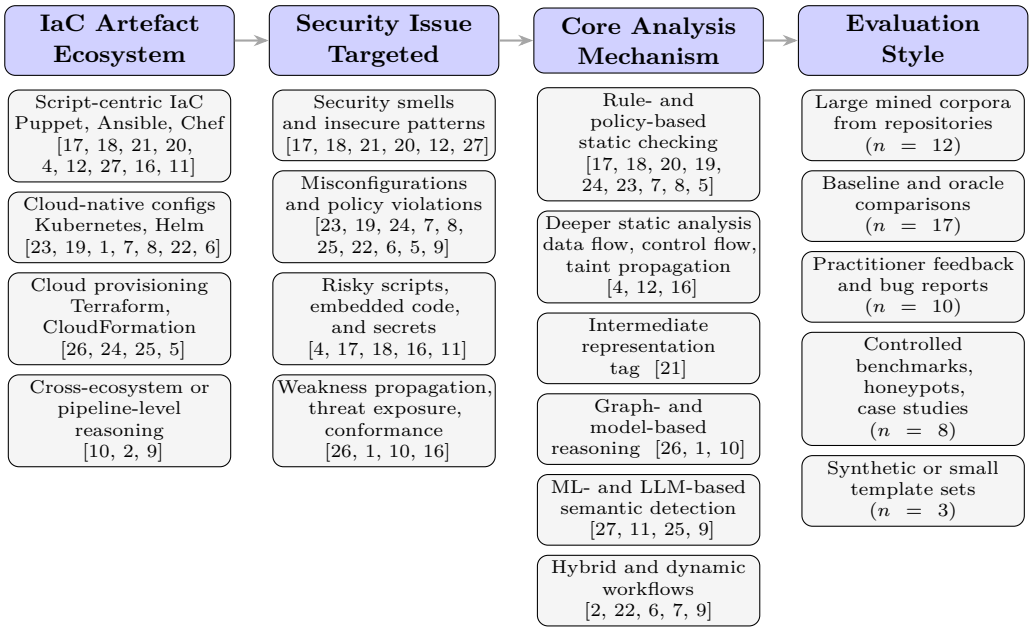

**Figure 2** Graphical taxonomy of the reviewed literature along four complementary dimensions.

## 4 Proposed Taxonomy

Based on the results of Section 3, we propose a four-dimensional taxonomy. The goal is to classify the studies according to the targeted IaC artefacts, the security issues they consider, the technical core of the detection approach, and the way it is evaluated. Categories are non-exclusive when a study combines mechanisms or evaluation designs. Study role – for example, proposing a detector or comparing existing tools – is recorded separately.

Figure 2 summarizes the taxonomy. The first two dimensions characterize what is analysed and which types of security issues are targeted. The last two dimensions characterize how detection is performed and how the resulting tools or methods are evaluated. This organization makes it possible to keep deployment-oriented and runtime-observation studies inside the same review map: such studies differ not only by where they observe the issue, but also by the mechanism they use and by the kind of evaluation they report.

### Dimension 1: IaC artefact ecosystem

The first dimension distinguishes the artefact families targeted by the reviewed studies. A first family concerns script-centric IaC, mainly Puppet, Ansible, and Chef [17, 18, 21, 12, 16, 27, 11]. A second family concerns container orchestration such as Kubernetes manifests and Helm charts, including studies that observe their security effects after deployment [19, 23, 1, 8, 7, 22, 6]. A third family addresses cloud-provisioning, mainly Terraform and CloudFormation [26, 24, 25, 5]. Finally, a small group reasons across ecosystems rather than on a single IaC language [10, 2, 9].

### Dimension 2: Security issue targeted by the detector

The second dimension concerns the type of security issue under consideration. A large group of studies targets security smells and insecure coding patterns [17, 18, 21, 12, 27]. Another group targets security misconfigurations or policy violations in manifests, charts, cloud templates, generated IaC, or deployed configurations traceable to IaC artefacts [19, 23, 8, 24, 25, 22, 6, 5, 9]. Other studies focus on risky embedded scripts, secrets, weakness propagation, or architectural and threat-exposure analyses [4, 11, 16, 1, 10, 26]. These issue classes are not distributed uniformly across ecosystems: smell-oriented work remains concentrated in configuration-management languages, whereas misconfiguration and policy-compliance studies dominate Kubernetes, Helm, Terraform, and the newer LLM-related papers.

### Dimension 3: Core analysis mechanism

The third dimension records the reasoning mechanism rather than the study's contribution type. It distinguishes rule- and policy-based static checking [17, 18, 19, 5], deeper static analysis based on control flow, data flow, or taint propagation [12, 16], graph- and model-based reasoning [1, 10, 26], ML- and LLM-based semantic detection [27, 11, 25, 9], and hybrid or dynamic workflows [2, 22, 6]. Intermediate representations are coded as a supplementary implementation tag because they support, rather than replace, a reasoning mechanism [21]. Comparative papers are classified by the mechanisms of the analysers they evaluate and separately identified as comparison studies.

### Dimension 4: Evaluation

The fourth dimension captures how a tool or method is evaluated. Some papers use large corpora mined from open-source repositories and report classical detection metrics [21, 18, 19, 16]. Others emphasize baseline or oracle comparisons, practitioner feedback, or accepted bug reports [17, 20]. A further group relies on controlled benchmarks, honeypots, case studies, deployment-oriented observations, or synthetic templates [7, 24, 25, 2, 22, 6, 5, 9]. This dimension matters because technically similar detectors may rely on very different evaluation settings. This dimension therefore cautions against comparing studies solely through their reported metrics: e.g. even evaluations of Kubernetes security tools may differ substantially in dataset construction, oracle definition, observation point, and validation procedure.

### Cross-dimensional synthesis

This taxonomy shows that the reviewed literature is diverse, but not uniformly so. The field remains concentrated on a few ecosystems and on a few dominant evaluation styles. The cloud-native part of the corpus is methodologically the most diverse because it spans manifest-level checking, topology- or conformance-oriented reasoning, and deployment-oriented observation. By contrast, other ecosystems are represented by fewer technical families. The taxonomy also shows that the recent diversification of detection mechanisms is not yet matched by equally mature empirical support across all families of approaches.

## 5 Challenges and Perspectives

The evaluation heterogeneity identified in RQ3 makes the development of a shared benchmark a central challenge for IaC security detection. A useful benchmark should include versioned, appropriately licensed artefacts and combine vulnerable and secure examples from real-world

projects and controlled cases. For each labelled issue, it should identify the location, the relevant policy or weakness class, and whether the issue is observable in source artefacts or only after deployment. It should also control for duplicates and data leakage. These properties would support reproducible evaluations.

A second, closely related challenge is establishing a minimum reporting checklist. Studies should report dataset provenance and selection criteria, exact tool and ruleset versions, the observation level, oracle construction, baselines, per-class metrics, analysis failures, procedures for validating false positives and false negatives, runtime and cost, and links to publicly available replication artefacts. The Kubernetes and Helm comparisons show why this is necessary: tools targeting similar artefacts may implement different policy semantics, check different resources, and produce outputs that are not directly comparable [8, 7].

A third challenge is evaluation realism. Public repositories, benchmark datasets, and intentionally vulnerable artefacts are useful for controlled experimentation, but they do not always reflect the operational constraints of industrial IaC pipelines, organization-specific policies, or multi-tool development workflows. A promising direction is therefore to complement public datasets with industrial case studies, longitudinal observations, or deployment-oriented evaluations. The deployment and CI/CD studies illustrate both the value of these settings and the current lack of common evaluation designs [22, 6, 2, 9].

A fourth challenge concerns ML- and LLM-based detectors [27, 11, 25, 9]. Their evaluation should, at minimum, include an appropriate deterministic baseline where one exists, record exact model versions and prompts, repeat runs to quantify variability, report latency and cost, and independently validate a sample of findings. Releasing prompts and retrieval sources would support reproducibility, while evaluations across prompt variants and over time would help quantify prompt sensitivity and model drift. Until such evidence accumulates, hybrid use with deterministic checks is more defensible than treating an LLM as a sole security gate.

## 6 Threats to Validity

This review is subject to several threats to validity. First, validity is limited by the operational definition of IaC security detection, since the boundary between detection, prevention, policy enforcement, and compliance checking is not always sharp. To reduce this ambiguity, the review restricts inclusion to studies whose primary contribution concerns detection. Second, selection bias may arise from the restriction to English-language studies with accessible full text, as well as from the chosen publication window. These decisions improve feasibility and reproducibility, but they may exclude relevant studies.

A further threat to completeness comes from the search configuration itself. The automated search was restricted to ACM Digital Library and IEEEXplore, and the retrieval query relied on title and abstract metadata rather than full-text search. This design keeps the review protocol focused and auditable, but it may miss relevant studies that are indexed in other databases, that use different terminology, or that describe their security contribution outside the queried fields. For this reason, the findings should be interpreted as a focused review of the currently retrieved corpus, not as a claim that every relevant IaC security detection study has been captured. Third, publication bias remains a concern because peer-reviewed literature tends to over-represent positive or mature results, while underrepresenting negative findings, industrial tools, and unpublished systems used in practice. Fourth, classification bias may affect the categorization of technical approaches and reported evaluations, especially when papers use inconsistent terminology or provide limited methodological detail.

Finally, external validity is limited because the review reflects the state of reported research rather than actual industrial adoption or operational effectiveness of IaC security tools. Consequently, the findings should be interpreted as an overview of the reported research landscape, rather than as a complete representation of all tools used in practice.

## 7 Conclusion

This paper presented emerging results from a focused literature review of tools for detecting security issues in IaC artefacts. The reviewed studies show that the area is active and technically diverse. The literature includes rule-based detectors, deeper static analyses, graph- and model-based approaches, and more recent ML and LLM based techniques. It also spans several IaC ecosystems, especially Puppet, Ansible, Kubernetes, Helm, and Terraform.

Despite this technical breadth, heterogeneous datasets, oracles, and evaluation settings limit direct comparison and cumulative evidence. Shared benchmarks and consistent reporting are therefore practical priorities for strengthening the evidence base.

These findings should be interpreted in light of the review's focused scope: they characterize the corpus of IaC security *detection* studies retrieved through our protocol, rather than all IaC security research.

Future work includes extending the search protocol to additional digital libraries and complementing automated search with backward and forward snowballing. The present review can serve as a basis for separate or explicitly broadened reviews on adjacent topics such as repair, prevention, or runtime enforcement.

## Data Availability Statement

A public archival artefact is available at: `https://zenodo.org/10.5281/zenodo.21820732`. The repository contains the ACM and IEEE BibTeX exports, screening decisions for the title, abstract, and full-text phases, phase-count summaries, and metadata and extraction tables for the 23 included studies. It also contains the full-text audit and derived category mapping used for the quantitative evaluation synthesis.

# QModel: A Time-Aware GitHub Mining Framework for Empirical Software Quality Studies

**Dmytro Polishchuk**
Jagiellonian University, Kraków, Poland

## Abstract

Quality-oriented mining software repositories studies require more than access to commits, issues, pull requests and CI logs. They require a reproducible way to represent how technical, social, temporal and defect-related evidence is linked across repository history. Existing MSR infrastructures provide important support for repository mining, but they do not directly expose a project-level, time-aware empirical model in which cross-artifact quality evidence can be queried, inspected and reused across alternative study designs.

This paper presents *QModel*, an emerging infrastructure for reproducible GitHub mining in empirical software quality studies. QModel stores Git, GitHub, CI, timeline, reaction, graph, churn and SZZ-style candidate-defect evidence in a project-centric relational schema. Its SQL-based compilation layer allows researchers to define feature-target datasets over arbitrary analysis units, including pull requests, issues, commits, files, time windows and custom cross-artifact objects.

We evaluate QModel on `ansible/ansible` and `facebook/react`, mining 76,475 commits, 70,509 pull requests, 45,908 issues, 2,174,020 timeline events, 315,235 file-change records and 446,161 CI records. The early results show that QModel can materialize analysis-ready datasets with computable target, graph, churn and provenance features, while also making evidence gaps explicit when historical links, CI records, or fixing evidence are incomplete. These results support QModel as an empirical infrastructure for making quality-oriented repository operationalizations explicit, reusable and systematically evaluable.

## 1 Introduction

Open-source repositories contain rich traces of software development, including commits, pull requests, issues, review discussions, continuous-integration checks, file changes, timelines and user reactions. These traces have made mining software repositories a central methodology in empirical software engineering. However, raw repository traces are not yet empirical datasets. A quality-oriented study must still decide which artifacts form the unit of analysis, which events define the target variable, which links among artifacts are valid and which derived metrics are available for each row of the dataset.

This operationalization step is a major reproducibility risk in repository-mining research. MSR workflows transform repository data into analytical datasets through retrieval, parsing, cleaning, filtering, parameterization and analysis; these intermediate steps and artifacts are frequently incompletely reported or unavailable [13, 5, 18]. A researcher may need to combine Git history traversal, GitHub API extraction, issue-pull-request linking, pull-request-commit mapping, timeline reconstruction, CI aggregation, churn computation, commit-graph analysis and SZZ-style defect tracing. Git and GitHub introduce additional ambiguity concerning

branch and merge traversal, forks, repository selection and pull-request merge status [9], while Git timestamps are frequently noisy and can affect time-based analyses [4]. Cross-artifact links and defect labels are also heuristic: alternative issue-linking algorithms recover different sets of defect-fixing commits [11] and SZZ variants are often underspecified and can produce substantially different or noisy defect-provenance labels [14, 8, 1]. Consequently, two studies may mine the same repository yet construct different analytical datasets because of different linking rules, filters, timestamp definitions, branch and merge handling, aggregation choices, or defect-provenance heuristics.

The problem is especially important for software-quality research. Concepts such as maintainability, reliability, reviewability, or defect-proneness are not directly stored in GitHub. They must be represented through observable signals. Therefore, the central challenge is not only to collect repository artifacts, but to preserve the relations among them so that quality hypotheses can be expressed, inspected and repeated.

This paper presents *QModel*, an emerging infrastructure for time-aware, quality-oriented GitHub mining. We do not claim that repository mining, pull-request analysis, or SZZ-style defect tracing are new. The contribution is instead the operationalization of these elements in a single project-centric framework. QModel persists Git, GitHub, CI, timeline, reaction, graph, churn, and candidate-defect evidence as linked, queryable relations. Researchers can then define issue-level, pull-request-level, commit-level, or file-level datasets in SQL and reuse the same mined database across multiple empirical studies.

This work is submitted as an *Emerging Results* paper. The new idea under initial evaluation is an *executable operationalization*: a study definition that can materialize its analysis rows and audit whether target and predictor evidence are jointly computable. The initial empirical result is that computability varies sharply by analysis unit and evidence path, even when the underlying repository database is fixed. Thus, the contribution is not only that the pipeline executes, but that it makes the consequences of alternative operationalization choices directly observable. The paper does not claim a universal theory of software quality or a final review-time benchmark.

## Study Goal

The pilot evaluates two stages of reproducible study construction: materializing analysis-ready datasets under alternative operationalizations and instantiating an empirical analysis from the same persisted evidence.

## Research Questions

### RQ1

How complete are the datasets materialized by QModel with respect to the target variable, metrics derived from the directed acyclic graph (DAG) of commits and churn measures?

The commit DAG comprises commits and their parent relationships. Completeness is the proportion of rows containing the target and the required DAG and churn metrics.

### RQ2

Can QModel materialize an analysis-ready dataset from persisted repository artifacts, cross-artifact links and derived metrics for a reproducible empirical analysis?

We examine this question using pull-request review time as a worked example. Researchers can define other analysis units, targets and features over the same persisted repository data.

### Contributions

QModel makes three contributions. First, its project-centric ingestion pipeline and schema integrate Git, GitHub and CI artifacts, compute churn and commit-DAG metrics, link defect-related issues to fixing commits and identify candidate bug-introducing commits (BICs) using an SZZ-style tracer. Second, its SQL-based compilation layer makes analysis units, targets, features, links, filters and aggregations explicit. Third, the pilot shows that completeness varies across operationalizations and that the same persisted evidence can support different empirical analyses.

## 2 Background and Research Gap

The mining software repositories community has produced several important infrastructures. GHTorrent mirrors GitHub metadata into a queryable database [6]; Boa provides a language and infrastructure for large-scale repository mining [3]; World of Code indexes a large universe of version-control objects [12]; and PyDriller offers a convenient Python framework for mining Git histories [15]. These infrastructures substantially lower the cost of obtaining repository evidence. However, quality-oriented empirical studies need more than artifact access: they need a reproducible way to turn repository history into analysis objects whose links, timestamps, derived metrics and uncertainties are explicit.

This is the operationalization gap targeted by QModel. In a quality study, the same repository history can support many plausible datasets depending on the chosen unit of analysis, linking rules, event timestamps, feature definitions, and defect-provenance assumptions. If these choices remain embedded in project-specific scripts, it becomes difficult to inspect why two studies over the same repository produce different rows, targets, or predictors. QModel therefore treats the repository not only as a source of artifacts, but as a linked empirical model from which alternative quality-oriented datasets can be defined, inspected and reused.

Table 1 summarizes this distinction. The comparison does not claim that the listed infrastructures cannot be extended. Rather, it asks whether the capability is available as a native, analysis-ready abstraction for linked, quality-oriented GitHub studies.

Prior work on pull requests and code review shows that contribution evaluation and review outcomes depend on both social and technical factors [7, 17]. Prior work on just-in-time quality assurance shows that commit-level history and churn can support defect-oriented analyses [10], while SZZ-style tracing shows that candidate defect links are useful but sensitive to implementation choices [1]. These observations motivate a framework that stores cross-artifact relations explicitly and treats derived evidence as queryable but inspectable empirical constructs.

QModel addresses this operationalization gap. It does not replace broad ecosystem-scale infrastructures. Instead, it targets reproducible, project-level empirical studies in which researchers need linked GitHub artifacts, time-aware process and graph metrics, CI evidence, candidate defect-provenance relations and analysis-ready datasets. The key idea is to separate ingestion from analysis: once the database is mined, multiple issue-level, pull-request-level, commit-level, or file-level datasets can be defined using SQL.

## 3 QModel Framework

QModel represents a GitHub repository as a linked empirical database rather than as a collection of independent artifacts. Its architecture comprises an ingestion framework and a compilation and analysis framework, connected through a project-centric relational

**Table 1** Comparison with MSR infrastructures for linked, quality-oriented GitHub analyses.

| Tool | Native abstraction | Native SZZ evidence | Native linked quality-analysis object |
|---|---|---|---|
| PyDriller [15] | Git history, commits, file changes and evolution metrics. | No. | No native GitHub issue/PR/timeline/reaction/CI/SZZ linking; external integration is needed. |
| GHTorrent [6] | GitHub metadata for projects, users, issues, pull requests and comments. | No. | Partial GitHub metadata, but no analysis-ready fixing commits, CI evidence, or candidate-BIC relations. |
| Boa [3] | Large-scale repository mining through a domain-specific language. | No. | No native GitHub-centered quality-linking schema for PR-issue-CI-defect provenance objects. |
| World of Code [12] | Large-scale VCS object graph for commits, projects, files, authors and blobs. | No. | No native GitHub social-artifact layer for PRs, issues, reactions, timelines, or CI evidence. |
| GrimoireLab | Multi-forge retrieval, enrichment, identity management, indexes and dashboards [2]. | No. | Cross-source enriched indexes, but no feature-target SQL compiler. |
| SmartSHARK | VCS, issue, PR/review, CI, code metrics and validated bug evidence [16]. | Yes. | No dedicated feature-target SQL compiler. |
| QModel | Project-centric database integrating Git, GitHub, CI, timelines, reactions, graph/churn metrics and defect evidence. | Yes. | Yes; linked artifacts and candidate-BIC relations are stored as explicit queryable relations. |

schema (Figure 1). The ingestion framework obtains version-control data from the repository and development artifacts through the GitHub API. It computes commit-graph metrics, reconstructs cross-artifact and candidate-defect links and stores both collected and derived data in the schema. The compilation framework uses the persisted data to materialize SQL-defined datasets and manage reusable intermediate data. The analysis layer selects an implementation from a registry keyed by the configured strategy name and executes it on the materialized dataset. The registered strategies include correlation analysis, PCA, ANOVA, linear regression, random forest and elastic net regression. The resulting outputs are then passed to the result renderer.

## 3.1 Design Principles

QModel is designed around three principles. First, cross-artifact evidence is stored explicitly: pull requests, commits, issues, timelines, reactions, CI runs, file changes, graph metrics and candidate-defect links can be joined rather than reconstructed. Second, repository history is time-aware: QModel stores the commit DAG and derives graph and branch/merge metrics that describe where a change occurs in history. Third, empirical operationalization is SQL-defined: researchers can define analysis rows, targets, joins, filters and feature aggregations over the schema without changing the mining pipeline.

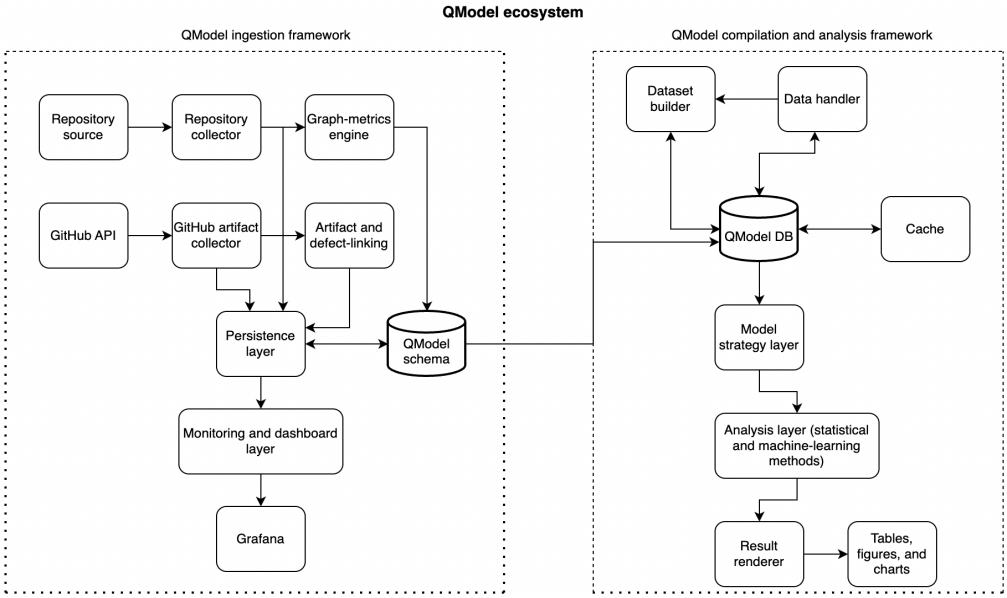

**Figure 1** QModel architecture and principal data flows.

## 3.2 Ingestion Pipeline

The ingestion pipeline collects both Git and GitHub evidence.

- The repository collector clones a target repository and extracts commits, parent relations, file changes, changed lines, patches, author metadata and commit timestamps.
- The GitHub artifact collector retrieves issues, pull requests, labels, assignees, reviewers, timeline events, reactions and check runs.
- The graph-metrics engine reconstructs the commit directed acyclic graph and computes time-aware graph and branch/merge metrics.
- The linking layer connects issues, pull requests, commits, timelines, reactions and CI evidence using explicit association schema.
- The defect-linking component links issues to fixing pull requests and applies SZZ-style tracing to identify candidate bug-introducing commits.
- The persistence layer stores raw artifacts, derived metrics and cross-artifact relations in a normalized relational schema.

The result is not only a raw mirror of repository data. It is a database of analysis-ready empirical evidence. For example, a pull request can be connected to its commits, commit-level churn, CI outcomes, reviewer activity, linked issues, issue timelines and candidate defect-provenance relations without re-running the mining process.

## 3.3 Relational Schema

The central schema entity is a project, identified by repository owner and name. Around this entity, QModel organizes repository evidence into relational families for version-control history, GitHub collaboration artifacts, continuous-integration records, derived history metrics and defect-provenance relations. The full entity-relationship diagram and SQL schema definition are included in the supplementary artifact; the main paper summarizes the schema at the level needed to explain the empirical workflow.

**Listing 1** Abridged SQL definition of the issue-level candidate-BIC dataset.

```
SELECT pi.project_owner, pi.project_name,
pi.id AS analysis_id,
TIMESTAMPDIFF(HOUR, pi.created_at, pi.closed_at)
AS target_hours,
AVG(c.distance_to_branch_start) AS avg_fp_distance,
SUM(cc.total_changes) AS total_changes
FROM project_issue pi
JOIN project_issue_bug_introducing_commits pibic
ON pibic.project_issue_id = pi.id
AND pibic.project_issue_project_name = pi.project_name
AND pibic.project_issue_project_owner = pi.project_owner
JOIN commit c
ON c.sha = pibic.bug_introducing_commits_sha
LEFT JOIN commit_churn cc ON cc.sha = c.sha
WHERE pi.state = 'closed'
AND pi.created_at IS NOT NULL
AND pi.closed_at IS NOT NULL
GROUP BY pi.project_owner, pi.project_name, pi.id,
pi.created_at, pi.closed_at;
```

The schema is designed around analysis joins rather than around isolated raw tables. Version-control relations preserve commits, parent structure, file changes, changed lines and graph metrics. GitHub relations preserve issue and pull-request metadata together with labels, assignees, reviewers, timelines, reactions and cross-links among artifacts. Defect-provenance relations connect reported issues to fixing evidence and to SZZ-style candidate bug-introducing commits. As a result, technical evidence, process evidence, social activity, and candidate defect provenance can be assembled in one SQL-defined analysis row.

The unit of analysis is intentionally not fixed by the schema. Depending on the study, a row can represent a pull request, issue, commit, file, developer, time window, release interval, or custom cross-artifact object. This design lets researchers reuse the same mined database while changing the empirical operationalization: for example, one query can construct pull-request rows with review, CI, churn and history context, while another can construct issue rows focused on resolution time, fixing evidence and candidate defect provenance.

## 3.4 SQL-to-Dataset Compilation

QModel Compilation separates dataset definition from statistical analysis. A researcher defines a dataset using SQL over the `qmodel` schema. The SQL query specifies the unit of analysis, target variable, predictors, filters and aggregation logic. The resulting table can then be passed to descriptive statistics, correlation analysis, regression, random forests, or other analysis strategies.

Listing 1 illustrates how these decisions are encoded in SQL. The excerpt is taken from the definition of the issue-level candidate-BIC dataset used in the pilot evaluation.

The query makes the operationalization directly inspectable: `project_issue` establishes the issue as the analysis unit, `target_hours` defines the resolution-time target and the candidate-BIC relation specifies the path from issues to candidate bug-introducing commits. The `WHERE` clause defines the eligible population, while `AVG` and `SUM` aggregate commit-graph and churn measures into one row per issue. In the complete query, `commit_churn` is defined

as a common table expression (CTE), which is a temporary named result available within the query. It aggregates file-change measures by commit and is joined to the main query through the alias `cc`. Its definition is omitted from the listing for brevity. The complete executable query is provided in the replication artifact.

# 4 Time-Aware Metrics and Defect Linking

QModel computes derived variables that describe not only what changed, but also where and when the change occurred in the repository history. This section summarizes the main derived evidence used later in the evaluation: commit-history metrics, churn and CI summaries, process metrics and SZZ-style candidate defect links.

## 4.1 Commit-History Metrics

QModel therefore stores the full commit DAG and derives a deterministic auxiliary structure called a continuity line. This structure is used only to compute path-based metrics such as distance to line start, upstream integration, and days since last merge; the original commit DAG is still preserved.

For a commit with one parent, the parent is used as the continuation parent. For a merge commit with multiple parents, QModel scores candidate parents and selects the parent that continues the longest visible non-branching line. Ties are broken deterministically using commit timestamp and SHA. The resulting metric `distance_to_branch_start` should therefore be interpreted as distance to the start of the selected continuity line, not as a verified distance to the creation point of a developer-intended branch.

QModel also stores minimum and maximum depth in the commit history, degree statistics, branch visibility from references available at mining time and days since the previous merge on the selected continuity line. These metrics are not intended to replace standard churn or process measures. They provide additional history context that can be joined with commits, pull requests, issues, files, or any other SQL-defined analysis object.

## 4.2 SZZ-Style Candidate Defect Links

QModel implements an SZZ-style defect-linking procedure based on prior work [1]. We do not introduce a new SZZ algorithm. Instead, QModel uses SZZ-style tracing as an infrastructure component and stores the resulting links as explicit relations in the database.

The stored links are interpreted as *candidate* bug-introducing commits, not as ground truth. This distinction is important because SZZ-style links can be affected by incomplete issue-fix links, refactorings, code movement, squash/rebase workflows and limitations of line-based blame. QModel therefore keeps these relations queryable and inspectable rather than treating them as validated defect labels.

In the issue-level datasets, a candidate BIC is an earlier commit linked to the fixing evidence for that issue by the SZZ-style procedure. In the pull-request-level datasets, a candidate-BIC indicator means that at least one commit contained in the pull request later appears in an issue-level candidate-BIC relation. Thus, the pull-request-level variable does not label the pull request as definitively defective; it records later defect-provenance evidence associated with commits contained in that PR.

# 5 Early Evaluation Design

The early evaluation assesses QModel as research infrastructure. The objective is not to establish universal laws about software quality. Instead, the study asks whether QModel can extract and link heterogeneous GitHub artifacts, compute derived metrics and support SQL-defined analysis contexts over the same persisted repository data.

## 5.1 Subject Systems

Repositories were selected in two steps. First, they had to provide the raw artifacts required by the evaluation: an extended commit history, sustained pull-request and issue activity, metadata from which cross-artifact links could be constructed and CI records. We favored long-running projects because their histories span changes in repository-management practices and platform support, including the adoption of pull-request workflows, CI services and GitHub Checks. This temporal variation allows QModel to be exercised on both recent, data-rich periods and older periods in which some artifact types may be unavailable.

The eligibility criteria did not require the datasets produced by QModel to be complete. In particular, repositories were not selected according to the availability of derived commit-DAG or churn measures, because dataset completeness is the outcome evaluated by RQ1.

Second, we selected repositories from different development contexts. `ansible/ansible` is a Python-based infrastructure-automation project, whereas `facebook/react` is a JavaScript-based user-interface library. This contrast allows the pilot to examine QModel across different application domains, programming ecosystems and repository practices.

The two repositories are pilot cases and are not intended to represent the GitHub population. A broader evaluation should define an eligible repository population and sample projects across relevant characteristics, including ecosystem, project size and age, merge strategy, CI configuration and issue-linking practice.

Across the two projects, QModel extracted 76,475 commits, 70,509 pull requests, 45,908 issues, 2,174,020 timeline events, 315,235 file-change records and 446,161 CI records. The number of CI records should not be interpreted as the number of CI-covered commits. A commit may generate several check runs, whereas older commits may predate GitHub Checks or rely on external CI systems.

## 5.2 Operationalization

For RQ1, we evaluate whether QModel can transform persisted repository evidence into analysis-ready datasets. The evaluation focuses on candidate-BIC datasets because they require several linked evidence paths at once: issues or pull requests, fixing evidence, candidate bug-introducing commits, graph-history metrics and churn summaries. We measure whether each analysis row has a computable target variable, graph summary, churn summary and combined graph+churn evidence. Issue-level candidate-BIC rows test whether QModel can construct defect-provenance datasets from issues and their associated candidate introducing commits. Pull-request-level candidate-BIC rows test whether QModel can identify PRs containing commits that later appear in issue-level candidate-BIC relations.

For RQ2, we instantiate a pull-request-level dataset as a worked empirical analysis. The target is $\log(1 + \textit{review\_hours})$, where review time is derived from pull-request creation and merge timestamps. Predictors include timeline-event counts, reviewer counts, assignee counts, reaction counts, graph summaries over PR commits, churn summaries, CI summaries and

**Table 2** RQ1 derived-metric computability for SQL-defined analysis datasets. Each metric cell reports rows with computable evidence and the corresponding percentage of analysis rows.

| Project | Dataset | Rows | Target | Graph | All graph | Churn | Graph+Churn |
|---|---|---|---|---|---|---|---|
| `ansible` | Issue-level candidate-BIC | 2,001 | 2,001 (100.00%) | 1,995 (99.70%) | 1,704 (85.16%) | 1,995 (99.70%) | 1,995 (99.70%) |
| `ansible` | Issue-level fixing-commit | 6,323 | 6,323 (100.00%) | 1,115 (17.63%) | 373 (5.90%) | 1,093 (17.29%) | 1,093 (17.29%) |
| `ansible` | PR-level candidate-BIC | 3,680 | 3,680 (100.00%) | 3,680 (100.00%) | 3,680 (100.00%) | 3,680 (100.00%) | 3,680 (100.00%) |
| `react` | Issue-level candidate-BIC | 724 | 724 (100.00%) | 724 (100.00%) | 724 (100.00%) | 724 (100.00%) | 724 (100.00%) |
| `react` | Issue-level fixing-commit | 730 | 730 (100.00%) | 728 (99.73%) | 728 (99.73%) | 244 (33.42%) | 244 (33.42%) |
| `react` | PR-level candidate-BIC | 4,720 | 4,720 (100.00%) | 4,720 (100.00%) | 4,720 (100.00%) | 4,720 (100.00%) | 4,720 (100.00%) |

indicators or counts related to candidate defect provenance. The model is used only as a feasibility demonstration of SQL-defined analysis construction, not as a claim of state-of-the-art prediction performance.

# 6 Early Results

This section reports results for two questions: whether QModel materializes datasets with computable derived metrics and whether they support empirical analysis.

## 6.1 RQ1: Derived Metric Computability

RQ1 asks whether QModel can transform mined repository evidence into analysis rows where the target variable and derived metrics are available together. We evaluate three SQL-defined datasets: issue-level candidate-BIC rows, issue-level fixing-commit rows and PR-level candidate-BIC rows. These datasets exercise different evidence paths. Candidate-BIC datasets require defect- provenance links, graph-history metrics and churn summaries. Fixing-commit datasets test the fixing side of issue evidence. PR-level candidate-BIC rows test whether pull requests containing later candidate-BIC commits can be materialized as analysis objects.

Table 2 reports the computability results. The reported columns are row-level availability measures. *Target* means that the row has a non-null, non-negative duration: issue creation-to-closure time for issue-level rows and pull-request creation-to-merge time for PR-level rows. *Graph* means that at least one commit in the row has the complete graph metric vector used by the query, including degree, history-depth, branch-distance, upstream-head, merge-recency, branch-count and average-degree fields. *All graph* is stricter: every commit associated with the row must have that complete graph metric vector. *Churn* means that at least one commit in the row has a file-change summary with non-null total changes and at least one changed file. *Graph+Churn* means that the same analysis row has at least one graph-ready commit and at least one churn-ready commit.

The target duration is complete in all six project-dataset combinations. Candidate-BIC datasets are highly computable. In `ansible/ansible`, 1,995 of 2,001 issue-level candidate-BIC rows have both graph and churn summaries. In `facebook/react`, all 724 issue-level candidate-BIC rows have both graph and churn summaries. At PR level, both projects are fully computable: all 3,680 Ansible rows and all 4,720 React rows have graph, churn, and combined graph+churn evidence.

The fixing-commit datasets reveal a different evidence boundary. Although their target durations are complete, graph and churn computability is lower for `ansible/ansible`: 1,093 of 6,323 rows have both graph and churn summaries. The stricter all-graph measure is lower still, at 373 of 6,323 rows (5.90%). This value is expected because the all-graph measure requires every fixing commit associated with an issue to have the complete graph-metric

vector. For historical GitHub data, this can fail when commits are associated with branches or integration paths that are no longer visible at mining time, when branch references have been deleted, or when some graph-derived quantities cannot be reconstructed consistently.

For `facebook/react`, graph metrics are available for nearly all fixing-commit rows, but churn summaries are available for 244 of 730 rows. This shows that fixing evidence, graph evidence and churn evidence are distinct forms of empirical availability: an issue may have fixing commits, while the corresponding local history or file-change evidence needed for metric computation is incomplete.

## 6.2 RQ2: Worked Example Analysis Instantiation

RQ2 asks whether the same mined database can instantiate a concrete empirical analysis. We use pull-request review time as a worked example because it requires multiple linked evidence sources: PR metadata, commits, graph-history metrics, changed files, CI outcomes, review activity, timeline events, reactions and candidate-defect evidence. The goal is methodological rather than predictive: review time is not a direct quality label and the model is not intended as a universal benchmark for review latency.

### Dataset Construction

The unit of analysis is a merged pull request with at least one associated commit. Review time is computed as `TIMESTAMPDIFF(SECOND, created_at, merged_at)`/3600 and the modeled target is $\log(1 + \texttt{pr\_review\_hours})$. The transformation limits the influence of extremely long-lived pull requests but does not make review time a quality label. The SQL workflow aggregates commit-level evidence into six PR-level feature groups: process and social activity, commit counts, graph-history metrics, churn, CI summaries and candidate-defect indicators. Each row is therefore a linked empirical object assembled from multiple repository artifacts rather than raw pull-request metadata.

### Exploratory modeling setup and baseline comparison

We evaluate whether the SQL-materialized PR-level dataset supports a standard modeling workflow. The target is `log_pr_review_hours`. The SQL query assigns pull requests to a stable deterministic hash-based hold-out split: rows labeled `train` are used for fitting and rows labeled `validation` are used only for evaluation. The retrospective covariates cover process and social activity, evidence counts, graph-history metrics, churn, CI summaries and candidate-defect indicators.

We compare a `RandomForestRegressor` with an ordinary least-squares linear-regression baseline using the same SQL-materialized features and complete-case training and validation rows. The random forest uses 200 trees, random seed 42 and no maximum-depth restriction. The linear baseline includes an intercept, with features standardized using training-set statistics only. Both models are evaluated on the held-out validation rows using $R^2$ and MSE.

The random forest performs modestly better than the linear baseline. For `ansible/ansible`, it obtains $R^2 = 0.3521$ and MSE $= 3.7919$, compared with $R^2 = 0.3061$ and MSE $= 4.0607$ for linear regression. For `facebook/react`, the corresponding results are $R^2 = 0.2265$ and MSE $= 3.5550$, compared with $R^2 = 0.1977$ and MSE $= 3.6874$. Thus, the random forest increases held-out $R^2$ by 0.0460 and 0.0288 and reduces MSE by approximately 6.6% and 3.6%, respectively. These modest improvements suggest some nonlinear signal but do not establish a competitive review-time predictor. Instead, the comparison shows that QModel can instantiate a reproducible analysis and evaluate it against a simpler baseline.

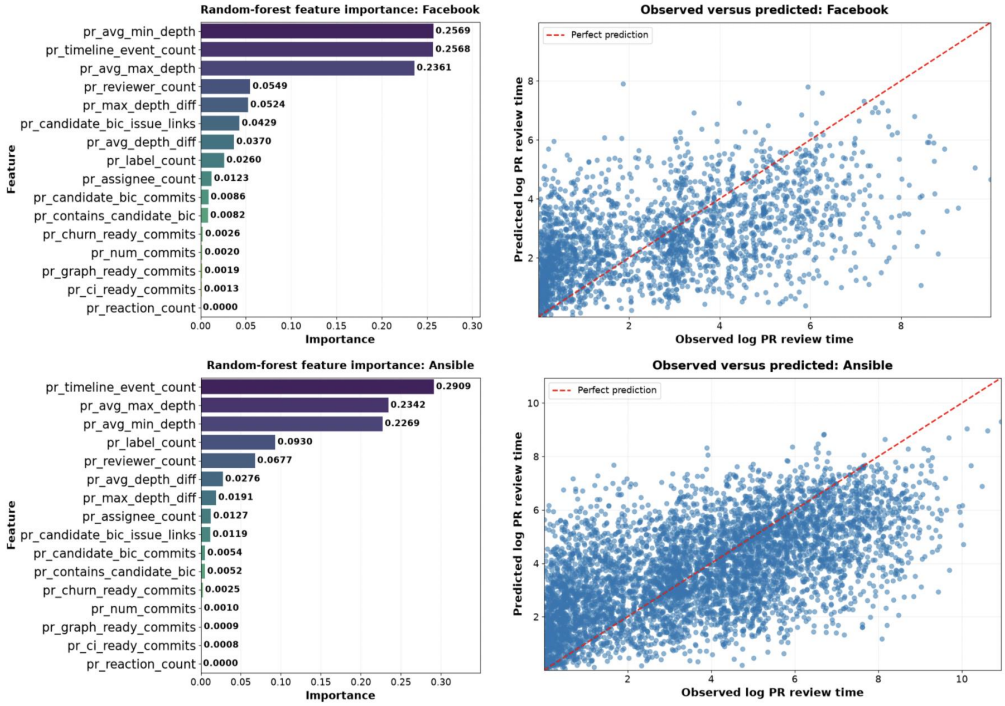

**Figure 2** Exploratory random-forest diagnostics for PR-level review time.

Figure 2 presents the random-forest diagnostics. In both projects, process and graph-history covariates are more influential than CI/action covariates. The actual-versus-predicted plots show positive trends with substantial dispersion, indicating useful structure but limited pull-request-level precision.

### Roadmap

We will evaluate QModel across repositories with different sizes, branching practices, linking conventions and CI histories. Planned extensions include evidence-quality indicators for link confidence, graph/churn completeness and workflows such as squash/rebase, deleted branches, refactorings, renames and formatting-only changes. Reusable SQL templates will support alternative analysis units, targets, filters and features, enabling studies of whether conclusions remain stable across projects and operationalization choices.

## 7 Threats to Validity

The early evaluation has several validity threats. For construct validity, QModel does not claim that review time, CI outcomes, or SZZ-style links are direct measures of software quality. Review time is a retrospective process measure and candidate bug-introducing commits are noisy evidence rather than ground-truth defect labels. Similarly, CI/action records indicate available repository evidence, not complete CI coverage for every historical commit.

For internal validity, the computed datasets depend on issue-pull-request links, fixing-commit identification, commit-to-PR mappings, line-based blame, and GitHub metadata available at mining time. Squash and rebase workflows, deleted branches, refactorings, code

movement, formatting-only changes, missing check runs and incomplete issue references can affect both defect-provenance relations and derived commit-DAG or churn summaries. QModel mitigates this threat by storing such evidence as explicit, inspectable relations and by reporting computability gaps instead of silently discarding them.

For external validity, we purposefully selected `ansible/ansible` and `facebook/react` because they provide long commit histories, sustained pull-request and issue activity, linkable cross-artifact metadata and CI records. They also represent different application domains and programming ecosystems, but two projects are not a representative sample. Results may differ for smaller or non-GitHub projects and repositories with different branching, issue-linking, or CI practices.

## 8 Conclusion

This paper presented QModel, an emerging infrastructure for reproducible, time-aware GitHub mining in empirical software quality studies. QModel persists commits, issues, pull requests, file changes, reactions, timelines, CI check runs, graph metrics and SZZ-style candidate defect links in a unified relational schema. Its SQL-to-dataset layer allows researchers to define units of analysis, target variables, feature aggregations and filtering criteria explicitly.

The early evaluation on `ansible/ansible` and `facebook/react` shows that QModel can support reusable pull-request-level datasets and expose coverage limitations for issue-level and CI-based analyses. The worked review-time analysis demonstrates feasibility rather than final predictive performance. The main contribution is therefore infrastructural: QModel makes quality-oriented MSR operationalizations inspectable, reusable and suitable for systematic empirical evaluation. By separating repository ingestion from SQL-defined dataset construction, QModel provides a foundation for comparing alternative quality operationalizations over the same persisted evidence.

## Data Availability Statement

The replication artifact is available on Zenodo at `https://zenodo.org/records/21737012`. It contains snapshots of the QModel mining framework, which collects Git and GitHub evidence and persists the relational database and the QModel Compilation repository, which provides the SQL queries, analysis scripts, derived result tables, generated figures and README files needed to reproduce the reported analyses.

For RQ1, `queries/RQ1.sql` constructs the issue-level fixing-commit, issue-level candidate-BIC and pull-request-level candidate-BIC computability datasets in Table 2. For RQ2, the main entry point is `clients/proven/rq2/RQ2_models.py`, together with the SQL query that materializes the pull-request-level review-time dataset. Derived outputs are in the `results/` directory of the qmodel_compilation repository. The artifact also documents the expected database schema and data-processing steps used to construct the SQL-defined datasets.

The artifact prioritizes executable and derived materials rather than the full mined database, which is approximately 500 GB before compression and contains GitHub metadata, Git history, patches, CI/action records, timelines and raw text/JSON payloads. The database can be regenerated using the mining framework and documented configuration; a compressed dump may be provided separately when storage and review logistics permit.

## Abstract

Threat modeling remains a central task in secure software engineering, as it enables the identification of security issues from system architectures. As Generative Artificial Intelligence (GenAI) becomes increasingly pervasive across software systems, traditional threat modeling methods (e.g., STRIDE) are insufficient to assess emerging GenAI-specific risks. In this work, we present the first results from an exploratory assessment of GenAI-aware threat modeling methods in a Small and Medium Enterprise (SME) setting. For this, we conducted a rapid literature review to select relevant techniques and systematically applied three shortlisted methods to an industrial case study involving a GenAI-augmented system. The results highlight differences in the threats identified by each technique and reveal limited support for certain GenAI-specific risk categories, particularly those related to software supply chains and human-centered security issues. We further report practitioners' perceptions of the usability and integration of these methods in SME development workflows, including their perceived effort and adoption challenges.

## 1 Introduction

The security of software-intensive systems is a multifaceted challenge that requires coordinated efforts from stakeholders across the entire development lifecycle. Threat Modeling (TM) is a key component of the security toolkit, as it provides a structured set of methods and artifacts to support the early identification of potential security threats at the design stage [34]. Over the years, several architecture-centered TM methods have been proposed and extensively discussed in the current literature [40]. One of the most widely adopted is STRIDE [11], a methodology introduced by Microsoft in 2008, which enables practitioners to

licensed under Creative Commons License CC-BY 4.0

systematically identify threats by categorizing them into six classes: (S)poofing, (T)ampering, (R)epudiation, (I)nformation Disclosure, (D)enial of Service, and (E)levation of Privilege [22]. Similar approaches also rely on mnemonic threat taxonomies and structured representations of system components (e.g., data flow diagrams) to reason about potential attack vectors and security violations [30, 19, 16]. Furthermore, dedicated tool support is often available to facilitate their application, thereby reducing manual effort [8].

**Motivation.** General-purpose methods such as STRIDE often struggle to capture the full threat landscape of complex, domain-specific systems. Consequently, several variants have emerged over the years to address the specific security challenges of domains such as IoT [31], automotive systems [1], and industrial control systems [26] among others. These variants typically extend existing taxonomies with additional threat categories or introduce domain-specific modeling constructs to better represent the system under analysis. The rapid adoption of Generative Artificial Intelligence (GenAI) technologies has further motivated the adaptation of State-of-the-Art (SotA) TM techniques to account for risks specific to these systems, such as prompt injection and data leakage through model interactions [17, 9, 36, 13]. Still, there is limited empirical evidence on the applicability of these techniques in real-world settings. In particular, it remains unclear how well these approaches support practitioners, especially in Small and Medium Enterprise (SME) contexts, and where their most salient gaps and challenges lie [12].

**Contribution and Research Questions.** In this work, we explore the gaps and emerging challenges of TM techniques when applied to GenAI-augmented software systems. To this end, we first conducted a rapid literature review to identify SotA methods tailored to the analysis of GenAI-specific security threats. We then applied three shortlisted techniques to an industrial case study provided by a local SME to examine their performance in practice. Finally, we complemented our analysis with a practitioner survey to capture perceptions regarding the usability and integration of these techniques in real-world development workflows. Overall, we aim to answer the following Research Questions (RQs):

- ***RQ1****: How effective are state-of-the-art threat modeling techniques in identifying GenAI-specific security issues in an SME setting?* To answer this RQ we modeled and analyzed the system architecture of the given case study following the steps prescribed by each of the three selected TM methodologies. The outputs of each method (e.g., type and number of security threats) were then assessed in terms of their coverage against the OWASP Top 10 for LLM Applications [23], a taxonomy of threats specific to Large Language Models (LLM) systems developed by security practitioners.
- ***RQ2****: How do practitioners perceive the adoption and integration of these techniques in an SME context?* We conducted a follow-up survey with members of the development team of the SME that provided the case study, aiming to elicit their perceptions of each of the applied TM techniques. The survey included a set of items assessing dimensions such as perceived usefulness (e.g., ability to identify relevant and actionable threats), effort required for regular use, and integration with current tools and practices. Thereby, we provide initial insights into practitioners' perceptions, including practical gaps, challenges, and barriers to adoption and integration.

## 2 Background and Related Work

**(i) Threat modeling in practice.** Threat Modeling (TM) is central to many security-by-design frameworks and standards, as it supports the systematic identification of risks arising from system architectures and information flows. Typically, it involves modeling the target system, eliciting threats using structured taxonomies, and prioritizing them to inform mitigation strategies. Data Flow Diagrams (DFDs) are frequently used to create a graphical, high-level representation of the software architecture and depict how information moves across the main system components [33]. In their most basic variant, DFDs include four types of elements, namely (i) external entities, (ii) data flows, (iii) processes, and (iv) data stores [28]. During threat analysis, security and domain experts inspect each of these elements with the help of heuristics provided by the TM method to identify potential security threats. In STRIDE, these heuristics take the form of a structured mapping between DFD elements and threat categories (e.g., data stores associated to information disclosure threats) [11].

Because of its relative ease of use and adaptability, STRIDE has become a de facto baseline in security TM and has been evaluated across multiple studies. These evaluations have highlighted not only its lightweight design but also practical limitations regarding scalability and applicability to complex systems [8, 40]. In a nutshell, architecture-centered TM methods like STRIDE require significant manual effort and expert knowledge to model the system under analysis with sufficient detail and extract meaningful security threats [19]. Scandariato et al. [27] assessed the performance of STRIDE through a descriptive study and concluded that, despite its lightweight approach, it is relatively time-consuming and prone to *false negatives* (i.e., threats that analysts fail to identify). Recent work by Mbaka et al. [19] investigated the role of DFDs and supplementary material in validating the completeness of a STRIDE-driven threat analysis. Overall, their findings suggest that case study descriptions and threat descriptions are sometimes more useful than DFDs for assessing the coverage of a given analysis output. Nevertheless, proper tool support remains a critical factor for the usability of TM techniques, especially in collaborative team settings [2].

**(ii) GenAI-specific security challenges.** As GenAI becomes increasingly central to modern software architectures, it introduces new security threats that require systematic identification and mitigation [37]. The OWASP Top 10 for LLM Applications [23] provides a suitable reference taxonomy for characterizing these threats, covering issues related to the use of malicious prompts, mishandling sensitive data, and adversarial model behavior. Prompt injection emerges at the top of the list, representing the use of carefully crafted inputs to override LLMs' instructions and trigger unintended or unsafe behavior. Next comes sensitive information disclosure, a critical security issue that can affect both users and the LLMs themselves, for instance, when personal information or technical details (e.g., fragments of LLMs' source code) are leaked in their output [6]. The use of third-party pretrained LLMs can also introduce severe upstream vulnerabilities (e.g., biased outputs or system failures) if their security is compromised. Such vulnerabilities are often the consequence of data or model poisoning attacks, in which malicious actors manipulate the training data or the model itself to influence the behavior of downstream applications [41, 5]. LLMs are also prone to producing inaccurate or flawed outputs, especially when applied to complex tasks such as source code development [4]. Hence, over-reliance on these systems and granting them excessive agency can introduce significant security risks, particularly when model outputs are accepted or executed without sufficient human oversight or validation [7].

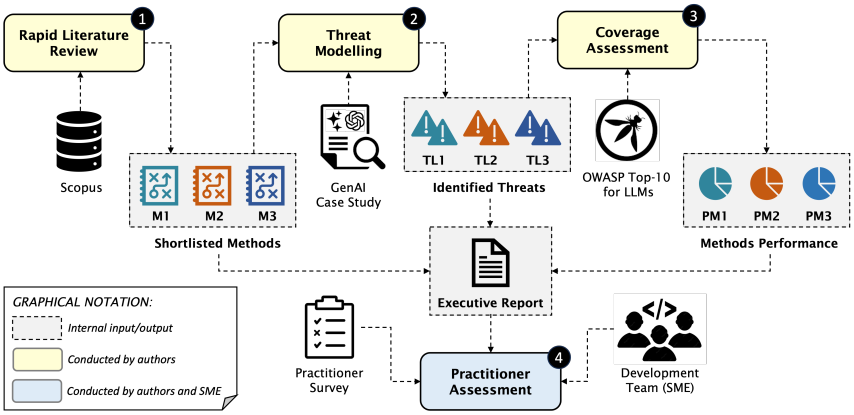

**Figure 1** Applied research methodology.

Recent TM approaches have begun incorporating AI- and GenAI-specific security threats into their analysis frameworks. Mauri and Damiani [17] extended STRIDE with AI-specific assets distributed across the ML lifecycle, namely data collection, model training, and deployment. Their method defines *failure models* for each asset category and derives the corresponding threats from violations of the associated security properties (e.g., authenticity, integrity, and confidentiality). Similarly, von der Assen et al. [36] introduced *ThreatFinderAI*, an approach geared towards contemporary AI and LLM-driven architectures in which assets such as pre-trained models and prompts are explicitly represented and analyzed. Threat identification is then supported through the construction of *attack graphs* based on prospective risk scenarios collected from multiple authoritative AI-security knowledge bases, including OWASP AI Exchange [24] and MITRE ATLAS [21]. Still, to the best of our knowledge, empirical evaluations of these and other methods alike remain limited, especially regarding their application to real-world scenarios and industrial settings. Moreover, little is known about practitioners' acceptance of these techniques, the effort required to integrate them into existing development workflows, and the practical frictions that may hinder their regular use.

## 3 Research Methodology

Fig. 1 illustrates the methodology we applied to address the RQs proposed in Section 1. We first conducted a Rapid Literature Review (RLR) to identify SotA TM techniques suitable for the analysis of security threats in GenAI-augmented systems (STEP 1). We shortlisted three candidate methods based on their maturity level (e.g., validation extent) and applied them to a case study provided by a local SME (STEP 2). The performance of each method was then assessed regarding its coverage of security threats included in the OWASP Top-10 for LLMs [23] relevant to such a case study (STEP 3). It is worth noting that the SME development team was kept informed of the progress at each method step before compiling the results (i.e., the RLR, the TM analysis, and the coverage assessment) into an Executive Report (ER). Once finalized, the team was then asked to review the ER and complete a survey on their perceptions of each method's suitability, the actionability of its outputs, and the anticipated integration effort in the current SME development setting (STEP 4). In the following subsections, we provide further details on each methodological step and the supporting artifacts employed throughout the study.

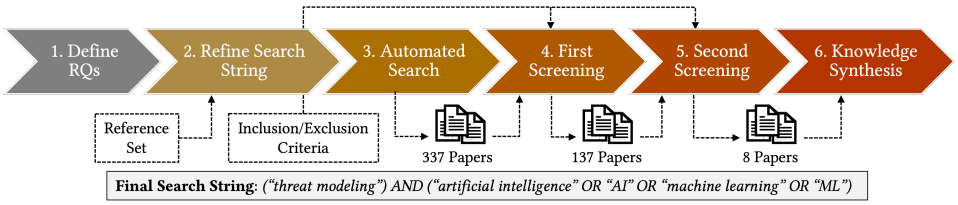

**Figure 2** Applied Rapid Literature Review (SLR) methodology (STEP 1).

## 3.1 Rapid Literature Review

Rapid Literature Reviews (RLRs) provide a lightweight framework for characterizing the SotA within a limited time frame while still following a structured and transparent process [25]. In contrast to more exhaustive evidence synthesis methods, RLRs typically involve narrower search scopes and simplified screening procedures, making them suitable for exploratory and early-stage studies. Given the emerging nature of GenAI-oriented TM research and the exploratory goals of this work, we considered an RLR appropriate for identifying candidate methods applicable to GenAI-augmented systems.

Fig. 2 illustrates the steps we conducted through the RLR. We first started defining the RQs that would guide the literature search. Particularly, we centered around the following RLR-specific RQ: *"What threat modeling techniques documented in the current literature are suitable for the analysis of GenAI-augmented systems?"*. Next, we defined the search engine and keyword string employed for the automated literature search. We selected Scopus[1] as the primary search engine due to its broad coverage of major software engineering publication venues, including ACM Digital Library and IEEE Xplore. To refine the search string, we constructed a small reference set of representative publications on TM for GenAI-augmented systems (i.e., [17, 36]) and iteratively adjusted the search terms until all reference studies were retrieved. The final query is depicted at the bottom of Fig. 2.

The automated search was conducted in June 2025 and returned 337 candidate studies, which were subsequently processed during the screening stages. We retained studies that (i) described architecture-centered TM techniques, (ii) considered security threats relevant to GenAI-based systems, (iii) were written in English, and (iv) were published at well-established software engineering or security venues. These inclusion and exclusion criteria were first applied to the title and abstract of the candidate studies during the initial screening stage, resulting in 137 potentially relevant papers. The same criteria were then applied to the full text of these studies during a second screening stage, ultimately leading to the selection of 8 primary studies that underwent a knowledge synthesis process. For this, we followed a lightweight open coding approach in which one author extracted emerging themes and patterns relevant to the proposed RLR-specific RQ. Another author reviewed these themes afterward and, if discrepancies arose, these were resolved through a negotiated agreement.

## 3.2 Methods Selection

The thematic analysis of the selected primary studies surfaced a set of recurring dimensions characterizing the identified TM methods. First, we analyzed the *System Type* targeted by each method, namely whether the technique was designed for traditional ML-based

[1] `http://www.scopus.com`

systems or more contemporary GenAI-oriented architectures involving LLMs and transformer-based components. Second, we examined the prescribed *Modeling Approach*, including the architectural representation and modeling artifacts employed throughout the TM process (e.g., traditional or custom DFD syntax). Third, we assessed the extent of *Tool Support*, particularly whether the method provided (semi-) automated support for threat identification. Finally, we considered the reported *Evaluation* strategy of each method, including proof-of-concept applications, case studies, and developer-centered usability evaluations.

**Table 1** Characterization of the selected primary studies.

| Source | Year | System Type | Modeling Approach | Tool | Evaluation |
|---|---|---|---|---|---|
| Von der Assen et al. [35] | 2024 | GenAI | Asset-Enriched DFD | YES | Case study |
| Von der Assen et al. [36] | 2024 | GenAI | Asset-Enriched DFD | YES | Case study |
| Mauri and Damiani [17] | 2021 | ML | Asset-Enriched DFD | NO | Case study |
| Mauri and Damiani [18] | 2022 | ML | Asset-Enriched DFD | NO | Case study |
| Wilhjelm and Younis [38] | 2020 | ML | DFD | NO | Case study |
| Gülen et al. [10] | 2024 | GenAI | DFD | NO | Proof of concept |
| Messas et al. [20] | 2024 | ML | Unspecified | NO | Usability study |
| Kumar et al. [14] | 2024 | GenAI | DFD | NO | Case study |

Table 1 summarizes the characterization of the eight primary studies. The rows highlighted correspond to the TM methods selected for their application to the case study. Our selection criteria centered on techniques (i) geared towards GenAI-enriched system architectures and (ii) validated through case studies. Since these criteria narrowed the selection to only two methods (i.e., [36, 10]), we decided to relax the latter and include one additional TM approach (i.e., [14]). This resulted in the following TM techniques being selected for application to the case study:

- **M1** – *AI-as-a-Service (AIaaS) Framework* [10]. Relies on DFD-based system representations and structures the analysis around asset groups such as *Data*, *Model*, *Environment*, and *Process*. For each asset category, the framework provides STRIDE-based threat listings along with prospective mitigation actions.
- **M2** – *Attacks on Dataset, Model and Input (ADMIn) Framework* [14]. It adopts an attack-centric perspective around three major attack surfaces, namely *Datasets*, *Models*, and *System inputs*. The analysis is structured through DFD-like architectural representations and predefined attack categories associated with each attack surface. The method further provides guidance on threat prioritization and mitigation activities.
- **M3** – *ThreatFinderAI* [36]. This approach extends traditional DFDs with AI-specific assets (e.g., prompts and pre-trained models), which are subsequently analyzed through attack graphs and risk scenarios. Threat identification is semi-automated through the integration of external security knowledge bases such as MITRE ATLAS [21] and OWASP AI Exchange [24]. Unlike M1 and M2, this method is tool-supported.

## 3.3 SME-Provided Case Study

Fig. 3 illustrates a DFD of the SME-provided case study. It describes the main architectural components (i.e., data stores, processes, data flows, and entities) of a business intelligence system that automatically processes e-mails from customers and generates customized market reports. It encompasses four major tasks, namely e-mail processing (T1), report generation (T2), customer registration (T3), and dashboard display (T4). Such tasks (T1 and T2 in particular) are partially supported by LLM agent processes (marked with a $\star$) in charge of (i) processing incoming emails and their attachments (i.e., PDF files), (ii) validating such emails

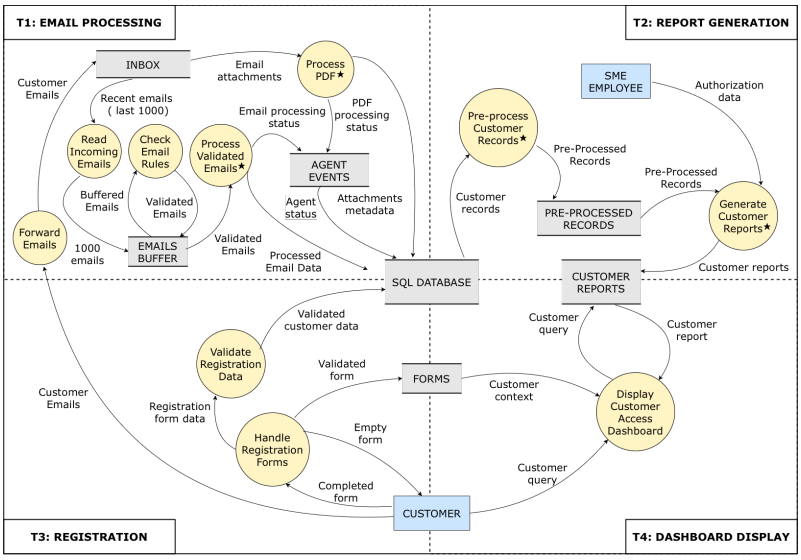

**Figure 3** Data Flow Diagram (DFD) of the analyzed case study.

(e.g., checking for duplicates), (iii) pre-processing internal records (e.g., customer profiles and historic data), and (iv) generating reports tailored to the requirements of each client. From a technological perspective, the system leverages Microsoft Power Platform[2] services for workflow orchestration and customer data management, while Azure OpenAI[3] is employed to support the LLM-based processing components embedded within the architecture. The generated business intelligence reports and dashboards are further integrated with Power BI services for visualization and customer-facing reporting activities. Overall, the analyzed architecture comprises 10 processes, including 3 LLM-assisted components, as well as 7 data stores, 27 data flows, and 2 external entities.

## 3.4 Practitioner Survey

Seven members of the SME development team participated in a survey to identify potential adoption and integration challenges associated with the evaluated TM techniques. Particularly, they were first asked to review the content of the ER, namely a description of the three shortlisted TM methods, their output for the given case study, and their coverage regarding the OWASP Top-10 for LLMs. Then, we asked them to provide their perspectives on each method by assessing a set of statements across seven dimensions, including the method *effectiveness* (i.e., *"The method helped identify important security threats for our system"*), *actionability* (i.e., *"The method provided clear mitigation actions for addressing the identified threats"*), and *awareness* (i.e., *"The method surfaced threats we would likely have missed otherwise"*), among others. Each participant assessed each statement three times (i.e., for each method) using 6-point Likert values (i.e., *completely disagree*; *disagree*; *somewhat disagree*; *somewhat agree*; *agree*; *completely agree*). The survey concluded with the following open-ended questions aimed at collecting further insights into the added value, limitations, and adoption challenges of GenAI-aware TM techniques:

- **OE1**: *What were the top 3 most valuable threats identified across the methods, and why?*
- **OE2**: *What would have to change for this method to be adoptable in your workflow?*

[2] `https://www.microsoft.com/en-us/power-platform`
[3] `https://azure.microsoft.com/en-us/products/ai-services/openai-service`

All study materials are available in the paper's **Replication Package** (Section 7), including the RLR protocol, the corresponding code book, the survey instrument, the aggregated survey results, and the OWASP Top-10 for LLMs mapping.

# 4 Results

In the following subsections, we report the findings obtained from the assessment of the selected TM methodologies (Section 4.2) and the practitioner survey (Section 5). We narrowed the former to the GenAI-aided processes within the system, along with their corresponding incoming and outgoing data flows. Thereby, we focus the analysis on the system components directly influenced by GenAI capabilities and, therefore, more likely to expose GenAI-specific security threats. In particular, we considered the following processes and data flows:

- ***P1: PDF Processing***, with incoming flow *IF-1.1: Email attachments* and outgoing flows *OF-1.1: PDF processing status* and *OF-1.2: Attachment metadata*.
- ***P2: Validated Email Processing***, with incoming flow *IF-2.1: Validated emails* and outgoing flows *OF-2.1: Processed email data* and *OF-2.2: Email processing status*.
- ***P3: Customer Report Generation***, with incoming flows *IF-3.1: Authorization data* and *IF-3.2: Pre-processed records* and outgoing flow *OF-3.1: Customer reports*.
- ***P4: Customer Record Pre-Processing***, with incoming flow *IF-4.1: Customer records* and outgoing flow *OF-4.1: Pre-processed records*.

## 4.1 RQ1: Effectiveness of Threat Modeling Techniques

Although all three TM techniques addressed some GenAI-related security threats, they differed substantially in terms of abstraction level, threat granularity, and analysis focus. M1 [10] adopts a STRIDE-inspired approach, while incorporating security threats traditionally associated with adversarial ML [15], including *model poisoning*, *model inversion*, *evasion*, *membership inference*, and *model extraction* attacks. In this context, *model inversion* and *membership inference* refer to attempts to infer sensitive information (e.g., data used for fine-tuning) through interactions with the LLM-based components, whereas *evasion attacks* aim to manipulate externally controlled inputs to alter model behavior or bypass intended processing logic. While *data poisoning* (i.e., injecting malicious or manipulated data into LLM-based workflows) is not explicitly represented in the taxonomy, it can still be operationalized through classical STRIDE categories such as tampering or manipulation during data transmission. As shown in Table 2, these threats, which emerge from all GenAI-aided processes and incoming data flows, largely align with two of the OWASP Top-10 threat categories for LLMs, namely *Sensitive Information Disclosure* and *Data and Model Poisoning*.

Compared to M1, M2 [14] more explicitly captures GenAI-specific runtime threats, particularly by incorporating *prompt injection* in addition to traditional adversarial ML attacks. These threats, which directly correspond to OWASP's *Prompt Injection* category, were considered relevant to all analyzed GenAI-aided processes. Furthermore, the method identifies outgoing data flows as potential targets of membership inference attacks (referred to as "data exfiltration" attacks), which, similarly to M1, are conceptually related to OWASP's *Sensitive Information Disclosure* category. Certain outgoing data flows, particularly operational status flows such as *OF-1.1* and *OF-2.2*, could not be naturally mapped to this category as they do not expose, in principle, semantically rich and potentially sensitive information.

**Table 2** Coverage of OWASP Top-10 for LLMs across the evaluated TM methods.

| OWASP Top-10 for LLMs | M1 | M2 | M3 |
|---|---|---|---|
| 1. Prompt Injection | - | P1,P2,P3,P4 | P1,P2,P3,P4 |
| 2. Sensitive Information Disclosure | P1,P2,P3,P4 | OF-1.2,OF-2.1,OF-3.1 | P1,P2,P3,P4,OF-1.2, OF-2.1,OF-3.1 |
| 3. Supply Chain Vulnerabilities | - | - | - |
| 4. Data and Model Poisoning | P1,P2,P3,P4,IF-1.1, IF-2.1,IF-3.1,IF-3.2, IF-4.1 | P1,P2,P3,P4,IF-1.1, IF-2.1,IF-3.1,IF-3.2, IF-4.1 | IF-1.1,IF-2.1,IF-3.1, IF-3.2,IF-4.1, OF-1.2,OF-2.1,OF-3.1 |
| 5. Improper Output Handling | - | - | - |
| 6. Excessive Agency | - | - | - |
| 7. System Prompt Leakage | - | - | - |
| 8. Vector and Embedding Weaknesses | N/A | N/A | N/A |
| 9. Misinformation | - | - | - |
| 10. Unbounded Consumption | P1,P3 | P1,P3 | P1,P3 |

M3 [36] was the only approach providing dedicated tool support, together with a custom syntax and semantics for representing AI-related architectural components and threats. Consequently, the analysis was conducted on a different but semantically-equivalent DFD, requiring the identified threats to be mapped back to the original processes and data flows. Although this mapping was not always one-to-one, it remained relatively straightforward in practice (e.g., *data ingestion* were generalized to all incoming data flows), leading to results largely comparable to those of M2 (Table 2). Despite their differing abstractions and threat modeling strategies, all three methods identified processes *P1* and *P3* as potential targets of *Denial-of-Service (DoS)* attacks, mainly due to their reliance on computationally intensive LLM operations and externally controlled inputs. These threats are conceptually related to OWASP's *Unbounded Consumption* category, as attackers may attempt to trigger excessive inference operations or resource exhaustion scenarios through malicious or oversized inputs. Nevertheless, the evaluated methods showed limited support for several OWASP Top-10 for LLMs categories, particularly those associated with agentic behavior, system prompt exposure, and unsafe downstream integration of generated outputs.

**Findings RQ1.** Although the evaluated TM techniques identified several GenAI-related issues, their coverage was strongest for input- and model-interaction threats (e.g., *Prompt Injection*, *Data and Model Poisoning*). Coverage was limited or absent for categories requiring broader architectural, supply-chain, or human-centered reasoning (e.g., *Supply Chain Vulnerabilities* and *Excessive Agency*). M3 provided the broadest support due to its tool-supported analysis and dedicated AI-oriented modeling syntax.

## 4.2 RQ2: Practitioner Perceptions

Fig. 4 shows participants' average scores and standard deviations for each of the seven survey dimensions and TM methods. Overall, M3 received the highest scores across all dimensions, with particularly strong results regarding its capability to identify GenAI-specific security threats (*GenAI Threats*) and the effort required for regular use (*Effort*). This may be attributed to M3's tool support and its incorporation of external, GenAI-specific security knowledge in the underlying threat catalog. Conversely, M1 and M2 received comparable scores regarding effort, which may be explained by their lack of automation.

Both M1 and M3 received relatively higher scores than M2 in terms of identifying system-relevant threats (*Effectiveness*) and security issues that participants would otherwise have overlooked (*Awareness*). This may be associated with the limited relevance of one of M2's main attack surfaces (i.e., "Models") in this particular case, since the SME does not develop

**Figure 4** Practitioner ratings across M1 (*AIaaS*), M2 (*ADMIn*), and M3 (*ThreatFinderAI*).

its own ML models but rather relies on externally provided LLM services. Furthermore, both M1 and M3 provide a more fine-grained catalog enriched with detailed threat descriptions, affected assets, and, in the case of M3, also prescriptive appraisal mechanisms. This may also have affected practitioners' perception of M2's support for deriving clear mitigation actions (*Actionability*) and integrating the resulting outputs into existing development workflows (*Integration*), which were rated lower than those of M1 and M3.

In line with the mapping results (Section 4.2), all methods received their lowest scores in identifying socio-technical security threats. This is consistent with Table 2, where none of the evaluated methods surfaced threats related to OWASP's *Excessive Agency* category, which is the most closely related to socio-technical concerns in our analysis. Still, the slightly higher scores of M1 and M3 may be explained by their explicit consideration of potential threat actors, which can help practitioners reason about who may exploit a given threat.

When analyzing participants' answers to OE1, we observed that they consistently identified *prompt injection*, *data poisoning*, and *sensitive information disclosure* as the most valuable threats surfaced by the methods. These were perceived as particularly relevant because the system processes external, potentially untrusted inputs, while also handling sensitive customer information: *"Prompt injection was a real eye-opener. Data poisoning too – silent and sneaky. And data leakage through cloud APIs, honestly we wouldn't have caught that on our own."* (P6). On the other hand, responses to OE2 emphasized that adoption would require lightweight integration into existing development routines, including ticketing workflows and clear ownership. Furthermore, they underscored the need for structured templates (e.g., checklists) and short training sessions on system modeling and GenAI security threats: *"Templates would make it so much easier. A quick onboarding session for the team. And just connect it to our tickets – that alone would make a huge difference."* (P5).

**Findings RQ2.** Practitioners rated M3 highest across all survey dimensions, particularly for its support in surfacing *GenAI Threats* and its relatively low perceived *Effort*. M1 and M3 received higher scores than M2 for *Effectiveness*, *Awareness*, *Actionability*, and *Integration*. Across methods, *Socio-technical Threats* received the lowest scores, consistent with the RQ1 findings. Participants also emphasized the need for better integration with existing development workflows, especially issue-tracking and security review processes.

## 4.3 Threats to Validity

The findings of this study should be interpreted in light of its exploratory nature. *External validity:* The assessment was conducted on a single case study, which limits the generalizability of the results to other GenAI-augmented systems, domains, or organizational settings. *Construct validity:* The evaluated TM techniques differ in their abstraction levels, modeling assumptions, and expected inputs, making direct comparison challenging. To mitigate this issue, we normalized the analysis around GenAI-aided processes, their associated data flows,

and the OWASP Top-10 for LLMs as a common reference baseline. *Internal validity:* The mapping of method-specific threats to OWASP categories may have been influenced by the researchers' interpretation. Therefore, we followed a conservative mapping strategy and avoided assigning categories when the correspondence was not sufficiently clear. *Conclusion validity:* the practitioner survey involved a small number of participants from the involved development team, who assessed the methods based on the Executive Report rather than by applying the techniques themselves. Hence, the survey results should be understood as initial perceptions of usefulness, actionability, and adoption challenges rather than as evidence of actual long-term adoption in practice.

## 5 Prospective Research Pathways

In principle, the study results suggest that current TM techniques are useful for identifying GenAI-related threats, such as *prompt injection*, *data poisoning*, and *sensitive information disclosure*. However, they show limited support for some critical threat categories, particularly those directly associated with (i) the software supply chain and (ii) the interaction between LLMs and developers. As third-party GenAI solutions become an integral part of system architectures, TM methods should provide means for identifying security risks stemming from LLM dependencies [39]. Still, none of the three TM techniques we assessed offered a threat catalog and modeling syntax enriched with explicit supply-chain, GenAI-specific elements (e.g., third-party ML libraries, container images) that could help practitioners reason about such risks. Furthermore, in line with prior work [2], the survey results indicate that tool support should not be neglected, as M3 received the highest overall perception scores among participants. This motivates the following Research Pathway (RP):

> **RP1**: GenAI-aware TM approaches should explicitly incorporate knowledge of supply-chain security into their frameworks while supporting some degree of automation.

Prior work on the automatic extraction of security-enriched DFDs from source code [29] could, in principle, provide a promising basis for this direction. In particular, these extraction capabilities could be extended to cover supply-chain artifacts such as LLM-relevant dependency manifests, SBOMs, and container definitions. Alongside this, recent work by Jedrzejewski et al. [13] introduced a prompt-driven threat analysis concept that leverages LLMs with RAG to generate and maintain threat models over time. As vibe coding begins to displace traditional programming practices, such approaches could help align TM with emerging AI-assisted development workflows. This integration could be further supported by structured prompt templates and checklists, as suggested by participants in the survey:

> **RP2**: Future work should explore prompt-guided and checklist-supported workflows for integrating GenAI-aware TM into LLM-assisted development practices.

Finally, the limited coverage of human-centered security threats across all assessed TM techniques is concerning. Prior work has shown that LLMs may produce unreliable or hallucinated results under certain conditions; therefore, GenAI-aided processes require careful scrutiny before their outputs are integrated into downstream development activities. At the same time, multiple studies raise concerns about developers' over-reliance on such outputs and reduced critical engagement during their operationalization [7]. This calls for TM approaches that explicitly capture (i) where flawed LLM-generated content may propagate across GenAI-augmented architectures, (ii) which actors are responsible for validating or acting upon them,

and (iii) situations in which over-reliance may become security-threatening. Furthermore, suitable mitigation actions should go beyond traditional offline training and combine online behavioral interventions [3] with interactive, personalized security assistance [32] to support practitioners when engaging with LLM-generated outputs.

**RP3**: GenAI-aware TM approaches should account for developers' over-reliance on LLM-generated outputs by modeling human-centered threat propagation paths and identifying intervention points across the system architecture.

## 6 Conclusion

TM remains a cornerstone of secure software engineering, enabling practitioners to systematically identify and mitigate security risks at the architectural level. However, as GenAI becomes increasingly embedded into modern software systems, traditional TM techniques require new abstractions and supporting mechanisms to account for the distinctive characteristics of LLM-based applications. In this paper, we presented emerging results from an exploratory assessment of three GenAI-aware TM techniques in an industrial SME case study. Our findings indicate that, although current techniques can capture prominent GenAI-related threats such as prompt injection and data poisoning, they provide only limited support for broader architectural, supply-chain, and human-centered risks.

Beyond threat coverage, our results highlight the importance of practical adoption. The survey results indicate that practitioners value TM techniques that are easy to integrate into existing development workflows while requiring minimal additional effort. As software development continues to evolve toward increasingly AI-assisted and prompt-driven practices, next-generation TM techniques should not only broaden their coverage of GenAI-specific risks but also facilitate their seamless incorporation into modern software development pipelines. Altogether, these findings suggest that the future of GenAI-aware TM depends on combining comprehensive threat coverage with lightweight, tool-supported, and actionable integration into software development practice.

## 7 Data Availability Statement

All study materials are available in the following link to the paper's **Replication Package**: `https://doi.org/10.5281/zenodo.21706295`. The package includes the RLR and extraction forms, the characterization of the selected TM methodologies, the survey instrument, aggregated survey results, and the OWASP Top-10 for LLMs mapping produced during the analysis.

# An Agentic Approach Towards Replication Package Quality Evaluation

**Maximilian Alexander Amougou Mbida**
Technical University of Munich, Germany

**Florian Angermeir**
fortiss, Germany
Blekinge Institute of Technology, Sweden

## Abstract

Reproducibility in empirical software engineering relies on complete, accessible, and reusable research artifacts, yet artifact evaluation remains largely manual and difficult to scale. This emerging results paper explores an agentic approach for assessing replication package quality by translating open-science guidelines into machine-verifiable criteria. We consolidate 380 requirements from 34 sources into 51 reproducibility criteria, of which 31 are operationalized for automated artifact-based evaluation. Based on these criteria, we implement a multi-agent prototype that inspects replication packages and produces evidence-grounded improvement reports. A preliminary evaluation on five replication packages shows high inter-run consistency of 91.4% and 75.4% correctness, through micro-averaged agreement with a manual baseline. The agent performs best on structural criteria such as code, environment, and artifact availability, but struggles with qualitative or mixed-method studies. A pilot survey with seven software engineering researchers indicates well perceived usefulness and adoption potential, while revealing cognitive load in the human-in-the-loop planning step. Overall, within these small samples, the results indicate that agentic research artifact evaluation has the potential to support authors and reviewers by automating selected routine checks.

## 1 Introduction

Reproducibility is a fundamental prerequisite for cumulative scientific progress, enabling independent verification of findings and fostering confidence in published research [17, 6]. In large parts of empirical software engineering, reproducibility depends not only on textual reporting, but also on the availability and quality of accompanying research artifacts such as source code, datasets, execution scripts, configuration files, and experimental environments [24]. To enhance transparent research practices, conferences and publishers have introduced artifact-evaluation tracks, open science guidelines, and reporting standards [18, 2]. Despite these efforts, research artifacts frequently suffer from a plethora of issues, including incomplete source code [16, 12], missing dependencies [23, 13], and fragmented documentation [11]. Consequently, verifying whether these packages are sufficiently complete, accessible, and reusable remains a manual, time-consuming process that scales poorly and is subject to interpretation [25, 24, 9, 21].

© Maximilian Alexander Amougou Mbida and Florian Angermeir;

While existing guidelines outline what researchers should report, they provide limited support for automatically assessing the quality of heterogeneous artifact types against predefined criteria representing open science best practices. As a result, artifact evaluation continues to impose substantial effort on reviewers, slows down review processes, and creates barriers for large-scale reproducibility assessments. This challenge is particularly pronounced in contemporary software engineering research, where replication packages lack standardization and often bundle a mix of source code, raw datasets, and configuration files across various directories and formats.

In this paper, we explore whether an agentic approach can support replication package quality evaluation by operationalizing open-science guidelines into machine-actionable verification procedures. We propose an agent-based approach that autonomously retrieves, structures, and evaluates research artifacts against reproducibility criteria, enabling a scalable assessment of research artifacts quality as a proxy to the potential for reproducibility. We target computational, code-centric replication packages containing inspectable artifacts such as source code, datasets, and configuration files. We do not aim to assess the context-dependent rigor of qualitative or theoretical artifacts. Conceptually, our approach can act as a "replication package linter": it flags evidence-backed quality issues before formal artifact review rather than establishing that a study's results are reproducible. We hope that our contribution in the long-term can support authors in improving their research artifact quality even before artifact review and to consequently reduce review overhead in artifact review tracks. To investigate the feasibility of this idea, we implemented a prototype based on a multi-agent architecture and conducted a pilot survey. Our preliminary evaluation indicates promising results. The approach achieves an inter-run consistency of 91.4% and a 75.4% micro-averaged agreement with manual baseline. While still preliminary, these results strengthen our confidence in the potential and long-term value of the proposed approach.

The main contributions of this paper are (1) an operationalization of open-science guidelines into a set of machine-verifiable criteria for automated artifact assessment, (2) a novel agentic approach for assessing the reproducibility potential of software engineering research artifacts, and (3) preliminary empirical evidence from a pilot survey that demonstrates the potential and limitations of our approach.

## 2 Related Work

We structure existing related work into challenges with manual and static artifact evaluation, and autonomous reproduction systems.

**Challenges and Automated Artifact Evaluation.** Achieving sustainable reproducibility is hindered by the post-publication fragility of long-term archiving [24] and a pre-publication reliance on manual human labor during peer review. This constraint leads to inconsistent evaluation depth and limits scalability, driving the necessity for automated review assistance. While earlier automation focuses on static analysis of manuscripts, such as Metacheck [8], such solutions can be limited by the lacking of semantic analysis depth of research artefacts. Our approach resolves this through fully automated, end-to-end evaluation of both the artifact content and the structural alignment.

**Agentic Reproducibility Benchmarks and Frameworks.** Recent benchmarks quantify LLM capabilities in scientific reproduction, typically reporting low success rates (20% to 40%) that highlight domain complexity. Evaluation paradigms target either execution and consistency

checks (such as dependency installation in CORE-Bench [21] and paper-to-claim alignment in REPRO-BENCH [14]), or the harder task of generating reproduction code from scratch, as evaluated by PaperBench [22] and LMR-BENCH [26]. To tackle these complexities, several architectures employ specialized reasoning pipelines. For instance, AutoReproduce [27] and ResearchCodeAgent [10] leverage paper lineages and execution feedback to iteratively refine scripts, while SciRep/SciConv [4, 5] automate Docker-based setups. Closest to our work, ArtifactCopilot [25] maps unstructured documentation to dependency graphs for end-to-end ACM badging [9]. However, most of the agentic approaches assume well-structured repositories, complete documentation, or explicit instructions. In contrast, our framework focuses on evaluating the *reproducibility potential* of heterogeneous, inconsistently structured research artifacts where documentation may be partial with the goal of enhancing artifact quality.

## 3 Methodology

To guide the design, implementation, and evaluation of our approach, we organized our methodology around three central research questions:

**RQ1:** How can an agentic approach assess the potential for reproducibility given a research artifact set?

**RQ2:** What are the potential and limitations of an agentic approach to assess the quality of a replication package?

**RQ3:** How useful is the agentic approach for stakeholders assessing replication package quality?

### Reproducibility Criteria

To establish robust reproducibility criteria, we analyzed official guidelines and reviewer resources from top-tier (CORE A/A* [3]) computer science conferences featuring artifact evaluation tracks or explicit checklists (e.g., ICSE, OSDI, ICML, RE). This was supplemented by open science policies from major publishers, leading empirical software engineering journals (EMSE, IST, IEEE Access [20]), and community-driven best practices.

**Extraction Process.** We categorized the source documents into four groups: **(1)** conferences with artifact badges, **(2)** checklist-only venues, **(3)** journals and publishers, and **(4)** general guidelines. Verbatim criteria were extracted into a centralized repository, semantically merged within each category, and then consolidated into a unified, hierarchical reproducibility criteria knowledge base. We assigned each criterion a unique identifier to maintain full traceability to its original source, and organized them into hierarchical topics and subtopics. Finally, because raw textual descriptions were insufficient for automated reasoning, we enriched the criteria with structured attributes to enable systematic evaluation by our agent.

For example, the raw requirements "A ReadMe file that includes a table of results accompanied by precise command to run to produce those results" (`fairer_34`) and "make it easy to reproduce all of the data for your paper, ideally with a single batch script or mouse click" (`aec_16`) were first normalized into requirements for step-by-step instructions and exact commands. These and related requirements were then merged into the criterion "Provide detailed step-by-step instructions (e.g., in a README) to reproduce all results with exact commands." We enriched this criterion by specifying the required input as a README, installation or usage documentation, and example commands. The detection strategy checks for sequential instructions and executable command examples and the decision boundary requires a README or installation file containing commands for every experimental step. The database retains links from the merged criterion to all source requirements.

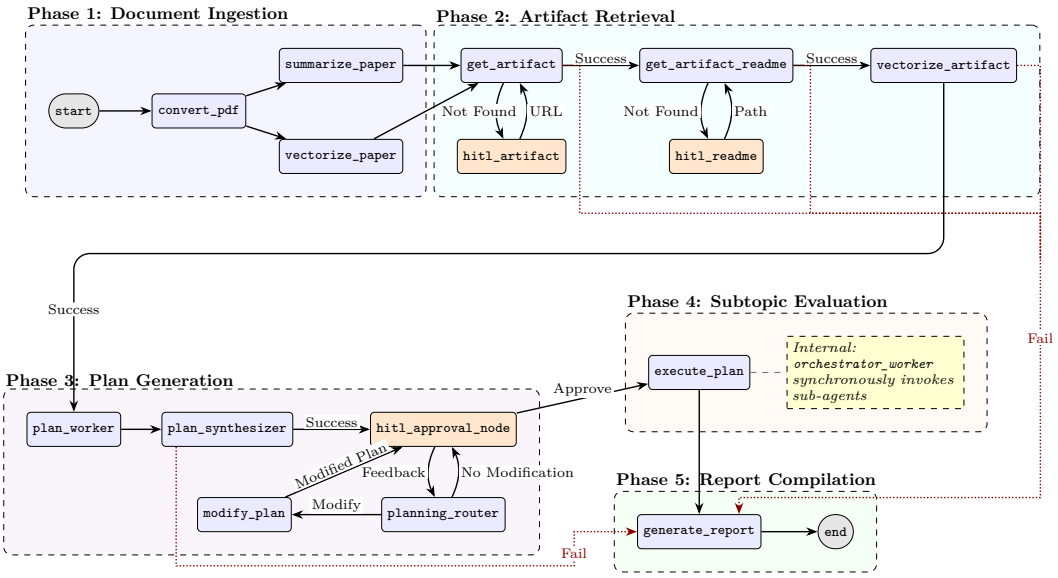

**Figure 1** Overview of the five-phase agentic evaluation pipeline. Solid lines indicate standard execution and progression pathways, while dotted lines represent early-exit failure or abort routing back to the report generation phase.

**Enrichment.** Raw textual criteria are often high-level and ambiguous, leading to high evaluation variance that is further exacerbated by LLM non-determinism. To ensure consistent assessment trajectories, we manually enriched each criterion with four structured auxiliary fields: **(1)** `additional_information` (contextual scope and definitions), **(2)** `input_needed` (abstract evidence types to seek), **(3)** `detection_strategy` (initial evaluation heuristics), and **(4)** `success_failure_conditions` (explicit decision boundaries). We instantiated these specifications in an SQLite knowledge base that preserves relationships and source traceability, and supports relevance-based retrieval for the agent via the full-text search.

## Agentic System Design

The approach was implemented as a stateful, graph-based workflow. As illustrated in Figure 1, the architecture consists of a five-phase pipeline: (1) ingestion and embedding, (2) artifact retrieval and analysis, (3) plan generation, (4) subtopic evaluation, and (5) report compilation. The workflow leverages LangGraph's `Command` API for dynamic routing and an `interrupt` mechanism for synchronous Human-in-the-Loop (HITL) interactions, persisting agent state to ensure conversation continuity.

**Phase 1: Ingestion and Embedding.** The input paper is converted from PDF to markdown to extract key metadata (title, abstract, artifact details) and a global summary. Concurrently, the text is chunked and embedded into a vector database for retrieval-augmented generation (RAG) throughout execution.

**Phase 2: Artifact Retrieval and Analysis.** A sub-agent extracts artifact references (e.g., GitHub, Zenodo, OSF) from the paper summary. If automatic retrieval or entrypoint (e.g., README) identification fails, a HITL interrupt requests user guidance, e.g., the correct artifact URL, an upload, or the explicit entrypoint path. If no entry file exists, the agent

logs a failure, and skips to an error report. The retrieved README is summarized to ground planning, a multi-stage filter then prunes the vector index, combining fast rule-based exclusion of irrelevant files (e.g., binaries, dependencies, logs) with an LLM-based classifier for extensionless or ambiguous files. The remaining relevant files are chunked and embedded for hybrid retrieval in the next phase.

**Phase 3: Evaluation Plan Generation.** Worker sub-agents analyze the retrieved context and concurrently generate per-criteria inspection steps for the user-selected subtopics, synthesized into a unified, hierarchical strategy conforming to the knowledge base layout. A HITL loop then lets users iteratively refine this strategy via natural language feedback, suspending execution until explicit user approval.

**Phase 4: Parallel Subtopic Evaluation.** An orchestrator dispatches sub-agents to evaluate each subtopic concurrently within isolated reasoning contexts over a shared, read-only filesystem, gathering evidence via pattern search and hybrid retrieval (lexical and semantic). Evaluation demands evidence-based reasoning with explicit citations (e.g., file paths, code snippets), defaulting to a *fail* status if required evidence is missing. Findings are then synthesized into subtopic- and topic-level summaries and a final structured output.

**Phase 5: Report Compilation and Tracing.** The structured output is transformed into a hierarchical markdown report aggregating evaluation metadata, paper summaries, and detailed criterion assessments linked to their guidelines. For transparency and reproducibility, it logs the complete execution plan and embeds Langfuse trace IDs.

**Frontend.** A web-based prototype exposes four views mirroring the agent's workflow: configuration, planning (the HITL loop), the execution (real-time reasoning and tool invocations), and the report dashboard.

**Agent Models and Configurations.** The approach uses five agents: artifact retrieval, plan, orchestrator, executor, and reporting. For cost reasons, the retrieval and the executor agent use gpt-5-nano-2025-08-07, the plan agent and orchestrator agents use gpt-5-mini-2025-08-07. The reporting agent uses gpt-5.1-2025-11-13. We set the temperature for all agents to 0. The full agent setup is published in the replication package [1].

## Evaluation

**Reliability and Consistency.** To establish the technical reliability of the automated evaluation, we measured the approach's *inter-run consistency* and *agreement with a manual baseline* on a small, purposive sample of five replication packages. We selected packages from publications familiar to the authors to support detailed manual assessment. This convenience sample is not representative of replication packages in software engineering, and familiarity may have made the manual assessment easier or more favorable than an assessment of unfamiliar artifacts. Consequently, the resulting scores are exploratory and should not be interpreted as population-level performance estimates.

To evaluate inter-run consistency, we executed the agentic pipeline 10 independent times per package. Stability across identical inputs was evaluated for the execution plan and the evaluation report on a per-element basis for each artifact. We evaluated those elements in two ways. Where possible we used deterministic classification (e.g., Pass/Fail for a subtopic).

Here stability was calculated using a categorical overlap score that aggregates consensus via a bottom-up hierarchical macro-average. Where deterministic classification was impossible (e.g., for the improvement suggestions) we employed an LLM-as-Judge (gpt-5.4-mini-2026-03-17) to evaluate the semantic consistency across randomly paired runs. This judge analyzed the alignment of the agent's generated outputs on a 1–4 rubric (1 = Not Consistent, 4 = Fully Consistent). We verified the judge's reliability against a manually created sample, achieving approximately 85% accuracy in score assignment. All scripts, judge prompts, and raw data logs are available in the online material [1].

Second, to quantify the agents agreement with the manual baseline, the authors manually assessed the same five replication packages using the operationalized criteria to establish a structured ground-truth dataset. The agent's classifications were benchmarked against this manual baseline. To capture granular performance across distinct criteria states (Pass, Fail, Not Applicable), we computed two alignment metrics: a macro-accuracy (to enforce strict schema matching and weights all hierarchical topics equally) and a standard micro-accuracy (to evaluate a flattened intersection of shared criteria, weighting every individual criteria equally). These deterministic metrics were supplemented by the aforementioned LLM-as-Judge, which similarly scored the semantic alignment of the agent's generated qualitative reports against the human baseline. These measures quantify correspondence with an author-created reference under our operationalized criteria, they do not establish objective correctness, or completeness of the recommendations.

**Perceived Usefulness and Usability.** To assess the practical value of the generated reports, we conducted a survey with active software engineering researchers, ranging from PhD candidates to professors. Participants were recruited via direct email invitations. Prior to interacting with the approach, participants were provided with instructions and context. They were briefed on the prototypes' objective, provided with credentials for the hosted instance of the prototype, and asked to evaluate one of their own recent research artifacts. Crucially, to ensure data privacy, participants were instructed to avoid uploading confidential or unpublished materials due to the prototypes reliance on commercial LLMs.

Following this setup, participants used the prototype and evaluated their chosen artifact by interacting with the agent's evaluation plan and reviewing the final report. Participants then completed a structured questionnaire, which was informed by the Technology Acceptance Model (TAM) [7], comprising five-point Likert-scale items and open-ended questions. This allowed us to evaluate the prototypes perceived usefulness and quality (assessing the accuracy, actionability, and detail of the feedback) alongside its usability and adoption potential (ease of use, interaction design, and the likelihood of integration into regular workflows). The survey instrument and anonymized responses are published in the online material [1].

## 4 Emerging Results

This section presents our findings structured around our three research questions: the formulation of the reproducibility criteria (RQ1), an analysis of the agent's strengths and limitations (RQ2), and an empirical assessment of the approach's perceived usefulness to stakeholders (RQ3).

### RQ1: Reproducibility Criteria

We distill an initial pool of 380 raw requirements from 34 sources into a unified set of 51 reproducibility criteria. Because some requirements demand paper-text analysis rather than artifact inspection, we distinguish between the full set and a subset of 31 operationalized

criteria that are fully amenable to automated, artifact-based evaluation. The extracted criteria are organized into a hierarchical structure comprising five high-level topics and fourteen subtopics. In the list below, the numbers in parentheses indicate the total count of individual criteria assigned to each respective topic and subtopic:

**Documentation (15):** Covers the core information required to comprehend and reproduce the research. Subtopics: *Theoretical & Mathematical* (7), *Data* (5), and *Experimental & Methodological* (3).

**Data and Artifact Availability (16):** Focuses on ensuring artifacts remain accessible, reusable, and secure over time. Subtopics: *Archiving & Accessibility* (6), *Data Integrity & Privacy* (4), *Licensing & Citation* (2), and *Reproducibility Support* (4).

**Code and Environment (7):** Addresses the executability of the software artifact. Subtopics: *Automatization* (1), *Code Availability & Management* (3), *Integration & Documentation* (1), and *Reproducibility & Infrastructure* (2).

**Experimental Rigor (7):** Captures transparency and reliability of empirical setups. Subtopics: *Experimental Reliability & Statistical Reporting* (2), *Hyperparameter Transparency* (3), and *Model & Randomness Control* (2).

**Ethical and Governance (6):** Encompasses ethical design and reporting considerations. Subtopics: *Human-Subject Research* (2) and *Responsible Use of Models & Code* (4).

### RQ2: Strengths and Limitations

To answer RQ2, we analyze the potential and limitations of using the agentic approach to assess the quality of replication packages.

**Strengths.** The approach shows strong potential in automating the foundational, labor-intensive steps, particularly for computational and code-centric research. Its retrieval pipeline robustly ingests diverse sources, autonomously cloning GitHub repositories, fetching Zenodo archives, and parsing direct URLs or manual uploads.

**Inter-Run Consistency (Stability).** The agent demonstrated high determinism across repeated executions. Using a hierarchical macro-averaging metric that follows our predefined knowledge base schema (i.e., calculating categorical overlap exactly across the established topics, subtopics, and criteria), the approach achieves an overall consistency score of 91.4% across all runs. Stability was particularly strong in structured domains, such as *Data and Artifact Availability* (94.8%) and *Ethical and Governance* (94.0%).

When evaluating via the LLM-as-Judge semantic rubric (scored 1–4), the agent's high-level qualitative outputs proved similarly stable. Applying this validated judge, the agent's natural language reasoning (3.36/4.0) and replication improvement suggestions (3.23/4.0) consistently achieve a "Mostly Consistent" rating across runs. Interestingly, the lowest stability is observed in exact evidence path extraction (2.64/4.0), indicating that while the agent's final reasoning and evaluations are deterministic, the localized text snippets it cites to justify those decisions can vary stochastically between runs.

**Limitations and Failure Cases.** Despite its strengths, testing revealed several limitations and failure cases driven by the tension between rigid automated evaluation and heterogeneous scientific reporting:

**Rigidity and Prompt Engineering Overhead:** To preserve internal consistency, the success and failure boundaries for criteria must be defined very strictly, which reduces flexibility. For example, evaluating whether data was appropriately anonymized initially resulted

in inconsistent penalties for purely technical datasets. Preventing these false negatives required engineering the criteria's applicability conditions to explicitly distinguish between human-subject data and inherently synthetic data (e.g., regex syntax or physics simulations).

**Contextual Blind Spots (The "If Applicable" Problem):** The approach struggles with conditional criteria. For instance, criteria requiring authors to provide pre-trained model weights or parameter counts caused false failures when the agent evaluated replication studies. Lacking the semantic awareness that the authors were re-running previous code rather than training a novel model, the agent incorrectly demanded non-existent artifacts.

**Extraction and Attribution Ambiguity:** Artifact links frequently hide in footnotes, unstructured data availability sections, or inline citations, and are inconsistently labeled (e.g., "online material" versus "replication package"). This occasionally causes the agent to misclassify a supplementary dataset as a primary code repository.

**Preprocessing and Pipeline Fragility:** Edge cases in formatting can quickly exceed the context window size and processing constraints. During evaluation, oversized or malformed inputs (e.g., data-heavy PDFs, image-laden Jupyter Notebooks, and deeply nested archives) triggered an explosion of text chunks, system timeouts, or an empty workspace with subsequent execution faults. As a preliminary mitigation, we instruct users to provide flattened, non-nested archives prior to uploading their artifacts.

### RQ3: Usefulness for Stakeholders

Since a report is only useful if its judgments are correct, we first benchmark the agent against a manual baseline, then survey researchers on perceived usefulness.

**Agreement with Manual Baseline.** When comparing against human-authored baselines, the agent achieved a micro-accuracy of 75.4% and a macro-average of 68.2%. Breaking down the classification metrics reveals performance differences. The agent is reliable at identifying compliant practices, achieving 86.4% precision and 81.5% recall ($F1 = 0.83$) when classifying criteria as "Passed" (True) in the final report. Conversely, when flagging non-compliant ("False") criteria, it exhibited high recall (85.8%) but lower precision (56.7%), suggesting a slight bias toward strictness, which represents our prompting strategy, instructing the agent to default to false if the answer is not clear.

Crucially, the intersection analysis highlights a massive performance variance depending on the evaluation topic. The agent performs well on structural verifications like *Code and Environment* (84.6%) and *Data and Artifact Availability* (77.2%), but performance plummeted on *Experimental Rigor* (38.0%). See Figure 2 for the full breakdown. Our review indicates that this discrepancy is bidirectional, a point we examine in Section 5.

Finally, qualitative semantic alignment with the human reports reflects this broader performance variance. We used an LLM-as-Judge to score the agent's semantic alignment against the human-authored ground truth (1–4). The agent achieved a mean alignment score of (2.99/4.00) for improvement suggestions, significantly higher than the (1.92/4.00) observed for evidence paths. We examine this divergence in Section 5.

**Pilot Survey.** Across the seven survey participants (3 quantitative, 3 qualitative, and 1 mixed-method study authors), results indicate high usability and strong adoption potential. Within this small pilot sample, participants rated the tool's clarity and integration positively, with subtopic understanding (Mean, standard deviation $M = 3.83, SD = 0.75$ Clarity) scoring highest and frequency-of-use intention ($M = 3.50, SD = 0.84$ Frequency) also high.

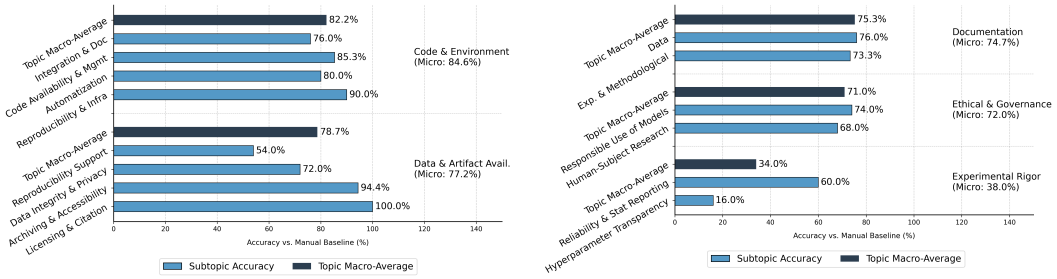

**Figure 2** Accuracy benchmarked against the manual baseline, detailing both granular subtopic accuracy (blue) and the overall topic macro-average (dark slate).

Perceived usefulness was favorable, as participants felt confident using the tool to improve artifacts ($M = 3.67, SD = 0.52$ Confidence). However, qualitative consistency and report accuracy showed higher variance ($M = 3.33, SD = 0.52$ Consistency; $M = 3.17, SD = 1.47$ Accuracy; respectively), reflecting mixed performance across diverse methodology types. With only seven participants, these means and standard deviations can not be considered stable descriptive summaries and do not support statistical or population-level inference. The study-type counts likewise do not support subgroup comparisons. The qualitative responses provide initial explanations for the high variance. Participants reported that the tool worked better for code-centric, quantitative artifacts than for complex qualitative or mixed-method material. Figure 3 lists the overall ratings and standard-deviations.

**Cost.** Based on the Langfuse traces collected during development and evaluation, the per-paper cost of running the agent ranged from $0.11 to $2.23, with an average cost of $0.71 per report.

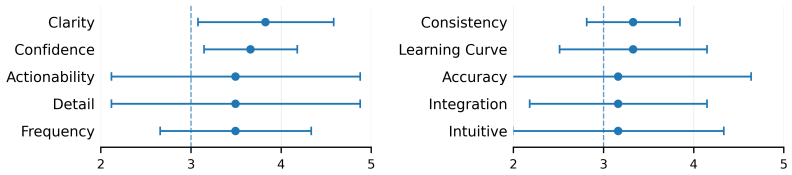

**Figure 3** Descriptive participant ratings of the prototype ($n = 7$). The five-point Likert scale ranges from 1 (strongly disagree) to 5 (strongly agree), with 3 as the neutral midpoint (vertical line). Points show item means and horizontal bars show ±1 standard deviation. Because this is a small pilot sample, the values summarize these participants only and should not be interpreted as population estimates.

## 5 Discussion

The findings from this study demonstrate that agentic approaches can successfully operationalize broad open-science rules into automated checks, particularly for computational and code-centric research. The approach's high inter-run consistency indicates that the inherent non-determinism of LLMs can be effectively constrained through explicit graph-based state management, structured tool use, and operationalized criteria. The proposed approach can handle high heterogeneity of replication packages reasonably well. Furthermore, the architecture introduces robust artifact ingestion that gracefully handles the structural heterogeneity

and format diversity of replication packages. Unlike end-to-end models that generate opaque judgments, the agent strictly grounds its evaluations in extracted evidence. By mandating explicit file-path citations, the approach provides verifiable proof, allowing reviewers to independently audit its reasoning. This is supported by the high semantic consistency scores observed via the LLM-as-Judge evaluation for the agent's reasoning and suggestions.

The agent's bias toward strictness, reflected in its lower precision on non-compliant criteria, stems from a reliance on narrowly defined criteria that cause it to penalize artifacts organized in non-standard ways. For instance, when an author provides a unified `reproduce_everything.sh` script rather than the one-to-one figure mapping the agent expects, the approach might flag it as a failure. The same rigidity drives the low agreement on *Experimental Rigor*, where the agent's sub-condition checks diverge from the heuristics human reviewers apply. The challenge for the future is therefore to move beyond rigid, checklist-based verification and recognize when an alternative implementation is functionally equivalent to the expected standard. Likewise the low semantic agreement on evidence extraction reflects differing retrieval strategies. The agent's, more exhaustive, retrieval surfaces secondary, corroborating evidence that human reviewers bypass once a sufficient proof is found, paradoxically penalizing its alignment score.

Furthermore, the approach's limited applicability to qualitative research remains a limitation. Qualitative research relies on context and researcher judgment, expressing rigor through traceability and logical consistency [15], rather than strict re-execution. Future work could explore the integration of structured qualitative reporting frameworks into machine-operationalizable representations. Fortunately, the approach's modular knowledge base supports this extensibility. By separating the core execution logic from the underlying relational database, the approach can dynamically adapt to venue-specific checklists, publisher mandates, or emerging domain standards (e.g., guidelines for LLM studies [2]) without requiring architecture modifications.

Rather than offering a simple pass-or-fail judgment, the approach diagnoses specific shortcomings and generates a to-do list for artifact improvement. However, user feedback regarding usability underscores a tension between this detailed transparency and cognitive load. As one participant noted regarding the Human-in-the-Loop (HITL) step: "*The planning step expecting human-in-the-loop guidance is overwhelming and it is very unclear to a new user, in how much detail they would need to understand and adjust the plan.*" Future iterations of the frontend would benefit from adaptive interfaces that support progressive disclosure, allowing users to verify high-level decisions while exploring detailed reasoning traces only when explicitly needed. Ultimately, integrating such agentic evaluation approaches has the potential to reshape empirical software engineering research by shifting artifact evaluation from a retrospective, manual process to a scalable, proactive workflow. While confidentiality is crucial when reviewing unpublished work, our prototype relied on commercial models, which is appropriate at this early stage but of course unsuitable in the long run.

## 6 Threats to Validity

We discuss the threats to validity of this study as outlined by Runeson and Höst [19].

**Internal Validity.** Our prompting strategies may favor specific document structures or reporting styles, and model-specific traits, such as phrasing sensitivity, pretraining biases, and stochastic variations that we cannot mitigate within an emerging results report. The use of proprietary LLMs also risks implicit data leakage should the evaluated paper or public

repository appear in their training datasets. We deem this risk as negligible. Because the selected packages came from publications familiar to the authors, this familiarity may have simplified evidence discovery or influenced borderline judgments, thereby distorting measured agreement. We did not measure inter-rater reliability for the manual reference, so its own reliability remains unknown. The reference should therefore be understood as a fallible author-created comparison rather than ground truth.

**External Validity.** Our approach and underlying criteria are systematically biased toward computational, code-centric research, limiting generalizability to qualitative or theoretical software engineering paradigms. In our study, this expected bias stemming from the alignment of the open-science policies we drew on, caused the agent to inappropriately recommend restructuring a qualitative artifact into a code repository. Results also depend on the specific LLM versions used, and neither generalization across LLM versions nor comparison to other models was in scope of this work. The five purposively selected packages are too few to represent the diversity of replication packages in software engineering, and the seven recruited researchers are too few to represent the broader researcher population. Moreover, participants evaluated their own artifacts, so familiarity with and ownership of those artifacts may have influenced perceived usefulness, accuracy, and adoption intentions. We deem those risks acceptable for an emerging results report.

**Construct Validity.** Operationalizing reproducibility through a set of quality criteria may not fully capture its multifaceted nature in practice, a risk we accept as these criteria reflect the current state of practice. Employing an LLM-as-Judge adds a layer of approximation, relying on semantic, prompt-based comparison rather than deterministic verification, which we quantified through manual verification in Section 4.

**Reliability.** The non-deterministic nature of LLMs poses challenges for evaluation consistency. Although our prototype reached a high inter-run consistency, minor stochastic discrepancies persist across repeated executions. We mitigate this by triangulating automated judgements through multi-run aggregation and benchmarking against manual baseline assessments.

## 7 Conclusion

This study demonstrates that agentic workflows have the potential to operationalize high-level open-science policies into machine-verifiable tasks. Our prototype achieved high inter-run consistency and substantial agreement with manual baseline assessments. While the agent excels at offloading labor-intensive tasks (e.g., discovery and structural analysis) for quantitative, code-centric repositories, it exhibits a structural bias against qualitative research and unconventional artifact layouts. While its evidence-based traceability builds user trust, the interactive HITL phase can introduce a noticeable cognitive load, highlighting the need for a more streamlined user experience.

Our three contributions are a relational knowledge base of operationalized open-science criteria, a multi-agent prototype that autonomously retrieves, structures, and evaluates research artifacts, and a pilot survey on the usefulness of the approach. Together they take a step toward shifting artifact evaluation from a manual, resource consuming process, into a scalable, proactive workflow. Ultimately, we hope that in the future this approach can serve authors as a proactive “replication package linter” that flags quality issues prior to peer review, and supports artifact evaluation committees as a force multiplier that automates routine structural checks so reviewers can focus on deep semantic validation.

Future work will harden preprocessing against complex formats such as deeply nested archives and Jupyter Notebooks, integrate study-type detection for adaptive, context-aware criteria selection, apply ensemble methods such as majority voting to further stabilize consistency, and refine the frontend while adding support for open LLMs to broaden adoption. Finally, future work will have to evaluate the impact on resources in artefact evaluation tracks envisioned with our solution.

## Data Availability Statement

The replication package supporting this study, including the scripts, raw repository data, agent configurations, survey instrument and data, is openly available on Zenodo at in our online material [1] under a CC-BY 4.0 license. The replication package contains all materials necessary to reproduce our findings.

## AI Usage

We employed LLMs for textual editing, as well as diagram improvements.

## Abstract

**Context.** Generative AI coding agents are increasingly used to automate software maintenance and issue resolution. However, current evaluations mainly focus on test-passing behavior and provide limited insights into whether agents modify the same software entities selected by developers.

**Aim.** This study investigates the accuracy of issue localization performed by agents across different software granularities.

**Method.** We analyzed 2,441 issue-fixing commits from 10 large-scale Java projects and evaluated three agents, each combining the OpenCode harness with a different open-weight LLM. We compared agent-modified entities against human-implemented fixes at the package, class, and method levels using Accuracy, Precision, Recall, F1-score, and MCC.

**Results.** Agents partially identified the software entities requiring modification, but localization performance strongly depended on software granularity. Agents achieved the strongest results at the package level, while performance progressively degraded at the class and method levels. GLM-5 consistently achieved the strongest localization performance, although practical differences among agents remained limited. Our findings showed a limitation of agents implementing functionally plausible yet structurally different packages, class or methods leading to consistently negative MCC values worsening with finer granularity.

**Conclusion.** Current agents can often identify the general architectural region affected by an issue, but still struggle to precisely localize fine-grained implementation points. These findings highlight both the potential and the limitations of agents for issue localization and motivate larger-scale investigations on localization behavior, architectural impact, and long-term maintainability implications.

## 1 Introduction

The rapid adoption of Large Language Model (LLM)-based generative AI agents is reshaping how developers write, modify, and maintain software. These tools can already generate syntactically correct and functionally plausible code for tasks such as bug fixing, feature

© Antonino Coppola, Matteo Esposito, Rick Kazman, and Valentina Lenarduzzi;
licensed under Creative Commons License CC-BY 4.0

implementation, and refactoring. They are becoming part of everyday development workflows. However, despite the short-term productivity gains that they bring, their long-term impact on software quality and maintainability remains largely unexplored [1, 10].

A central concern is whether agents act *where* a human developer acted; that is, whether they modify the same parts of a codebase that a maintainer with deep project knowledge would have done. Recent benchmarks such as SWE-Bench [13] have shown that agents such as SWE-agent [32], OpenDevin [27], and AutoCodeRover [34] can resolve a substantial fraction of real GitHub issues, as measured by hidden test suites. However, test-based evaluation alone cannot distinguish *correct localization* (editing the right files, classes, and methods) from *incidental coverage*, where a patch satisfies the tests while modifying entities that the human developer would never have touched. This ambiguity has been documented in the Automated Program Repair (APR) literature as the *plausibility vs. correctness* distinction [19], but it remains largely unexplored for modern LLM-based agents.

To address these gaps, we designed and conducted an exploratory study on agent-based issue localization accuracy. We reconstructed historical issue-fixing contexts, reverted repositories to pre-fix states, generated agent-based fixes, and evaluated them against the human ground truth. We evaluated three OpenCode-based agent configurations using different underlying LLMs. We refer to such configurations as "agents" for the remainder of the paper.

Our study provides the following contributions:

- A multi-agent evaluation of how accurately agents identify the software entities requiring modification within a codebase.
- A fine-grained analysis of agent performance in localizing changes at the package, class, and method levels.
- A comparison between agents and human developers in terms of accuracy and precision of issue localization.

**Paper Structure.** Section 2 describes the empirical study design and analysis methodology. Section 3 presents our findings and Section 4 discusses them. Section 5 addresses the threats to validity of this work. Finally, Section 6 discusses the related works and Section 7 concludes the paper.

## 2 Empirical Study Design

This section presents the empirical study design, including the study goal and research questions, the study context, the data collection methodology, and the data analysis approach [29].

### 2.1 Goal and Research Questions

We aim to analyze agent-generated solutions in issue-resolution tasks to evaluate their ability to accurately identify the software entities requiring modification, with respect to correctness and granularity (package, class, and method levels).

Therefore, we derived the following research question (RQ) from our goal:

> **$RQ_1$.** Can agents accurately determine the software entities that must be modified to address a reported issue?

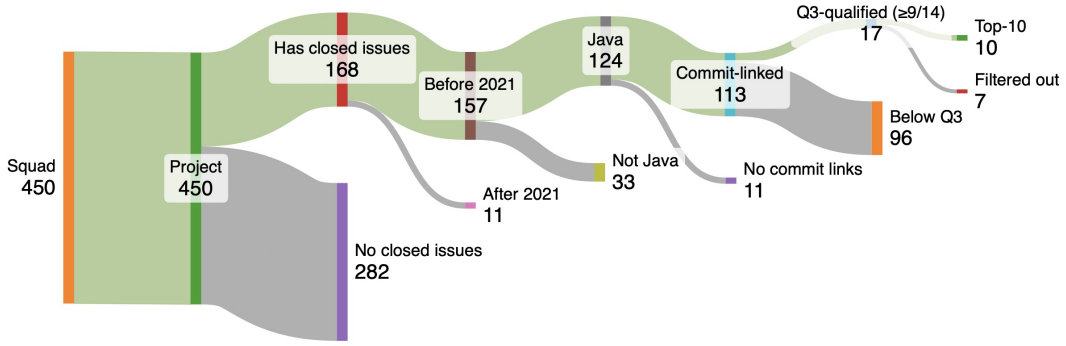

**Figure 1** Project filtering and selection process from the SQuaD dataset to the final study set.

Understanding where an issue should be resolved within a codebase is a central step in software maintenance and evolution [36]. With the increasing adoption of agents, an open question concerns their ability to localize the software entities requiring modification reliably. In this study, a **change** refers to the modification, addition, or removal of a software entity touched by a commit. We investigate whether agents can identify the correct **packages**, **classes**, and **methods** modified in the human-implemented reference fix. We operationalize localization performance using Accuracy, Precision, Recall, $F_1$-score, and Matthews Correlation Coefficient (MCC) computed by comparing agent-modified entities against the ground-truth human implementation. Since localization requires increasingly fine-grained contextual understanding, we expect localization performance to vary across software granularities. Therefore, we test the following hypotheses:

- $H_{0.1}$ There is no significant difference in localization performance among the evaluated agents.
- $H_{0.2}$ There is no significant difference in localization performance across package-, class-, and method-level software entities for agents.
- $H_{1.1}$ Localization performance significantly differs among the evaluated agents.
- $H_{1.2}$ Localization performance significantly differs across package-, class-, and method-level software entities for agents.

## 2.2 Study Context and LLM Selection

We based our **project selection** on SQuaD, introduced by Robredo et al. [21], a multi-dimensional, time-aware dataset of software quality metrics from 450 mature open-source projects. With over 700 metrics at the method, class, file, and project levels. Covering 63,586 releases, SQuaD also includes version control, issue tracking, vulnerability data (CVE/CWE), and process metrics for JIT defect prediction and over 628k issues. We applied a sequence of filters to obtain a focused subset of large-scale, mature Java projects as detailed in Section 2.3.

We implemented an **agent** using the OpenCode[1] framework to integrate LLMs into software engineering tasks. We consolidated three independent LLM ranking sources accessed in March 2026: Artificial Analysis[2], LLMstats[3], and OpenCompass[4], to identify the most

[1] https://opencode.ai/
[2] https://artificialanalysis.ai
[3] https://llm-stats.com
[4] https://rank.opencompass.org.cn

**Table 1** Overview of the evaluated LLMs.

| Model | Parameters & Quantization | Developer | Details |
|---|---|---|---|
| GLM-5 | 744B, not quantized | Zhipu AI | Transformer-based MoE with DeepSeek Sparse Attention (DSA) |
| Kimi-K2.5 | 1T, not quantized | Moonshot AI | Transformer-based MoE with MLA attention and MoonViT 400M vision encoder |
| Qwen3.5 | 397B, not quantized | Alibaba | Hybrid architecture: Gated Delta Networks (linear attention) + Transformer MoE |

performant models for code-related tasks across different evaluation metrics. Artificial Analysis employs Terminal Bench Hard and SciCode benchmarks, LLMstats leverages the Code-Arena benchmark, and OpenCompass utilizes the LiveCodeBench[5] metric for assessment. Following consolidation, we computed the median ranking position across these sources and subsequently selected the top-performing models demonstrating consensus across multiple ranking systems. Based on this methodology, we identified three models for experimental evaluation: GLM-5[6], Kimi-K2.5[7] and Qwen3.5[8] (Table 1).

## 2.3 Data Collection

We divided our data collection workflow into three processing steps, as follows.

**(1) Project and Issue Collection.** The final study set was constructed using SQuaD [21] as the initial reference corpus, followed by a multi-stage filtering and sampling procedure as illustrated in Figure 1. At the project level, we restricted the corpus to Java repositories hosted on GitHub with closed issues linked to commits and tracked on JIRA. We retained only issues closed before January $1^{st}$, 2021. This cutoff predates the widespread availability of LLM-based coding assistants, ensuring that the human-implemented fixes used as ground truth reflect unassisted developer decisions rather than AI-suggested ones. We then ranked projects according to 14 SQuaD size-and-maturity metrics [21] covering repository scale, code volume, defect history, longevity, and tracker availability, and selected the top 10 projects ranking above the third quartile on at least 9 of the 14 dimensions. The selected projects are listed in Table 2. At the issue level, we applied quality filters according to previous works that investigated similar problems. In particular, we selected issues that were implemented at most across 3 fix commits [11] touching at most 10 Java files [17]. The number of surviving issues per project is reported in the *Issues* column of Table 2. Then, we deterministically extracted a statistically significant sample population of $n_p$ with 95% confidence and 5% margin of error [5]. We chronologically sorted the surviving issues by first fix-commit date, and we selected $n_p$ issues at uniformly spaced indices across the temporal range. The per-project sample sizes are reported in the *Sample($n_p$)* column of Table 2.

**(2) Collecting Human-Implemented Issue-Fixing Commits.** We linked each issue to its corresponding implementation commit(s), referred to as Human-Implemented Issue-Fixing Commits (HIFC). Since issue-to-commit linkage is inherently noisy, we adopted a best-effort

**Table 2** Overview of the selected projects, issue counts, sampled issues, and completed executions.

| Project | Domain | Issues | Sample ($n_p$) | Completed |
|---|---|---|---|---|
| Camel | Integration framework | 8,103 | 368 | 329 |
| Cloudstack | Cloud platform | 3 | 3 | 3 |
| Flink | Stream processing | 5,728 | 361 | 335 |
| Hadoop | Batch processing | 1,618 | 312 | 310 |
| Hbase | Distributed DB | 9,407 | 370 | 363 |
| Hive | Data warehouse SQL | 10,089 | 371 | 340 |
| Ignite | In-memory database | 3,559 | 348 | 326 |
| Iotdb | Time-series DB | 228 | 144 | 189 |
| Netbeans | IDE platform | 558 | 229 | 245 |
| Cxf | Web services framework | 1 | 1 | 1 |
| **Total** | | **39,294** | **2,507** | **2,441** |

approach based on the regular expression matching used by Robredo et al. [20], specifically the JIRA pattern `[A-Z]{2,}-\d+`. We acknowledge that this approach may miss some issue-fixing commits due to heterogeneous commit practices, and we discuss this as a threat to validity. For each HIFC, we extracted the commit metadata, including message, diff, touched files, author, timestamp, and parent commit. The parent of the earliest HIFC, which we refer to as the Pre-Human-Initial-Fix-Commit (PHIFC), represents the exact context available to developers before the fix and serves as the reference state for our analysis. To extract the ground truth, we check out the repository at PHIFC in a detached worktree and apply the cumulative diff between PHIFC and HIFC restricted to `.java` files. We parse each pre-fix file with tree-sitter [9] and identify the Abstract Syntax Tree (AST) nodes whose source range overlaps the changed lines, projecting them to three granularities: package, class, and method.

**(3) Agent-Based Re-Implementation.** We then instantiate a fresh `git worktree` at PHIFC for the agent and remove references to the post-PHIFC state to prevent future-state leakage. We invoke the agent through the OpenCode harness with a model-agnostic prompt that provides the issue description and the corresponding codebase snapshot and instructs the agent to produce a fix. The resulting unified diff constitutes the Agent-Implemented Issue-Fixing Commit (AIFC), from which we extract entities using the same tree-sitter pipeline employed for ground truth. We evaluate three agents, each instantiated by pairing the OpenCode harness with one of the open-weight LLMs listed in Section 2.2, and accessed through Ollama Cloud[10]. All inference is performed remotely on Ollama's infrastructure. We did not provide any information from the human implementation, such as diffs, commit messages, future code states, nor access to tools, i.e., git, that would reveal the commit history to the agent.

**Validity and Timeout Handling.** A non-trivial fraction of agent runs failed in the initial execution due to a 600-second timeout. Rather than re-executing all timed-out runs, we selectively re-ran issues from projects exhibiting a high number of timeout failures using a

[9] `https://tree-sitter.github.io/tree-sitter/`
[10] `https://ollama.com`

1,200-second timeout, to verify whether the time bound was a significant constraint. The number of issues recovered through extended execution varies substantially across models: Qwen3.5 recovered 139 issues, GLM-5 recovered 18, and Kimi-K2.5 recovered only one. After the retry, we classify a run as valid only if it completed with exit code 0 and did not time out. Out of 2,506 total runs per model, Qwen3.5 failed on 144 issues (5.74%), GLM-5 on 44 issues (1.75%), and Kimi-K2.5 on 59 issues (2.35%): verbose-reasoning models are markedly more affected by the timeout budget. To ensure fair cross-model comparison, we restrict the analysis to the intersection of valid issues, meaning the 2,441 issues for which all three models produced a valid run, for a total of 7,323 executions. Since each execution is evaluated at three granularity levels, this yields 21,969 granularity-level observations used in the analysis.

## 2.4 Data Analysis

This section outlines the data analysis procedure adopted to answer the research questions and evaluate the associated hypotheses. To identify the appropriate statistical techniques, we first assessed the distribution of the collected data [9] through the following hypotheses:

$\mathbf{H}_{0\mathcal{N}}$ *The collected data is normally distributed.*

$\mathbf{H}_{1\mathcal{N}}$ *The collected data is not normally distributed.*

We tested $\boldsymbol{H_{0\mathcal{N}}}$ using the Anderson-Darling test [2], which is suitable for large datasets and sensitive to departures from normality [25]. Across all RQs, we report the statistical test, $p$-value, effect size, and practical interpretation of the results. We adopted a significance threshold of $\alpha = 0.05$, applying Bonferroni correction [8, 29] and additionally reporting Benjamini–Hochberg-adjusted (BH) $p$-values [4] as sensitivity analysis.

To test $H_{01}$ and $H_{02}$, we analyzed localization performance across package-, class-, and method-level entities using Accuracy, Precision, Recall, $F_1$-score, and MCC. Since the data followed a repeated-measures design and normality was rejected in all cases, we used the Friedman test followed by post hoc Wilcoxon signed-rank tests with multiple-comparison correction. We report Kendall's $W$ and rank-biserial correlation ($r_{rb}$) [7] as effect sizes.

# 3 Results

This section presents the findings of our investigation and addresses our RQ. We computed all results on the intersection of issues for which all three agents produced a valid run, resulting in 2,441 issues across 10 projects.

Figure 2 shows the distributions of Accuracy, Precision, Recall, F1-score, and MCC across the evaluated agents. GLM-5 achieved the strongest localization performance across most metrics, particularly for Recall and MCC, while Qwen3.5 and Kimi-K2.5 showed lower and more variable performance. Across all agents, Precision remained comparatively high whereas Recall remained substantially lower, indicating that agents often identified relevant entities correctly but failed to capture the full set of entities modified by developers. Moreover, MCC values remained consistently negative, suggesting limited structural agreement with the human-implemented fixes despite partial overlap in modified entities. Since the Anderson-Darling test rejected normality in all cases, we applied the Friedman test followed by Wilcoxon signed-rank post-hoc analyses. The omnibus analysis revealed statistically significant differences among agents for all localization metrics. However, all Kendall's $W$ effect sizes remained negligible, indicating limited practical differences among models. Recall produced the strongest separation among agents, whereas F1-score showed no significant pairwise differences despite the significant omnibus result (Table 3). Therefore, the results

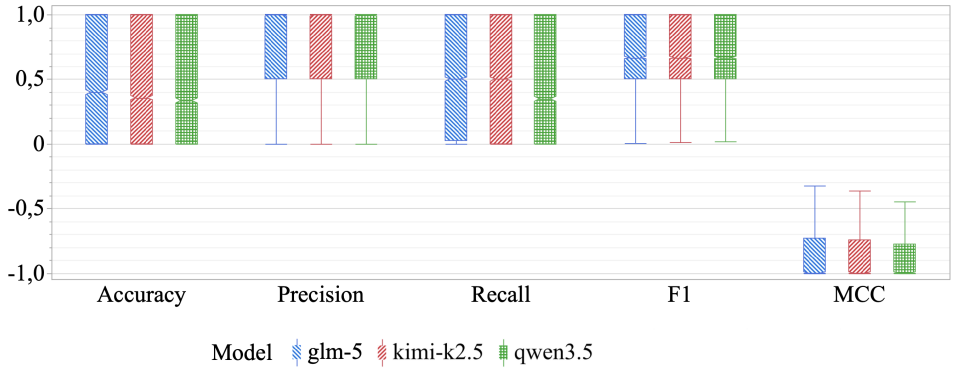

**Figure 2** Distribution of localization metrics across the evaluated agents, aggregated over all granularity levels (package, class, and method).

**Table 3** Statistical comparison of localization performance across agents, aggregated over all granularity levels (package, class, and method).

| Metric | Best Group | Mean | Significant | Posthoc Summary |
|---|---|---|---|---|
| Accuracy | GLM-5 | 0.473 | ✓ | 2/3 both, 0/3 borderline, 1/3 ns |
| Precision | GLM-5 | 0.756 | ✓ | 2/3 both, 0/3 borderline, 1/3 ns |
| Recall | GLM-5 | 0.492 | ✓ | 3/3 both, 0/3 borderline, 0/3 ns |
| F1 | GLM-5 | 0.714 | ✓ | 0/3 both, 0/3 borderline, 3/3 ns |
| MCC | GLM-5 | -0.840 | ✓ | 2/3 both, 0/3 borderline, 1/3 ns |

reject $H_{0.1}$: agents differ in localization performance, although the practical differences among models remain limited. Table 3 aggregates results across all granularity levels, a per-granularity breakdown is reported in Table 4, the two should be read together rather than compared directly.

Figure 3 summarizes localization performance across package-, class-, and method-level entities. Localization quality degrades as granularity becomes finer: Accuracy, Recall, and F1-score consistently decrease from packages to classes to methods. At the package level, agents achieved their strongest overall performance, whereas at the method level Accuracy and Recall reached their lowest values, indicating difficulties in pinpointing the exact implementation points modified by developers.

GLM-5 achieved the best mean performance across most metrics and granularities; exceptions are package-level Precision and class-level MCC, where Kimi-K2.5 ranked highest (Table 4). Nevertheless, the practical differences among agents remained limited at every granularity, as reflected by negligible Kendall's $W$ values despite several statistically significant comparisons. Method-level MCC showed significant differences among agents, suggesting that fine-grained localization amplifies behavioral differences between models.

Overall, the results reject $H_{0.2}$: **localization quality degrades as granularity becomes finer.** Agents reliably localized coarse-grained entities, whereas fine-grained method-level localization remained substantially more challenging. The architectural region of the issue is often correctly identified, but the exact implementation points modified by developers are not.

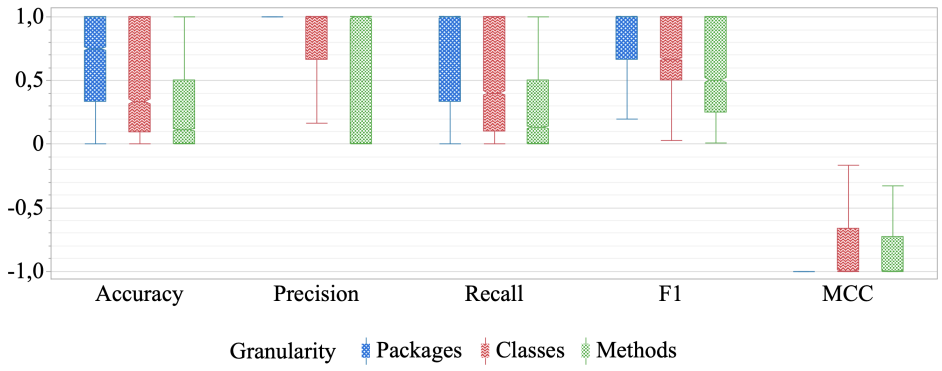

**Figure 3** Distribution of localization metrics across package-, class-, and method-level entities.

**Table 4** Statistical comparison of localization performance across software granularities.

| Granularity | Metric | Best Group | Best Mean | Significant | Posthoc Summary |
|---|---|---|---|---|---|
| packages | Accuracy | GLM-5 | 0.646 | ✓ | 2/3 both, 0/3 borderline, 1/3 ns |
| | Precision | Kimi-K2.5 | 0.877 | ✗ | No post-hoc (omnibus ns) |
| | Recall | GLM-5 | 0.661 | ✓ | 2/3 both, 0/3 borderline, 1/3 ns |
| | F1 | GLM-5 | 0.833 | ✗ | No post-hoc (omnibus ns) |
| | MCC | GLM-5 | -0.906 | ✗ | No post-hoc (omnibus ns) |
| classes | Accuracy | GLM-5 | 0.459 | ✓ | 2/3 both, 1/3 borderline, 0/3 ns |
| | Precision | GLM-5 | 0.779 | ✓ | 1/3 both, 1/3 borderline, 1/3 ns |
| | Recall | GLM-5 | 0.479 | ✓ | 3/3 both, 0/3 borderline, 0/3 ns |
| | F1 | GLM-5 | 0.686 | ✓ | 2/3 both, 0/3 borderline, 1/3 ns |
| | MCC | Kimi-K2.5 | -0.858 | ✗ | No post-hoc (omnibus ns) |
| methods | Accuracy | GLM-5 | 0.296 | ✓ | 2/3 both, 0/3 borderline, 1/3 ns |
| | Precision | GLM-5 | 0.597 | ✓ | 1/3 both, 0/3 borderline, 2/3 ns |
| | Recall | GLM-5 | 0.316 | ✓ | 3/3 both, 0/3 borderline, 0/3 ns |
| | F1 | GLM-5 | 0.562 | ✓ | 2/3 both, 0/3 borderline, 1/3 ns |
| | MCC | GLM-5 | -0.861 | ✓ | 2/3 both, 0/3 borderline, 1/3 ns |

## 4 Discussion

As expected, agents localized coarse-grained software entities substantially better than fine-grained ones: the larger the target, the easier it is to hit. Performance progressively degraded from packages to classes and methods, indicating that current agents can often identify the general architectural region affected by an issue, but still struggle to precisely pinpoint the exact implementation locations. In particular, the **strong reduction in Recall at the method level** suggests that agents frequently miss relevant implementation points even when they partially identify the correct area of the codebase.

Despite the reduction in Recall, **Precision remained comparatively high across all evaluated models and granularities**. Agents rarely modified completely unrelated entities and instead tended to modify only a subset of the entities touched by developers. This conservative behavior may reduce invasive or destabilizing edits, but it also increases the likelihood of incomplete fixes, especially when issues require coordinated modifications across multiple methods or classes.

The **consistently negative MCC values** indicate limited structural agreement between agent- and human-modified entities. In several cases, agents modified entities different from those touched by developers, yet may still have implemented semantically equivalent behavior, a possibility that overlap-based metrics alone cannot confirm or rule out. This raises the question of whether such structurally divergent solutions are genuinely incorrect or merely alternative implementations of the same fix. To quantify the potential extent of this effect, we identified the divergent cases, i.e., observations in which the agent both modified entities not touched by the developer and missed entities the developer modified. Such cases account for 25.07% of all 21,969 observations, and their proportion grows with finer granularity: 11.73% at the package level, 23.42% at the class level, and 40.05% at the method level (7,323 observations each), with consistent proportions across models (24.65% - 25.70%). We discuss the implications of this measurement limitation for the validity of our findings in Section 5.

The negligible effect sizes across models suggest that localization limitations currently represent a broader characteristic of agents rather than a weakness of a specific model family. Although GLM-5 achieved the strongest overall performance, the practical differences among agents remained limited despite large differences in model scale. These findings raise an important question: do substantially larger models actually improve issue localization quality? Current results suggest that model scaling alone may not be sufficient, and that future agents will likely require stronger repository-aware reasoning mechanisms, including dependency analysis, structural navigation, execution-context understanding, and architectural awareness. From a practical standpoint, these results suggest that coding agents can already provide useful support in the early triaging phase of issue resolution, helping maintainers narrow down the relevant architectural area. However, they should not be relied upon for precise method-level localization without human verification, as the high rate of divergent cases at finer granularities indicates a substantial risk of incomplete or misplaced fixes.

Future research should investigate the relationship between localization quality and long-term software quality indicators, including maintainability, architectural degradation, and technical debt accumulation. Moreover, future evaluation frameworks should move beyond **strict entity-overlap metrics** and incorporate semantic and behavioral equivalence between human and agent implementations. Finally, larger-scale and longitudinal studies are needed to better understand the characteristics and long-term impact of agent-based issue localization and re-implementation.

## 5 Threats to Validity

This section discusses the main threats to validity of our study following established guidelines [29].

**Construct Validity.** We operationalize issue localization through Accuracy, Precision, Recall, $F_1$-score, and MCC computed against human-implemented fixes. As discussed in Section 4, our overlap-based metrics treat any divergent case as incorrect, even when the agent may have produced a semantically equivalent fix through different entities. These metrics therefore cannot recognize functionally valid but structurally divergent solutions, and our findings should be interpreted as a lower bound on agent localization performance. Consistent with the scope of an Emerging Results paper, a systematic analysis of functional equivalence on these cases is left to future work. Additionally, our results should be read as differences across LLMs within a fixed orchestration environment rather than as a general comparison of agent frameworks. Finally, fix commits may contain spurious changes unrelated to the reported issue, such as unrelated refactorings or formatting updates, which could inflate the ground-truth entity set and affect the overlap-based metrics.

**Internal Validity.** We link issues to commits through regular-expression matching, which may introduce noise due to inconsistent commit practices. To mitigate this limitation, we adopted established matching patterns and selected issues with clear traceability. Agent-generated outputs may also vary because of prompt design, issue complexity, and model behavior. So, we standardized prompts and execution settings across all evaluated agents. Furthermore, LLM outputs are inherently non-deterministic, each (agent, issue) pair was executed once due to the computational cost of 7,323 total runs, which may not fully capture the variance in agent localization behavior. We also did not characterize the quality of the issue descriptions provided to the agents. JIRA reports vary considerably in detail, from one-line titles to structured descriptions with stack traces and reproduction steps, and this variation likely interacts with localization difficulty. Controlling for issue-report quality is a natural extension of this work.

**External Validity.** All three agents share the same OpenCode orchestration layer, and our results therefore characterize how different LLMs behave within a fixed harness rather than how agents behave in general. Harness design shapes repository exploration, context construction, and editing strategy, so localization behavior may differ under alternative frameworks. Our study focuses on open-source Java projects and may not generalize to industrial systems, other programming languages, or alternative development ecosystems. Finally, the pre-2021 cutoff guarantees an AI-free ground truth but does not exclude these issues from the models' training corpora, agents may therefore have encountered some of these fixes during training.

**Conclusion Validity.** We mitigated statistical conclusion threats by testing data normality, applying non-parametric statistical tests, reporting effect sizes, and adopting multiple-comparison correction procedures. Nevertheless, several statistically significant results showed negligible effect sizes, indicating limited practical differences among models.

## 6 Related Work

Classical bug localization research relies on developer fix commits as ground truth and ranks source files or methods according to their similarity to bug reports [35, 22, 30]. Later studies introduced deep learning approaches to improve localization performance [14, 31]. However, these approaches treat localization as a static ranking problem and do not capture the exploratory behavior of agents, which actively navigate and modify the codebase before producing a solution.

Recent work has introduced agentic approaches for automatically identifying the code entities requiring modification. ORCALOCA [33], COSIL [12], and COGNIGENT [23] rely on iterative exploration strategies based on code graphs, reasoning, and multi-agent workflows to localize buggy entities. TOOLTRAIN [15] and LLMLOC [16] instead improve localization through enhanced retrieval and training mechanisms. Batole et al. [3] focus on identifying refactoring targets through static-analysis summaries. While these studies mainly propose techniques to improve localization, they do not empirically analyze whether agents modify the same software entities selected by developers across different granularities. In parallel, empirical studies have analyzed how AI-generated code differs from human-written code in terms of defects, vulnerabilities, complexity, readability, coding style, and structural properties [6, 28, 26, 18]. These works focus on the characteristics of the generated code after the modification has been applied. In contrast, our work investigates whether agents act in the *right place* to begin with by comparing agent-modified entities against the human-implemented fix at the package, class, and method levels.

Our work is also complementary to Automated Program Repair studies on plausible versus correct patches [24]. While APR research focuses on whether generated patches satisfy tests despite diverging from human fixes, we focus on the localization perspective, analyzing where agents apply modifications and how closely these locations align with developer-selected entities.

## 7 Conclusion

Agents can partially localize the software entities that require modification, but their performance strongly depends on software granularity. Agents reliably identified coarse-grained package-level entities; however accuracy progressively degrades as we move to the class and method levels, revealing the difficulty in pinpointing the exact areas that developers modified. Although GLM-5 achieved the strongest localization performance across most metrics and granularities, the practical differences among models are limited. Our results also show that agents frequently produce structurally divergent solutions whose functional equivalence to the human fix cannot be established through overlap-based metrics, which may therefore underestimate the practical usefulness of some generated solutions. Overall, these findings highlight both the potential and the current limitations of agents for issue localization and re-implementation tasks. Future large-scale studies should further investigate localization behavior, architectural impact, and the long-term characteristics of agent-generated modifications across diverse software systems and development scenarios.

## Data Availability Statement

We provide all raw data, scripts, model prompts, and analysis configurations in a FAIR [11] replication package on Zenodo [12].

## Declaration on the use of generative AI

The authors used ChatGPT for suggestions to improve textual clarity. All research design, data analysis, interpretation, and manuscript writing was conducted by the authors.

## Abstract

Large Language Models (LLMs) are increasingly embedded in software projects, yet little is known about how developers configure LLM parameters in the wild. Characterizing which parameters are defined, how many per project, which groups are co-defined, and what values are preferred can inform academics and tool builders about practices. This article mines open-source Python repositories on GitHub that integrate LLMs and uses AST-based static analysis to extract parameter assignments. Project-level definitions are analyzed to address prevalence (RQ1), configuration complexity and its structure (RQ2), and value distributions (RQ3). The final corpus includes 363 projects and gathers 7892 parameter definitions, with both the dataset and the code available for reproducibility. We observe that *temperature* is most frequently defined (90.36%), followed by *max_tokens* (56.75%), *top_p* (49.86%), and *top_k* (42.70%); penalty parameters are comparatively rare (RQ1). Projects typically define few parameters (mean $\approx$ 3), and this limited set expands incrementally around a stable core (*temperature* + *max_tokens*) (RQ2). Distributions suggest "defaults-in-practice": *temperature* $\approx$ 0.0, 0.7 and 1.0, *top_p* $\approx$ 0.9, *top_k* $\approx$ 0–50, and *max_tokens* at $2^k$ values (*e.g.,* 256/512/1024) (RQ3). In conclusion, developers favor minimalist, sampling-centric configurations with convergence around specific ranges. These descriptive findings support clearer configuration reporting, offer practical baselines for tools and education, and motivate future work on causes, longitudinal evolution and task/domain stratification.

## 1 Introduction

Large Language Models (LLMs) have rapidly transitioned from research prototypes to widely adopted components across software projects, powering code assistants, conversational agents, and task-specific tools. This fast-paced adoption has sparked an equally rapid growth of empirical studies and community discussions around evaluation practices, reproducibility, and the transparent reporting of model configurations in software engineering (SE) contexts [2, 16, 17].

In particular, configuration parameters exposed by LLM APIs (*e.g.,* temperature, top_p, top_k, token limits, etc.) directly influence output diversity, determinism, and verbosity [10]. Therefore, they are central to understanding how developers shape model behavior in practice [17] [1,2]. Despite the relevance of configuration to the behavior and reliability of LLM-enabled software, we still lack a systematic characterization of *which* parameters developers actually define in real-world software projects, *how many* of them are typically defined, *which groups* of parameters tend to appear within the same project, and *what concrete values* are assigned in practice. Clarifying these aspects matters for at least three reasons: (i) it informs reproducibility and reporting standards in LLM-in-SE studies [2,16]; (ii) it surfaces *de facto* practices and emergent conventions (*defaults-in-practice*) that can guide future evaluations; and (iii) it provides an empirical baseline for tool builders and academics.

This paper adopts a repository-mining perspective to study LLM configuration practices in the wild. It focuses explicitly on software projects that integrate LLMs as part of their functionality, and it analyzes configuration at the project level, as manifested in source code. Guided by the evidence accessible through static analysis, it addresses the following research questions:

- **RQ1.** Which LLM parameters are defined by developers in real-world software projects?
- **RQ2.** How complex are LLM configurations at the project level, and how is this complexity structured across parameters?
- **RQ3.** What values do developers assign to the LLM parameters they define?

We mine open-source repositories on GitHub and extract parameter assignments using an AST-based analysis pipeline tailored for Python code (*e.g.,* mining keyword arguments, dictionary literals, and class instantiations). We then construct a dataset of occurrence-level parameter definitions. The proposed study design is consistent with current recommendations on transparency, scoping, and limitation reporting for empirical studies involving LLMs [2,16].

Across hundreds of projects, we observe that: (i) *temperature* is the most frequently defined parameter, with *max_tokens* and *top_p* also appearing in over half of the projects, whereas penalty-style parameters are comparatively rare; (ii) projects typically define a *small* number of parameters (mean $\approx 3$), indicating a prevalent minimalist practice; (iii) the most common parameter groups defined at project level consistently include *temperature* plus *max_tokens* and either *top_p* or *top_k*; and (iv) value distributions suggest emerging *defaults-in-practice* – e.g., *temperature* commonly set to 0.0, 0.7 and 1.0, *top_p* near 0.9, moderately small *top_k*, and rounded *max_tokens* (*e.g.,* 256, 512, 1024). These observations complement recent calls for clearer reporting of model versions and configurations and help situate real-world tuning practices within the broader Software Engineering literature on LLMs [2,16,17].

**Paper structure.** The remainder of this paper is organized as follows. Section 2 presents related work. Section 3 describes the study design. Section 4 reports the results, followed by threats to validity and conclusions.

## 2 Related Work

**LLMs in Software Engineering.** Recent research has increasingly studied Large Language Models (LLMs) as integral components of software systems rather than isolated tools. Beyond prompt design and standalone evaluation, several works analyze how LLMs are embedded into real software pipelines to support tasks such as repository analysis, conversational interfaces, program comprehension, and developer assistance [17].

Empirical guidelines and surveys emphasize the need to treat LLMs as software artifacts whose behavior depends on contextual integration choices, including model selection, prompting strategies, and configuration parameters [2,16]. Zheng et al. [17] provide a comprehensive survey of LLM usage across software engineering tasks, highlighting that most applications deploy LLMs as part of larger systems (e.g., assistants, agents, and analysis tools), and explicitly call for empirical studies grounded in real-world usage.

Several studies focus on LLM-enabled tools that operate over software repositories. Abedu et al. [1] report on the challenges of integrating LLM-based chatbots for mining software repositories, showing that system design decisions strongly affect effectiveness and reliability. Complementarily, De Martino et al. [4] propose PRIMES, a methodological framework for using LLMs within mining software repositories pipelines, emphasizing reproducibility, transparency, and controlled configuration of LLM components embedded in research workflows.

More broadly, experience reports and system-oriented studies stress that LLM behavior in software systems cannot be understood independently of how models are parameterized and orchestrated within applications [5].

Our study aligns with this body of work by focusing on software projects that integrate LLMs to deliver functionality. Rather than examining prompts or outcomes, we analyze how developers explicitly configure LLM parameters in the source code of real projects, providing complementary evidence on configuration practices that shape LLM behavior in deployed software systems.

**LLMs and Mining Software Repositories.** Mining Software Repositories (MSR) have been widely adopted as a methodological approach to characterize developer practices at scale. Previous work has applied MSR to study software architecture, development processes, and tool usage in a large corpus of projects [14]. More recently, some studies have explored how LLMs can be incorporated into MSR workflows themselves, for example, in data extraction or analysis pipelines [1,4]. In contrast, our work takes the complementary perspective of applying MSR techniques to systematically analyze how LLMs are configured in practice, focusing specifically on parameter definitions observed directly in source code. This approach enables empirical characterization of real-world configuration practices grounded in actual software artifacts.

**LLM parameter configuration in practice.** While prompt-engineering surveys classify strategies for steering model behavior, LLM parameters remain central levers that developers tune in real systems [12]. Beyond general Machine Learning, where hyperparameter reporting and tuning are often under-documented, empirical software engineering with LLMs has specifically called for clearer configuration reporting to support comparability and replication [2,13]. Our repository-based characterization complements these lines by documenting the prevalence of parameter definitions, common groups in projects, and the observed value bands that emerge as *defaults-in-practice*.

# 3 Study Design

This section introduces the research questions addressed by this article and describes the study design.

## 3.1 Research Questions

To understand how developers configure Large Language Models (LLMs) in real-world software projects, we define a set of research questions that align strictly with the evidence obtainable from the static analysis of code from repositories. Following community guidance on transparency and scoping for empirical studies involving LLMs [2,16] and recent overviews of LLM use in software engineering [17], our questions avoid presuming that parameters observed in the same repository are necessarily used together in the same call to the model's API. Instead, we study which parameters are *defined* in the projects, how many are defined, which groups of parameters tend to be co-defined within projects, and which concrete values developers assign.

**RQ1. Which LLM parameters are defined by developers in real-world software projects?**
Establishing the prevalence of parameter definition provides a baseline characterization of which aspects of LLM behavior developers consider worth controlling in practice. It also supports reproducibility-oriented reporting by clarifying which parameters are most commonly set explicitly, as recommended by recent guidelines [2,16].

**RQ2. How complex are LLM configurations at the project level, and how is this complexity structured across parameters?**
The number of parameters defined within a project is a proxy for configuration complexity. Understanding this number informs discussions about typical effort and the granularity at which practitioners customize LLM behavior across diverse codebases [17]. Furthermore, regarding how this complexity is structured, instead of assuming co-use in a single model's API call, we analyze project-level co-definition to reveal emergent defined parameter groups (*e.g., temperature* with *max_tokens*, or *temperature* with *top_p*). This perspective respects the observational limits of repository mining while still surfacing meaningful patterns that may inform future, finer-grained studies [2,16].

**RQ3. What values do developers assign to the LLM parameters they define?**
Distributions of parameter values capture *defaults-in-practice* and tuning conventions (*e.g.,* concentration of *temperature* around certain values). Such evidence can guide future controlled evaluations and help contextualize reported configurations in empirical research [17].

## 3.2 Data collection

In this section, we describe the data collection process. This involves selecting GitHub repositories of software projects that use LLMs and then extracting the LLM parameter definitions from the project's source code, resulting in a dataset of defined LLM parameters. The data collection process is shown in Figure 1. The source code used to create the dataset and the dataset is available online [9].

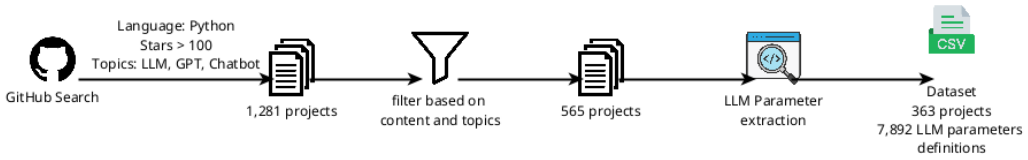

**Figure 1** Data collection process.

### 3.2.1 Project Selection

For this study, we focus on software projects that use LLMs in their code. Given the need for transparent access to source code and metadata [6], we restrict our analysis to open-source projects hosted on GitHub, the most widely used platform for open-source software development. To identify relevant projects, we queried the GitHub REST API and applied the following inclusion criteria:

1. **Project Topics:** Projects that include at least one of the following topics: *GPT, LLM, or Chatbot.*
2. **Programming Language:** Python. We restrict our analysis to Python projects as this language is predominant for integrating LLMs into software systems, serving as a primary ecosystem for LLM SDKs and frameworks [7, 15].
3. **Popularity Threshold:** Projects that have more than 100 stars. Prior work has shown that the number of stars is a proxy for project maturity, visibility, and community interest [3]. This filter helps exclude prototypes, proofs of concept, and early-stage repositories with little adoption.

Applying these filters yielded 1281 candidate projects.
