# 20th International Symposium on Empirical Software Engineering and Measurement

**ESEM 2026, October 8–9, 2026, Munich, Germany**

Edited by

Robert Feldt
Maria Paasivaara
Daniel Mendez
Stefan Wagner
Marvin Muñoz Barón

*Editors*

**Robert Feldt**
Chalmers University of Technology, Gothenburg, Sweden
Mid Sweden University, Östersund, Sweden
robert.feldt@chalmers.se

**Maria Paasivaara**
LUT University, Lahti, Finland

## LIPIcs – Leibniz International Proceedings in Informatics

LIPIcs is a series of high-quality conference proceedings across all fields in informatics. LIPIcs volumes are published according to the principle of Open Access, i.e., they are available online and free of charge.

*Editorial Board*

- Patricia Bouyer-Decitre (Université Paris-Saclay, CNRS, ENS Paris-Saclay, FR)
- Roberto Di Cosmo (Inria and Université Paris Cité, FR)
- Faith Ellen (University of Toronto, CA)
- Holger Hermanns (Universität des Saarlandes, Saarbrücken, DE and Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Wadern, DE)
- Laura Kovács (TU Wien, AT)
- Daniel Král' (Leipzig University, DE and Max Planck Institute for Mathematics in the Sciences, Leipzig, DE – Chair)
- Sławomir Lasota (University of Warsaw, PL)
- Meena Mahajan (Institute of Mathematical Sciences, Chennai, IN)
- Chih-Hao Luke Ong (Nanyang Technological University, SG)
- Eva Rotenberg (IT University of Copenhagen, DK)
- Pierre Senellart (ENS, Université PSL, Paris, France)
- Alexandra Silva (Cornell University, Ithaca, US)

# Contents

Preface
*Robert Feldt, Maria Paasivaara, Daniel Mendez, Stefan Wagner, and Marvin Muñoz Barón* ..... 0:xiii

List of Authors
..... 0:xv

## Technical Track

CognixShield: PoV-Guided Vulnerable API Usage Detection in Large Codebases via LLMs
*Quanzhi Fu, Wang Lingxiang, Wenjia Song, Gelei Deng, Yi Liu, Dan Williams, and Ying Zhang* ..... 1:1–1:21

Modeling Dependency-Propagated Ecosystem Impact of Changes in Maintenance Activities: Evaluating Support Strategies in the PyPI Network
*Alexandros Tsakpinis, Emil Schwenger, and Alexander Pretschner* ..... 2:1–2:20

What Makes Software Issue Resolution Tasks Difficult for Agents?
*Ebtesam Al-Haque and Brittany Johnson* ..... 3:1–3:20

Whispers and Watts: An Empirical Study of the Energy Consumption of ROS 2 Topic-Based Communication
*Michel Albonico and Nuno Macedo* ..... 4:1–4:20

Explanation-Guided Metamorphic Testing of Specialized Language Models: An Empirical Study
*Xingcheng Chen, Mehmet Besenk, and Andrea Stocco* ..... 5:1–5:21

The Influence of Fraudulent AI-Generated Responses on Software Engineering Surveys
*Ronnie de Souza Santos, Italo Santos, Maria Teresa Baldassarre, Cleyton Magalhães, and Mairieli Wessel* ..... 6:1–6:21

Characterising Meeting Practices in Software Engineering Teams: A Mixed-Methods Study of Perceptions, Objective Patterns, and Impacts
*Nitish Patkar, Xeno Isenegger, Gideon Monterosa, Sebastiano Panichella, and Norbert Seyff* ..... 7:1–7:19

Making Impact Visible in Funding of Open Source Software: A Study of the Funders' Perspective
*Johan Linåker, Kevin Lumbard, and Georg Link* ..... 8:1–8:20

Out of Place in My Own Work: How Generative AI Displaces Software Engineers
*Theocharis Tavantzis, Stefano Lambiase, and Daniel Russo* ..... 9:1–9:20

Assessing the Construct Validity of Object-Oriented, Class-Level Code Quality Metrics
*Hera Arif, Miikka Kuutila, and Paul Ralph* ..... 10:1–10:20

20th International Symposium on Empirical Software Engineering and Measurement (ESEM 2026).
Editors: Robert Feldt, Maria Paasivaara, Daniel Mendez, Stefan Wagner, and Marvin Muñoz Barón
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Don't Bother to Use a Second LLM and Write Tests Yourself! A Study on Elixir
*Noah Leu, Julian Oertel, and Regina Hebig* ..... 11:1–11:20

Assessing the Substitution of LLM-Based Decision Components
*Sergio Cobos, Robert Clarisó, and Javier Luis Cánovas Izquierdo* ..... 12:1–12:21

Characterizing Feedback Statements in Machine Learning Jupyter Notebooks
*Arumoy Shome, Luís Cruz, Diomidis Spinellis, and Arie van Deursen* ..... 13:1–13:21

Global Miscommunication in Privacy Requirements Engineering: Legal Experts' Experiences Collaborating with Software Engineers
*Claudia Negri-Ribalta, Ioana Visescu, Muriel-Larissa Frank, Anastasia Sergeeva, Alberto García Simon, Rene Noel, and Lorena Sánchez Chamorro* ..... 14:1–14:22

Evaluating CI/CD Security Best Practices in the GitHub Actions Documentation
*Lukas Boschanski and Marco Vieira* ..... 15:1–15:20

What Do We Really Know About Fortran?
*Austen Rainer, Andrew Brown, Rebecca Taylor, and Simon Hettrick* ..... 16:1–16:20

TypePatrol: Adversarial Testing for Uncovering Security-Relevant Type Inconsistencies in JavaScript Libraries
*Sai Mallikarjun Galipelli, Cristian-Alexandru Staicu, and Jibesh Patra* ..... 17:1–17:21

Coordinating Agents on a Shared Git Workspace: An Empirical Study of Action-Space Observation for Agentic Software Engineering
*Hasen Özaytürk and Feza Buzluca* ..... 18:1–18:20

Towards Reliable AI-Assisted Behavioral Modeling: Evaluating Prompting, Retrieval, and Repair Strategies for UML State Transition Diagram Generation
*Mussammat Maimuna Faria, Mashiat Amin Farin, Yasin Sazid, and Ahmedul Kabir* ..... 19:1–19:21

FDRRestTest: Feedback-Driven Logical Testing for REST APIs
*Yutong Huo and Dongcheng Li* ..... 20:1–20:20

How Reliable Is LLM-as-Judge for Patch Correctness Assessment? An Empirical Study
*Shanggui Zhan, Xingqi Wang, Dan Wei, and Xin Xiang* ..... 21:1–21:20

Beyond FLOPs: Energy-Aware Knowledge Distillation for Sustainable LLMs on Code-Related Task
*Enrique Barba Roque, Luís Cruz, and Annibale Panichella* ..... 22:1–22:21

Beyond Standard English: L1-Aware Benchmarks for Evaluating API-Calling in LLM Agents
*Vitor Gaboardi dos Santos, Boualem Benatallah, and Silvana Togneri MacMahon* ..... 23:1–23:20

Test Alert Snooze: An Empirical Study of Consecutive Test Failures on CI
*Ayane Shirakawa, Tatsuya Shirai, Yutaro Kashiwa, Masanari Kondo, Yasutaka Kamei, and Hajimu Iida* ..... 24:1–24:20

An Empirical Study of Problem-Aligned Multilingual Code Generation and Directed Code Translation by Large Language Models
*Quanhe Wang, Cheng Wen, Dugang Liu, Xingjian Han, Bin Yu, Ping Chen, Shengchao Qin, and Cong Tian* ..... 25:1–25:21

How Developers Use Relation Chains in Gerrit-Based Review Ecosystems: An Empirical Study Across Three Open-Source Ecosystems
*Ahmed Belhouchette, Moataz Chouchen, Marouene Chaieb, Mohammad Hamdaqa, and Abdelwahab Hamou-Lhadj* ..... 26:1–26:21

A Multivocal Review of AutoML Practices, Challenges, Opportunities and Open Issues
*Keerthiga Rajenthiram, Faezeh Amou Najafabadi, Ilias Gerostathopoulos, and Patricia Lago* ..... 27:1–27:20

Do LLM Vulnerability-Detection Agents Reason Better? An Empirical Decomposition of Robustness, Resistance, and Grounding
*Ziyu Chen, Qiangpu Chen, Yuwei Li, Taiyan Wang, Shiwen Ou, Qingsong Xie, Lu Zhang, and Zulie Pan* ..... 28:1–28:21

Balancing Green and Clean Code: Prompting for LLM-Based Refactoring
*Feray Gulu-zada and Hina Anwar* ..... 29:1–29:20

Beyond Response Time: Investigating the Power Behavior of Performance Antipatterns
*Alessandro Aneggi, Vincenzo Stoico, and Andrea Janes* ..... 30:1–30:20

How Students Construct Human–AI Boundaries in Software Engineering Teamwork
*Isabella Graßl* ..... 31:1–31:21

Large-Scale Evaluation of Android-Related Research Artifacts
*Philipp Holzinger and Philipp Rajwa* ..... 32:1–32:21

Blurred Compliance Boundaries: Analyzing Open Source License Conflicts in MCP-Based Agent Workflows
*Xing Cui, Jingzheng Wu*, Tianyue Luo, and Xiang Ling* ..... 33:1–33:20

Bigger Is Not Always Better: Performance and Sustainability Trade-Offs in LLMs for Python Bug-Fixing Tasks
*Syed Fakhar Abbas Naqvi and Hina Anwar* ..... 34:1–34:20

ReqGenX: An Empirical Study of Atomic Decomposition, Artifact Regeneration, and Reconstruction for Legacy SRS Documents
*Ragib Shahariar Ayon, Rayed Fahmi, Sumon Biswas, and Shibbir Ahmed* ..... 35:1–35:20

Is Self-Admitted Technical Debt Tested? An Empirical Study of Coverage, Co-Change, and Impact
*Suzuka Yoshimoto, Kosei Horikawa, Daniel Feitosa, Yutaro Kashiwa, and Hajimu Iida* ..... 36:1–36:20

A Factorial Comparison of LLM-Based Multi-Agent Architectures for Automated Python Refactoring
*Alexander Puma Pucho and Bruno B. P. Cafeo* ..... 37:1–37:21

Does GCC Compiler Development Pay for Itself? GCC Versions' Impact on Energy Consumption
*Brage Isak Keiserås, Bo Markussen, Ingrid Chieh Yu, Ken Friis Larsen, Maja H. Kirkeby, and Michael Kirkedal Thomsen* ..... 38:1–38:19

A Catalog of Transformations to Remove Dockerfile Smells
*Eduardo Barros, Márcio Ribeiro, Valeria Pontillo, Luana Martins, Fabio Palomba, Baldoino Fonseca, Rohit Gheyi, and Ivan Machado* ..... 39:1–39:20

Rethinking Automated Program Repair: The Impact of Bug Complexity, Fault Localization, and LLM Cost-Efficiency
*Junchi Liu, Ali Bigdeli, Roya Daneshi, Atu Ambala, Sudipto Ghosh, and Fabio Santos* ..... 40:1–40:21

Evaluating Language Models on Cross-Language Code Functional Equivalence
*Hui Sun, Anderson Uchôa, Rohit Gheyi, and Wesley K. G. Assunção* ..... 41:1–41:21

Green AI: Cost of LLM-Based Code Completion
*Negar Alizadeh, Nishant Saurabh, and Fernando Castor* ..... 42:1–42:21

The Overlooked Spirit of Open Source: LLM-Based Analysis of Non-Explicit Mentoring in OSS Communities
*Xing Cui, Jingzheng Wu, Tianyue Luo, and Xiang Ling* ..... 43:1–43:20

Can LLM Coding Assistants Support Emerging Programming Languages? An Empirical Study on Cangjie
*Junhang Cheng, Fang Liu, Jia Li, Chengru Wu, Nanxiang Jiang, and Li Zhang* .. 44:1–44:21

Do Smart Contract Auditing Results Transfer Across Datasets? A Two-Benchmark Empirical Study of Static and LLM-Based Security Tools
*Shawal Khalid, Joaquin Tuckett, and Chris Brown* ..... 45:1–45:21

On the Quality of Vulnerability-Contributing Commit Datasets: A Systematic Review and Exploit-Based Evaluation
*Vinicius Carvalho Lopes, Matthew Zampino, Christian Garcia, Joanna C. S. Santos, and Adriana Sejfia* ..... 46:1–46:21

Beyond Heuristics? Rethinking Targeted Unit Test Generation in the Era of LLM Agents
*Jiayu Liu and Yanjun Wu* ..... 47:1–47:21

Why Do LLMs Fail at OCL Generation? A Graph Reasoning Perspective
*Hamza Attarwala, Moataz Chouchen, Mohammad Hamdaqa, and Omar Alam* .... 48:1–48:21

Beyond Rule-Based Mutation Testing: Test-Aware Mutant Generation Using Large Language Models
*Nils Kiele, Zainab Saad, Zirui Wang, Steve Drew, and Samira Ebrahimi Kahou* .. 49:1–49:20

Does Fixing Break Security? An Empirical Study of Security Degradation in Iterative LLM-Driven Infrastructure-As-Code Repair
*Benjamin Agyekum and Fabio Santos* ..... 50:1–50:20

Hidden Dependencies in LLM-Enabled Code Generation: An Empirical Study of Regressions and Escaped Failures
*Gyumin Nam and Geunseok Yang* ..... 51:1–51:20

## Emerging Results, Vision & Reflection Track

A Facet-Based Perspective on Code Comprehension Task Design for Empirical Research
*Luisa Bartl, Marvin Wyrich, Sven Apel, and Janet Siegmund* ..... 52:1–52:15

PQC-Readiness of Open-Source Software: An Empirical Study
*Lukas Mehl* ..... 53:1–53:14

An Exploratory Study of Agent Plans for Agentic AI Coding Tools in Open-Source Software
*Muhammad Auwal Abubakar, Seyedmoein Mohsenimofidi, Jai Lal Lulla, Jie M. Zhang, Christoph Treude, Sebastian Baltes, and Matthias Galster* ..... 54:1–54:14

Tools for Detecting Security Issues in Infrastructure-As-Code: A Focused Literature Review
*Mohamed Haady Tiemtore and Frédéric Loulergue* ..... 55:1–55:14

QModel: A Time-Aware GitHub Mining Framework for Empirical Software Quality Studies
*Dmytro Polishchuk* ..... 56:1–56:14

Emerging Challenges in Threat Modeling for GenAI-Augmented Systems: A View from the Trenches
*Nicolás E. Díaz Ferreyra, Manish Mahesh Kumar, Nohemí Villarreal, Pankaj Pantel, Immo Brueggemann, and Riccardo Scandariato* ..... 57:1–57:15

An Agentic Approach Towards Replication Package Quality Evaluation
*Maximilian Alexander Amougou Mbida and Florian Angermeir* ..... 58:1–58:13

On Coding Agent Issue Localization Accuracy – An Exploratory Study
*Antonino Coppola, Matteo Esposito, Rick Kazman, and Valentina Lenarduzzi* .... 59:1–59:13

Parameterizing LLMs in Practice: An Empirical Study of LLMs Integrated into Software Systems
*Agustín Olmedo, Jannik Laval, Christelle Urtado, and Sylvain Vauttier* ..... 60:1–60:12

How Many Interviews Are Enough in a Software Engineering Study? Preliminary Findings on Sample Size and Saturation
*Ronnie de Souza Santos, Italo Santos, Mauricio Rodrigues Lima, and Cleyton Magalhães* ..... 61:1–61:12

Can Agents Reconstruct Microservice Architecture?
*Venla Liljas, Matteo Esposito, Valentina Lenarduzzi, and Davide Taibi* ..... 62:1–62:13

A Direction-Aware Study of LLM-Based Code Translation Across Eight Programming Languages
*Quanhe Wang, Xiangyun Zhan, Cheng Wen, Bin Yu, Ping Chen, Xingjian Han, and Shengchao Qin* ..... 63:1–63:14

Software Supply Chains Are Dead: Use-Case-Oriented Regeneration
*Tanmay Singla and James C. Davis* ..... 64:1–64:14

Towards Competence-Based Management for Open Source Software Projects
*Sabahat Younas, Márcia Moraes, and Fabio Santos* ..... 65:1–65:15

Does Gamification Improve Video-Based Soft Skills Training of Software Engineering Professionals?
*Pasan Peiris, Matthias Galster, Antonija Mitrovic, Sanna Malinen, Raul Vincent Lumapas, and Jay Holland* ..... 66:1–66:14

Does Working with AI Agents Change How Developers Code, Test, and Review?
*Muhammad Hamza, Dominik Siemon, and Wardah Naeem Awan* ..... 67:1–67:13

`TerraRepair`: A Tool-Grounded LLM Agent for Infrastructure-As-Code Repair
*Minase Mekete Mengistu, Juri Di Rocco, Phuong T. Nguyen, and Davide Di Ruscio* ..... 68:1–68:14

Beyond Individual Prompting Efficiency: A Socio-Technical Perspective on Computational Efficiency in AI-Assisted Software Engineering
*Darja Smite, Viggo Tellefsen Wivestad, Gabrielle O'Brien, Italo Santos, Giuseppe Destefanis, Maria Teresa Baldassarre, Mircea Lungu, Elda Paja, and Ronnie de Souza Santos* ..... 69:1–69:14

Which Neurons Detect Malicious Code? A Probing Study of LLM Security Knowledge
*Lam D. Dao, Vang T. Nguyen, Anh M. T. Bui, and Phuong T. Nguyen* ..... 70:1–70:14

Prompts Blend Requirements and Solutions: From Intent to Implementation
*Shalini Chakraborty and Jan-Philipp Steghöfer* ..... 71:1–71:14

Ethical Requirements for Healthcare AI Software Systems: Emerging Results from a Multi-Stakeholder Interview Study
*Yutan Huang, Chetan Arora, Tanjila Kanij, Anuradha Madugalla, and John Grundy* ..... 72:1–72:14

When Work Relations Matter: A Vision of Forgiveness in Software Testing
*Mary Sánchez-Gordón, Ricardo Colomo-Palacios, and Rahul Mohanani* ..... 73:1–73:6

Do Large-Scale Agile Frameworks Encode Socio-Technical Resilience?
*Chukwudi Uwasomba, Helen Sharp, Tamara Lopez, Michel Wermelinger, Advait Deshpande, and Peggy Gregory* ..... 74:1–74:6

AI-to-AI Code Reviews of GitHub Pull Requests
*Niruthiha Selvanayagam and Taher A. Ghaleb* ..... 75:1–75:15

Do LLMs Understand Validity? An Empirical Study of Machine-Generated Threats to Validity in Software Engineering
*Ryan Dang, Noshin Tahsin, and Thomas Zimmermann* ..... 76:1–76:14

APCA in the Loop: An Empirical Study of In-Loop Patch Correctness Assessment for APR
*Sahand Moslemi Yengejeh and Anil Koyuncu* ..... 77:1–77:15

CWEFT: CWE-Aware Evaluation of Free-Text vs. Typed Prompts
*Lanaya A. Carbonell and Anıl Koyuncu* ..... 78:1–78:14

Toward Entanglement Dependence Metrics for Quantum Software Complexity
*Haibo Yu and Jianjun Zhao* ..... 79:1–79:13

## Software Engineering in Practice Track

CoEvolve: Feedback-Driven Policy-Harness Maintenance for Industrial LLM Auditing Systems
*Yiyang Peng, Gang Lv, Yifeng Gou, Qizhao Wang, Bo Zhang, Ming Zhang, Qing Xu, Xiaosong Ding, Yu Shen, Yusang Xiong, Xinyao Xiao, and Xinyu Liu* ..... 80:1–80:18

A Nightly Feedback-Driven Strategy for Quality Control in Safety-Critical Software Development
*Simin Sun, Peter Nemeth, Staffan Johansson, Theo Wiik, David Friberg, Farnaz Fotrousi, and Miroslaw Staron* ..... 81:1–81:20

Can LLMs Identify Missing Elements in Requirements Elicitation? An Empirical Evaluation Using Production-Derived User Stories in an Industry Setting
*Vinay Kabadi, Abhiram Wuntakal, Naresh Gutha, Lahiri Bellarykar, Xuan Bach D. Le, Patanamon Thongtanunam, and Christoph Treude* ..... 82:1–82:20

ARIA – An Agentic Framework for Autonomous Testing of Infotainment Systems
*António Azevedo, Bruno Lima, and João Pascoal Faria* ..... 83:1–83:20

Specification Artifacts in Open-Source Pull Request Workflows Do Not Reduce Defects: An Empirical Test of Spec-Driven Development Claims
*Brenn Hill* ..... 84:1–84:20

Why Industry Migrates and When It Trusts LLMs: A Practitioner Survey on LLM-Assisted Software Migration
*Sivajeet Chand, Gedeon Lenz, Patrick Funke, Derui Zhu, and Alexander Pretschner* ..... 85:1–85:21

CORA: Config Risk Analyzer – Predicting Risk of Configuration Changes at Scale
*Weiyan Sun, Audris Mockus, Brian Ellis, Jun Ge, Madigan Kim, Sahil Kumar, Gursharan Singh, Matt Steiner, Siri Uppalapati, and Nachiappan Nagappan* ..... 86:1–86:22

AI Ethics to Requirements Practice: Building and Evaluating the HealthAI Ethics Assistant
*Yutan Huang, Jingfan Chen, Fanyu Wang, Chetan Arora, John Grundy, and Cheng Zhang* ..... 87:1–87:13

Local LLMs for End-To-End Testing in Practice: Lessons from a Smart City Web Application
*Fabio Moretti, Simone Ronzoni, Patrizia Scandurra, and Vincenzo Scotti* ..... 88:1–88:21

Trust-Calibrated Code Review: A Participatory Design Study of Review Workflows for LLM-Generated Multi-File Changes
*Lo Gullstrand Heander, Agnia Sergeyuk, Ilya Zakharov, Emma Söderberg, and Nikita Mukhortov* ..... 89:1–89:21

When Review Alone No Longer Scales: Layered Supervision in AI-Assisted Software Engineering
*Markus Stolze and Mirco Strässle* ..... 90:1–90:12

Faster Than the Team, Faster Than the Customer: Tool Integration, Collaboration, and Organisational Lag in AI-Assisted RE
*Jan-Philipp Steghöfer* ..... 91:1–91:20

AI-Enabling Requirements: An Industrial Experience Report from a Data-Driven Recruitment System
*Sylwia Kopczyńska, Mirosław Ochodek, Eryk Kosmala, Jędrzej Musiał, Rafał Mroziewski, and Dominik Nitychoruk* ..... 92:1–92:13

A Preliminary Analysis of the Impact of AI Assisted/Generated Code on Quality, Centrality and Review Time at Scale
*Audris Mockus, Peter C. Rigby, Don Stewart, Chandra Maddila, and Nachiappan Nagappan* ..... 93:1–93:23

Operationalizing the EU AI Act in Agile Software Development: A Guideline-Based Approach
*Dennis Schrader, Eva-Maria Schön, Henning Fritzemeier, and Michael Neumann* ..... 94:1–94:21

Evaluating LLM-Based Test Generation for a Large Industrial C++ Database System. A Case Study on SAP HANA
*Vekil Bekmyradov, Thomas Bach, Alexander Berndt, Noah C. Puetz, Bartosz Bogacz, and Thomas Bartz-Beielstein* ..... 95:1–95:20

# Preface

For two decades now, the International Symposium on Empirical Software Engineering and Measurement (ESEM) has been the premier venue for publishing and discussing original work in empirical software engineering and measurement. Traditionally, the conference forms part of the Empirical Software Engineering International Week (ESEIW) that features several events, such as tutorials, a doctoral school, the industry day, and the annual meeting of the International Software Engineering Research Network. The conference's 20th edition, held in Munich, Germany, on October 8–9, 2026, is a milestone in more than one sense. It marks two decades of a symposium that has shaped how our community gathers, reports, and scrutinizes empirical evidence, and it is the edition in which ESEM's long-standing commitment to open science becomes the default.

Beginning with this edition, ESEM is transitioning to the Leibniz International Proceedings in Informatics (LIPIcs) to further align with its open science principles and ensure free and unrestricted access to all conference papers, regardless of authors' affiliations. This step builds on more than a decade of open science trials pioneered by the ESEM community, which also culminated in the SIGSOFT open science policies. With this edition, ESEM goes one step further: it is open by default, fostering a mandatory open science policy. Every submission had to include a dedicated Data Availability section describing the availability of the research artifacts associated with the paper. Artifacts had to be disclosed using a permanent identifier or a stable repository link, or a reasonable justification had to be provided when non-disclosure agreements or other legal or ethical restrictions prevented full disclosure. This was not a formality: submissions omitting the section were desk-rejected, and those with insufficient disclosure were rejected during review. Through these policies, we strengthen transparency, reproducibility, and replicability in software engineering research. This year's ESEM edition also drew an unprecedented response with a record number of contributions. Across its six tracks, we received 484 submissions, of which 127 were accepted.

- Technical Track: **51** out of **268** submissions (19%)
- Emerging Results, Vision, and Reflection: **28** out of **119** submissions (24%)
- Software Engineering in Practice: **16** out of **57** submissions (28%)

In addition, the Registered Reports Track (**18** submissions), IDoESE Doctoral Symposium (**7** submissions), and the Journal First track (**15** submissions) admitted eligible contributions following their respective nomination and mentoring processes. A volume of this size rests on a great deal of careful and largely invisible work. Our first thanks go to the authors, who entrusted their work to ESEM, and to the program committee members and external reviewers across all tracks, who spent their time providing substantive, constructive assessments. Without their contributions, this volume would simply not exist. We are equally grateful to our fellow track chairs, who meticulously organized and directed the paper selection process and track programs. Our thanks also go to the LIPIcs editorial office for guiding us through this transition, and to the entire organizing committee, whose efforts made this edition possible. Finally, we thank everyone who takes part in ESEM 2026 in Munich, especially our student volunteers. The discussions at the event are what truly make ESEM a community.

**Daniel Mendez** and **Stefan Wagner**, General Co-Chairs
**Robert Feldt** and **Maria Paasivaara**, Technical Track Co-Chairs
**Marvin Muñoz Barón**, Proceedings Chair

20th International Symposium on Empirical Software Engineering and Measurement (ESEM 2026).
Editors: Robert Feldt, Maria Paasivaara, Daniel Mendez, Stefan Wagner, and Marvin Muñoz Barón
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

## Organizing Committee

- **Daniel Mendez** and **Stefan Wagner**, General Co-Chairs
- **Justus Bogner** and **Daniel Graziotin**, Open-Science Co-Chairs
- **Tayana Conte**, **Riccardo Coppola**, and **Hideaki Hata**, Publicity Co-Chairs
- **Marvin Muñoz Barón**, Proceedings Chair
- **Andreas Bauer**, Web Chair
- **Michael Dorner**, Financial Chair
- **Alexander Serebrenik**, Review Quality Chair

## Track Chairs

- **Robert Feldt** and **Maria Paasivaara**, Technical Track Co-Chairs
- **Zadia Codabux** and **Paolo Tell**, Emerging Results, Vision, and Reflection Papers Co-Chairs
- **Sebastian Baltes** and **Markus Borg**, Software Engineering in Practice Co-Chairs
- **Bianca Trinkenreich** and **Marvin Wyrich**, Registered Reports Co-Chairs
- **Claudia Ayala** and **Grischa Liebel**, IDoESE Doctoral Symposium Co-Chairs
- **Marcos Kalinowski** and **Viktoria Stray**, Journal First Co-Chairs

# List of Authors

Muhammad Auwal Abubakar (54)
University of Bamberg, Germany

Benjamin Agyekum (50)
Department of Electrical Engineering, Colorado State University, Fort Collins, CO, USA

Shibbir Ahmed (35)
Texas State University, San Marcos, TX, USA

Ebtesam Al-Haque (3)
Department of Computer Science, George Mason University, Fairfax, VA, USA

Omar Alam (48)
Trent University, Peterborough, ON, Canada

Michel Albonico (4)
Centre for Software Technology, University of Southern Denmark (SDU), Vejle, Denmark; Federal University of Technology, Paraná (UTFPR), Francisco Beltrão, Brazil

Negar Alizadeh (42)
Utrecht University, Utrecht, The Netherlands

Atu Ambala (40)
Colorado State University, Fort Collins, CO, US

Maximilian Alexander Amougou Mbida (58)
Technical University of Munich, Germany

Alessandro Aneggi (30)
Free University of Bozen-Bolzano, Bolzano, Italy

Florian Angermeir (58)
fortiss, Germany; Blekinge Institute of Technology, Sweden

Hina Anwar (29, 34)
University of Tartu, Estonia

Sven Apel (52)
Saarland University, Saarbrücken, Germany

Hera Arif (10)
Dalhousie University, Halifax, Canada

Chetan Arora (72, 87)
Monash University, Melbourne, Australia

Wesley K. G. Assunção (41)
North Carolina State University, Raleigh, NC, USA

Hamza Attarwala (48)
Polytechnique Montréal, Montréal, QC, Canada

Wardah Naeem Awan (67)
Department of Software Engineering, LUT University, Lahti, Finland

Ragib Shahariar Ayon (35)
Texas State University, San Marcos, TX, USA

António Azevedo (83)
Critical Techworks, Porto, Portugal; Faculty of Engineering, University of Porto, Portugal

Xuan Bach D. Le (82)
School of Computing and Information Systems, The University of Melbourne, Australia

Thomas Bach (95)
SAP, Walldorf, Germany

Maria Teresa Baldassarre (6, 69)
University of Bari, Italy

Sebastian Baltes (54)
Heidelberg University, Germany

Enrique Barba Roque (22)
Delft University of Technology, Delft, The Netherlands

Eduardo Barros (39)
Federal University of Alagoas, Maceió, Brazil

Luisa Bartl (52)
Chemnitz University of Technology, Germany

Thomas Bartz-Beielstein (95)
TH Köln, Gummersbach, Germany

Vekil Bekmyradov (95)
TH Köln, Gummersbach, Germany

Ahmed Belhouchette (26)
ENSI, Manouba University, Tunisia

Lahiri Bellarykar (82)
Industry Practitioner, Australia

Boualem Benatallah (23)
School of Computing, Dublin City University, Ireland; Rinn AI Research Ireland Centre on AI and Data Science, Dublin, Ireland

Alexander Berndt (95)
Heidelberg University, Heidelberg, Germany

Mehmet Besenk (5)
Technical University of Munich, Munich, Germany

20th International Symposium on Empirical Software Engineering and Measurement (ESEM 2026).
Editors: Robert Feldt, Maria Paasivaara, Daniel Mendez, Stefan Wagner, and Marvin Muñoz Barón
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Ali Bigdeli (40)
Colorado State University, Fort Collins, CO, US

Sumon Biswas (35)
Case Western Reserve University, Cleveland, OH, USA

Bartosz Bogacz (95)
SAP, Walldorf, Germany

# CognixShield: PoV-Guided Vulnerable API Usage Detection in Large Codebases via LLMs

**Quanzhi Fu**[1]

## Abstract

**Background.** The integration of open-source libraries in Java development introduces severe security risks through vulnerable APIs. Existing program analysis and deep learning tools face challenges in capturing inter-procedural vulnerability semantics at scale. While LLMs show promise for semantic reasoning, they cannot handle large codebases due to context limits, and they lack the vulnerability-specific understanding needed to determine exploitability.

**Aim.** This work aims to overcome these limitations and enable LLM-based detection of vulnerable API usage in large-scale Java applications.

**Method.** We present CognixShield, an LLM-powered framework for detecting vulnerable API usage through three core components. First, semantic-preserving AST-based fragmentation partitions large codebases while maintaining syntactic completeness within LLM context windows. Second, vulnerability-aware multi-agent RAG traces relevant program context across these fragments, iteratively assembling security-critical context spanning functions and files. Third, PoV-guided semantic reasoning uses Proof-of-Vulnerability tests that encode precise triggering conditions and exploitation mechanics to determine vulnerability.

**Results.** CognixShield achieves 84% precision, 95% recall, 84% accuracy, and an 89% F1-score on 57 real-world Java applications, outperforming state-of-the-art tools.

**Conclusions.** Our results show that vulnerability detection requires specialized architectural innovations beyond generic LLM applications.

**2012 ACM Subject Classification** Security and privacy → Software security engineering

**Keywords and phrases** Vulnerable API usage detection, program analysis, LLMs, agentic RAG

## 1 Introduction

Developers rely on many open-source libraries (Lib) and their application programming interface (API) to accelerate development. However, APIs that contain vulnerabilities can be exploited by hackers, turning widely used libraries into powerful attack vectors [51]. Attackers can introduce or discover exploitable vulnerabilities in Libs through (1) contributing flawed code to open-source projects, (2) inspecting library implementation, or (3) consulting publicly available vulnerability databases like Common Vulnerabilities and Exposures (CVE) [55]. By crafting malicious inputs and propagating them from Apps to **vulnerable APIs**, attackers can compromise Applications (Apps) as long as the underlying Libs accept such inputs. The Open Web Application Security Project (OWASP) ranked "software supply chain failures" as the third most critical security risk in 2025 [3].

To mitigate these security risks, existing software composition analysis (SCA) tools [40, 54, 27, 45, 1, 4] identify Apps affected by vulnerable API usage via scanning code bases for (1) dependencies on vulnerable Lib versions and/or (2) calling vulnerable APIs in Libs. However, these tools suffer from low accuracy for two reasons. First, dependency-based analysis is overly coarse-grained and lacks context: an App may depend on a Lib that contains vulnerable APIs, yet never invokes those methods and therefore remains unaffected. As noted previously, "*SCA without context generates too many false positives, this results in your team wasting time chasing ghosts* [39]". Second, SCA tools overestimate feasible attack paths at scale due to imprecise code semantic reasoning. VAScanner [54], for example, flags a vulnerability whenever a vulnerable API invocation is reachable along an approximate call chain, without verifying whether the usage is actually exploitable in the calling context.

Large Language Models (LLMs) have emerged as a promising alternative solution for vulnerability detection [57, 49]. They offer semantic reasoning over code [15] and can be guided through prompt engineering without large labeled datasets. Nevertheless, applying LLMs to detect vulnerable API usage in Apps has two challenges: ***Challenge 1: Maintaining inter-procedural context.*** LLMs struggle to track repository-level context across deep function hierarchies [32]. Since vulnerable API usage frequently spans multiple files connected by complex call chains, accurate detection requires preserving inter-procedural context. ***Challenge 2: Reasoning about vulnerability-specific semantics.*** Trained on general-purpose corpora, LLMs lack the specialized security knowledge needed to reason about vulnerable API usage. Without vulnerability-oriented guidance, they misinterpret program semantics and produce unreliable detections.

In this paper, we introduce CognixShield, a high-accuracy framework for detecting vulnerable API usage in Apps using LLMs. Given a vulnerable API from an upstream Lib and an App's source code, CognixShield determines whether the API is exploitable from a public entry point in the app. CognixShield combines program analysis with LLM-based reasoning through two key designs. To maintain repo-level program context (***Challenge 1***), we design a multi-agent pipeline in which specialized LLM agents iteratively retrieve missing security-critical context from AST-aligned code blocks and progressively assemble code fragments across functions/ files until the program context from vulnerable API invocation to public entry points is captured. To guide vulnerability-specific semantic reasoning (***Challenge 2***), we leverage Proof-of-Vulnerability (PoV) tests from upstream Libs. PoV tests encode precise triggering conditions, exploitation mechanics, and observable impacts. CognixShield extracts these semantics from PoV tests and applies them to the repository-level context to determine whether the vulnerability is reachable and exploitable from public entry points.

We evaluate CognixShield on 57 real-world Java projects to assess its detection effectiveness. CognixShield achieves a precision of 84%, a recall of 95%, an F1-score of 89%, and an accuracy of 84%. Compared with five state-of-the-art (SOTA) tools, two based on program analysis (Eclipse Steady [40] and VAScanner [54]), two DL-based approaches (DeepDFA [45] and LineVul [19]), and one LLM-agent based approach (Codex [36]), CognixShield demonstrates substantial improvements, achieving at least 18%, 210%, 123%, and 100% higher performance, respectively, across four evaluation metrics. To assess robustness, we further evaluate CognixShield varying configurations of embedding models, LLMs, and code fragmentation granularities. Across these settings, CognixShield maintains better performance against SOTAs, with F1 scores ranging from 64% to 89% and accuracy between 58% and 84%, demonstrating effectiveness across different models and code fragment sizes.

Our research contributions are summarized as follows:

- We propose CognixShield, an LLM-powered approach for vulnerable API usage detection in large-scale real-world applications, which overcomes LLMs' context window limitations through an agent-based RAG that iteratively retrieves inter-procedural code fragments across multiple files.
- We evaluated CognixShield on 57 real-world Java projects, demonstrating that it outperforms five SOTA tools across all metrics.
- We conducted an extensive evaluation of different large language models (LLMs) and embedding models for vulnerability detection in code segments of varying lengths. We observed that for vulnerability detection, with OpenAI embeddings and Claude-3.5-Sonnet, consistently demonstrated higher performance compared to other tested models across all metrics.

Our code and dataset is available at: `https://github.com/ying-selab/CognixShield`.

## 2 Background and Motivation Example

In this section, we first present a motivating example that illustrates the challenges of accurately detecting vulnerable API usages in large-scale software projects. We then provide the background on our system design.

### 2.1 Motivation Example

We use a concrete example to illustrate how the same vulnerable API can be exploitable in one application but not in another. Consider a vulnerability analyst, Alex, who is assigned to audit two large software applications, Apache Kylin [9] and Alibaba Nacos [7], for potential risks caused by a CVE-2020-5408. CVE-2020-5408 reveals a crypto failure in versions 4.2.x prior to 4.2.16. Specifically, the `BCryptPasswordEncoder.encode` method throws an `NullPointerException` when given a `null` input. This vulnerability was later patched in version 5.4.0-M1 by properly handling null inputs with an `IllegalArgumentException` as shown in Listing 1.

**Listing 1** Simplified Fix Commit for CVE-2020-5408 [44].

```
public String encode(CharSequence rawPassword) {
+ if (rawPassword == null) {
+   throw new IllegalArgumentException("rawPassword + cannot be null");}
                ...
  return BCrypt.hashpw(rawPassword.toString(), salt);}

//unit test for NPE
+ @Test(expected = IllegalArgumentException.class)
+ public void encodeNullRawPassword() {
+    BCryptPasswordEncoder encoder = new BCryptPasswordEncoder();
+    encoder.encode(null); }
```

Both Apache Kylin and Alibaba Nacos depend on the vulnerable library version and contain large codebases with over 5,000 source files and 500K lines of code. Alex needs to determine whether either application is actually exploitable due to this vulnerable API usage. As shown in Listing 2, Nacos invokes `BCryptPasswordEncoder.encode` within `PasswordEncoderUtil.encode` without a null check (line 11), so an untrusted `null` can propagate through `createUser` (line 4) and trigger an application crash, enabling denial-of-service attacks. Conversely, as shown in Listing 2, Apache Kylin [9] validates all passwords via `checkPasswordLength` before encoding, ensuring null cannot reach the vulnerable API. Thus, despite using the same vulnerable library, Kylin is not exploitable.

**Listing 2** Usage of `BCryptPasswordEncoder.encode`: (a) vulnerable usage in Nacos [7] – `null` propagates unchecked to the API; (b) secure usage in Kylin [10] – `checkPasswordLength` rejects `null` before encoding.

**(a)** Nacos (vulnerable).

```
1 public Object createUser(String username,
  ↪  String password) {
2   ...
3   userDetailsService.createUser(username,
4   PasswordEncoderUtil.encode(password));
5   return RestResultUtils.success("create user
    ↪  ok!");
6 }
7
8 public class PasswordEncoderUtil {
9   ...
10  public static String encode(String raw) {
11    return new
      ↪  BCryptPasswordEncoder().encode(raw);}
12 }
```

**(b)** Kylin (secure).

```
1 public EnvelopeResponse save(
2     @RequestBody PasswdChangeRequest user) {
3   ...
4   checkNewPwdRule(user.getNewPassword());
5   if (existing != null) {
6     existing.setPassword(
7       pwdEncode(user.getNewPassword())); }}
8
9 private void checkNewPwdRule(String newPwd) {
10  if (!checkPasswordLength(newPwd)) {...} }
11
12 private boolean checkPasswordLength(String
   ↪  password) {
13  return !(password == null
14        || password.length() < 8); }
```

Given the scale of these projects, manual code review is impractical, so Alex must rely on automated tools. Programming analysis tools [40, 2] encounter scalability challenges to accurately report vulnerable API usage. DL-based approaches [19, 45] may not fully capture vulnerable API usage in Nacos, or overlook safeguard checks in Kylin.

While LLMs provide enhanced semantic reasoning capabilities, applying them directly to large-scale applications faces similar limitations. Their finite context window makes it impractical to analyze entire large codebases [15]. In our preliminary experiments (detailed in Section 5.3), we found that the majority of real-world projects in our dataset exceed the context limits of the tested LLMs. Without an effective mechanism to selectively capture code relevant to vulnerable API usages and guidance for vulnerability-specific semantic reasoning, repo-wide analysis remains infeasible.

## 2.2 Retrieval-Augmented Generation

RAG [26] is a widely used framework that combines information retrieval with LLMs. A typical RAG architecture consists of a retriever and a generator: RETRIEVER searches an external knowledge source and the GENERATOR integrates the retrieved information into its prompt to produce a more context-aware response. The general workflow involves: (1) embedding the knowledge base into a searchable index [34, 48], (2) generating a query from the task prompt, (3) retrieving relevant entries, and (4) augmenting the prompt with these retrieved results before final response generation. An LLM agent is an autonomous system built on top of the LLM (e.g., GPT-4o [35], Claude [8]). When combined with RAG, such agents form agentic RAG [42], where the model dynamically refines its retrieval queries based on partial context (e.g., reasoning about what information is missing) and performs multiple retrieval iterations.

# 3 Methodology

## 3.1 Overview

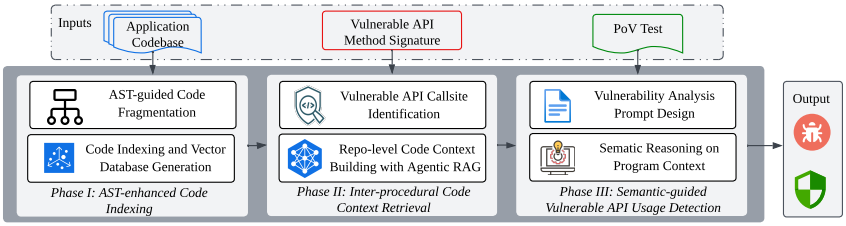

**Figure 1** The Overview of CognixShield.

The overall workflow of CognixShield is depicted in Figure 1. Given an application that depends on a vulnerable library version, the corresponding vulnerable API, and an available PoV patch, CognixShield analyzes whether the application context can make that API usage exploitable. The workflow is organized around the two challenges in the introduction: Phase I maintains inter-procedural context for Challenge 1, and Phase II applies vulnerability-specific semantic reasoning for Challenge 2.

*Phase I: maintaining inter-procedural context.* CognixShield first parses the application source code with AST-guided structural segmentation, partitions the repository into semantically self-contained code blocks, and stores each block with its metadata and code embedding. This AST-enhanced code indexing makes repository-scale code searchable while preserving method, class, and file boundaries needed to recover caller/callee relationships around vulnerable library API invocations. Starting from each vulnerable API query, CognixShield then drives an Agentic RAG loop that iteratively retrieves and filters security-relevant program context, assembling sufficient repo-level inter-procedural context for the downstream exploitability decision (Section 3.2.2).

*Phase II: reasoning about vulnerability-specific semantics.* Given the retrieved inter-procedural context and the PoV patch, CognixShield extracts PoV-derived vulnerability semantics, including trigger conditions, patch constraints, exploit mechanics, and observable impact. It then checks whether those conditions can propagate from public entry points through application data and control flows to the vulnerable API invocation. The output is an application-level decision that distinguishes exploitable vulnerable API usages from safe usages of the same library API.

## 3.2 Phase I: Maintaining Repo-level Inter-procedural Context

### 3.2.1 AST-enhanced Code Indexing

Phase I addresses Challenge 1 by turning the application repository into a searchable context index for vulnerable API usage analysis. A local invocation of a vulnerable library API rarely carries all the information needed to judge whether the usage is safe: the relevant caller, helper callee, field definition, object construction site, or guarding check often lives in another file, and the security-relevant data and control constraints span the structural units that the source code already exposes. The index must therefore preserve these program-defined units so that callers, callees, cross-file definitions, and data/control constraints remain reconnectable during retrieval. CognixShield builds the index from the program's AST rather than

flattening the repository into arbitrary token chunks. The root node (`compilationUnit`[1]) corresponds to a source file, and each child node denotes a syntactic element such as a class, method, or statement. Each node contains metadata, including node type and source code location, and hierarchical relationships. Parent nodes structurally encompass their children; for example, a `classDeclaration` node encapsulates modifiers, fields, methods, constructors, and other elements defined at the class level within the class body.

To preserve semantically self-contained and contextually relevant code blocks, we leverage the AST to guide code partitioning. We convert the application source code into an AST forest as $G = \{g_1, g_2, \ldots, g_n\}$, where each $g_i$ corresponds to a `compilationUnit`. To obtain contextually relevant code blocks, we perform top-down, structure-guided fragmentation on each compilation unit. If a compilation unit is smaller than the predefined threshold $\theta$, it is preserved as a whole. Otherwise, oversized nodes are recursively divided into child-nodes. Recursion stops when a node falls below $\theta$ or reaches a leaf with no further structural decomposition. For instance, a `compilationUnit` can be fragmented as `ImportDeclaration` and `classDeclaration`. This AST-guided structural segmentation keeps repository code aligned with source-level method, class, and file boundaries, so later retrieval can reconnect vulnerable API invocations with surrounding caller/callee paths and security-relevant data/control constraints.

Following the AST-enhanced code segmentation, CognixShield converts each code block $b_i$ in $B = \{b_1, b_2, \ldots, b_m\}$ into a fixed-length dense vector representation using pre-trained encoders. These embeddings capture the semantics and functionality of the fragments, positioning semantically similar blocks closer together in the vector space, even if their syntactic forms differ. For instance, the following two snippets perform the same task of summing elements despite having different token sequences:

```
a) for (int i = 0; i < n; i++)  sum += arr[i];
b) total = Arrays.stream(list).sum();
```

Although these snippets use different tokens and syntax, once embedded, they yield a high similarity score because they perform the same functionality. Within Phase I, these embeddings serve as retrieval keys rather than standalone predictions. CognixShield therefore stores all processed data in a database $D = \{d_1, d_2, \ldots, d_m\}$, where each entry $d_i = (b_i, v_i)$ consists of the original code block $b_i$, which includes the source snippet and associated metadata , and its corresponding vector embedding $v_i$. This database becomes the searchable substrate for the subsequent Phase I context-retrieval step, where semantically related fragments are assembled into sufficient repo-level inter-procedural context before Phase II performs vulnerability-specific semantic reasoning.

### 3.2.2 Agentic RAG for Inter-procedural Context Retrieval

To address Challenge 1 for context retrieval, CognixShield assembles the required inter-procedural context through an Agentic RAG framework built on LLM-based reflection [11], consisting of two collaborating LLM-based agents: a *Reflector* and a *Grader*. At each iteration, the *Reflector* reasons about missing caller/callee, data-construction, validation, or control-flow links and formulates focused embedding queries against the AST-enhanced vector database $D$ described above, while the *Grader* retains only fragments with semantic relevance to the vulnerable API usage.

[1] We use the terms defined in Tree-sitter [12] for ease of understanding.

The loop iterates over a set of candidate vulnerable API invocation sites. Given a vulnerable library API ($API_{vul}$), CognixShield first locates its invocation sites in the application by matching the method signature $API_{vul}$, forming the initial statement-level candidates $C_{candidate} = \{c_1, c_2, \ldots, c_n\}$.

Given these candidates, the *Reflector* and *Grader* interact as follows:

- *Self-Reflection:* For each candidate $c_i \in C_{candidate}$, the *Reflector* evaluates whether the current fragment set provides sufficient inter-procedural context for analyzing the vulnerable API usage. It issues the reflection query $Q(c_i, API_{vul}) \rightarrow (\{\texttt{Complete|Incomplete}\}, \text{reason})$. A `Complete` response indicates that the current fragments contain the relevant elements needed for the Phase II Expert agent to reason about the invocation path, while an `Incomplete` response explains which related code is missing and guides subsequent inference. The missing link may be a caller, callee, public entry point, object construction statement, validation check, or control-flow constraint. For example, the *Reflector* examines candidate snippet (a) in Figure 2, where the vulnerable API `pwdEncoder.encode()` is invoked inside a private method. This fragment alone lacks sufficient context because it does not show how the password value is constructed or guarded before the call; the *Reflector* therefore returns an `Incomplete` verdict naming the missing caller, data-construction, and validation links.
- *Code-inference & Retrieval:* When the context is `Incomplete`, the *Reflector* formulates a focused retrieval query for the missing element identified by the reflection verdict. The query takes the form of an inferred code sketch that approximates the missing element's expected signature and surrounding scope. As shown in pseudo-code (b), the *Reflector* sketches how `pwdEncode()` may be invoked by its callers and whether the `password` parameter is checked for null before reaching `pwdEncoder.encode()`. This inferred information drives an embedding-based search over the repository vector database $D$, allowing CognixShield to retrieve AST-aligned fragments from across the repository.
- *Grading*: The *Grader* evaluates the raw retrieval results at the source level and verifies their semantic relevance to the vulnerable API usage. A retained snippet must extend the security-relevant inter-procedural chain, for example by establishing a caller/callee relationship, defining data passed into the API, implementing a validation check, or constraining the control path to the invocation. Snippets that share lexical similarity but do not affect the vulnerable API usage are filtered out. Validated snippets are merged into the candidate set: $C_{candidate_i} = C_{candidate_i} \cup C_{validated}$. This step mitigates false positives that embedding similarity alone may introduce.

The process repeats until the *Reflector* judges that the current fragment set provides sufficient inter-procedural context for vulnerability reasoning, or until retrieval produces no additional non-duplicated validated fragments. The process is shown at Algorithm 1.

## 3.3 PoV-guided Vulnerable API Usage Detection

To address Challenge 2, CognixShield performs vulnerability-specific semantic reasoning over the inter-procedural context assembled in Phase I. After retrieving the sufficient inter-procedural context, we introduce an *Expert* agent that applies PoV-derived vulnerability semantics to that context. The *Expert* receives a structured system prompt and standardized inputs/outputs to ensure reliable reasoning.

The system prompt is specifically designed to enable context-aware detection of vulnerable API usage. Unlike generic prompts that merely classify code as vulnerable or secure, our prompt instructs a two-stage reasoning process: (i) **PoV-derived vulnerability semantics extraction**, where the model extracts trigger conditions, patch constraints, exploit mechanics,

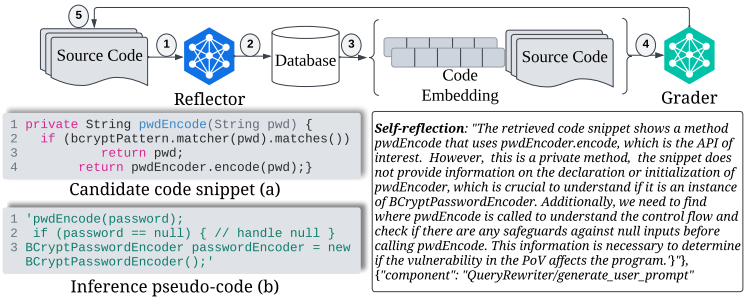

**Figure 2** Interaction process between *Reflector* and *Grader* agents on an exemplar candidate for the `BCryptPasswordEncoder.encode()` in Apache Kylin.

**Algorithm 1** Iterative Phase-I Inter-procedural Context Retrieval.

**Require:** $C_{candidates} = \{c_1, c_2, \ldots, c_n\}$, $API_{vul}$
**Auxiliary Functions:**
`Search(code, scope)` $\rightarrow C$: Search for similar code based on embeddings
`Reflector_evaluate(`$C$, $API_{vul}$`)` $\rightarrow$ (hasSufficientContext, missingContext): Determines whether $C$ provides sufficient inter-procedural context for analyzing $API_{vul}$
`Grader_filter(`$C_{raw}$`, context)` $\rightarrow C_{filtered}$: Filters out irrelevant snippets from raw search results based on context relevance
`Reflector_Inf(missingContext)` $\rightarrow (c_{missing}, scope)$: Generates missing code snippet and structural constraints

**for** each $c_i \in C_{candidates}$ **do**
  $C' \leftarrow \{c_i\}$
  $(hasSufficientContext, missingContext) \leftarrow$ `Reflector_evaluate`$(C', API_{vul})$
  **while** not $hasSufficientContext$ **do**
    $(c_{missing}, scope) \leftarrow$ `Reflector_Inf`$(missingContext)$
    $C'_{raw} \leftarrow$ `Search`$(c_{missing}, scope)$
    **if** $C'_{raw} == \emptyset$ **then**
      **break**
    **end if**
    $C'_{candidate} \leftarrow$ `Grader_filter`$(C'_{raw}, C' \cup \{API_{vul}\})$
    **if** $C'_{candidate} == \emptyset$ **then**
      **break**
    **end if**
    $C' \leftarrow C' \cup C'_{candidate}$
    $C_{candidates} \leftarrow C_{candidates} \cup C'_{candidate}$
    $(hasSufficientContext, missingContext) \leftarrow$ `Reflector_evaluate`$(C', API_{vul})$
  **end while**
**end for**

and observable impact from the provided PoV; and (ii) **semantic propagation analysis**, where multiple related code fragments are analyzed collectively to deduce cross-method path or data constraints, determining whether the exploit condition can propagate to the vulnerable API invocation. For each candidate $c_i$ in the set $C_i = \{c_1, c_2, \ldots, c_n\}$ from Phase I, we construct a *task-specific* guidance prompt to the *Expert*:

***Vulnerable API Usage Analysis Prompt***

*You are an expert in Java vulnerability analysis. Your task is to determine if a project is affected by a library vulnerability. Given a project, a vulnerable API, and a library PoV, analyze whether the complete snippet set is affected by the vulnerable API Usage.*
`Vulnerable API:`
`Library POV:`
`Related code snippet:` ...

Given this structured input, the *Expert* executes the two stages above and produces an interpretable vulnerability detection result. For instance, based on the code example in the Kylin project (Section 2.1), CognixShield analyzes whether variables `pwd` and calls to `pwdEncoder.encode(pwd)` can result in a null value reaching the vulnerable API `BCryptPassword`

`Encoder.encode()`, as described in the PoV. The *Expert* generates conclusions such as: *"The code has multiple safeguards preventing null passwords from reaching the encoder."*, and the project is not vulnerable to the API usage.

Building on this analysis, CognixShield evaluates each candidate $c_i$ independently using its corresponding prompt $Q_i$, and the LLM returns a binary decision: 1 (vulnerable) or 0 (secure). The application is classified as vulnerable if any candidate query is identified as exploitable; it is classified as secure only when all candidates are assessed as non-exploitable.

## 4 Implementation

In phase I, we employ the tree-sitter [12] to generate an AST representation of the codebase. Subsequently, our tool partition the codebase into code blocks via recursive AST decomposition with a $\theta = 2500$ token threshold, which are then serialized into a single JSON file. Each JSON object encapsulates essential metadata, including the filename, start line, end line, code snippet, and relevant contextual information. After fragmentation, each code block is embedded using the OpenAI text-embedding-3-small model [34], which is widely used in industry AI coding tools, while its metadata fields are preserved. We store the resulting embeddings and metadata in Qdrant [48], a vector database, using cosine distance and a similarity threshold of 0.35 for retrieval. Both the *Reflector* and *Grader* use GPT-4o with temperature 0 to minimize output randomness. We use Tai-e [47] to locate candidate invocation sites of $API_{vul}$ with the vulnerable API signature given as input, e.g., `com.alibaba.fastjson.JSON.parseObject` in the project's compiled bytecode to initialize the context retrieval; when the signature names an overloaded API, the sites of all overloads are included as candidates. In Phase II, the *Expert* agent is implemented as a GPT-4o-based LLM agent with temperature 0.

## 5 Evaluation

Our evaluation aims to answer the following Research Questions (RQs):

- **RQ1 (Effectiveness):** *How effectively does CognixShield identify vulnerable API usage in large projects?*
- **RQ2 (Component Contribution):** *How does each of CognixShield's three core components contribute to its effectiveness?*
- **RQ3 (Baseline Comparison):** *How well does CognixShield compare with SOTA solutions?*
- **RQ4(Robustness):** *How robust is CognixShield's vulnerability detection capability across different LLM-related configurations?*

**Datasets.** To evaluate our tool, we construct the evaluation dataset based on the following sources. The foundation of our dataset comes from Transfer [23], a third-party benchmark that provides paired Java projects and their vulnerable libraries. Due to compatibility issues in Transfer, many vulnerable libraries lack corresponding client projects. To enlarge the dataset, we search on GitHub using vulnerable library names as keywords and retrieve the top 100 Java projects for each vulnerable library. We then filter these projects based on vulnerable library version and actual API invocation. The resulting dataset includes 57 projects corresponding to 26 distinct vulnerabilities. To establish ground truth, two security experts independently analyze and cross-verify the exploitability of all projects in the dataset. Among them, 40 applications are confirmed to be vulnerable where PoV tests

"-" means that a tool does not report vulnerability of API usage for applications, so the related precision and F-score values cannot be calculated.

are successfully generated to demonstrate vulnerabilities caused by the vulnerable API usage in these applications. The remaining 17 projects are verified as unaffected. The complete project list and labels are provided in the replication package (see Data Availability). On average, each project contains 1,685 Java files and 193,541 lines of code.

**Metrics.** Following prior work [41], we use four metrics to evaluate CognixShield:

**Precision (P):** The ratio of correctly identified vulnerable projects to the total number of projects flagged as vulnerable by the tool. $P = \frac{\text{\# of correctly identified vulnerable projects}}{\text{Total \# of projects flagged as vulnerable}}$

**Recall (R):** The ratio of correctly identified vulnerable projects to the total number of actual vulnerable projects in the ground truth dataset.
$R = \frac{\text{\# of correctly identified vulnerable projects}}{\text{Total \# of vulnerable projects in ground truth}}$

***F1-score (F1)*** is the harmonic mean of precision and recall; it reflects the trade-off between precision and recall. $F1 = \frac{2 \times P \times R}{P+R}$

**Accuracy (A):** The ratio of correctly classified projects to the total number of projects in the ground truth dataset. $A = \frac{\text{\# of correctly classified projects}}{\text{Total \# of projects in ground truth}}$

## 5.1 RQ1 (Effectiveness of CognixShield)

We evaluate CognixShield on the 57 open-source Java projects using the same hyperparameters as Section 4. CognixShield analyzed 57 applications that invoke the vulnerable API and correctly classified 48 of them as shown in Table 1. Specifically, among the 40 projects confirmed to be vulnerable, CognixShield successfully identified vulnerabilities in 38 of them. For the 17 projects verified as secure, 10 were correctly classified as unaffected. Overall, CognixShield achieves a P of 84%, R of 95%, F1 of 89%, and A of 84%. We then manually inspected the running logs on the evaluated applications to understand the effectiveness of CognixShield. The nine incorrect detections fall into three categories:

1) *Incomplete context retrieval.* Oversized AST leaf nodes exceeded the fragment size limit, forcing semantic fragmentation that disrupted contextual reconstruction. Three false positives arose when large leaf nodes, like string literals, exceeded the token limit and could not fit within a single fragment. Since leaf nodes are syntactically atomic, CognixShield's hierarchical decomposition had to split them at arbitrary points, disrupting their semantic meaning. For instance, in Findbugs [14], a long statement in `branchOperations` was split mid-expression, preventing CognixShield from reconstructing the inter-procedural context. Such fragmentation makes it challenging for CognixShield to reconstruct the relevant context needed for accurate analysis.

2) *Relevant code fragments missed.* Large, security-critical code blocks were often missed because their embeddings were dissimilar to the retrieval query. Four failures (2 FPs, 2 FNs) resulted from embedding-based retrieval, missing large but relevant code blocks. For

example, in the Badlion project [24], the 40-50 LOC `URIUtils` class containing the vulnerable API fell below the similarity threshold. Instead, CognixShield retrieved the API's library implementation, misinterpreting library code as application logic and producing a false positive.

3) *Reasoning failures for vulnerability semantics.* Two false positives occurred when LLM reasoning introduced assumptions beyond those specified in the PoV. For example, in `ia-recruiter` application [50], the code hardcodes the ZIP file path to prevent directory traversal. However, CognixShield assumed attackers could replace the hardcoded file itself, incorrectly flagging it as vulnerable to CVE-2019-10094 [33] despite the PoV indicating otherwise. While prompt engineering with additional constraints helps, LLMs inevitably generate assumptions beyond provided information, making these reasoning errors difficult to eliminate entirely.

**Finding 1:** *CognixShield correctly classifies 38 vulnerable and 10 secure applications, achieving a precision of 84%, recall of 95%, F1-score of 89%, and accuracy of 84% across 57 applications. The unbalanced code structures can disrupt AST-guided fragmentation and degrade the quality of retrieved context.*

Upon further inspection, we observed that the embedding cost increases with project size because the entire codebase must be indexed. For example, the largest project, Hadoop (2.63M LoC), requires 19.8M embedding tokens and takes approximately 76 minutes to generate embeddings. However, the overall analysis cost is primarily determined by the number of vulnerable API invocations rather than project size. Among the two projects exceeding 1M LoC, Hadoop and Druid (1.21M LoC), our approach successfully analyzed both: Hadoop requires 339K input tokens and 7K output tokens for LLM analysis (approximately $1.30), whereas Druid requires 2.4M input tokens and 360K output tokens (approximately $10.02). This difference is mainly because Druid contains 28 vulnerable API invocations, compared to only 8 in Hadoop. On average, our approach used 1,772,500 tokens for embedding and 174,196 LLM tokens (88.2% input and 11.8% output), resulting in an average cost of approximately $0.60 per project analysis.

**Finding 2:** *CognixShield tool analyzes large-scale codebases at low cost, for an average of $0.60 per project analysis. This cost is primarily determined by the number of vulnerable API invocations rather than project size, keeping CognixShield practical for multi-million-LoC repositories.*

## 5.2 RQ2 (Component Contribution)

**Experiment setting.** To better understand the contribution of each component, we conducted an ablation study to evaluate the effectiveness of CognixShield under the following settings: (1) w/o AST, where the AST-guided code segmentation is replaced with naive line-based chunking; and (2) w/o RAG, where only the target function that invokes the vulnerable API is provided as context; and (3) w/o PoV, where the PoV test is not included.

As shown in Table 2, all three settings led to substantial performance degradation. Specifically, without AST, recall dropped by 41% and accuracy dropped by 27%, while no RAG reduced recall by 42% and accuracy by 34%. Excluding PoV guidance decreased both precision and recall by 12%. we observed that both AST-based indexing and RAG are critical for retrieving security-relevant inter-procedural context. Without AST-based indexing. CognixShield loses structural information needed to identify semantically coherent code fragments. For example, when analyzing CVE-2022-25845 in the `commerce` project, the

**Table 2** Ablation experiment results of CognixShield components.

| Model | P (%) | R (%) | F(%) | A(%) |
|---|---|---|---|---|
| CognixShield | 84 | 95 | 89 | 84 |
| CognixShield w/o AST | 79 | 54 | 64 | 57 |
| CognixShield w/o RAG | 70 | 53 | 60 | 50 |
| CognixShield w/o PoV | 72 | 83 | 77 | 65 |

vulnerability is exploitable only when `JSON.parseObject` deserializes malformed JSON strings. Without AST-based indexing, the retrieved code snippets consist primarily of isolated variable assignments and omit the surrounding control-flow structure.

**Inter-procedural Context Retrieval.** We observed that CognixShield retrieves security-relevant context on demand, adapting its retrieval scope to the vulnerability under analysis rather than reconstructing the entire program. Across 47 projects, CognixShield retrieved cross-function and cross-file code fragments to establish exploitability, whereas for the remaining 10 projects, reasoning within a single function was sufficient. Listing 3 shows a simplified prompt automatically generated by *Reflector* for the Nacos project. CognixShield performed control-flow related code fragments retrieval across multiple files; it retrieved code blocks from the public interface `createUser` down to the vulnerable API invocation `PasswordEncoderUtil.encode`. While in the Kylin project (Listing 3), CognixShield gathered data constraints context instead of the entire control flow. It includes the `checkNewPwdRule` function, which has security-related logic for password validation. For both cases, the retrieved context enabled CognixShield to correctly identify the trigger condition, impact, and exploitation flow. When RAG is disabled, CognixShield analyzes only the local function containing the vulnerable API, preventing it from determining whether the invocation is reachable under exploitable conditions. These findings indicate that accurate detection depends on retrieving security-relevant inter-procedural context rather than analyzing the function containing the vulnerable API invocation in isolation.

**Listing 3** Context retrieved by *Reflector*: (a) Nacos [7] – cross-file control-flow from `createUser` to the vulnerable API; (b) Kylin [10] – data-constraint chain showing null validation before encoding.

**(a)** Nacos (vulnerable).

```
Related code snippet:
--------------------
file_path: PasswordEncoderUtil.java
Code:
public class PasswordEncoderUtil {
  ...
  public static String encode(String raw) {
    return new BCryptPasswordEncoder()
               .encode(raw);}}
--------------------
file_path: UserController.java
Code:
public Object createUser(
    String username, String password) {
  ...
  userDetailsService.createUser(username,
    PasswordEncoderUtil.encode(password));
  return RestResultUtils.success("ok!");}
```

**(b)** Kylin (secure).

```
Related code snippet:
--------------------
file_path: UserController.java, L252-260
Code:
private void checkNewPwdRule(String newPwd) {
  if (!checkPasswordLength(newPwd)) {...}}
--------------------
file_path: UserController.java, L262-264
Code:
private boolean checkPasswordLength(
    String password) {
  return !(password == null
        || password.length() < 8);}
--------------------
file_path: UserController.java, L201-238
Code:
public EnvelopeResponse save(
    @RequestBody PasswdChangeRequest user) {
  ...
  checkNewPwdRule(user.getNewPassword());
  if (existing != null) {
    existing.setPassword(
      pwdEncode(user.getNewPassword()));}...}
```

**PoV-guided Vulnerability Semantic Reasoning.** With PoV-guided, CognixShield interprets the retrieved code context with vulnerability semantics (e.g., vulnerability's triggering conditions) with the PoV guidance. For example, to analyze the Kylin and Nacos projects, CognixShield first deduces from the PoV test (Listing 1, Section 2.1) that exploitation is only possible when a null password is passed to the `BCryptPasswordEncoder.encoder()` method. Leveraging this semantic understanding, the *expert* agent reasons over the retrieved code fragments, examining control flow and data constraints surrounding each vulnerable API invocation. In the Kylin project (Listing 4), CognixShield identifies built-in safeguards, including password-pattern validation checks (Listing 3), and correctly determines that the API usage is secure despite the presence of the vulnerable call. Conversely, in the Nacos project (Listing 4), the expert agent's `poc_understanding` field captures a feasible trigger condition, its resulting impact (e.g., throwing an `IllegalArgumentException` when a null password is provided), and the exploitation path. Without PoV guidance, CognixShield lacks vulnerability-specific semantics to validate exploitation conditions and paths, causing it to classify both projects as vulnerable based solely on vulnerable API usage.

**Listing 4** CognixShield's analysis: (a) insecure usage in Nacos [7]: exploit triggered by null password; (b) secure usage in Kylin [10]: mitigated by input validation.

**(a)** Nacos (vulnerable).

```

**Finding 3:** *Each component plays a critical role in CognixShield's effectiveness. AST-based indexing and RAG enable retrieval of security-relevant inter-procedural context, whereas PoV-guided semantic reasoning allows CognixShield to understand vulnerability-specific trigger conditions, impacts, and exploitation paths.*

## 5.3 RQ3 (Baseline Comparison)

To assess the performance of CognixShield relative to existing solutions, we compare it against naive LLM and four baseline tools from two categories: static programming analysis tools and deep learning-based software approaches.

- **Naive LLM** is our baseline, where we use GPT-4o and provide the entire codebase with a system prompt that includes the PoV test.
- **Codex** [36] is an OpenAI LLM agent that autonomously explores and analyzes repositories.

**Table 3** Runtime performance of five tools.

| Tools | Time (Total) | Time (Average) | Failed Cases |
|---|---|---|---|
| **CognixShield** | 275 mins | 5 mins | 0 |
| **Naive LLM** | 3 mins | 9 secs | 38 |
| **Codex** | 122 mins | 128 secs | 0 |
| **Eclipse Steady** | 722 mins | 13 mins | 18 |
| **VAScanner** | 41 mins | 2 mins | 35 |
| **DeepDFA** | 364 mins | 6 mins | 0 |
| **LineVul** | 361 mins | 6 mins | 0 |

- **VAScanner** [2] uses call-graph analysis to determine whether vulnerable APIs from library dependencies are reachable and actually invoked within the application code.
- **Eclipse Steady** [40] performs reachability analysis by combining static and dynamic techniques, tracing execution paths from known vulnerable APIs to their invocation points in the application. It then produces detailed assessments of vulnerability exploitation.
- **LineVul** [19] is a transformer-based model leveraging CodeBERT [17] for code representation and vulnerabilities at line level.
- **DeepDFA** [45] combines dataflow analysis (DFA) with graph neural networks (GNNs) for detecting software vulnerabilities. It encodes dataflow information at each node of a program's control flow graph and learns data usage patterns.

**Experiment settings.** To ensure a fair comparison, we run experiments for all tools on the same machine. Naive LLM uses GPT-4o with a 128K context window, packing each codebase's source code with Repomix 1.6.0 [53]. Codex uses the gpt-5.2 model in full-auto mode, with the PoV test and vulnerable API signature as the task prompt; we disable web search to ensure the agent relies solely on repository exploration. VAScanner runs on its published code [2] with default settings, with program-issue fixes we applied, while Eclipse Steady version 3.2.5 runs with its default configuration; we set a 150-minute per-project analysis time limit for both tools. For the machine-learning-based tools LineVul and DeepDFA, we use their default parameter settings with function-level inputs. Since neither tool was designed for project-level exploitability assessment, we include them as reference. For CognixShield, we use the same settings as described in Section 4.

CognixShield achieves an overall F1 of 89% and A of 84%, outperforming Naive LLM (F1: 42%, A: 30%), Codex (F1: 76%, A: 65%), LineVul (F1: 42%, A: 42%), EclipseSteady (F1: 40%, A: 28%), VAScanner (F1: 33%, A: 25%), and DeepDFA (F1: 33%, A: 24%). The naive LLM achieved only 28% recall across 57 projects; due to the agentic RAG design, CognixShield uses 5.7× fewer LLM tokens at significantly lower cost.

Although Codex outperforms all other baselines, CognixShield is still ahead by 13% in F1 and 19% in accuracy. Codex's iterative grep-and-read strategy struggles with cross-file reachability: when a vulnerable sink requires traversing multi-file chains (AOP aspects, factories, runtime configuration), it commits to a verdict before resolving the full chain, whereas CognixShield's RAG retrieval co-locates all relevant fragments in a single prompt. For example, in `PLMCodeTemplate` (CVE-2020-26217), the agent found no live callers of `XMLConfig.toBean()` and concluded the sink was dead code. The sink is in fact reachable via a four-file Spring AOP chain: a `@Log`-annotated controller triggers `LogAOP`, which evaluates attacker-controlled SPEL via `SPELUtil`, enabling `T(XMLConfig).toBean(...)` as a gadget. The agent read `XMLConfig.java` but never traversed the annotation-to-aspect-to-SPEL path, while CognixShield's retrieval co-located all four files in a single context, correctly identifying the project as vulnerable.

VAScanner achieves precision of 64%, but yields low recall (23%) due to scalability failures on large codebases. Eclipse Steady exhibits a similar trend, achieving 30% R and an F1 of 40%, failing to analyze 18 projects due to limitations in building call graphs for complex projects. The DL-based tools, LineVul and DeepDFA, achieve low recall rates of 30% and 15%, respectively. These approaches overlook a substantial number of vulnerable API usages. This limitation may be due to their function-level detection strategy, where each function is analyzed in isolation. Detecting vulnerable API usage, however, often requires a broader context that spans across multiple functions and files.

*Runtime Performance.* As shown in Table 3, CognixShield averages 5 minutes per project (275 minutes total) and completed all 57 applications without failures. Eclipse Steady required 722 minutes and failed on 18 projects; VAScanner finished in 41 minutes but failed on 35 cases. DL-based tools averaged 6 minutes per project including training time. CognixShield eliminates training requirements and achieves 100% project coverage, making it more practical for real-world deployment.

**Finding 4:** *CognixShield outperforms all baselines across every metric (F1 89%, accuracy 84%). The strongest baseline, the Codex agent, reaches 76% F1 and 65% accuracy, while the remaining static-analysis, DL-based, and naive-LLM baselines fall below 42% accuracy. It demonstrates better scalability and efficiency on large real-world projects, overcoming memory and dependency challenges faced by existing approaches.*

## 5.4 RQ4 (Robustness Analysis)

**Experiment settings.** We evaluate CognixShield on two popular text embedding models *voyage-code-3*[6], and *OpenAI text-embedding-3-small* [34]; five state-of-the-art closed-source LLMs and one open-source LLM: GPT-4o [35], GPT-o1 [35], Claude-3.5-Sonnet [8], Google-Gemini-2.0-Flash [21] and Llama-3.1-405B [5], while varying the maximum code fragment size ($\theta$) over 500, 1000, 1500, 2000, 2500, and 3000. Figure 3 presents the performance results across four key metrics (P, R, F1, A). The first row shows results using the *voyage-code-3* embedding, while the second row shows results using the *OpenAI text-embedding-3-small* embedding.

**Embedding Models.** CognixShield shows minimal sensitivity to the choice of embedding models. The *openAI* embedding achieves more stable precision and the highest F1 of 90% (P: 84%, R: 95%) with GPT-4o at $\theta = 2500$ tokens, while the *voyage* embedding consistently yields higher recall (up to 96% for GPT-4o) but lower precision, with recall differences reaching up to 12% between the two embeddings.

**Impact of LLMs.** Across five different LLMs, CognixShield achieves precision ranging from 74% to 87% and recall from 53% to 96%. GPT-4o achieves the highest overall performance (F1: 89%, A: 84%), while Llama-3.1-405B reaches the highest precision (87%) but the lowest recall (53%–66%), resulting in the worst F1 (below 72.5%) and accuracy (below 66%). These findings indicate that the choice of LLM substantially affects detection effectiveness, with GPT-4o demonstrating the strongest capability.

**Code Fragmentation Length.** Most models maintain stable precision across fragment sizes, while recall improves for GPT-4o and Google-Gemini-2.0-Flash as fragment length increases (e.g., GPT-4o's recall grows from 91% at 500 tokens to 95% at 2500 tokens). Beyond 2500 tokens, some models show degradation: GPT-o1's F1 drops from 83% to 72%

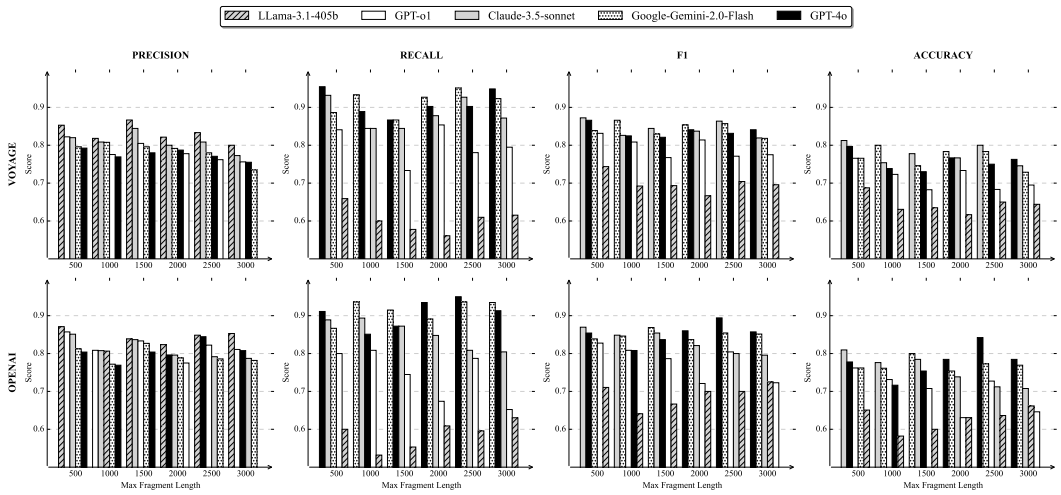

**Figure 3** Performance evaluation of LLM-embedding model combinations across six code fragment lengths. The top legend denotes the LLMs, while the left legend indicates the embedding models. Each subplot corresponds to a distinct evaluation metric as listed (Precision, Recall, F1-score, and Accuracy).

when increasing from 500 to 3000 tokens, likely due to overly long fragments introducing noise. This suggests that 2000–2500 tokens represents the optimal balance for large-scale vulnerability detection.

**Finding 5:** *CognixShield demonstrates stable performance across embedding models and fragment sizes, while LLM choice has a substantial impact on detection effectiveness (F1: 64%–89%, A: 58%–84%). GPT-4o consistently achieves the best results (F1: 81%–89%, A: 75%–84%), whereas Llama-3.1-405B underperforms (F1: 64%–73%). Code segments of 2,000–2,500 tokens with openAI embeddings yield the highest overall performance.*

## 6 Threats to validity

*Internal Validity.* 1) Parameter Sensitivity: Our approach's performance may be sensitive to parameters like similarity thresholds and LLM settings. While we set the temperature to 0 for reproducibility, other parameters (e.g., similarity threshold) may still influence results. 2) Ground Truth Accuracy: The manual labeling data requires significant effort. To ensure labeling accuracy, two authors who have industry experience in security domains labeled the data. However, this approach might impact the overall accuracy of the classification. 3) Prompt Template Limitation: We used fixed prompt templates for the LLM. This could limit the range of vulnerabilities detected and affect the accuracy of our results. 4) Implementation Choices: CognixShield's effectiveness may be influenced by specific implementation choices (e.g., AST parser, encoder models).

*External Validity.* The generalizability of our findings may be limited by the following factors: 1) The principle of our retrieval-augmented analysis is language-agnostic, but our concrete implementation includes Java-specific components, so the generalizability of our quantitative findings to other languages is not directly established. We chose to instantiate the approach on Java, motivated by Java's prevalence in open-source software and growing

security concerns over supply chain attacks in popular Java libraries. 2) Our observations and conclusions are based on the third-party datasets [23] complemented by additional data collected from GitHub. While these datasets offer valuable insights, they do not cover all possible scenarios or vulnerabilities in real-world applications. 3) Our study relies on exemplar security tests from libraries to illustrate vulnerability contexts. According to [23], over 51% of vulnerabilities have associated test cases. While this approach is effective for evaluation, it may be limited by the availability of PoV tests.

## 7 Related Work

**Vulnerable API Detection.** Researchers and engineers created tools to detect the invocation of vulnerable APIs or misuse of APIs [43, 40, 56, 18]. These tools are designed for identifying insecure cryptographic API usage patterns that may introduce security risk. Specifically, tools such as CryptoTutor [43], and SEADER [56] adopted static analysis to identify whether Java cryptographic APIs are invoked with secure parameter configurations and correct sequential orders. Fischer et al. [18] trained models on labeled code snippets that demonstrate both secure and insecure cryptographic API usage. These models are then applied to detect potentially insecure API usage patterns in new Java code snippets, learning from examples to identify code that deviates from secure usage patterns. For vulnerable APIs introduced through library dependencies, version-based scanners such as DependencyCheck [37] match declared dependency versions against vulnerability databases, whereas reachability-based tools decide whether the vulnerable API is actually invoked: VAScanner [54] and Eclipse Steady [40] build call graphs from the application to the vulnerable API, and ViperScan [46] further uses an LLM to distill exploit conditions from security patches into static reachability rules. These tools rely on syntactic patterns or reachability, and do not reason about whether a reached API is actually exploitable in the surrounding program context.

**Deep Learning-based Software Vulnerability Detection.** Deep learning-based software vulnerability detector approaches [19, 28, 30, 45, 13, 29] have been proposed to automatically learn vulnerability patterns from various code representations. IVDetect [28] utilized RNN-based models to generate code representations from source code and identify vulnerable code patterns. LineVul [19] leverages CodeBERT, a pre-trained model for programming language, to generate code vector representations and employs BERT's self-attention layers to capture long-term dependencies in code sequences. DeepDFA [45] encodes dataflow analysis information into graph neural networks to better capture program semantics for vulnerability detection. These methods often focus on detecting vulnerabilities within individual functions or code snippets rather than considering the broader inter-procedural context required for dependency vulnerability detection.

**LLM for Vulnerability Detection.** Recent work has explored LLMs' capabilities in security tasks [49, 57, 31]. SecLLMHolmes [49] evaluates the ability of various LLMs to detect security-related bugs under different configurations, concluding that current models are non-deterministic and not robust. Liu et al. [31] introduce GPTAid which adopted LLM to infer API misuse parameter rules and adopts existing tools (CodeQL [20]) for detection. Several studies investigated vulnerable code repair [38, 22, 52] through LLMs. For instance, Pearce et al. [38] examine LLMs in repairing vulnerable code in a zero-shot prompt, finding that while models can successfully repair hand-crafted examples, they struggle with complex, real-world cases. To move beyond single functions, Vul-RAG [16] retrieves distilled vulnerability

knowledge to judge individual functions, and LLMxCPG [25] uses code-property-graph slices to steer the LLM toward vulnerability-relevant code, but both remain function- or slice-level rather than repository-scale. CognixShield instead combines AST fragmentation, embedding retrieval, agentic RAG, and LLM reasoning to assemble repository-scale inter-procedural context and determine exploitability.

## 8 Conclusion

We presented CognixShield, a novel Agentic RAG approach for detecting vulnerable API usage in large-scale codebases, which combines inter-procedural context retrieval with LLM-driven vulnerability code semantic reasoning. Unlike traditional analyzers, CognixShield constructs repo-level program contexts capturing control flow and data constraints, enabling accurate distinction between exploitable and safe API usages. This work demonstrates that LLM-based techniques, when integrated with domain knowledge, can make vulnerability detection more practical and scalable. Future directions include extending CognixShield to support additional languages, such as Golang and JavaScript, developing adaptive context retrieval strategies that adjust to code complexity, and enhancing interpretability by providing actionable fix suggestions alongside detection results.

# Modeling Dependency-Propagated Ecosystem Impact of Changes in Maintenance Activities: Evaluating Support Strategies in the PyPI Network

**Alexandros Tsakpinis**
fortiss GmbH, Munich, Germany

**Emil Schwenger**
fortiss GmbH, Munich, Germany

**Alexander Pretschner**
Technical University of Munich, Munich, Germany

## Abstract

**Background.** Open source software ecosystems exhibit dense dependency networks in which maintenance degradation of structurally central packages can propagate widely. Despite increasing attention to open source sustainability, existing support mechanisms lack an explicit, dependency-aware notion of ecosystem-level impact to guide support decisions.

**Aims.** In this paper, we introduce a dependency-aware model of ecosystem impact that captures how changes in maintenance activities propagate through the Python Package Index (PyPI) ecosystem and affect its overall state. Based on this model, we prioritize packages for ecosystem support using our dependency-propagated notion of ecosystem impact.

**Method.** Applying this framework to a snapshot of 718,750 PyPI packages and over 2 million dependencies, we compare our impact-driven support strategy with existing support mechanisms (Tidelift, Ecosyste.ms, and GitHub Sponsors) and with PageRank as a baseline measure of structural importance.

**Results.** Our results show that a large share of the modeled ecosystem impact (approximately 80%) can be attributed to just 0.1% of all PyPI packages when prioritized based on dependency-propagated impact. In contrast, externally defined support sets vary substantially in their alignment with ecosystem impact. We further analyze maintainer reach and metadata accessibility, revealing that ecosystem impact, social footprint, and operational feasibility represent distinct but complementary dimensions of ecosystem support.

**Conclusions.** Dependency-aware ecosystem impact modeling provides a transparent and systematic basis for prioritizing support in large-scale software ecosystems. Our findings suggest that effective support strategies, driven by ecosystem stewards, funding bodies, and organizations operating support programs, should complement existing allocation logic with impact-informed decision making.

## 1 Introduction

Over the past decades, Open Source Software (OSS) has become a fundamental component of modern software systems, with estimates suggesting that 80% to 90% of commercial software relies on open source components [16, 34, 43]. Within this landscape, reusable software libraries play a central role. Typically distributed as packages through ecosystem registries, they provide specialized functionality that reduces development effort [4]. Integrated as

dependencies, they collectively form large-scale, layered dependency networks [11]. This structural interdependence introduces systemic risks: vulnerabilities or failures in a single package can propagate through direct and transitive dependencies, affecting large parts of the ecosystem [14], as illustrated by incidents such as Log4j [2], LiteLLM [32], and XZ Utils [35]. While OSS communities often respond quickly to security issues [48], sustained maintenance is not guaranteed. Libraries may experience declining activity or be abandoned entirely [4, 28, 47]. In such cases, insufficiently maintained dependencies can propagate risks across the ecosystem, impacting potentially thousands of downstream projects [24, 58].

However, while maintenance-related risks in software libraries are well recognized [28, 47] and the propagation of risks through dependency networks is well established [19, 23], there is no formalization that combines these perspectives into a dependency-aware notion of ecosystem-level impact, which quantifies how improving or degrading the maintenance activities of a given library affects the overall state of the ecosystem. This limitation is particularly relevant in the context of OSS support mechanisms, which are essential for sustaining maintenance through financial and non-financial interventions [25, 27, 56]. A key challenge for these support mechanisms is the allocation of limited resources across libraries. However, existing support mechanisms operate without a notion of ecosystem impact [10, 40, 51, 67]. As a result, it remains unclear which subset of libraries should be prioritized to maximize ecosystem impact [15, 42, 65]. Beyond this structural perspective, additional challenges arise when operationalizing ecosystem support. The maintainer populations behind structurally critical libraries remain insufficiently characterized, limiting our understanding of how support strategies translate into social reach [3, 8, 9, 42, 68]. Furthermore, even when relevant libraries can be identified, practical constraints such as missing metadata (e.g., contact information, donation links, or repository URLs) can hinder maintainer outreach and support allocation [5, 60–62]. Finally, existing support mechanisms such as Tidelift, Ecosyste.ms, and GitHub Sponsors have not been systematically evaluated with respect to their dependency-propagated ecosystem impact, with available reports typically focusing on project-level improvements rather than transitive ecosystem-wide effects [52]. To guide our empirical analysis, we formulate the following research questions (RQs):

**RQ1:** When support is concentrated on libraries with the highest ecosystem impact on PyPI, how many libraries are required and what proportion of the ecosystem is affected?

**RQ2:** Given the libraries selected in RQ1, how does the selection translate into the number of maintainers reached?

**RQ3:** Given the libraries selected in RQ1, to what extent are maintainers reachable and supportable through PyPI and repository metadata, and how frequently are packages excluded from the analysis due to missing repository links?

**RQ4:** How do libraries associated with existing support mechanisms compare to the selection identified in RQ1 under the same analytical dimensions used in RQ1–RQ3?

We address these research questions by introducing a dependency-aware definition of ecosystem impact that models how changes in maintenance activities propagate through package dependency networks. We ground our analysis in the Python Package Index (PyPI), a widely used ecosystem in modern software development characterized by strong library integration patterns [1, 13, 20]. At a high level, ecosystem impact captures how changes in the maintenance state of a single package influence the overall state of the ecosystem. We operationalize this by modeling the ecosystem as a set of interdependent packages, where maintenance changes at the package level propagate through the dependency network and contribute to a global ecosystem state. By quantifying how individual packages affect this global state, we obtain a measure of their relative impact on the ecosystem. Aggregating

these effects yields a global view that enables comparison across packages. Building on this definition, we frame ecosystem support as a constrained selection problem: given a target share of overall ecosystem impact, which packages should be prioritized for support? Using this framework, we analyze an impact-driven support allocation strategy that prioritizes libraries based on their dependency-propagated ecosystem impact. We examine how this strategy translates into the number and concentration of supported packages, the number of maintainers reached, and the availability of metadata required for delivering financial and non-financial support. Finally, we benchmark existing support mechanisms (Tidelift, Ecosyste.ms, and GitHub Sponsors) against our impact-driven selection strategy.

In response to the identified gaps, this paper makes the following contributions: First, we introduce a dependency-aware definition of ecosystem impact that models how simulated maintenance changes propagate through package dependency networks. Second, we operationalize ecosystem support allocation as a constrained selection problem and analyze an impact-driven prioritization strategy. Third, we extend the evaluation of support strategies beyond ecosystem impact by integrating maintainer reach and metadata accessibility as complementary dimensions of practical feasibility. Fourth, we provide a benchmark of existing support mechanisms (Tidelift, Ecosyste.ms, and GitHub Sponsors) against our dependency-propagated impact model, enabling comparison between impact-driven and externally defined allocation logics. Fifth, we systematically compare our proposed impact metric to PageRank as a baseline measure of structural importance, identifying when structural centrality serves as a suitable proxy for ecosystem impact and where it fails to capture the effects of maintenance changes and their propagation. Our contributions provide a dependency-aware basis for evaluating and prioritizing ecosystem support and may inform decision-making of ecosystem stewards, funding bodies, and organizations operating support programs.

# 2 Background and Related Work

## 2.1 Open Source Sustainability and Support Mechanisms

Open source software constitutes critical infrastructure in modern software supply chains, yet its sustainability is constrained by limited maintainer capacity and the often unpaid nature of maintenance work. Recent work conceptualizes sustainability as maintaining the socio-technical conditions that allow projects to remain healthy over time, emphasizing the need to support the "human infrastructure" behind OSS (e.g., reducing burnout and enabling stable maintenance routines) [25]. In dependency-rich package ecosystems, sustainability also has a systemic dimension: the maintenance status of upstream libraries can affect many downstream projects through direct and transitive dependencies [65]. To address these risks, a range of support mechanisms has emerged. Institutional support includes foundations that provide legal, organizational, and operational assistance, although prior work shows that such institutionalization complements rather than replaces project-level engineering and governance practices [22]. Financial mechanisms include donations, crowdfunding, and sponsorship platforms. Empirical studies show heterogeneous outcomes: donations are used for diverse purposes but do not consistently translate into increased development activity [40], while evidence from Open Collective highlights diverse donation and spending patterns across projects [67]. Similarly, studies of donation platforms suggest that their effectiveness depends strongly on project characteristics such as size, maturity, and community engagement [66]. Platform-mediated sponsorship mechanisms such as GitHub Sponsors provide another funding channel and shape developer activity and social dynamics in OSS ecosystems [51].

Beyond these academic perspectives, industry and public-sector initiatives increasingly use dependency information to guide funding decisions. For example, Tidelift distributes subscription revenue based on their customer's dependency usage [55]. Ecosyste.ms has introduced ecosystem-level funds that allocate sponsorship to widely reused projects [17], while public-sector programs such as the Sovereign Tech Agency fund open digital infrastructure to strengthen resilience and security [53]. Additional initiatives aim to normalize corporate contributions (e.g., Open Source Pledge) [31] or support dependency-aware giving (e.g., thanks.dev) [7]. Recent work has also begun to systematize the evaluation of public funding interventions in open source ecosystems by proposing toolkits for measuring their impact [39].

Despite the diversity of support mechanisms, none considers in their library selection how dependency networks amplify downstream effects of insufficient maintenance, limiting the assessment of ecosystem-level impact. This motivates our ecosystem-aware selection strategy that combines dependency-propagated impact and maintenance signals.

## 2.2 Maintenance Activities and Project Health

OSS project health is frequently operationalized through maintenance activities and the risk of inactivity, abandonment, or failure. Broader OSS health assessments combine multiple indicators, many of which are represented by metrics developed by the **C**ommunity **H**ealth **A**nalytics in **O**pen **S**ource **S**oftware (CHAOSS) project [26]. Empirical studies indicate that project failure or deprecation is multi-causal and influenced by socio-technical practices. For example, prior work analyzed deprecated GitHub projects and identified multiple factors contributing to project abandonment, including limited maintainer availability, project obsolescence, and competition from alternative solutions [9]. More broadly, recent work emphasizes that maintenance capacity is constrained by maintainer resources and the socio-technical conditions supporting maintainer labor [25]. In package ecosystems, maintenance must also be considered in relation to dependency structure. A study of the PyPI ecosystem found that dependency-network properties and organizational support significantly influence sustained project activity [65]. This implies that upstream packages with many dependents carry ecosystem-wide maintenance obligations. Given the role of dependency structure in maintenance, prior work investigated automated monitoring of maintenance activities for direct and transitive dependencies, highlighting limitations of approaches that ignore transitive relationships [58]. Closely related to this limitation, existing work on maintenance activities of libraries has not systematically investigated how maintenance changes propagate through dependency networks and affect the ecosystem as a whole, motivating our formalization of a dependency-propagated notion of ecosystem impact that incorporates maintenance signals.

## 2.3 Maintainer Reach and Metadata Accessibility

Beyond identifying impactful libraries, the practical feasibility of ecosystem support depends on the availability of actionable maintainer and funding information. Missing or outdated metadata (e.g., repository URLs, donation links, or contact channels) can limit empirical analysis and hinder interventions such as sponsorship or coordinated support with maintainers [5]. Several prior studies examine these constraints in the PyPI ecosystem. Analyses of repository-link accessibility show that a non-trivial share of packages lacks valid repository links [60]. Studies of donation-platform usage report limited adoption of donation links across projects [61]. Both findings indicate that metadata availability tends to increase with structural importance and for packages appearing in dependency chains. Additional work on maintainer reachability shows that e-mail contact information is broadly available across

PyPI, with only a small share of invalid or missing entries [62]. To explain why such metadata gaps persist for repository and donation-platform links, prior work reports survey-based evidence on barriers that maintainers face when providing such metadata [64]. Together, these findings motivate metadata accessibility as an important feasibility dimension of ecosystem support, which we evaluate across the package sets produced by different support strategies.

## 2.4 Structural Importance in Dependency Networks

Package ecosystems can be modeled as directed dependency networks in which nodes represent packages and edges represent dependency relations. In such networks, packages may influence large portions of the ecosystem through transitive dependencies. Empirical studies show that these dependency graphs evolve over time and exhibit strong concentration effects, where relatively few packages accumulate many dependents [15]. Consequently, importance in package ecosystems should be assessed at the ecosystem level rather than relying solely on project-local popularity metrics. Structural importance is also closely related to systemic risk. Prior work on vulnerabilities in dependency networks demonstrates that issues in upstream packages can propagate widely to downstream projects, highlighting the need for ecosystem-level reasoning when analyzing propagation and mitigation [14]. Similar dynamics apply beyond security, as maintenance degradation or abandonment in upstream dependencies can impose huge downstream costs [65]. Quantifying such propagated effects requires measuring the transitive influence of packages within the dependency network. Centrality measures provide a natural baseline for this purpose, with PageRank capturing global influence based on the network's link structure and serving as a proxy for transitive importance [6]. Prior studies have applied PageRank to identify critical projects in package ecosystems, often in combination with maintainer-risk indicators such as the Truck Factor [42]. Additionally, research suggests that trends in structural centrality can help identify declining packages earlier than traditional popularity metrics and support the identification of alternatives [29,30]. Beyond academic studies, initiatives such as the OpenSSF Criticality Score identify critical open source projects by aggregating repository-level signals including activity, community engagement, and usage proxies [33]. While such approaches provide a practical notion of project criticality, their aggregation limits the ability to focus on specific dimensions such as maintenance dynamics. Taken together, while established importance measures such as PageRank are capable of capturing the potential influence of packages within a dependency network and prioritizing highly influential libraries, they lack the ability to capture how changes in maintenance state affect the ecosystem. Building on this observation, we use PageRank as a baseline measure of structural importance in the PyPI dependency network and compare it with our proposed impact metric for prioritizing libraries for support. This comparison allows us to analyze when PageRank serves as a suitable proxy for ecosystem impact and where it fails to capture the effects of maintenance changes and their propagation.

# 3 Methodology

We conduct a large-scale, quantitative, observational study of the PyPI ecosystem based on mining, integrating, and analyzing package- and repository-level metadata. Our methodology combines dependency network analysis, repository-derived maintenance indicators, and ecosystem-level importance measures. We evaluate alternative ecosystem support strategies in terms of the number and concentration of supported packages, maintainer reach, supportability via contact and donation channels, and metadata-driven exclusion effects.

## 3.1 Data Collection and Preprocessing

To study ecosystem support strategies in the PyPI ecosystem, we collected a snapshot of all packages together with their dependency information and associated package- and repository-level metadata. Data collection was implemented as a reproducible pipeline, which combines multiple data sources and integrates them at package level into a consolidated dataset.

### 3.1.1 PyPI Package Discovery and Filtering

We collected a comprehensive list of Python packages using an official API endpoint [46]. Each package listed at the time of data collection was treated as a single unit of analysis. Packages that could not be resolved through the detailed PyPI endpoint [44] or that appeared only as dependency references without a package entry in the initial package list were excluded from the dataset. This preprocessing step ensures that all analyzed packages are associated with consistent dependency information. The resulting package list defines the scope of the ecosystem and serves as the baseline for all analyses and selection strategies.

### 3.1.2 PyPI Package Metadata

For each package, we retrieved package-level metadata using an official PyPI API [44]. These metadata include project URLs, which are used to identify source code repositories and donation platform links, as well as contact information of authors and maintainers in the form of available e-mail addresses. To protect the privacy of individuals, whenever valid contact information is available, we store only a reference to the corresponding project page rather than the e-mail address itself. In addition, we extracted direct and optional dependencies for the latest available version of each package. This dependency information is used to construct the PyPI dependency network, modeled as a directed graph with unrestricted transitive depth, which enables the computation of package importance based on PageRank. As described in more detail in Section 3.1.4, PageRank serves as a baseline for structural importance, against which we compare our dependency-propagated ecosystem impact metric. The retrieved PyPI metadata, including contact information, donation platform links, and repository URLs, is used for the analysis of maintainer reachability, supportability, and systematic exclusion effects in RQ3.

**Repository-level metadata.** For packages with resolvable GitHub repositories, we collected repository-level metadata using the GitHub API. This includes repository ownership data (individual user vs. organization), and, where available, contact information listed at the repository owner level. To protect an individual's privacy, we do not store raw e-mail addresses but retain only references to the corresponding repository owner pages. In addition, we collected linked donation platform URLs, including GitHub Sponsors and externally referenced funding links. For organization-owned repositories, we collected associated members to quantify the number of maintainers reached by different package selection strategies, central to RQ2. The presence of contact information and donation links enables assessing maintainer reachability and supportability via repository metadata, relevant to RQ3.

### 3.1.3 Maintenance Indicator

To assess maintenance-related characteristics of packages, we used the *Maintained* check from the OpenSSF Scorecard [37], a framework widely adopted across software repositories in academia and industry [36, 38, 59]. This check provides a score from 0 to 10 based on

commit and issue activity during the past 90 days. We selected this bounded and consistently computable signal for controlled large-scale comparisons of recent maintenance activity, not as a comprehensive measure of project health.

### 3.1.4 Comparison of Impact Metric with Existing Importance Measures

To systematically compare our notion of dependency-propagated ecosystem impact with established ecosystem-level importance measures in the context of prioritizing libraries for support, we consider two complementary importance measures: (i) a structural importance measure based on PageRank derived from the dependency network, and (ii) a usage-based importance measure based on package download counts obtained from the pepy.tech API [41]. While both measures are retained in our dataset, PageRank is used as a baseline measure of structural importance against which we compare our proposed impact metric. This choice is motivated by conceptual, institutional, and practical considerations.

First, usage-based popularity and structural centrality capture different aspects of ecosystem importance. In our dataset, the two measures exhibit only a low-to-moderate association, with a Spearman rank correlation of $r_s = 0.31$, indicating that they frequently differ in their ranking and should not be treated as interchangeable signals [12]. Structural centrality reflects the extent to which packages are relied upon by others and provides a natural baseline for assessing dependency-mediated influence in the ecosystem [6]. Second, PyPI deprecated download statistics from its official infrastructure due to concerns regarding data reliability and interpretation, including the influence of automated downloads and caching effects [45]. In alignment with this decision, we avoid using download counts as a primary basis for ecosystem importance and instead use PageRank as a baseline for our comparison. Third, PageRank provides practical advantages for large-scale ecosystem studies, as it can be computed solely from dependency information without requiring costly third-party services [41].

## 3.2 Data Analysis: Modeling dependency-propagated Ecosystem Impact

All analyses are part of a reproducible workflow implemented as a dashboard web application. Conceptually, the analysis evaluates an ecosystem support strategy based on dependency-propagated ecosystem impact by selecting sets of packages and examining the resulting implications in terms of package set size and concentration (RQ1), maintainer reach (RQ2), metadata accessibility (RQ3), and alignment with existing support mechanisms (RQ4).

As motivated in Section 1, maintenance changes in individual packages can propagate through dependency networks and affect large parts of the ecosystem. To reason about such system-wide effects, we require a measure that captures how local maintenance changes translate into ecosystem-level consequences. We therefore define *ecosystem impact* as the dependency-propagated effect of changes in a package's maintenance state. To enable comparison across packages, this effect is normalized with respect to the total dependency-propagated impact in the ecosystem. This definition reflects two key requirements: first, maintenance changes should propagate through direct and transitive dependencies, and second, their effect should scale with the extent to which a package influences other parts of the ecosystem. We use a linear additive baseline that treats transitive dependency occurrences equally to keep attribution transparent and scalable without imposing unvalidated weights. Richer models could distinguish direct and indirect dependencies to account for dependency depth, trace propagation through method-level call graphs, and represent structural relations such as imports, inheritance, and function calls [50, 54].

Concretely, we model the ecosystem as a set $\mathcal{P}$ of interdependent packages and define the overall ecosystem maintenance state $M_{\text{eco}}$ as the sum of maintenance levels of all packages, i.e., $M_{\text{eco}} = \sum_{q \in \mathcal{P}} m_q$, where $m_q$ denotes the maintenance score of package $q$. To incorporate dependency effects, we assume that the maintenance state of a package is not only determined locally, but also by the maintenance of the packages occurring in its dependency structure. To account for this, we replace the local maintenance state with a dependency-propagated maintenance measure. For a package $q$, we therefore express its dependency-propagated maintenance as $m_q^{\text{eff}} = \sum_{p \in \mathcal{P}} o_{p,q} \cdot m_p$, where $m_p$ denotes the maintenance score of package $p$ and $o_{p,q} \in \{0, 1\}$ indicates whether package $p$ appears in the transitive dependency closure of $q$, including $q$ itself as the root package. Substituting $m_q^{\text{eff}}$ into the ecosystem state yields $M_{\text{eco}}^{\text{eff}} = \sum_{q \in \mathcal{P}} \left( \sum_{p \in \mathcal{P}} o_{p,q} \cdot m_p \right)$. Reordering the finite sums leads to $M_{\text{eco}}^{\text{eff}} = \sum_{p \in \mathcal{P}} \left( \sum_{q \in \mathcal{P}} o_{p,q} \right) \cdot m_p$. This reformulation shifts the perspective from aggregating contributions at the level of affected packages $q$ to expressing the ecosystem state in terms of contributions of individual packages $p$. The inner sum $\sum_{q \in \mathcal{P}} o_{p,q}$ captures how broadly package $p$ propagates through the ecosystem, i.e., the number of packages that directly or transitively depend on it, while the outer sum aggregates these contributions across all packages. This representation makes it possible to isolate the contribution of a single package and analyze how changes to its maintenance score affect the overall ecosystem state. We define a scenario $\sigma$ as a specification of maintenance changes $\{\Delta m_p^{(\sigma)}\}_{p \in \mathcal{P}}$, where for each package $p \in \mathcal{P}$ the value $\Delta m_p^{(\sigma)}$ denotes the change in its maintenance score, e.g., by setting it to its maximum or minimum value in improvement and regression scenarios. The simulated maintenance change is given by $\Delta m_p^{(\sigma)} = m_p^{\text{after}} - m_p^{\text{before}}$, such that positive values indicate improvements in maintenance, while negative values indicate regressions. The resulting ecosystem impact $E_\sigma(p)$ of package $p$ is then given by:

$$E_\sigma(p) = \Delta m_p^{(\sigma)} \cdot \sum_{q \in \mathcal{P}} o_{p,q} \tag{1}$$

which captures how a change in the maintenance score of $p$ propagates through the dependency network and affects other packages in the ecosystem. The resulting value $E_\sigma(p)$ can be positive or negative, where positive values correspond to improvements in ecosystem maintenance and negative values to regressions. To obtain a comparable relative measure within a given scenario, we normalize this value by the total ecosystem impact induced by the same scenario:

$$\hat{E}_\sigma(p) = \frac{E_\sigma(p)}{\sum_{r \in \mathcal{P}} E_\sigma(r)} \tag{2}$$

The resulting normalized ecosystem impact $\hat{E}_\sigma(p)$ represents the share of total ecosystem impact attributable to package $p$ under scenario $\sigma$. For scenarios with nonzero total induced impact, i.e., $\sum_{r \in \mathcal{P}} E_\sigma(r) \neq 0$, the normalization satisfies $\sum_{p \in \mathcal{P}} \hat{E}_\sigma(p) = 1$. Aggregating these values over a selected subset of packages $S \subseteq \mathcal{P}$ yields the cumulative ecosystem impact:

$$\sum_{p \in S} \hat{E}_\sigma(p) \geq \tau \tag{3}$$

where $\tau$ denotes a predefined ecosystem impact threshold (e.g., $\tau = 0.80$). This formulation allows us to prioritize packages based on their dependency-propagated ecosystem impact and to analyze how impact-driven support on a small subset of packages translates into ecosystem-level effects. This definition of ecosystem impact and the associated threshold-based selection criterion are used across all analyses (RQ1, RQ4). Figure 1 illustrates the overall analysis framework and how ecosystem impact modeling connects package selection strategies in RQ1 and RQ4 with the evaluation dimensions of RQ2 and RQ3.

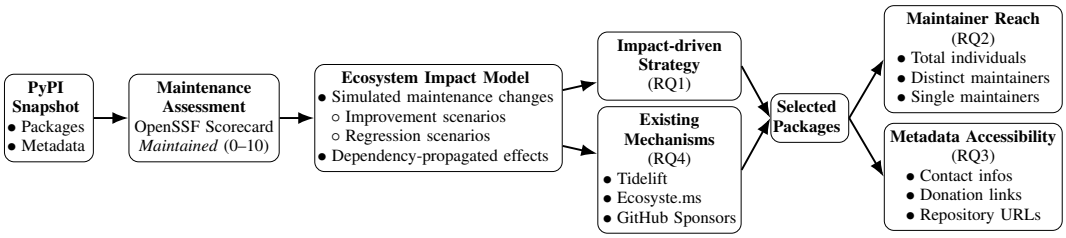

**Figure 1** Conceptual overview of the impact-driven ecosystem support analysis framework.

### 3.2.1 Impact-driven Support Strategy (RQ1)

To address RQ1, we analyze how a fixed ecosystem impact threshold of 80% can be achieved by concentrating support on a small number of packages, following a Pareto-optimal allocation of ecosystem impact. For each package, ecosystem impact is derived from simulated maintenance changes to the *Maintained* score on a bounded scale from 0 to 10. We define *improvement* and *regression* scenarios by setting the maintenance score of a package to the maximum value of 10 and the minimum value of 0. These endpoints are controlled bounds for comparing package selections, not predictions of realistic support outcomes. For each package, we compute the normalized ecosystem impact $\hat{E}_\sigma(p)$ under both improvement and regression scenarios and rank packages in descending order for each case. For a given ecosystem impact threshold, e.g., $\tau = 0.80$, we iteratively select top-ranked packages from each ranking until the cumulative normalized ecosystem impact satisfies Equation (3) in each scenario. The resulting package set is the union of the improvement-based and regression-based selections. We analyze the size and concentration of these package sets to determine how much of the total modeled ecosystem impact can be attributed to a small number of highly influential packages. To assess whether the selection achieves ecosystem impact beyond chance, we compare the resulting package set against a size-matched random baseline. Let $S$ denote the set of packages selected under RQ1 with size $|S|$. We draw $N = 10{,}000$ equally sized sets randomly from the ecosystem using a fixed random seed to support reproducibility, and compute their aggregated ecosystem impact. From these Monte Carlo simulations, we estimate (i) the empirical probability that a random set achieves equal or greater impact than $S$, and (ii) a standardized effect size (z-score) relative to the simulated distribution.

### 3.2.2 Maintainer Reach Analysis (RQ2)

For each selected package set, we analyze maintainer reach using repository ownership metadata. Individual repositories are counted as a single maintainer, whereas for organization-owned repositories, associated members are counted. Consequently, support strategies (RQ1, RQ4) can be compared by the total number of associated individuals and distinct maintainers reached. In addition, we report the number of single-maintainer packages, as these may indicate heightened concentration of responsibility and potential sustainability risks.

### 3.2.3 Metadata Accessibility and Exclusion Analysis (RQ3)

To address RQ3, we assess to what extent selected package sets are reachable and supportable through PyPI and repository metadata, based on the presence of contact information and donation platform links. In addition, we analyze systematic exclusion caused by missing repository links. For the impact-driven strategy (RQ1), we identify packages with comparable dependency-propagation reach, measured as $\sum_{q \in P} o_{p,q}$, that lack repository links

and therefore cannot be assessed for maintenance activities. For existing mechanisms (RQ4), we examine the corresponding package sets and record entries without repository URL. Such cases indicate structural limitations and potential bias in metadata-driven support strategies.

### 3.2.4 Comparison with Existing Support Mechanisms (RQ4)

For RQ4, we compare the package set selected under RQ1 with packages associated with existing support mechanisms. Specifically, we consider (i) PyPI packages covered by Tidelift [57], (ii) PyPI packages supported by Ecosyste.ms [18], and (iii) PyPI packages linking to GitHub repositories whose owners have received at least one donation via GitHub Sponsors [21]. This low threshold for considering a package supported by GitHub Sponsors is intentionally chosen to illustrate the results more clearly in Section 4. Tidelift's support model distinguishes between packages that are fully supported (referred to as *lifted*) and packages that receive partial financial support. To provide a realistic estimate of Tidelift's ecosystem impact, our analysis focuses exclusively on *lifted* packages. For each support mechanism in RQ4, ecosystem impact is evaluated under the same improvement and regression scenarios used in RQ1, i.e., by simulating maximal maintenance improvement (score set to 10) and maximal regression (score set to 0) for all packages in the respective set. This ensures that differences in ecosystem impact reflect differences in package selection rather than differences in simulated maintenance changes. Finally, we apply the same analytical dimensions as in RQ1–RQ3.

## 4 Results

Data collection started on February 17, 2026 and took approximately five days due to API rate limits imposed by GitHub and pepy.tech. The initial PyPI snapshot comprised 742,762 libraries retrieved via the PyPI simple index endpoint [46]. During preprocessing, libraries that appeared only as dependency references but were not part of the initial ecosystem list were removed. This filtering step removed 1.5% of libraries from a node perspective and 2.5% from a dependency perspective. An additional 3.2% of libraries were excluded due to errors when querying the PyPI JSON API [44], mostly HTTP 404 responses for packages that could not be resolved via the detailed endpoint. The final dataset contains 718,750 libraries connected through 2,070,814 dependencies from 93,411 unique sources. This dataset forms the basis for all analysis conducted in this study. To ensure temporal alignment with the main dataset, package sets associated with Tidelift and Ecosyste.ms were collected separately on February 19, 2026 using a dedicated script that completed in under one minute.

## 4.1 RQ1+RQ4: Comparative Ecosystem Impact Analysis

This subsection presents the ecosystem impact results for our impact-driven strategy (RQ1) and existing support mechanisms (RQ4). Table 1 summarizes the normalized, dependency-propagated ecosystem impact achieved by each strategy under simulated improvement and regression scenarios. For each strategy, we report the resulting impact share, the number of selected packages and their proportion relative to the full PyPI ecosystem.

The impact-driven strategy achieves 80.01% improvement impact and 82.15% regression impact by selecting 730 packages, corresponding to 0.10% of the ecosystem. This confirms that ecosystem impact in PyPI is highly concentrated: a very small subset of packages accounts for a large share of dependency-propagated ecosystem impact. To assess whether this result could arise under uniform allocation, we compare the selected set against 10,000 size-matched random selections. The impact-driven set exceeds the mean random impact by 161.04 standardized units in the improvement scenario and 295.51 in the regression scenario, with no random set achieving comparable impact ($p < 0.0001$).

**Table 1** Comparison of ecosystem support strategies under improvement and regression scenarios.

| Strategy | Research question | Improvement impact | Regression impact | Number of packages | % of ecosystem |
|---|---|---|---|---|---|
| Impact-driven | RQ1 | 80.01% | 82.15% | 730 | 0.10% |
| Tidelift (lifted) | RQ4 | 22.66% | 38.65% | 277 | 0.04% |
| Ecosyste.ms | RQ4 | 25.90% | 38.00% | 97 | 0.01% |
| GitHub Sponsors | RQ4 | 27.89% | 36.71% | 20,433 | 2.84% |

For the existing support mechanisms (Tidelift, Ecosyste.ms, and GitHub Sponsors), ecosystem impact is computed under the same improvement and regression scenarios as in RQ1, ensuring that differences reflect package selection rather than differences in simulated maintenance changes. For Tidelift, we consider only lifted packages, which receive full support. The lifted set comprises 277 packages (0.04% of the ecosystem) and achieves 22.66% improvement impact and 38.65% regression impact. Despite including a substantial number of packages, its ecosystem impact remains lower than for the impact-driven strategy, which is consistent with selection criteria that do not optimize dependency-propagated impact. Ecosyste.ms covers 97 packages (0.01% of the ecosystem) and achieves 25.90% improvement and 38.00% regression impact. Despite its relatively small size, its ecosystem impact is comparable to Tidelift, suggesting partial alignment with impactful packages. GitHub Sponsors, defined here as PyPI packages whose linked GitHub repository owner has received at least one sponsorship, includes 20,433 packages (2.84% of the ecosystem), making it the largest set among the analyzed mechanisms. Despite this size, its ecosystem impact remains lower than for the impact-driven strategy (27.89% improvement, 36.71% regression), which is consistent with sponsorship decisions being shaped by individual preferences for particular developers or projects rather than dependency-propagated ecosystem impact.

## 4.2 RQ2+RQ4: Comparative Maintainer Reach Analysis

This subsection analyzes how the package sets identified in RQ1 and RQ4 translate into maintainer reach. To contextualize maintainer-related metrics, Table 2 combines ecosystem impact results with maintainer metrics. For each strategy, we report (i) the number of packages, (ii) ecosystem impact shares under improvement and regression scenarios, (iii) the total number of associated repository individuals, (iv) the number of distinct maintainers, and (v) the proportion of single-maintainer packages. Total individuals count all repository members linked to the selected packages of a given strategy, while distinct maintainers represent unique individuals across all selected packages within that strategy. Single-maintainer packages indicate cases where maintenance responsibility is concentrated on a single individual.

**Table 2** Maintainer reach across ecosystem support strategies.

| Strategy | Research question | Number of packages | Improvement impact share | Regression impact share | Total individuals | Distinct maintainers | Single-maintainer packages |
|---|---|---|---|---|---|---|---|
| Impact-driven | RQ1 | 730 | 80.01% | 82.15% | 31,930 | 12,255 | 311 (42.6%) |
| Tidelift (lifted) | RQ4 | 277 | 22.66% | 38.65% | 4,070 | 1,119 | 101 (36.5%) |
| Ecosyste.ms | RQ4 | 97 | 25.90% | 38.00% | 1,880 | 1,001 | 23 (23.7%) |
| GitHub Sponsors | RQ4 | 20,433 | 27.89% | 36.71% | 3,204,168 | 6,504 | 5,361 (26.2%) |

Table 2 shows that maintainer reach differs substantially across strategies and does not scale proportionally with ecosystem impact. The impact-driven strategy (RQ1) achieves 80.01% improvement impact and 82.15% regression impact with 730 packages, reaching 31,930 individuals and 12,255 distinct maintainers. While this reflects a broad maintainer

reach, it is primarily driven by the larger number of selected packages rather than an inherent property of the prioritization approach. For Tidelift (lifted), 277 packages result in 22.66% improvement impact and 38.65% regression impact, reaching 4,070 individuals across 1,119 distinct maintainers. Compared to the impact-driven strategy, maintainer reach remains substantially lower, reflecting the smaller size of the selected package set. Ecosyste.ms covers 97 packages and achieves 25.90% improvement impact and 38.00% regression impact, reaching 1,880 individuals across 1,001 distinct maintainers. Despite its smaller package set compared to Tidelift, its distinct maintainer reach is relatively close, suggesting a higher density of maintainers per package, but without a corresponding increase in ecosystem impact. GitHub Sponsors includes 20,433 packages, corresponding to 27.89% improvement impact and 36.71% regression impact. The set is associated with 3,204,168 individuals but only 6,504 distinct maintainers, indicating substantial overlap in repository membership and the presence of large organizational repositories. Despite this broad maintainer reach, the associated ecosystem impact remains comparatively limited. Across strategies, the proportion of single-maintainer packages ranges from 23.7% (Ecosyste.ms) to 42.6% (impact-driven), with 26.2% for GitHub Sponsors and 36.5% for Tidelift (lifted). As single-maintainer projects are often more vulnerable to sustainability risks, higher proportions indicate packages that may particularly benefit from additional support.

## 4.3 RQ3+RQ4: Comparative Metadata Accessibility Analysis

This subsection examines the feasibility of operationalizing ecosystem support strategies based on the availability of actionable metadata. Table 3 reports, for each strategy, the number of selected packages, the proportion providing contact information, the proportion linking to donation platforms, and their overlap, as well as the number of packages excluded due to missing repository links. Repository links are required to assess maintenance activities and apply the dependency-propagated impact model. For the modeled strategy (RQ1), exclusions occur when packages with similar dependency-propagation reach as the selected sets do not provide a repository URL. For externally defined mechanisms (RQ4), they reflect packages in the supported sets without resolvable repository links.

**Table 3** Metadata accessibility and exclusion across ecosystem support strategies.

| Strategy | Research question | Number of packages | Packages with contact info (1) | Packages with donation link (2) | Packages with (1) and (2) | Excluded packages (no repository link) |
|---|---|---|---|---|---|---|
| Impact-driven | RQ1 | 730 | 705 (96.6%) | 245 (33.6%) | 241 (33.0%) | 26 (1.8%) |
| Tidelift (lifted) | RQ4 | 277 | 258 (93.1%) | 213 (76.9%) | 213 (76.9%) | 17 (6.1%) |
| Ecosyste.ms | RQ4 | 97 | 89 (91.8%) | 57 (58.8%) | 57 (58.8%) | 7 (7.2%) |
| GitHub Sponsors | RQ4 | 20,433 | 19,650 (96.2%) | 20,431 (99.99%) | 19,648 (96.2%) | 0 (0.0%) |

As shown in Table 3, the impact-driven strategy (RQ1) exhibits high contact information coverage (96.6%), indicating that maintainers of the selected packages are generally reachable. In contrast, donation link availability is substantially lower (33.6%), with 33.0% of packages providing both contact information and donation links. A total of 26 packages (1.8%) are excluded due to missing repository links, indicating limited but non-negligible constraints for applying the dependency-propagated impact model. For externally defined mechanisms (RQ4), metadata accessibility varies across support sets. Tidelift (lifted) shows similarly high contact coverage (93.1%) but substantially higher donation link availability (76.9%), with all packages providing donation links also providing contact information. However, 17 packages (6.1%) lack repository URLs and are therefore excluded. Ecosyste.ms exhibits slightly lower contact coverage (91.8%) and moderate donation link availability (58.8%), with identical overlap

between contact information and donation links. A total of 7 packages (7.2%) are excluded due to missing repository links. GitHub Sponsors shows near-complete donation-link coverage (99.99%) by construction, as inclusion in the set requires at least one sponsorship on the platform. Contact information is available for 96.2% of packages, with the same proportion providing both. No packages are excluded, as all entries link to resolvable repositories.

# 5 Discussion

## 5.1 Structural Concentration and Support Efficiency

Our findings show that ecosystem impact in the PyPI dependency network is highly concentrated. Under the dependency-propagated model, a large share of the overall impact (approximately 80%) can be attributed to a small subset of packages (0.10% of the ecosystem) when prioritized based on impact. This confirms that maintenance-related influence propagates unevenly through the dependency network, with relatively few packages affecting large portions of the ecosystem. These results align with prior observations of concentration effects in package dependency networks, where a small number of packages accumulate substantial influence through a disproportionate number of dependents [15]. However, our findings extend this work by quantifying how structural concentration translates into dependency-propagated maintenance impact under simulated interventions. From a support perspective, this concentration implies that targeting a small fraction of packages can achieve substantial ecosystem-level effects. At the same time, it does not necessarily reduce maintainer reach, as even small sets of high-impact packages can involve large maintainer populations.

## 5.2 Structural Alignment of Existing Mechanisms

The comparison with existing support mechanisms reveals notable variation in their alignment with dependency-propagated ecosystem impact. Ecosyste.ms shows comparatively strong alignment with high-impact packages despite its small size, whereas Tidelift's lifted set and GitHub Sponsors achieve lower impact shares despite larger package sets. This suggests that selection criteria driven by subscription participation or sponsorship preferences do not necessarily align with impact-driven prioritization. These observations do not imply that existing mechanisms are ineffective, but rather that different allocation logics optimize for different objectives. While impact-driven selection prioritizes packages based on their ecosystem-wide effects under maintenance changes, existing mechanisms reflect factors such as user demand, preferences, or visibility. This is consistent with prior findings that funding and sponsorship in OSS ecosystems are shaped by project-level characteristics and social signals, which do not necessarily align with ecosystem-level impact considerations [40, 51].

## 5.3 Maintainer Reach and Spillover Effects

Maintainer reach analysis (RQ2) shows that structural impact and social footprint are related but distinct dimensions. Strategies with similar ecosystem impact can reach very different numbers of maintainers, and large maintainer counts may reflect organizational repositories rather than increases in distinct individuals. This distinction between structural influence and social footprint complements prior work emphasizing the role of maintainer capacity and human infrastructure in OSS sustainability [25]. The prevalence of single-maintainer packages also indicates that impactful or externally supported packages rely on concentrated maintenance responsibility, which prior work links to elevated sustainability risk [3] and may therefore benefit disproportionately from additional support. Moreover, maintainers of

high-impact packages often contribute to multiple libraries, suggesting that supporting them may indirectly benefit additional packages beyond the selected set. Quantitative evidence for these developer-level spillover effects is provided in the replication package.

## 5.4 Metadata Accessibility as an Operational Constraint

The metadata accessibility analysis (RQ3) shows that contact information is widely available across all package sets, including impact-driven strategies (RQ1) and external support mechanisms (RQ4). In practice, this indicates that maintainers of relevant packages are generally reachable, enabling direct communication and coordination of support efforts. In contrast, donation-link availability varies more strongly: externally defined mechanisms exhibit high financial metadata coverage, while packages selected under RQ1 show more heterogeneous donation-link availability. This implies that, despite being reachable, many maintainers cannot be easily supported through established financial channels, limiting the immediate feasibility of monetary interventions. Missing repository links represent an additional operational constraint by limiting maintenance activity assessment and impact simulation. The primary bottlenecks therefore lie in the availability of financial support channels and repository links. Metadata accessibility thus represents an independent feasibility dimension for ecosystem support strategies. These findings align with prior studies on metadata accessibility, which report high availability of contact information but limited adoption of donation platforms and repository links across PyPI libraries [60–62].

## 5.5 Comparison of Ecosystem Impact Metric to PageRank Score

To assess the added value of our dependency-propagated ecosystem impact metric, we compare it against PageRank as an established measure of structural importance in dependency networks. While PageRank provides a global ranking of libraries based on their position in the dependency graph, our metric ranks libraries according to the extent to which changes in their maintenance state propagate and influence the global ecosystem state.

**Divergence in prioritized packages.** We first analyze the overlap between the package set obtained in RQ1 with the top-$k$ packages selected by PageRank ($k = 730$). The Jaccard similarity between the two sets is 41.06%, indicating that less than half of the selected packages are shared. The symmetric difference further reveals that 305 packages are selected exclusively by each method. This divergence shows that the two approaches prioritize fundamentally different subsets. In particular, packages selected by our metric but not by PageRank reflect cases where strong dependency-propagated impact is not captured by structural centrality, while PageRank-specific selections correspond to structurally central packages whose ecosystem impact is comparatively lower. These findings indicate that PageRank alone is insufficient to capture the effects of maintenance changes on the ecosystem.

**Performance under fixed support budgets.** To compare both approaches under identical resource constraints, we compare the package set obtained in RQ1 with the top-$k$ packages selected by PageRank ($k = 730$) and evaluate the resulting total ecosystem impact. The impact-driven strategy achieves a higher cumulative improvement impact (80.01%) than the PageRank-based selection (69.71%), indicating that it is more effective in identifying packages whose maintenance improvements yield larger ecosystem-wide benefits. For regression scenarios, the PageRank-based selection achieves slightly higher total impact (84.64% vs. 82.15%), suggesting that structural centrality is a strong proxy when modeling worst-case

degradation effects. This difference highlights that PageRank effectively identifies structurally central packages whose maintenance degradation has large ecosystem-wide effects, while our proposed metric more effectively identifies intervention points for improving ecosystem maintenance. Overall, these results show that the choice of prioritization strategy influences the effectiveness of support allocation depending on whether the objective is mitigation of risk or maximization of improvement.

**Correlation between PageRank and ecosystem impact.** To quantify the relationship between structural centrality and dependency-propagated ecosystem impact, we compute Spearman rank correlations between PageRank scores and the normalized ecosystem impact values $\hat{E}_\sigma(p)$ under improvement and regression scenarios. Spearman correlation is used as the primary metric, as PageRank and our impact metric are ultimately used for prioritizing libraries, making agreement in ranking the most relevant notion of similarity [12]. The correlation is low for improvement impact ($r_s = 0.17$) and slightly higher for regression impact ($r_s = 0.28$), indicating only weak agreement between the rankings. This suggests that PageRank is not a reliable proxy for ecosystem impact, particularly when considering maintenance improvements. The higher correlation in regression scenarios is consistent with the observation that maintenance degradation in structurally central packages propagates widely through the dependency network.

We also compute Pearson correlations to assess linear relationships between PageRank scores and the normalized ecosystem impact values $\hat{E}_\sigma(p)$ under improvement and regression scenarios. Here, we observe a moderate correlation for improvement impact ($r_p = 0.34$) and a strong correlation for regression impact ($r_p = 0.87$). This indicates that PageRank aligns more closely with regression impact in terms of magnitude, reflecting that structurally central packages tend to dominate worst-case degradation scenarios. However, Pearson correlation captures linear association rather than agreement in prioritization and is sensitive to skewed distributions and outliers [12], which are characteristic of dependency networks [15]. Therefore, while Pearson correlation helps explain the strong performance of PageRank in regression scenarios observed previously, it should not be overemphasized when evaluating selection strategies, where rank-based agreement is more relevant.

**Implications for resource allocation.** A key distinction between PageRank and our proposed metric lies in how they support decision-making. PageRank provides a static ranking of libraries and can be used as a heuristic for selecting influential packages. However, it does not account for how different levels of maintenance intervention affect the ecosystem. In contrast, our impact metric explicitly models the effect of changes in maintenance scores ($\Delta m$), enabling reasoning about the consequences of different intervention magnitudes. This makes it possible to frame support allocation as an optimization problem, where decisions are not limited to which libraries to support, but also how to distribute resources across them. While the present study focuses on threshold-based selection, the underlying formulation supports more general allocation strategies that trade off the number of supported packages against the magnitude of maintenance improvements and regressions.

**Summary.** These results show that PageRank and our ecosystem impact metric capture related but distinct aspects of ecosystem behavior. While PageRank is effective in identifying structurally central packages and modeling worst-case degradation scenarios, it fails to account for maintenance dynamics and intervention effects. The proposed metric complements structural centrality by incorporating maintenance changes and their propagation, providing a more expressive basis for prioritizing and allocating support in software ecosystems.

## 5.6 Practical Implications

Taken together, the results suggest that dependency-propagated ecosystem impact modeling provides a practical and transparent approach for prioritizing support under explicit structural criteria. Because ecosystem support is multi-dimensional, allocation decisions should jointly consider ecosystem impact, maintainer reach, responsibility concentration, and metadata accessibility. A key implication of the impact formulation is that it enables optimization-based resource allocation. Different configurations of supported packages can achieve the same ecosystem impact threshold while varying in the number of selected libraries and the maintenance effort required per package. This defines a trade-off space in which multiple configurations are feasible, with the appropriate choice depending on context-specific constraints such as available resources, desired maintainer coverage, or operational feasibility. The proposed framework is not intended to replace existing mechanisms, but to make such trade-offs explicit and measurable. Potential practitioners include ecosystem stewards, funding bodies, companies managing open source risk in their software supply chains, and platform providers operating support programs. For these actors, dependency-propagated impact modeling can serve as a decision-support layer that complements existing processes for evaluating and guiding open source support and funding interventions [39].

# 6 Threats to Validity

We structure threats to validity into the following four aspects [49]:

**Construct validity.** Ecosystem impact is operationalized as the normalized, dependency-propagated effect of simulated changes in the OpenSSF *Maintained* score. Because this metric captures only selected maintenance aspects and may not fully reflect project health, multidimensional assessments using suitable CHAOSS metrics could yield different rankings [26]. The model also excludes external signals such as industry adoption and usage beyond the ecosystem. Maintainer reach and metadata accessibility are inferred from repository ownership, member metadata, contact information, and donation links, which may not fully represent active contributors or the practical feasibility of direct contact and financial support. However, prior work suggests that e-mail availability is a reasonable reachability proxy, supported by validated deliverability, an undeliverable rate of approximately 11%, and the prevalence of established e-mail domains [62, 64].

**Internal validity.** Our analysis is based on a cross-sectional snapshot of PyPI and GitHub metadata. Because dependency structures and maintenance signals evolve over time, absolute impact values may change. Also, the linear model and 0/10 bounds support controlled comparison, but omit richer dependency effects and do not establish the effects of actual support interventions.

**External validity.** The study focuses on the PyPI ecosystem and publicly accessible metadata, limiting generalizability to ecosystems with different dependency structures, package management practices, or metadata availability (e.g., npm, Maven). In addition, repository-level analysis is restricted to GitHub, as PyPI libraries predominantly link to GitHub rather than alternatives such as GitLab or Bitbucket [60]. The methodology could nevertheless be applied to other ecosystems if comparable metadata is available.

**Reliability.** Details on the replication package are provided in Section 8. Since ecosystem and repository metadata evolve over time, re-collected data may yield different results.

## 7 Conclusion and Future Work

This paper introduced a dependency-aware ecosystem impact model that quantifies how simulated maintenance changes propagate through the PyPI dependency network. By combining dependency propagation with OpenSSF Scorecard maintenance signals, we operationalized ecosystem impact as a normalized dependency-propagated metric and framed ecosystem support allocation as a constrained selection problem. Our results show that ecosystem impact in PyPI is highly concentrated: a large share of the modeled impact can be attributed to a small fraction of packages when prioritized based on dependency-propagated impact. Benchmarking existing mechanisms shows substantial variation in their alignment with ecosystem impact. Maintainer reach and metadata accessibility further emerge as complementary dimensions shaping the practical feasibility of ecosystem support strategies.

Future work should extend the framework longitudinally to monitor evolving dependency structures and maintenance signals, enabling continuous ecosystem monitoring and earlier detection of emerging risks. Refining the propagation model to identify low-maintenance libraries near root packages as potential structural bottlenecks may improve intervention effectiveness by targeting points where degraded maintenance could limit upstream benefits. Additionally, the proposed impact formulation supports optimization-based support allocation, where resources can be distributed across libraries and intervention magnitudes to maximize ecosystem-level outcomes under practical constraints. Finally, future work should test multidimensional maintenance indicators and richer propagation models, validate modeled effects against observed support outcomes, and study other ecosystems.

## 8 Data Availability Statement

All data and analysis artifacts required to reproduce the results of this study are publicly available on Figshare under a CC-BY 4.0 license [63]. The package further includes the data collection pipeline, allowing re-execution of the study with updated data.

# What Makes Software Issue Resolution Tasks Difficult for Agents?

**Ebtesam Al-Haque**
Department of Computer Science, George Mason University, Fairfax, VA, USA

**Brittany Johnson**
Department of Computer Science, George Mason University, Fairfax, VA, USA

## Abstract

**Background.** Advances in agentic systems are simultaneously, and rapidly, saturating benchmarks. Despite this often discussed phenomena, benchmark scores remain difficult to interpret due to the lack of control and characterization of task difficulty. More specifically, we currently have little understanding of what makes one task harder than another, and to what extent task difficulty is predictable from static task properties.

**Aims.** We propose a measurement framework to investigate and systematically quantify what structural properties of software tasks correspond to agent success rates for issue resolution tasks.

**Method.** We conducted a large scale empirical study on CoderForge-Preview, the largest open dataset of coding agent trajectories to date, by extracting features across task patch, repository and prompt. We evaluated the predictive power of each feature against task outcomes using ensemble methods, SHAP attribution, and effect size analysis.

**Results.** We found that task difficulty is substantially predictable from static features ($AUC = 0.863$) and is largely driven by patch fragmentation and repository scale. Prompt linguistic features become visible among top contributors for tasks in the mid-band, revealing a layered structure of difficulty.

**Conclusion.** The difficulty of an issue resolution task is encoded in its structure. This enables static, pre-hoc difficulty estimation and lays the groundwork for difficulty-controlled benchmark construction for evaluation of agents.

## 1 Introduction

AI-based coding agents are rapidly advancing, with the best open-source systems now resolving more than half the tasks on SWE-bench Verified [28]. The aggregate solve rate, however, provides no account of *why* a task is hard. Understanding this in agent outcomes is critical as agentic decision-making systems become more widely deployed. Prior work has invested heavily in building larger and more diverse task collections [12, 37, 3] and in validating the correctness of existing ones [1, 28], but has not systematically characterized task difficulty from static properties. Item Response Theory (IRT) [17] offers a framework for difficulty estimation, and recent work applies it to the agentic coding setting using LLM embeddings and rubric scores [6]. However, their approach involves nondeterministic features that complicate reproducibility.

© Ebtesam Al-Haque and Brittany Johnson;
licensed under Creative Commons License CC-BY 4.0

To address this gap, we conducted a large-scale empirical study on CoderForge-Preview [2] to answer the following research questions:

**RQ1** Can static task features predict agent success?
**RQ2** Which feature groups account for predictive performance?
**RQ3** Which individual features are most strongly associated with agent success?

We represent task difficulty as agent success rate and engineer several features across three groups: the gold patch, the repository, and the natural-language prompt, grounded in prior literature on code change complexity, software navigation, and requirements engineering. We then train models, measure their predictive accuracy, ablate feature groups, and decompose predictions using SHAP values to identify which features drive difficulty and how.

To this end, our work makes the following contributions:

- We introduce a deterministic measurement framework for characterizing issue-resolution task difficulty from static patch, repository, and prompt properties.
- We provide large-scale evidence that agent success is predictable from static task structure.
- We identify factors that influence task success and briefly discuss how this varies across different levels of difficulty.

## 2 Related Work

### 2.1 Agentic Benchmarks for Issue Resolution

SWE-bench [14] established the standard task for evaluating LLM-based agents: given a repository and an issue description, produce a patch that passes a held-out test suite. Progress on the benchmark has been rapid, but so have concerns about what aggregate solve rates actually measure. SWEBench+ [1] and UTBoost [38] independently found that a large fraction of resolved instances involved solution leakage or tests too weak to discriminate correct from incorrect patches; once filtered, resolution rates drop by more than half. SWE-bench Verified [28] addressed this through manual developer vetting of 500 instances. Subsequent work has moved toward harder settings: long-horizon multi-file tasks in SWE-bench Pro [5], terminal-interaction tasks in Terminal Bench [24], and software performance optimization in GSO [31]. In parallel, training-oriented environments have scaled task supply: R2E-Gym [12], SWE-Smith [37], and SWE-Rebench [3] together generate tens of thousands of executable tasks from real commits. CoderForgePreview [2], the dataset we study, assembles 51K tasks from all three sources. What none of this work provides is an account of *why* some tasks are harder than others. Our study is the first to systematically quantify which structural properties of a task derived from the required patch, the repository, and the issue description drive agent success rates on a large scale.

### 2.2 Predicting Task Difficulty

Item Response Theory (IRT) has become the standard tool for modeling task-level difficulty in language-model evaluation [17], with recent work using it to reduce evaluation cost through adaptive task selection [29, 11, 32]. Ge et al. [6] bring IRT explicitly into the agentic coding setting, augmenting the Rasch model with LLM embeddings and LLM as-a-judge rubric scores to predict task difficulty on SWE-bench Verified, SWE-bench Pro, Terminal-Bench, and GSO.

Our features are fully deterministic measures grounded in empirical software engineering constructs rather than LLM encodings. This makes our difficulty scores reproducible without any model inference. The structural features we identify could serve as cost effective, interpretable inputs to an IRT difficulty predictor of the type they describe.

## 2.3 Code Change Complexity and Fault Localization

The patch and repository features we engineer are grounded in a long empirical literature on what makes software changes hard to understand and fix. Munson and Elbaum [26] and Nagappan and Ball [27] established code churn as a reliable predictor of defect density. The just-in-time defect prediction literature [16, 25, 39] further shows that it is not raw volume but *diffusion*, how scattered a change is across files and hunks, that most consistently distinguishes defect-inducing from clean commits. We carry these measures into the agentic setting and find similar patterns.

## 2.4 Linguistic Properties

The natural-language prompt an agent receives is functionally a software requirement. Two decades of work has discovered ways to measure specification quality and clarity. They identified coordination ambiguity, referential ambiguity, and attachment ambiguity as the three most consequential sources of misinterpretation in natural-language requirements [10, 30]. Recent empirical work shows that LLMs struggle to reliably identify ambiguous requirements [18] and that ambiguous specifications increase code generation uncertainty by introducing multiple valid interpretations [34]. What none of this work establishes is the *relative* importance of specification quality compared to structural task properties, or whether linguistic features carry independent signal once structural features are controlled for. We directly address this in our work.

# 3 Method

## 3.1 Dataset

CoderForge-Preview [2] is the largest open dataset of coding agent trajectories to date, consisting of 258K test-verified trajectories spanning 51K tasks across 1,655 repositories. Tasks are drawn from three sources: R2E-Gym (4,216 tasks) [12], SWE-Smith (37,221 tasks) [37], and SWE-Rebench (9,764 tasks) [3]. We generated trajectories using Qwen3-Coder-480B [35], one of the best-performing open-source models on agentic coding benchmarks, operating within an OpenHands v0.52.1 scaffold where the agent iteratively issues bash commands and file edits for up to 100 steps within an isolated Docker container. This makes CoderForge-Preview well-suited for studying the behavioral characteristics of capable coding agents rather than the failure modes of weaker models. They generated multiple trajectories per task (up to 8), and retained those whose final patches pass all repository tests as successful. For our work, we excluded R2E-Gym tasks due to lack of a compatible patch format. We also excluded tasks for which we could not map to the repository using the GitHub API. Our experiments therefore draw on 45,769 tasks from SWE-Smith and SWE-Rebench spanning 1,553 repositories, with a mean of 4.8 trajectories per task. 49.8% of tasks are solved by every trajectory (*always pass*), 32.5% by none (*always fail*), and 17.7% exhibit mixed outcomes where some but not all trajectories succeed.

## 3.2 Feature Engineering

We engineered features across three groups, each capturing a distinct dimension of task difficulty. **Patch features** characterize what a correct solution looks like. **Repository features** characterize the structural environment the agent must navigate. **Prompt features** characterize the natural-language specification the agent must interpret. An overview of

the three groups and their sub-constructs is shown in Table 1. Tables 2–4 list every feature with a description. Features marked † were dropped during the feature selection process (Section 3.3); the 54 retained features are used in all models.

**Table 1** Feature taxonomy overview. Each cell shows the sub-construct and its feature count.

| **Patch** (18) | **Repository** (14) | **Prompt** (31) |
|---|---|---|
| Edit volume (3) | Scale (5) | Component load (4) |
| Edit fragmentation (4) | Directory structure (4) | Coordinative complexity (6) |
| File scope (4) | Naming ambiguity (1) | Coordination ambiguity (5) |
| Churn distribution (3) | Test infrastructure (3) | Attachment ambiguity (7) |
| Spatial distribution (4) | Documentation (1) | Referential ambiguity (4) |
| | | Cohesion (5) |

### 3.2.1 Patch Features

The patch group captures *solution complexity*: how much the agent must find, understand, and change to resolve an issue. The features here draw on the JIT defect prediction constructs discussed in Section 2.3.

**Table 2** Patch features.

| **Sub-construct** | **Feature** | **What it measures** |
|---|---|---|
| Edit volume | `patch_lines_added` | Lines inserted in the gold patch |
| | `patch_lines_deleted` | Lines removed in the gold patch |
| | `patch_lines_changed_total`† | Total churn |
| Edit fragmentation | `patch_num_hunks` | Total disjoint edit blocks |
| | `patch_edit_fragmentation` | Hunks per changed file |
| | `patch_hunk_gap_mean` | Mean unchanged lines between consecutive hunks |
| | `patch_test_files_changed` | Test files in the diff |
| File scope | `patch_src_files_changed` | Non-test source files changed |
| | `patch_python_files_changed` | Python files changed |
| | `patch_extensions_changed_count` | Distinct file types touched |
| | `patch_num_files_changed`† | Total files changed |
| Churn distribution | `patch_churn_gini_over_files` | Edit concentration across files |
| | `patch_is_single_file` | Binary: all edits in one file |
| | `patch_entropy_over_files`† | Edit entropy |
| Spatial distribution | `patch_primary_file_depth` | Directory depth of most-edited file |
| | `patch_num_unique_dirs_changed` | Distinct directories touched |
| | `patch_mean_file_depth`† | Mean depth of changed files |
| | `patch_max_file_depth`† | Max depth of changed files |

### 3.2.2 Repository Features

The repository group captures *navigation difficulty*: how hard it is to locate the relevant code before making any edit. Fault localization is a prerequisite for patch generation; before an agent can write a fix, it must identify which files and lines are relevant to the issue. We represent navigation difficulty through two primary sub-constructs. *Scale* features (file count, codebase size, directory count) reflect the size of the search space the agent must traverse. *Directory structure* features (root-level breadth, maximum and mean nesting depth) reflect

the structural complexity of that space. A *naming ambiguity* feature (basenames shared by two or more files) captures another layer of complexity in identifying the right file to edit. *Test infrastructure* and *documentation* features capture repository organization conventions that may provide or withhold contextual signals useful for localization.

**Table 3** Repository features.

| Sub-construct | Feature | What it measures |
|---|---|---|
| Scale | `repo_file_count` | Total files in the repository |
| | `repo_python_file_count` | Python files |
| | `repo_total_known_size` | Codebase size in bytes |
| | `repo_mean_known_file_size` | Mean file size in bytes |
| | `repo_dir_count` | Total directory count |
| Directory structure | `repo_top_level_dir_count` | Breadth at root level |
| | `repo_max_depth` | Maximum directory nesting depth |
| | `repo_mean_file_depth` | Mean file nesting depth |
| | `repo_test_ratio` | Fraction of files that are tests |
| Naming ambiguity | `repo_basename_collision_count` | Basenames shared by $\geq$2 files |
| Test infrastructure | `repo_test_file_count` | Number of test files |
| | `repo_has_tests_dir` | Dedicated `tests/` directory present |
| | `repo_has_examples_dir` | `examples/` directory present |
| Documentation | `repo_has_docs_dir` | `docs/` directory present |

### 3.2.3 Prompt Features

The prompt group captures *specification interpretability*: whether the agent can derive an action plan from the issue text. We draw on the RE literature's taxonomy of natural-language defects to motivate four sub-constructs. *Component load* features measure how much information the agent must integrate. *Coordinative complexity* features represent structural processing difficulty at the sentence level, motivated by Gibson's Dependency Locality Theory [8] and the finding that syntactically complex prompts increase LLM code generation uncertainty [18, 34]. *Ambiguity* features represent the three defect types identified by the RE literature as most consequential for misinterpretation: coordination ambiguity (scope of conjunctions), attachment ambiguity (which constituent a modifier modifies), and referential ambiguity (which noun phrase a pronoun resolves to) [10, 36]. *Cohesion* features measure lexical and semantic connectivity between adjacent sentences [9, 22].

## 3.3 Feature Selection

We applied iterative Variance Inflation Factor (VIF) [4] filtering with threshold 10 [21], dropping the highest-VIF feature in each iteration until all scores fall below the threshold. This process dropped 9 features (marked † in Tables 2–4), leaving 54 features with a maximum VIF of 7.59. The same feature set is used for all three models.

## 3.4 Predictive Modeling

### 3.4.1 Outcome Variables

For each task, we compute three outcome variables: **(1) pass_rate**: the fraction of runs that passed all tests (continuous, $[0, 1]$; mean = 0.593, SD = 0.455). **(2) any_success** (*pass@k*): an indicator of whether at least one run succeeded (positive rate: 67.5%). **(3) maj_success** (majority success): an indicator of whether the majority ($\geq$ 50%) of runs succeeded (positive rate: 61.7%).

**Table 4** Prompt features.

| Sub-construct | Feature | What it measures |
|---|---|---|
| Component load | prompt_len_bpe | Prompt length in BPE tokens |
| | prompt_sent_count | Number of sentences |
| | prompt_clauses_per_sentence† | Clauses per sentence |
| | prompt_content_tokens_per_sentence† | Content tokens per sentence |
| Coordinative complexity | prompt_dep_distance_mean | Mean linear dependency distance |
| | prompt_dep_distance_max | Max linear dependency distance |
| | prompt_branching_factor_mean | Mean syntactic branching factor |
| | prompt_clause_nesting_depth_mean | Mean clause nesting depth |
| | prompt_clause_length_mean | Mean clause length |
| | prompt_clausal_branching_factor | Mean clause-level branching |
| Coordination ambiguity | prompt_coordination_density | Conjunctions per clause |
| | prompt_mean_conj_chain_len | Mean conjunction chain length |
| | prompt_max_conj_chain_len | Max conjunction chain length |
| | prompt_verb_coordination_ratio | Conjunctions with verb heads |
| | prompt_noun_coordination_ratio | Conjunctions with noun heads |
| Attachment ambiguity | prompt_pp_density_per_noun | PP count per noun |
| | prompt_pp_density_per_clause | PP count per clause |
| | prompt_mean_pp_chain_depth | Mean PP nesting depth |
| | prompt_max_pp_chain_depth | Max PP nesting depth |
| | prompt_multi_pp_head_ratio | Heads with $\geq$2 attached PPs |
| | prompt_attachment_competition_ratio | Heads with $\geq$2 competing dependents |
| | prompt_mean_competing_dependents_per_head | Mean competing dependents per head |
| Referential ambiguity | prompt_pronouns_per_sentence | Pronouns per sentence |
| | prompt_pronoun_candidate_antecedent_density | Candidate antecedents per pronoun |
| | prompt_multi_antecedent_pronoun_ratio | Pronouns with $\geq$2 antecedents |
| | prompt_pronoun_ratio† | Pronoun fraction |
| Cohesion | prompt_adjacent_lemma_overlap_mean | Lemma overlap between adjacent sentences |
| | prompt_sentence_embedding_sim_mean | Mean cosine sim of adjacent sentences |
| | prompt_sentence_embedding_sim_min | Min cosine sim of adjacent sentences |
| | prompt_entity_reuse_ratio | Entity reuse across sentences |
| | prompt_coref_chain_len_mean† | Coreference chain length |

**Table 5** Outcome variable distributions ($n$ = 45,7695 tasks).

**(a)** Continuous outcome.

| Outcome | Mean | SD |
|---|---|---|
| `pass_rate` | 0.593 | 0.455 |

**(b)** Binary outcomes.

| Outcome | Positive rate | Imbalance ratio |
|---|---|---|
| `any_success` | 67.5% | 2.08 |
| `maj_success` | 61.7% | 1.61 |

### 3.4.2 Data Split

We split the dataset at the task level into training and held-out test sets using an 80/20 split, resulting in 36,615 training tasks and 9,154 test tasks.

### 3.4.3 Model

We trained and three model classes for each outcome. We selected hyperparameters using `RandomizedSearchCV` with 4-fold inner cross-validation and 28 iterations per model group, using ROC-AUC as the classification scoring criterion and negative mean squared error for regression. All hyperparameters reported below reflect the tuned values found by this procedure.

- **Binary classification models.** For `any_success` and `maj_success`, we train: (i) Logistic Regression with L2 regularization and standardized features ($C = 0.013$ for `any_success`; $C = 0.037$ for `maj_success`); (ii) Random Forest with 500 trees, maximum depth 16, `max_features`= 0.25, and minimum 8 samples per leaf; and (iii) XGBoost with 400 trees, maximum depth 8, learning rate 0.03, and minimum child weight 2. Ensemble methods, particularly Random Forest and gradient boosting, consistently outperform linear classifiers in software defect prediction tasks [19, 7], motivating their inclusion alongside the interpretable linear baseline.
- **Regression models.** For `pass_rate`, we train: (i) Ridge Regression with $\alpha = 115.67$ and standardized features; (ii) Random Forest Regressor with 500 trees, unlimited depth, `max_features`= 0.25, and minimum 4 samples per leaf; and (iii) XGBoost Regressor with a squared-error objective and the same hyperparameters as the classifiers.

### 3.4.4 Evaluation

**Output Metrics.** We evaluated the models on the held-out test set. Classification performance is reported using AUC–ROC, Precision–Recall AUC (PR–AUC), Brier score, F1, and Matthews Correlation Coefficient (MCC). Regression performance is reported using RMSE, MAE, and $R^2$. We additionally perform 10-fold cross-validation on the training set for the XGBoost model and report mean ± SD to confirm stability.

**Feature Importance.** Beyond predictive accuracy, we quantify the direction and magnitude of each feature's association with task success.

- **Component ablation.** We trained XGBoost models using each feature group alone, all pairwise combinations, and the full three-way combination. We report test AUC and $R^2$ for each subset to estimate how much predictive signal is contributed by patch complexity, repository structure, and issue text.

- **SHAP feature importance.** We compute SHAP values for the best-performing XGBoost model and rank features by their mean absolute contribution to model predictions. SHAP additive explanations provide a theoretically grounded decomposition of model predictions [20], making them suitable for interpreting the relative importance of features in a non-linear ensemble model.

# 4 Results

## 4.1 Task-Level Feature Agent Success Prediction Accuracy (RQ1)

Static task features derived from the gold patch, repository structure, and agent prompt yield strong predictive performance across all three outcome targets. Table 6 reports held-out test performance for all models alongside a majority-class baseline that assigns the positive label to every task. The baseline achieves AUC = 0.500 and MCC = 0.000, confirming that it carries no discriminative information; its comparatively high F1 score of 0.806 is due to the 67.5% positive rate in the `any_success` target and should not be interpreted as predictive signal.

Among the three classifiers, XGBoost and Random Forest reach near-identical performance on `any_success` (XGBoost: AUC = 0.863, MCC = 0.549, Brier = 0.129; Random Forest: AUC = 0.863, MCC = 0.538, Brier = 0.128).

**Table 6** Held-out test performance. Majority denotes the always-positive baseline. Bold denotes best non-baseline result per metric per target.

| Target | Model | AUC | PR-AUC | Brier | F1 | MCC |
|---|---|---|---|---|---|---|
| `any_success` | Majority | 0.500 | 0.675 | 0.219 | 0.806 | 0.000 |
| | Logistic | 0.750 | 0.849 | 0.183 | 0.741 | 0.341 |
| | Random Forest | **0.863** | 0.914 | **0.128** | 0.832 | 0.538 |
| | XGBoost | **0.863** | **0.916** | 0.129 | **0.848** | **0.549** |
| `maj_success` | Majority | 0.500 | 0.617 | 0.383 | 0.763 | 0.000 |
| | Logistic | 0.738 | 0.809 | 0.198 | 0.722 | 0.330 |
| | Random Forest | **0.848** | **0.885** | **0.147** | 0.797 | 0.508 |
| | XGBoost | 0.845 | 0.884 | 0.148 | **0.811** | **0.517** |

*`pass_rate` regression*

| Model | RMSE | MAE | $R^2$ |
|---|---|---|---|
| Ridge | 0.415 | 0.374 | 0.169 |
| Random Forest | **0.350** | **0.276** | **0.409** |
| XGBoost | **0.350** | **0.276** | 0.408 |

The substantially lower performance of Logistic Regression (AUC = 0.750, MCC = 0.341) indicates that the relationship between task features and agent success is *non-linear* and cannot be adequately captured by a linear decision boundary.

Predicting the continuous `pass_rate` outcome is a harder problem. Ridge regression accounts for only 16.9% of variance ($R^2 = 0.169$), whereas Random Forest and XGBoost reach $R^2 = 0.409$ and $R^2 = 0.408$ respectively, showing a 2.4× improvement over the linear baseline. The two ensemble methods are essentially tied on this target. A portion of the remaining variance is likely irreducible: 17.7% of tasks show mixed outcomes across repeated runs, and no static task-level feature can account for the stochastic component of agent behavior within a fixed task.

Ten-fold cross-validation on the XGBoost training set confirms that held-out test performance is stable. For `any_success`, mean CV AUC is $0.851 \pm 0.009$ and mean CV MCC is $0.558 \pm 0.017$, both in close agreement with held-out test values. For `maj_success`, mean CV AUC is $0.838 \pm 0.006$ and mean CV MCC is $0.530 \pm 0.008$. For the `pass_rate` regression, mean CV $R^2$ is $0.386 \pm 0.008$, consistent with the held-out result of 0.408.

Calibration reliability diagrams for all three classifiers are shown in Figure 1. XGBoost is the best-calibrated model across both outcomes, with small deviations from the diagonal. Random Forest is well-calibrated in the upper probability range but exhibits overconfidence in the low-to-mid range, where predicted probabilities consistently exceed observed success rates. Logistic Regression shows the largest deviations across both outcomes, consistent with its compressed prediction range and weaker discriminative performance. The well-calibrated XGBoost probability estimates make it the preferred model for downstream applications such as task stratification and difficulty-weighted evaluation.

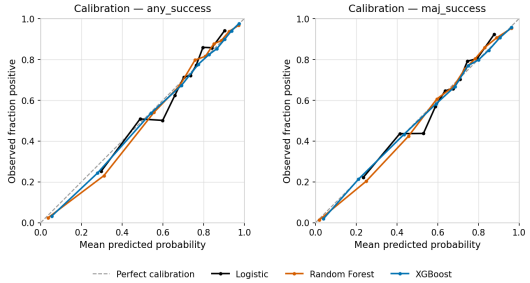

**Figure 1** Calibration reliability diagrams.

**Finding 1.** Task-level features derived from the patch, repository, and agent prompt predict agent success with AUC = 0.863 and MCC = 0.549 (XGBoost), explaining 41% of pass-rate variance ($R^2 = 0.408$), with well-calibrated probability estimates across the full prediction range.

## 4.2 Feature Groups Driving Predictive Performance (RQ2)

To determine the independent contribution of each feature group, we trained XGBoost models using each group alone and in all pairwise and three-way combinations, evaluating on the held-out test set across all three outcome definitions. Table 7 presents the results.

Patch features alone achieve AUC = 0.846 on `any_success` and $R^2 = 0.375$ on `pass_rate`. Repository features alone perform comparably, with AUC = 0.839 and $R^2 = 0.350$. Combining these two groups yields AUC = 0.861 and $R^2 = 0.401$, within 0.002 AUC and 0.006 $R^2$ of the full 54-feature model (AUC = 0.863, $R^2 = 0.406$).

Considered in isolation, the prompt group performs near chance on both binary outcomes (AUC = 0.599 for `any_success`; AUC = 0.593 for `maj_success`) and explains almost none of the continuous variance ($R^2 = 0.025$). Adding prompt features to patch alone yields marginal gains ($\Delta$AUC $\leq 0.004$, $\Delta R^2 = 0.005$ on `pass_rate`), and adding them to repository alone is similarly modest ($\Delta$AUC $\leq 0.004$, $\Delta R^2 = 0.012$ on `pass_rate`). Critically, once both patch and repository features are included, adding all prompt features produces negligible further gain: $\Delta$AUC $\leq 0.002$ and $\Delta R^2 < 0.01$ across all three outcome definitions. This pattern is consistent across both discrimination (AUC) and calibration (Brier score) measures.

**Table 7** Component ablation using XGBoost on the held-out test set. AUC and Brier score are reported for the two binary outcomes; $R^2$ and MAE for the continuous `pass_rate` outcome. Bold denotes the best value in each column.

| | | any_success | | maj_success | | pass_rate | |
|---|---|---|---|---|---|---|---|
| **Feature set** | **N** | **AUC** | **Brier** | **AUC** | **Brier** | **$R^2$** | **MAE** |
| Patch only | 13 | 0.846 | 0.135 | 0.830 | 0.154 | 0.375 | 0.285 |
| Repo only | 14 | 0.839 | 0.137 | 0.820 | 0.158 | 0.350 | 0.291 |
| Prompt only | 27 | 0.599 | 0.214 | 0.593 | 0.231 | 0.025 | 0.417 |
| Patch + Repo | 27 | 0.861 | 0.129 | 0.841 | 0.149 | 0.401 | 0.275 |
| Patch + Prompt | 40 | 0.850 | 0.135 | 0.832 | 0.154 | 0.380 | 0.290 |
| Repo + Prompt | 41 | 0.839 | 0.138 | 0.823 | 0.158 | 0.361 | 0.295 |
| All features | 54 | **0.863** | **0.129** | **0.846** | **0.148** | **0.406** | **0.277** |

These results indicate that the difficulty of a task, as measured by agent success rates, is determined almost entirely by the structural properties of the required solution. Specifically, how complex and scattered the patch is, and how large and complex the repository environment is are the strongest indicators. The linguistic and syntactic properties of the agent prompt, as operationalized by our feature set, carry negligible independent signal beyond these structural factors. Whether prompt properties matter conditionally, for specific tasks or in specific circumstances, is a question this ablation study alone cannot answer; we examine individual feature contributions in RQ3.

**Finding 2.** Patch complexity and repository structure together account for virtually all of the predictable variance in agent success across all outcome definitions, achieving AUC = 0.861 and $R^2 = 0.401$ with 27 features – within 0.002 AUC of the full model.

## 4.3 Individual Feature Association with Agent Success (RQ3)

We use SHAP values computed via `TreeExplainer` on the held-out test set to identify which features drive predictions and in what direction [20]. We report mean absolute SHAP value as the importance measure, SHAP dependence plots for directional effects, and SHAP interaction values for joint effects between feature pairs. All analyses use the tuned XGBoost model; we compare feature rankings between `any_success` and `pass_rate` to assess whether findings generalize across outcome definitions.

### 4.3.1 Feature Importance and Directional Effects

Figure 3 shows the top 20 features by mean absolute SHAP value for each outcome. Figure 4 shows the corresponding SHAP summary plot for `any_success`, which reveals the direction of each effect. The same three features occupy the top positions across all outcomes: `patch_lines_deleted`, `patch_num_hunks`, and `patch_hunk_gap_mean` (ranks 1–3, with only a 1/2 swap between targets, visible as near-flat connecting lines in Figure 3). For `any_success`, `patch_lines_deleted` has a mean absolute SHAP of 0.406– 2.65× larger than the fourth-ranked feature
(`repo_top_level_dir_count`, 0.153) – and the top three features together account for 29% of total mean absolute SHAP across all 54 features.

In the summary, all three plots show a clear monotone negative pattern: high feature values push predictions toward failure. `patch_hunk_gap_mean` additionally exhibits a small number of extreme outliers (SHAP $\approx -2.5$), indicating that tasks with unusually large

inter-hunk distances are especially penalized. SHAP values decay steeply below the leading group: the 20th-ranked feature (`prompt_len_bpe`) has a mean absolute SHAP 9× smaller than the top feature, and below rank 10 distributions are tightly clustered near zero with no directional gradient. Ranks 4–14 are occupied entirely by repository structural and patch features, all showing negative directional effects in Figure 4. These contribute independently of the top patch trio, suggesting that the navigational complexity of the repository the agent must traverse matters beyond the properties of the edit itself.

The waterfall plots (Figures 5a–5b) illustrate how these effects compose at the task level. All values are in log-odds space; the population baseline is $E[f(x)] = 0.73$. The easiest task ($\hat{p} = 0.997$, `pygments/pygments`) has a compact two-site edit: every structural contributor pushes the prediction upward from baseline. The hardest task ($\hat{p} = 0.013$, `getnikola/nikola`) has moderate patch volume but high `repo_top_level_dir_count` as the second-largest negative contributor – illustrating that the combination of moderate fragmentation and a wide repository suffices to drive the prediction to near-zero success. The average task ($\hat{p} \approx 0.68$, `kurtmckee/feedparser`, Figure 6a) sits just above baseline with mixed structural signals, a pattern examined further below.

Feature interactions are dominated by patch × repo pairs; Figure 2 shows the top four by mean absolute interaction value averaged across outcomes. The two leading pairs (`patch_hunk_gap_mean` × `lines_deleted` and `num_hunks` × `top_level_dir_count`) swap ranks between `any_success` and the other two targets but remain the top interactions throughout.

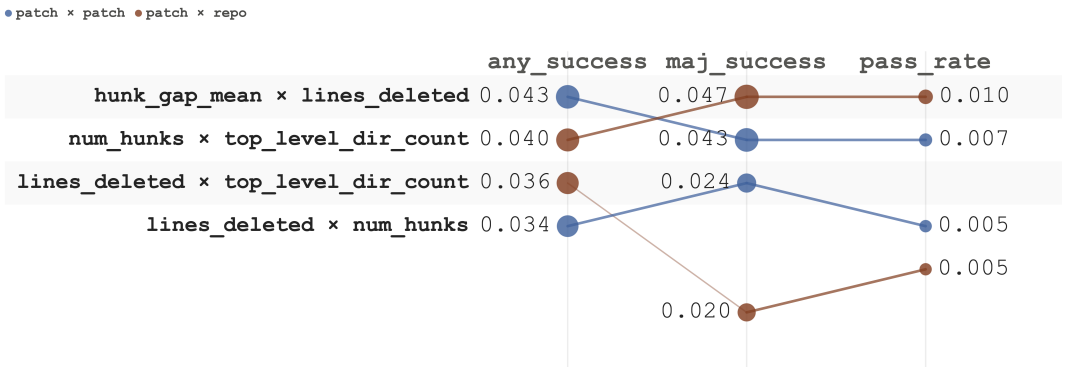

**Figure 2** Rank–magnitude bump chart for the top four SHAP interaction pairs by mean absolute interaction value averaged across outcome targets.

### 4.3.2 Prompt Features in the Mid-Band

At the population level, prompt features first appear at rank 16 and carry an order of magnitude less SHAP mass than the leading patch features (Figure 3), consistent with the RQ2 ablation. These aggregate results, however, can suppress changes in the relative importance of feature groups across the prediction range.

We stratify tasks by the predicted probability $\hat{p}$ for `any_success`: *easy* tasks fall in the top decile of $\hat{p}$ ($n$=893), *hard* tasks in the bottom decile ($n$=886), and *mid-band* tasks have predictions within 0.05 of the mean prediction ($\bar{\hat{p}}$=0.685; $n$=575). This group has a median summed SHAP contribution is +0.09 log-odds, compared with +2.84 for easy tasks and −3.76 for hard tasks.

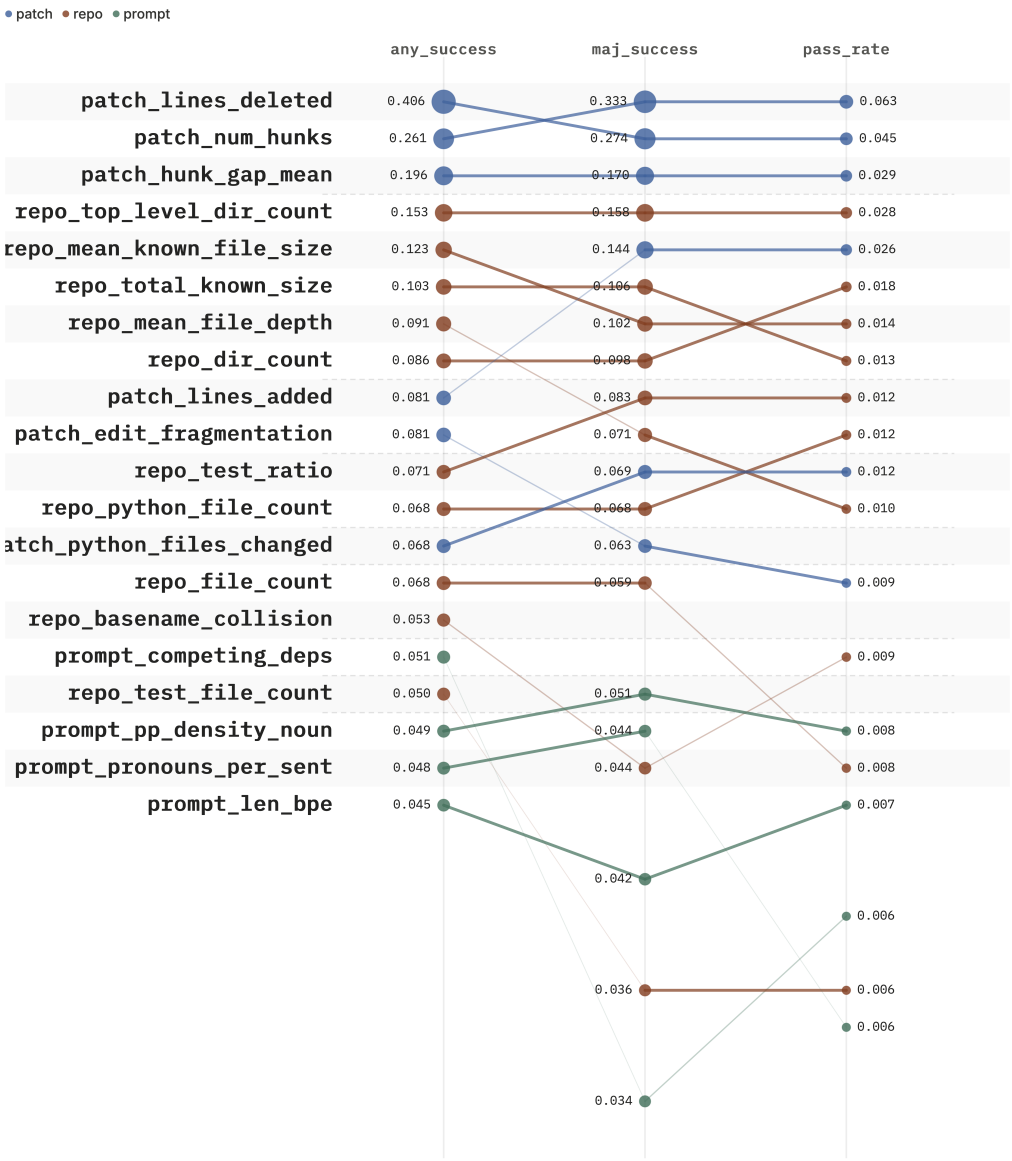

**Figure 3** Rank–magnitude bump chart for the top 20 features by mean absolute SHAP value across three outcome targets (XGBoost, held-out test set). Each dot is one feature–outcome pair; dot area is proportional to mean absolute SHAP. Connecting lines trace rank shifts across outcomes; steep slopes indicate instability. Color encodes feature family: patch (blue), repo (red-brown), prompt (green). The top six ranks are stable across all three outcomes (near-flat lines); prompt features first appear at rank 16 with visibly smaller dots and show greater rank instability below rank 16.

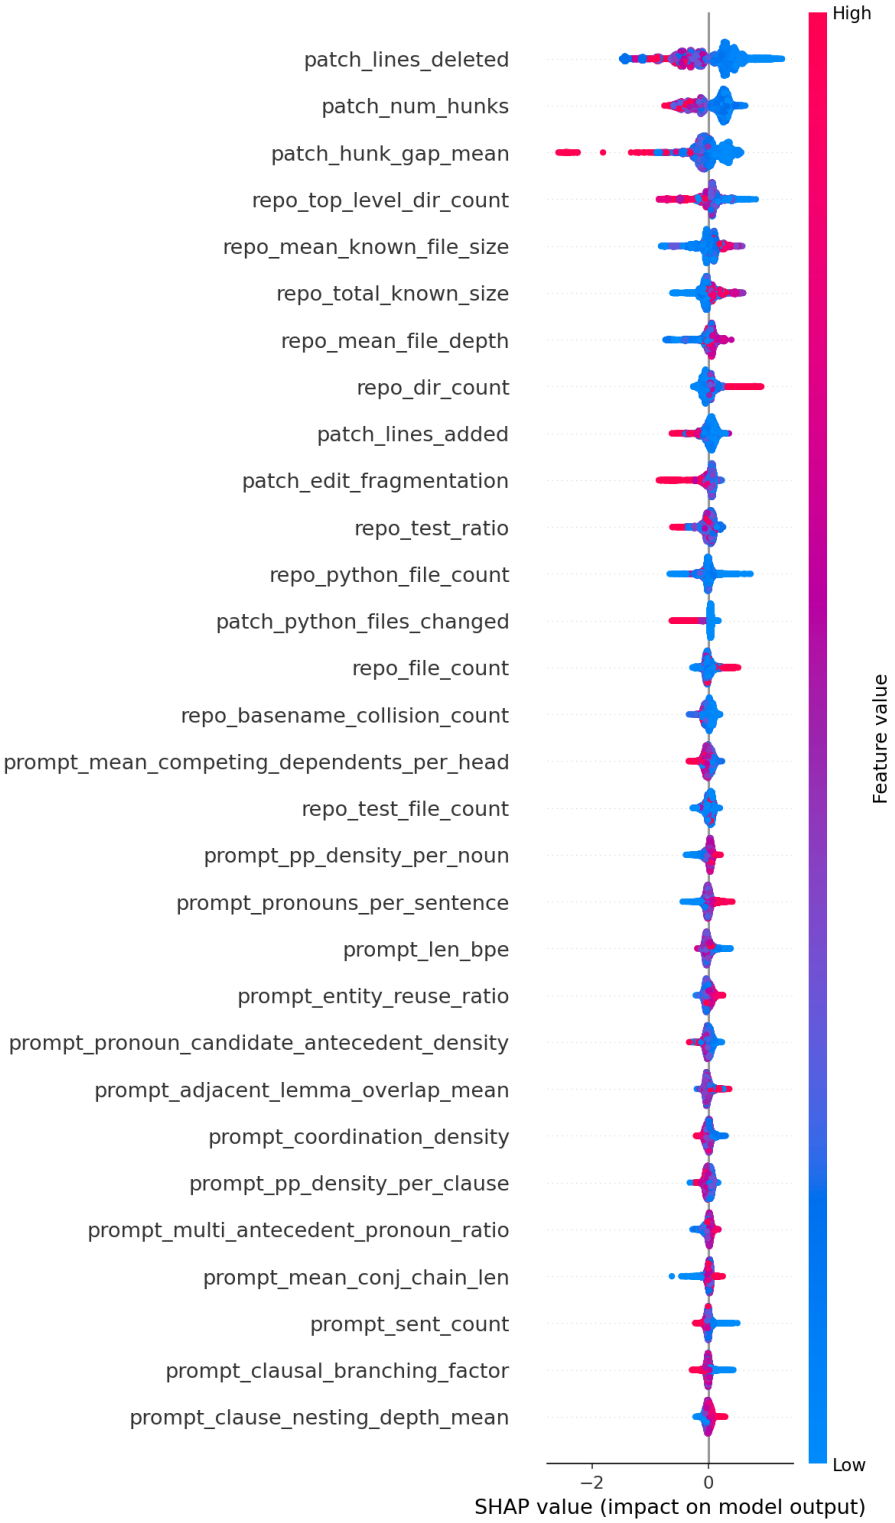

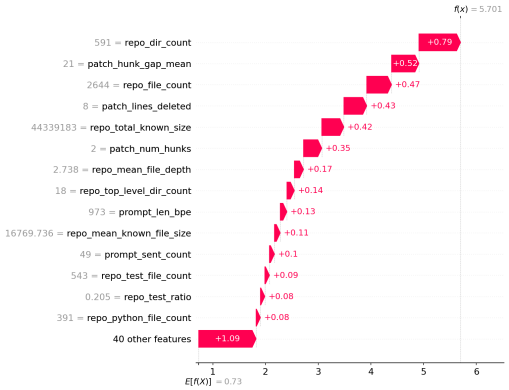

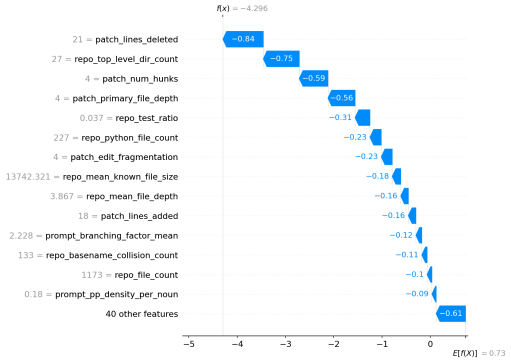

**Figure 4** SHAP summary plot for `any_success`.

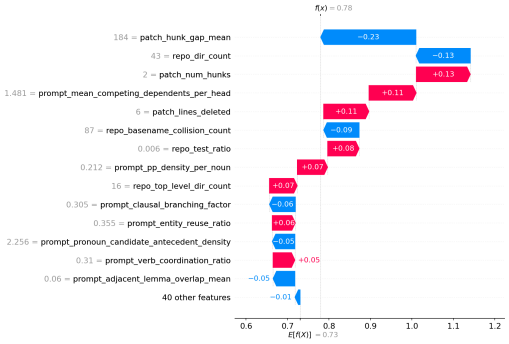
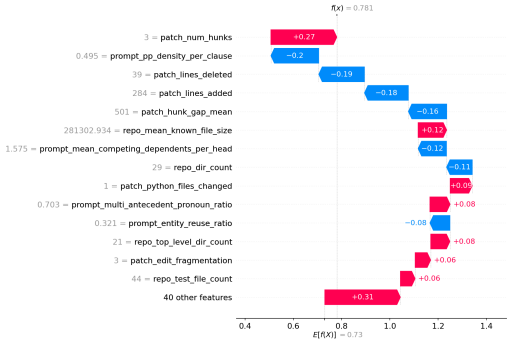


**(a)** Easiest task (`pygments/pygments`); $\hat{p} = 0.997$, $E[f(x)] = 0.73$, observed: success. Every structural contributor pushes the prediction upward from baseline.



**(b)** Hardest task (`getnikola/nikola`); $\hat{p} = 0.013$, $E[f(x)] = 0.73$, observed: failure. Despite only moderate patch volume, high `repo_top_level_dir_count` is the second-largest negative contributor, illustrating the patch–repository interaction.

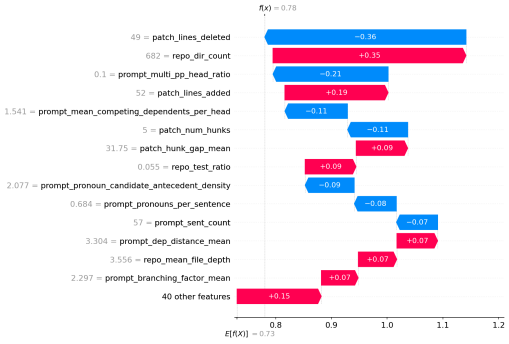


**Figure 5** SHAP waterfalls for extreme-difficulty tasks (XGBoost, `any_success` target). All values in log-odds space; $E[f(x)] = 0.73$ for both.

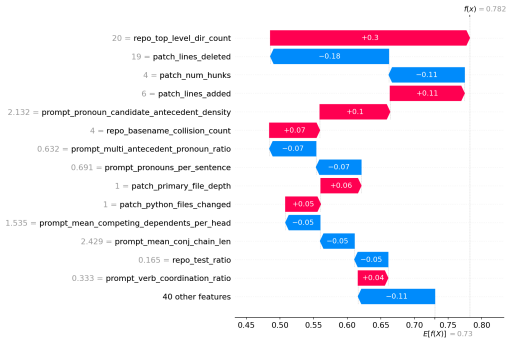

**(a)** `kurtmckee/feedparser`; $\hat{p} = 0.684$, observed: success. Mixed structural signals sit just above baseline.

**(b)** `sqlglot`; $\hat{p} = 0.685$, observed: failure. `prompt_pp_density_per_clause` ($-0.20$) is the second-largest contributor.

**(c)** `faker`; $\hat{p} = 0.684$, observed: success. `prompt_multi_pp_head_ratio` ($-0.21$) is the third-largest contributor.

**(d)** `parso`; $\hat{p} = 0.685$, observed: success. `prompt_pronoun_candidate_antecedent_density` ($+0.10$) ranks fifth among contributors.

**Figure 6** SHAP waterfalls for four representative average-difficulty tasks ($\hat{p} \approx 0.68$, $E[f(x)] = 0.73$, XGBoost, `any_success`). In three of four cases a prompt feature ranks among the top contributors, with magnitudes comparable to the structural features for those tasks.

Prompt features become substantially more prominent in the mid-band. At least one prompt feature ranks among the five largest contributors for **70.3**% of near-baseline tasks (404/575), **26.8**% of easy tasks (239/893), and **6.8**% of hard tasks (60/886). The same ordering holds for `pass_rate` and `maj_success`.

We observe that the gap between prompt and structural contributions begin to narrow here. We define $[R(x) = \frac{\max_{j \in \text{prompt}} |\phi_j(x)|}{\max_{j \in \text{structural}} |\phi_j(x)|}]$. Median $R$ rises to 0.404 near mid-band, compared with 0.205 (1.97×) for easy tasks and 0.108 (3.75×) for hard tasks.

No single prompt feature accounts for the pattern. The three most frequent contributors are `prompt_pronouns_per_sentence` (referential ambiguity, 11.1% of near-baseline tasks; 64/575), `prompt_mean_conj_chain_len` (coordination ambiguity, 10.1%; 58/575), and `prompt_mean_competing_dependents_per_head` (attachment ambiguity, 9.4%; 54/575), all established markers of processing difficulty in computational linguistics [8].

Figure 6 illustrates this at the task level with three representative examples:

`prompt_pp_density_per_clause`, another attachment-ambiguity feature, is the second-largest contributor in a `sqlglot` task (−0.20); `prompt_multi_pp_head_ratio` ranks third in a `faker` task (−0.21); `prompt_pronoun_candidate_antecedent_density` ranks fifth in a `parso` task (+0.10).

**Finding 3.** The composition of task-difficulty signals changes across the prediction range. Patch fragmentation and repository scale dominate at the extremes, reliably separating easy from hard tasks across all three outcome definitions. Near the mid-band, prompt features enter the top-5 SHAP contributors for 70.3% of tasks, versus 26.8% (easy) and 6.8% (hard). No single prompt feature displaces patch or repository features in aggregate importance.

## 5 Discussion

Our results make the structural composition of a benchmark directly observable. This helps reason about whether two benchmarks are measuring the same thing or whether an improvement in solve rate reflects a genuine capability gain in targeted dimensions.

One practical application for our findings is in benchmark auditing [33]. Computing difficulty scores for each task in an existing benchmark reveals whether the difficulty distribution is structurally balanced or concentrated in a narrow region of the task space. A benchmark heavily populated with compact, single-hunk patches in shallow repositories would systematically under-represent tasks that require broader navigation or multi-site coordination, which would be invisible in aggregate solve rates. This can also provide opportunities for more intentional benchmark design, where tasks structure and difficulty are explicit considerations.

A second application area is in difficulty-stratified evaluation. An agent that improves primarily on tasks that are already easy for the reference agent represents a qualitatively different kind of progress from one that improves on structurally difficult tasks. Reporting performance within difficulty quartiles would make this distinction visible. The model produces well-calibrated probability estimates across the full range, so predicted probabilities can be used directly as continuous difficulty scores without post-hoc recalibration.

The features required for these applications are entirely deterministic. This is a meaningful practical advantage over IRT-based difficulty estimation approaches such as that of Ge et al. [6], which require LLM embeddings and rubric scoring per task.

## 5.1 Toward Agent-Specific Difficulty Profiles

The difficulty patterns we found are relative to a specific reference agent, and that framing opens a natural extension of the work. Applying our framework separately to different agents would make per-agent difficulty profiles observable. Prior work in software engineering prediction shows why this matters. Menzies et al. found that global rules learned across heterogeneous populations were consistently outperformed by rules learned from neighboring clusters [23], and Jiang et al. showed that developer-specific defect models substantially outperformed pooled ones because developers differ too much in experience and coding style to be well-described by a single model [13]. The same principle likely applies here. What is hard for Qwen3 with this scaffold (due to, for example, its approach to navigating wide directory structures) may be easier for an agent with a different localization strategy. As trajectory data accumulates across frontier agents, this form of per-agent difficulty diagnosis becomes a practical step toward understanding and improving the specific structural bottlenecks each system faces.

## 5.2 Toward Calibrated Expectations in Development Tools

Though not the focus of our study, our efforts provide valuable insights towards trustworthy agentic developer solutions. Our findings connect to how developers decide how much to trust an agent's output on a given task. According to the PICSE [15] framework, trust in AI-assisted software tools is shaped in part by the expectations a developer brings to an interaction and by how well the system's reliability conditions are made explicit. A single aggregate benchmark score does not support this well as it hides the conditions under which the agent is more or less likely to succeed.

Difficulty scores give developers a more grounded basis for calibrating reliance. A developer who has a sense of how structurally complex a task is can look at an agent's performance within the corresponding difficulty band on a benchmark, rather than its overall solve rate, to form a more accurate expectation of whether the agent will succeed. This shifts the question from "how good is this agent" to "how good is this agent on tasks like this one," which is the question that matters most for deciding when and how to use an AI-assisted tool.

# 6 Threats to Validity

## 6.1 Internal

**Agent pretraining on benchmark repositories.** Qwen3-Coder-480B was pretrained on public code, and CoderForge-Preview draws from public GitHub repositories. Tasks from repositories present in pretraining may be solved at elevated rates unrelated to structural features.

**Outcome reliability and agent stochasticity.** Pass rate is estimated from trajectories generated at nonzero temperature, so outcomes conflate genuine task difficulty with sampling variance intrinsic to the agent's decoding process. No static feature can predict this stochastic component, which partially explains the irreducible variance in the regression target.

## 6.2 External

**Single model group.** All trajectories in CoderForge-Preview were generated by Qwen3-Coder-480B operating within an OpenHands scaffold. The features that predict difficulty for this agent may not generalize to agents with different architectures, context window sizes, or

scaffolding strategies. In particular, our finding that repository scale and directory breadth are important predictors implicitly reflects this agent's navigation strategy; an agent with a different file-localization approach might be less sensitive to these features. Replication with trajectories from other frontier agents would strengthen generalizability claims.

**Python-centric sample.** The underlying repositories are predominantly Python projects. Features related to Python file counts and test infrastructure reflect conventions of the Python ecosystem (e.g., `pytest`-based test organization). The absolute importance values for these features may not transfer directly to repositories in other languages, though the underlying constructs (test density, repository scale, edit fragmentation) are language-agnostic.

## 6.3 Construct

**Gold patch as ground truth.** Patch features are computed from the gold (oracle) patch provided with each task. In practice, an agent generates a candidate patch that may differ structurally from the gold. A task could have a simple gold patch but require complex agent reasoning, or vice versa. We use the gold patch as the best available proxy for "what a correct solution looks like," consistent with prior just-in-time defect prediction work. The strong predictive performance suggests this proxy is informative, but we acknowledge that gold-patch features do not capture all sources of task complexity.

**Prompt features.** Our linguistic prompt features operationalize structural conditions for ambiguity rather than ambiguity itself. The RE literature distinguishes *nocuous* ambiguity, where different readers reach genuinely different interpretations that lead to different implementations, from *innocuous* ambiguity, where the structure is syntactically ambiguous but context resolves it to a single intended meaning [36]. Our features cannot make this distinction. A syntactically complex issue description may still be pragmatically unambiguous as the domain, the surrounding code context, or simple common sense may resolve the attachment uniquely. Conversely, a structurally simple sentence can be genuinely nocuous if the two readings lead to different code changes. The consequence is that our prompt features measure a necessary but not sufficient condition for the kind of specification ambiguity that would actually mislead an agent. This upper-bounds their predictive power and is consistent with the low global SHAP signal we observe for prompt features. Whether finer-grained ambiguity detection, for instance, using LLM-as-judge to classify issues as nocuous versus innocuous – would recover additional predictive signal is an open question for future work.

# 7 Conclusion

The difficulty of a software issue resolution task is encoded in its structure. We showed that static, deterministic features derived from the gold patch, repository, and issue prompt predict agent success with AUC $= 0.863$ without any model inference. This enables pre-hoc difficulty estimation and opens the door to structurally controlled benchmark construction, difficulty-stratified evaluation, and more grounded developer reliance on agent tools. Future work will extend the framework across multiple agents to expose per-agent difficulty profiles and, in aggregate, a global difficulty landscape that characterizes the structural frontier of agentic software engineering. More broadly, the measurement framework generalizes naturally to other agentic SE tasks such as feature implementation, test generation, where analogous structural properties of the target artifact and the natural-language specification can be represented as static difficulty signals.

## Data Availability Statement

The replication package is available *here*.

## Abstract

**Background.** The Robot Operating System (ROS) is a framework widely adopted for developing robotics applications. Its topic-based communication model allows distributed components to exchange data via message-passing, where suboptimal messaging configuration can lead to performance degradation and resource inefficiency.

**Aims.** This paper aims to investigate the energy consumption for ROS 2 topic-based communication, focusing on messaging configurations commonly used in real-world robotics projects.

**Method.** We systematically mine 112 active ROS 2 GitHub repositories to identify prevalent message types, frequencies, sizes, and number of subscribers. These insights guide the design of a controlled experiment in which we measure the power consumption of ROS 2 nodes across multiple configurations.

**Results.** Analysis reveals that message type and interval significantly affect subscriber-side energy usage, with complex messages also affecting the publisher side. This evidence helps guide the design of energy-aware robotics software based on publish/subscribe communication.

**Conclusions.** ROS 2 topic-based communication design decisions, especially message type and publishing interval, have a substantial impact on energy consumption.

## 1 Introduction

Robots are increasingly being integrated into different sectors of society, such as industry, agriculture, and autonomous vehicles. Energy consumption is a critical concern in the development of robotics systems [35], affecting not only battery-dependent robots but also industrial applications where non-mobile robots account for a considerable portion of total energy usage. Software components have an increasingly central role in controlling robotics

systems, and studies show that design decisions can considerably impact robotics software energy consumption [19]. Although relevant studies are scarce [21], previous work has identified software architectural patterns used to improve the energy efficiency of robots [29].

The Robot Operating System (ROS) [16,33] is a middleware that has become the *de facto* standard for robotics software development in both industry and research [20]. Its topic-based publish/subscribe communication model enables interoperability and modularity between components, fostering reuse and flexibility. However, this flexibility leads to a substantial design space, where developers must choose among hundreds of message types, determine appropriate publishing frequencies, and design message structures suited to their systems. These decisions can have significant energy implications since they result in different resource demands. Therefore, good practices in designing ROS component communication could directly benefit the energy efficiency of robotics software systems. As a result, primarily, battery-powered robotic missions could operate for longer durations without sacrificing other quality attributes [35]. Secondarily, this approach helps to minimize the overall software emissions footprint, since lower energy consumption typically translates into reduced greenhouse gas emissions.

The main **goal** of this work is to evaluate how design decisions in topic-based communication impact the software energy consumption of ROS-based systems. Such insights are particularly relevant in a domain where developers are often not trained software engineers and software is modularly built from existing components. In **this study**, we first systematically mine 112 active ROS 2 GitHub repositories, identifying the most frequently used topic communication configurations. Guided by those factors, we then design and execute controlled benchmarking experiments to measure the energy consumption of ROS 2 nodes across various combinations of *message types*, *sizes*, *intervals*, and *number of subscribers*, using the RAPL interface [27] for fine-grained power monitoring. Lastly, from the analysis of the results, we compile guidelines on how to design energy-efficient ROS 2 topic communication.

Experimental **results** reveal that *message type* and *interval* have a significant and statistically measurable impact on power consumption, especially on subscriber nodes. Complex sensor messages such as `Image`, `PointCloud2`, and `LaserScan` incur the highest energy cost, while lightweight types (*i.e.,* simpler data structures) like `String`, `Float32`, and `Int32` offer more efficient communication. We also observe that short *message intervals* have a greater energy impact than increased *message size*. The *number of subscribers* does not affect publisher's energy profile, confirming the delivery decoupling assumptions of the DDS layer over which ROS 2 is built.

The main **contribution** of this paper is a comprehensive empirical investigation into the energy efficiency of topic-based communication in ROS 2, which also delivers a replication package[1] that includes a valuable dataset and the implementation of the experiment. The 6 resulting guidelines inform practitioners on how to design ROS 2 topic communication in an energy-efficient manner. The **target audience** of this work is robotics researchers, ROS developers, and software engineers concerned with the sustainability and efficiency of robotic systems. By providing empirical evidence, our study assists practitioners in making informed decisions in the design of ROS 2 systems.

## 2 Related Work

Considerable research has been conducted on the impact of software on the energy consumption of robotics systems, but most focuses on how software affects the energy consumption of the whole system, including the hardware, rather than the consumption of the software itself [35]. For instance, for ROS-based systems, there is work on mining architectural "green" tactics from code repositories, which were subsequently evaluated for their impact on the energy consumption of the system [23, 29].

A few works have systematically analyzed the impact of ROS-level design and parametrization decisions on software energy consumption. Previous work has explored the issue at the programming language level [21], and architectural decisions such as communication paradigm, number of nodes, and frequency of publication [19]. This work goes a step further by focusing on the impact of finer design decisions, taking into consideration widely used configurations extracted from a rigorous repository mining process. Beyond robotics, a few works have studied the impact of architectural decisions on software energy consumption, namely on cloud patterns [28] and IoT security patterns [26]. These studies concluded that architectural decisions can have a considerable impact on energy consumption.

## 3 Robot Operating System

ROS consists of a middleware that promotes the development of modular robotics software systems. There are two main versions, ROS 1 and ROS 2, the former having reached end-of-life in May 2025. *Nodes* are the main components of a ROS system, computational units that provide a well-defined functionality. They are written in general-purpose programming languages that connect to the ROS infrastructure through the ROS Client Library (RCL) [18]. The most popular clients built over RCL are `roscpp` (C++) and `rospy` (Python).

*Nodes* communicate with each other through *topics* (an asynchronous publish/subscribe model), *services* (a synchronous client/server model), or *actions* (a client/server model with asynchronous feedback), among which *topics* are the most widely used [34]. Multiple nodes may publish and subscribe to the same *topic*. Figure 1 illustrates an example of topic-based communication abstracted as a *computation graph*, where a *node /publisher* publishes to a *topic /t*, and 2 others, */subscriber1* and */subscriber2*, listen to what is published. To publish

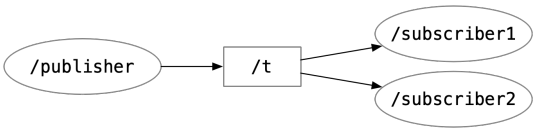

**Figure 1** Example of ROS topic-based computation graph.

to a *topic*, the *node* calls the primitive `create_publisher`, which requires a name of the *topic* and a message type. The publication of messages at a fixed rate is usually enforced through timers with callbacks (`create_timer`) or loops blocking in `Rate` objects, both provided by the ROS clients. To subscribe to a topic, the *node* calls the primitive `create_subscription`, which requires the topic name, a message type, and a callback procedure that processes incoming messages.

## 4 Research Design

In this section, we present how the research is planned after a Goal-Question-Metric (GQM) [36] definition. Then, we detail the data analysis of the experiment results. This study's main **goal** is to *analyze* the energy consumption of ROS 2 topic-based communication mechanisms *for the purpose of* understanding and improving their efficiency *with respect to* message design, communication architecture, and deployment decisions *from the viewpoint* of ROS 2 developers and researchers in the context of robotic software systems.

This research goal is unfolded in the following **research questions**:

**RQ1:** *What is the nature of active ROS 2 projects on GitHub?*
This RQ helps map the current state of ROS 2 development by identifying what types of systems, domains, and technologies active projects represent. This also helps us to understand the real impact of the findings by considering real applications.

**RQ2:** *How are ROS 2 topic message types distributed across the studied projects?*
This RQ aims to understand which message types are most prevalent across distinct robotic domains.

**RQ3:** *What is the impact of different message types on the energy efficiency of ROS 2 nodes?*
This RQ investigates whether certain ROS 2 message types inherently demand more energy for being processed.

- **RQ3.1:** *How does energy consumption scale in topics with different message types?*
  This RQ focuses on the scaling behavior with the number of clients, publishing interval, and message size.
- **RQ3.2:** *How does the architecture of publisher nodes affect other ROS nodes?*
  This RQ explores the importance of designing efficient publishers, as subscribers directly depend on their behavior – particularly in message size and publishing interval.

Table 1 describes the **metrics** used to answer the RQs, which are categorized into 2 main groups: *resource usage*, measured during experiment execution (Section 6); and *repository characteristics*, mined with the GitHub API (Section 5, phase *i*).

**Table 1** Research metrics.

| Metric | Unit | Description | RQ |
|---|---|---|---|
| | | **Resource Usage** | |
| CPU usage | % | Average CPU usage during execution. | *RQ 3* |
| RAM usage | KB | Average memory usage during execution. | |
| Power | W | Average power consumption during execution. | |
| | | **Repository Characteristics** | |
| Creation | Date | The date the repository was created. | *All RQs* |
| Last update | Date | The date of the last commit to the repository. | |
| Size | KB | The total amount of data of the repository. | |
| Forks | # | The number of forks from the repository. | |
| P. language | Category | The language in which nodes are implemented. | |

*Resource usage* metrics focus on *CPU*, *memory usage*, and *power*. Among these, *CPU* is widely recognized as the primary factor influencing software energy consumption [19, 29, 32]. The impact of *memory usage* remains less clear [25,32], but it is nonetheless a critical resource in algorithm execution. Lastly, *power* represents the energy required to run the ROS nodes.

*Repository characteristics* capture project activity, codebase size, popularity, and collaboration. *Qualitative attributes* describe the robot type, manipulation capabilities, system cardinality, project goal, and application field. *Topic information* is extracted from source code to characterize communication patterns.

## 4.1 Analysis of Experiment Results

The RQs are addressed through a careful analysis of the experimental results, supported by appropriate statistical tests. The process begins by verifying the assumptions required for parametric testing, namely normality and homogeneity of variances. When both assumptions are satisfied, parametric tests are applied; otherwise, non-parametric alternatives are used. Finally, whenever statistically significant differences are identified, post-hoc analyses are conducted to determine which groups differ while controlling for multiple comparisons.

# 5 Research Approach

In this section, we present the workflow of the research, which follows an empirical methodology combining systematic repository mining, descriptive and qualitative analysis, and controlled experiments. Figure 2 illustrates the workflow, divided into 5 phases: *(i) initial search*, *(ii) qualitative analysis*, *(iii) message extraction*, *(iv) experimentation*, and *(v) profiling and guidelines*.

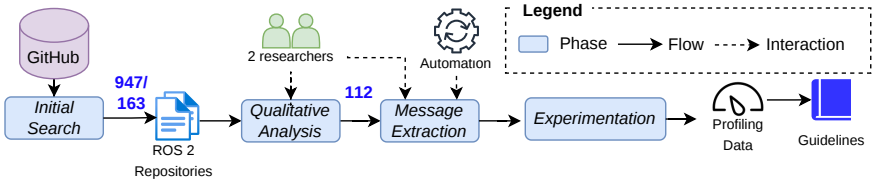

**Figure 2** Research workflow.

**(i) Initial Search.** To create a representative dataset of ROS 2 projects, we crawl GitHub repositories using its REST API [9] with Query 1, where keyword `ros2` is used to select only repositories that contain it in their name, description, or topics. The resulting list is representative and captures repositories with notable engagement (up to 566 forks), even though it excludes those indexed under alternative keywords like `robotics`. This search yields 947 repositories, which are further filtered to retain only the most relevant ones in terms of *size*, *engagement*, and *activeness*. The `size:>4000` filter selects repositories with more than 4000 kilobytes of code and content, intended to exclude very small repositories that are unlikely to contain a complete robotics application. The `forks:>10` condition ensures that only repositories with at least 10 forks are retrieved, used as a conservative indicator of community reuse or interest. The `is:public` filter limits the search to public repositories. The `pushed:>2024-01-01` criterion ensures the projects have been updated recently (within the previous year of the mining), implying ongoing development or maintenance. Finally, `archived:false` excludes repositories that have been archived and are no longer actively maintained. This query resulted in 163 potential ROS 2-related repositories.

**Query 1** Query for ROS 2 robotics software repositories.

```
ros2 size:>4000 forks:>10 is:public pushed:>2024-01-01 archived:false
```

**(ii) Qualitative Analysis.** In this phase, two independent researchers qualitatively classify each repository based on categories that reflect the nature of the robotic projects:

- *Robot's domain*: Specifies the environment in which the robot is intended to operate, *i.e.*, *grounded*, *aerial*, or *aquatic*. Projects without a specific domain are marked as *generic*.

- *Manipulation*: Indicates whether the robot in the project is designed to use manipulators, such as robotic *arms* or *grippers*.
- *Cardinality*: Describes whether the project involves a *single* robot or a *multi-robot* system.
- *Main goal*: Represents the primary objective of the project, such as *education*, *simulation*, *navigation*, and so on.
- *Robotic field*: Refers to the broader application domain the robot is intended for, such as *industrial automation*, *autonomous vehicles*, or *agriculture*, if any.

During the classification process, each repository was thoroughly examined by analyzing the repositories' structure, description, and `README` files. In this phase, 51 repositories were discarded based on the following exclusion criteria, leaving a total of 112 repositories retained for further analysis:

- *No ROS package*: Projects that do not contain the minimal structure required to be recognized as a ROS package.
- *Not in English*: Documentation in other languages prevents reproducibility and validation by the broader community.
- *Documentation only*: Projects that consist exclusively of documentation, without a ROS codebase.
- *Tool for ROS*: Tools for ROS development (*e.g.,* simulators), not associated with a specific robotics application.
- *Educational projects*: Projects intended for teaching purposes that are not targeted at a specific robotics domain/field.

The process started with a random sample of 20 repositories, which both researchers classified independently and in parallel. The simple agreement rate for each classification category was then calculated. Across all categories, an agreement of at least 84% was achieved, demonstrating strong alignment between the researchers' analyses. After resolving any discrepancies, each researcher independently analyzed half of the remaining repositories. Finally, to mitigate potential bias, each researcher reviewed and validated the other's classifications.

**(iii) Message Extraction.** In this phase, detailed information on how topic-based message exchanges are implemented is extracted for the selected repositories. This process is largely automated using custom Python algorithms, which identify and extract the *message types* and *publishers* and *subscribers* associated with each topic. The algorithm scans the repositories' codebase, locating files with calls to `create_publisher` and `create_subscription`. Next, each file translates to an Abstract Syntax Tree (AST), enabling the extraction of *message types*, topic names, and subscription points.

We mined a total of 354 distinct *message types* from various message description packages, the most frequent being `sensor_msgs`, `geometry_msgs`, and `std_msgs`. Regarding the number of *subscribers*, instances of 1, 2, 4, 5, 6, and 10 subscribers per topic were observed, where 1 subscriber is the most common configuration, with only 30 projects featuring multiple subscribers per topic (2 subscribers being the most popular among those). Additionally, 50 projects with *orphan topics* were identified; that is, topics with only publishers or only subscribers. This is expected due to the modular development approach of ROS.

Extracting the *message interval* poses additional challenges, as it can be specified in multiple ways, either directly in the source code or through external configuration files. Due to this variability, automated extraction is limited, and manual inspection is employed, searching for calls to ROS primitives related to timers and rates. The two researchers inspected a subset of 26 ROS 2 repositories, identifying 21 distinct message intervals, ranging from every 10 seconds to every 2 milliseconds. These are already distinct time intervals that can provide consistent scalability insights.

**(iv) Experimentation.** We implemented *publisher* and *subscriber* nodes that can be executed with parameters from previous phases as arguments. In Sections 6.1 and 6.2, we detail their implementations. We then orchestrated an experiment that invokes these nodes with parameters corresponding to independent variables. Section 6 details this experiment's design and execution.

**(v) Profiling and Guidelines.** During the *experimentation* phase, we profile resource usage (Table 1), which informs the research questions. We implement a customized profiler for CPU and memory usage of each ROS process, using the *psutil* Python library [14]. For *power* profiling, we use PowerJoular [31], a RAPL-based tool that provides real-time energy monitoring for individual processes across hardware components (e.g., CPU, GPU, and memory), and has been employed in several recent works on software energy analysis [19, 30]. These are subsequently translated into 6 *guidelines* (Section 8.3), designed to make the results more accessible and actionable for researchers and practitioners.

## 6 Experiment Design and Execution

The experiments were conducted on a single Desktop Computer with the following specifications: Ubuntu Linux 24.04, 64 GB of RAM, and an AMD Ryzen 5 7535HS CPU, with the resources never saturated during the experiments. We implement three algorithms: *generator*, *publisher*, and *subscriber*. The *generator* produces messages according to the experimental parameters and stores them in shared memory, from which the *publisher* retrieves the messages for transmission. This design isolates the computational overhead of message generation in a separate process. The *publisher* and *subscriber* are implemented as ROS 2 nodes running in a local ROS Jazzy [15] environment, each isolated as independent processes.

For the experiment, from the data collected in Phase *iii*, we carefully select design decisions of ROS topic-based communication as **independent variables**: *message interval*, *message type*, *message size*, and *number of clients*. The *resource usage* metrics are already described in Table 1.

- The *message interval* represents the frequency at which messages are published. We focused on 4 intervals within a range from 0.1–1.0 seconds (avoiding stressing the system). The factor levels were deliberately derived from the most frequently observed configurations in the mined repositories, while constraining the factorial design to 360 configurations and 3.600 experimental runs. For message intervals, the selected values (0.1, 0.2, 0.5, and 1 s) capture the most frequently occurring short-to-moderate publication intervals observed in the analyzed projects.
- The *message type* variable captures a range of widely used ROS message types, grouped by their respective ROS packages. To select a representable but feasible subset of types from the 354 extracted, we ranked them by number of occurrences and selected the 50 most frequent types, which are implemented in 12 distinct ROS 2 packages. Then, we selected the 3 packages with the most message types: `std_msgs`, `geometry_msgs`, and `sensor_msgs`, with 13, 11, and 9 message types in the top 50. Those packages account for more than half of message types found in that subset, with all other message packages counting 3 or fewer message types each. Therefore, the three selected packages can already offer valuable insights into how different message types affect the energy efficiency, with a feasible experimentation time. We then included the 5 most common types from each packages to ensure balanced coverage across groups, resulting in the following:
  - `std_msgs` = {`String`, `Int32`, `Float32`, `Float64`, `Float64MultiArray`}

  - `geometry_msgs` = { `Vector3`, `Twist`, `PoseStamped`, `PoseWithCovariance`, `PoseWithCovarianceStamped`}
  - `sensor_msgs` = {`Image`, `JointState`, `PointCloud2`, `Imu`, `LaserScan`}

- The *message size* was defined at 3 levels: *large* (the maximum payload for each message type), *medium* (half the maximum size) and *small* (one third the maximum size).
- The *number of clients* refers to how many subscriber nodes receive messages from the publisher. We used values of 1 and 2, which correspond to the most common subscriber counts observed in the mined repositories.

## 6.1 ROS 2 Message Publisher

We implemented a flexible ROS 2 *publisher* node in Python designed to generate synthetic messages of various types and sizes, allowing reproducible experiments. The *message type*, *message interval*, and *message size* are configurable at runtime via command-line arguments. Internally, the *publisher*, given the arguments, constructs a synthetic message and periodically publishes it to a ROS 2 topic for a fixed duration (*e.g.,* two minutes), also passed as an argument. The *publisher* (re-)generates the message every time with random data, mimicking a real application, where the message must be processed before publishing (*e.g.,* the *talker* file – `fogros2_examples/fogros2_examples /talker.py` – in repository *R35* [6]). The ROS 2 *message type* packages are loaded dynamically using Python's `importlib`, which avoids unnecessary overhead. Additionally, the *publisher* injects the header timestamp at each publication, avoiding identical messages and activating DDS features such as zero-copy [1], which prevents transmission of the same message in sequence.

Each message type in our *publisher* supports a configurable *message size* parameter that controls the message payload generated. For basic types like `String`, the content consists of repeated phrases, increasing linearly in length. Numeric types, such as `Float32` and `Int32`, use increasingly large values computed as fractions of their respective maximum representations. For structured types like `Imu` and `PoseStamped`, higher size levels incrementally fill in more fields (e.g., $x$ dimension only, then $xy$, and $xyz$ dimensions). For more complex *message types*, we carefully generate data with compatible length regarding the *message size* argument. `Image` messages are synthetic RGB images created using OpenCV [22], with increasing resolutions: 86×86 (∼22KB), 105×105 (∼33KB), and 148×148 (∼66KB). The `Float64MultiArray` message increases the number of double-precision elements up to a total byte size near 64KB. `PointCloud2` messages are 3D point arrays with random data, using up to 64KB in memory by adjusting the number of points. `LaserScan` messages increase the number of range and intensity samples proportionally.

## 6.2 ROS 2 Message Subscriber

We implemented a generic and configurable ROS 2 *subscriber* node that listens to the same topic where the *publisher* publishes messages. The *subscriber* runs until it does not receive any message for a preset timeout period of 5 seconds. It dynamically loads the specified *message type* based on a runtime parameter, allowing flexible support for different ROS 2 message structures and avoiding unnecessary overhead. Upon receiving a message, the node prints its content to the console, effectively mimicking the behavior of a process that unpacks or consumes the data. For example, in project *R653* [13], the *Rpicam_ai_node* node receives a `String` message with a command (*i.e.,* for the camera to take pictures) that must be read and interpreted.

### 6.3 Experiment Orchestrator

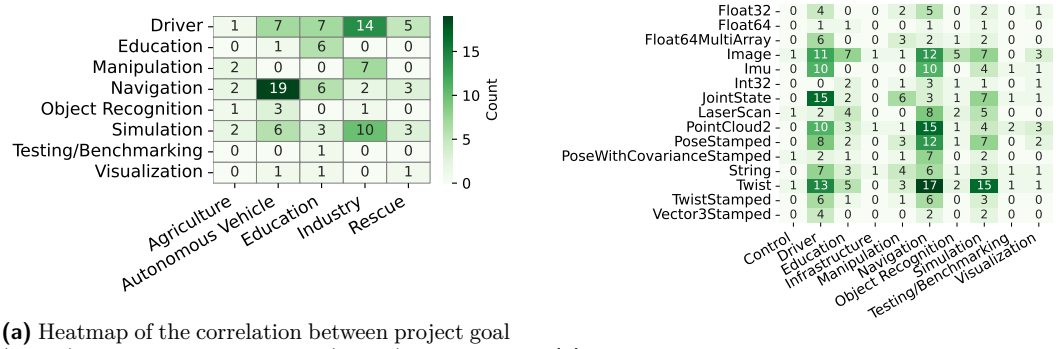
We designed a `bash` experiment *orchestrator script* to automate the execution of all experimental configurations. The number of *subscriber* nodes instantiated is determined by the *number of clients* factor, either 1 or 2, running in parallel. The full set of factor combinations (i.e., the Cartesian product) is stored in a *run_table* Comma-Separated Values (CSV) file, with each configuration repeated 10 times to ensure statistical robustness. Given the identified parameters, there are 360 configurations: 15 *message types* × 4 *message intervals* × 3 *message sizes* × 1–2 *subscribers*. This results in 3600 rows representing distinct runs. The *orchestrator script* sequentially reads each row, launches both the *publisher* and *subscriber* components with the corresponding parameters, and ensures the cleanup of the experimental environment after each run.

## 7 Results

This section presents the demographics (Section 7.1) from our qualitative analysis of the repositories and the subsequent experiment results (Section 7.2).

### 7.1 Projects' Nature

Our search identified projects created between 2019, shortly after the release of modern ROS 2 distributions, and July 2024, when the dataset was built. Although the repositories span a relatively long period, the dataset remains representative, since two of the three actively supported distributions were released before that date (i.e., *Humble*, launched in 2022, and *Iron*, launched in 2023). Furthermore, these ROS 2 distributions already included modern message types. The dataset should still provide a representative view since the study focuses primarily on identifying frequent message types rather than analyzing ROS 2 projects.



An analysis of the main ***programming language*** in the development of the selected projects indicates that the majority of the studied repositories are developed in C++ (50) and Python (42), which is already expected given that the ROS 2 documentation primarily focuses on these two languages. However, C (5), Elixir (2), and C# (1) are also used, even if they are not largely covered as the first two in the ROS documentation.

Considering projects across specific ***fields of application***, the ones focused on *autonomous vehicles* are the most prevalent. Like those in *rescue* and *agriculture*, these robots are mobile (*e.g., R159* [4] and *R292* [3]) and therefore reliant on battery power, which highlights the relevance of research aimed at reducing power consumption. The distribution also emphasizes the widespread adoption of ROS 2 in practice. We further analyzed application fields that depend on ***manipulators***, such as robotic arms or grippers. All 20 *industrial* projects and 3 out of 4 *agriculture* projects rely on this feature, as does one additional project classified under both *education* and *rescue*. Understanding this dependency is essential to assess the role of message exchange in energy efficiency for actuator devices. Lastly, regarding the ***robot type*** used across fields of application, the vast majority are *grounded robots*, which aligns with the findings by Garcia *et al.* [24]. Only 2 *aquatic* robots are used in *rescue* scenarios, and a single *aerial* robot appears in an *education* project.

We also measure project ***goals*** popularity by their ***number of forks***. This metric is relevant for our analysis, as it reflects how widely adopted the design of message exchange is for each project type. Among the goals, *navigation* (closely tied to the field of *autonomous vehicles*) emerges as the most popular, followed by *driver* projects, which implement robot-

specific drivers, and *simulation*, a key component in validating ROS-based software. Most of the highly forked projects are between 2 and 5 years old. A notable example is *R199* (*autoware.universe* [2]), a *navigation*-related project with over 500 forks and more than 250 contributors. Its popularity highlights the representativeness of our dataset in terms of project goals. In total, the *navigation* goal accounts for 1816 forks, reinforcing its prominence. Other influential goals include *simulation* and *driver*, which are critical to the ROS development pipeline. The most forked *driver* project is *R9* (*Universal_Robots_ROS2_Driver* [17] – 186 forks), which provides ROS 2 support for the CB3 and e-Series robotic arms from Universal Robots. The leading *simulation* project is *R462* (*linorobot2* [11] – 149 forks), offering a complete Gazebo-based simulation pipeline for various robot configurations, including 2WD, 4WD, and Mecanum drive systems. Some goals like *infrastructure* are underrepresented, with a single repository.

Figure 3a presents a heatmap illustrating the relationship between robotic ***goals*** and ***fields of application***. Vertically, we observe that most of the heat points are concentrated in the *industry* and *autonomous vehicle* domains. Within the *industry* field, the most common project goals are *driver*, *simulation*, and *manipulation*. The *driver* goal reflects the frequent use of diverse robotic platforms, necessitating dedicated ROS packages. The *simulation* goal represents a key step in robotic software development, enabling virtual testing before deploying on physical robots. The emphasis on *manipulation* is tied to the nature of industrial robots, which typically rely on actuator systems. In the case of *autonomous vehicles*, the dominant goal is *navigation*, which aligns with the core functionality of such systems. There is also a strong association with the *driver* and *simulation* goals, with the same motivations found in the industrial domain. We can also observe that the goals *driver*, *navigation*, and *simulation* are connected to every field of application in at least one instance, highlighting their general relevance across robotics projects.

**(a)** Heatmap of the correlation between project goal ($y$ axis) and field of application ($x$ axis).

**(b)** Correlation of *message types* and *project goals*.

**Figure 3** Relationships between project goals, application fields, and message types.

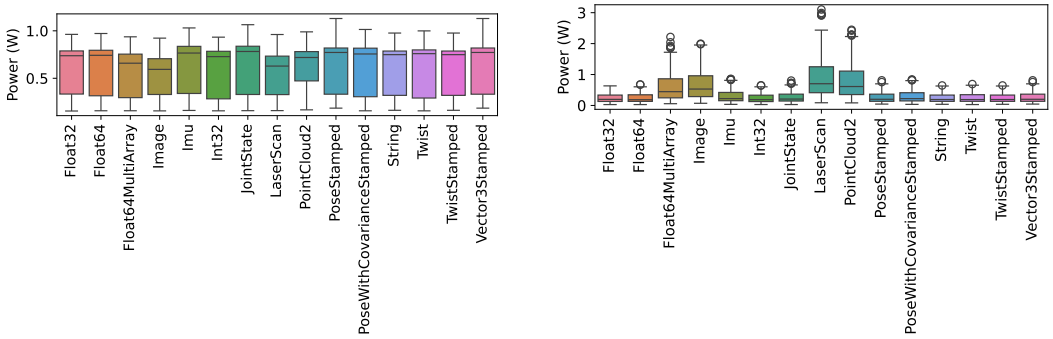


Figure 3b illustrates the relationship between the selected ***message types*** and the corresponding project ***goals***. The most frequent goals, *navigation*, *driver*, and *simulation*, are associated with all message types. The `Twist` message type stands out as widely used across all 3 goals, highlighting its relevance in various robotic applications. In *driver* projects, `JointState` is the most common message type, which aligns with the typical focus on manipulator devices such as *robotic arms* (e.g., *R31 – franka_ros2* [7]). This observation also reinforces the trend shown in Figure 3a, where *driver* projects are strongly tied to the *manipulation* field. In *navigation* projects, `PointCloud2` is the second most common message type after `Twist`, followed by `Image` and `PoseStamped`. These messages are essential for tasks

like mapping the environment and path planning. For *simulation* projects, `Twist` remains dominant, while message types `Float32`, `Float64`, and `Int32` appear less frequently, each with a single occurrence.

Finally, we analyze the ***cardinality*** of robotic systems across the studied projects, as it can indicate the degree of inter-robot communication. Despite only 6 of the projects being explicitly designed for multi-robot setups, during message extraction (Section 5, phase *iii*), we spot a dependency on external components (given the orphan topics), which reflects a modular design approach, in which ROS 2 packages are intended to be integrated into larger systems. These findings underscore the importance of examining the impact of multiple *subscribers* on a single topic, as project dependency through topic-based communication appears to be a consistent pattern.

## 7.2 Experiment Results

The experiments ran for a total of ≈150 hours/6.25 days: 360 combinations × 2.5 minutes each execution × 10 repetitions. Here we analyze the results of those executions. We start by investigating the impact of message types on the energy efficiency of both *publisher* and *subscriber* nodes. We then show results regarding the scalability of energy consumption for each of those message types.

**(a)** *Publisher* node average power.

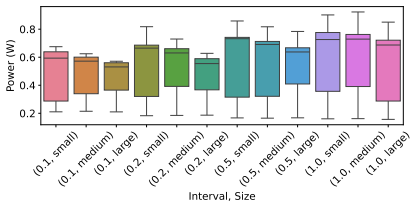
**(b)** *Subscriber* node average power.

**Figure 4** Average power by message type for *publisher* and *subscriber* nodes.

**Power Consumption by Message Types.** Figure 4 shows the power consumption distribution across multiple executions of each message type for both the *publisher* and the *subscriber*, considering different *message intervals* and *sizes*. For the publisher (Figure 4a), the power consumption shows high variability across message types (given the different *message intervals* and *sizes*), yet their median values are close, ranging from 0.6 W to 0.8 W, suggesting that the power required by each message type is comparable. The *subscriber* (Figure 4b) presents a different profile, with four message types standing out as more energy-intensive than the others: `Float64MultiArray`, `Image`, `LaserScan`, and `PointCloud2`. Those message types also produce the highest outlier values, meaning that, in some runs, they consumed exceptionally more energy (around 1.5 W more than the median) than typical. This is an expected behavior since they are larger and more complex messages that, as a consequence, may require more effort to be read. Additionally, the relative consumption of these message types differs from what is observed in the publisher, suggesting that the energy impact of publishers and subscribers should be considered independently during system design.

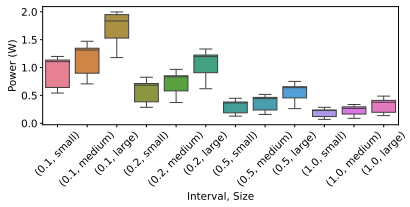
A similar pattern is observed for CPU utilization, as the power metric primarily reflects CPU power consumption. However, the CPU utilization varies far less than the power because these metrics capture fundamentally different aspects of execution. CPU utilization reflects how busy the processor is, but it does not indicate how intensive or costly that work is in terms of voltage, frequency, or memory activity. In contrast, power and energy measurements capture the actual electrical demand required to execute that workload. Another point is that, although one might expect higher CPU utilization to correspond directly to higher energy consumption, our results show that power does not scale proportionally with CPU usage. Nonetheless, although the difference between the two metrics is present, it remains relatively small. Such a discrepancy arises from the behavior of modern processors, which rely on sophisticated power-management mechanisms, such as Precision Boost 2 performance enhancement[2], that break any simple linear relationship between processor activity and energy consumed. The experiment factors do not affect memory usage; every execution using around 2772KB on average.

* *Statistical tests*: The statistical analysis revealed a significant overall difference between the *publisher* and *subscriber* groups. Post-hoc test demonstrate that the groups differ substantially from one another, with an extremely small p-value ($p = 7.67 \times 10^{-75}$), far below conventional significance thresholds. This indicates a robust and highly significant difference between the two distributions.



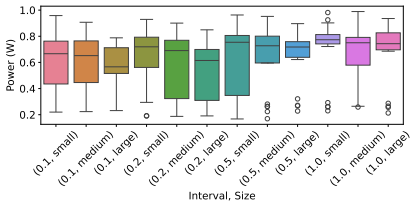
Grouping messages by their empirically observed energy demand further reveals strong within-group differentiation. On the *subscriber* side, the analysis of low energy–demanding messages showed no statistically significant differences across message types according to the Kruskal–Wallis test ($H = 12.83$, $p = 0.076$). Despite this, Welch's ANOVA indicated a significant effect ($F = 57.77$, $p = 2.22 \times 10^{-16}$), suggesting sensitivity to differences in group means under heteroscedasticity. In contrast, the high-energy– demanding messages exhibited clear differences across groups, as confirmed by the Kruskal–Wallis test ($H = 24.77$, $p = 1.72 \times 10^{-5}$). Post-hoc Dunn's tests showed that `LaserScan` differed significantly from both `Float64MultiArray` ($p = 1.9 \times 10^{-5}$) and `PointCloud2` ($p = 0.00135$), while other pairwise comparisons were not significant. These findings were further supported by Welch's ANOVA ($F = 29.47$, $p = 2.76 \times 10^{-10}$), confirming substantial performance variation among high-energy message types.

On the *publisher* side, we consider the same groups as in the *subscriber*, where low and high energy message types lead to differences across message categories, particularly pronounced effects for high energy message types. Kruskal–Wallis test for the high energy–demanding messages indicates a significant differences ($H = 28.65$, $p = 2.65 \times 10^{-6}$). Dunn's post-hoc analysis showed that `PointCloud2` displayed robust differences from several other message types, including `Float64MultiArray` ($p = 0.00157$), `Image` ($p = 3.5 \times 10^{-5}$), and `LaserScan` ($p = 1.09 \times 10^{-4}$). These strong differences were further confirmed by Welch's ANOVA ($F = 106.90$, $p \approx 0$).

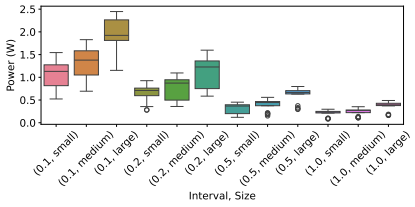


**Scalability of Message Types.** Figure 5 presents the energy measurements for 3 message types under varying *message sizes* and *intervals*. For a matter of comparison, we illustrate `Image` (which shows high energy demand only on the *subscriber* side), `PointCloud2` (consistently demanding on the *publisher* side), and `Twist` (a widely used standard message type – see Figure 3b). For all message types, the power consumption on the *publisher* side is slightly influenced by *message interval*, while *message size* shows no consistent effect. Despite

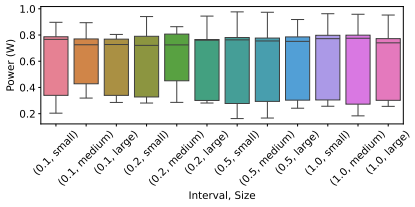
[2] `https://www.amd.com/en/resources/support-articles/faqs/CPU-PB2.html`



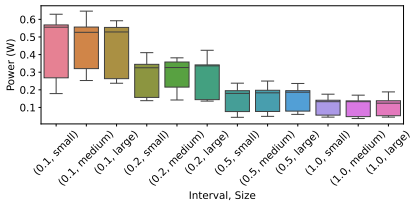
exhibiting high and discrepant energy demand for the *subscriber*, all *publisher* executions show a comparable power consumption level to `Twist`. This is explained by the fact that the *publisher* is only responsible for packing the message, while the *subscriber* needs to sequentially read it. For demanding types, i.e., `Image` (Figure 5b) and `PointCloud2` (Figure 5d), both *message size* and *interval* impact *subscriber* power. In contrast, for lightweight types such as `Twist` (Figure 5f), only *message frequency* appears to influence energy usage, possibly because even large messages of those types are not very complex.



**(a)** `Image` on *publisher*.



**(b)** `Image` on *subscriber*.



**(c)** `PointCloud2` on *publisher*.

**(d)** `PointCloud2` on *subscriber*.

**(e)** `Twist` on *publisher*.

**(f)** `Twist` on *subscriber*.

**Figure 5** Scalability of different message types on *publisher* and *subscriber* nodes, with different *message sizes* and *intervals*.

We do not observe a difference in the *publisher* power consumption means when increasing the **number of clients** from 1 to 2, a pattern consistent across all other message types. This finding aligns with results from a previous study focused solely on `String` message types [19]. In that work, there was no significant increase in power consumption for a *publisher* implemented in Python at high message frequencies. This behavior is likely due to the ROS 2 architecture, in which messages are dispatched to the DDS layer that manages delivery [37], effectively decoupling the sending process and preventing additional load on the *publisher* node.

∗ *Statistical tests*: When analyzing the impact of different *message intervals*, none of the *message types* exhibit normally distributed data. Whelch's ANOVA test reveals statistically significant differences in the power consumption of complex messages, such as `Image` and `PointCloud`, on the *publisher* side: `Image` ($F = 34.59$, $p < 0.001$), and `PointCloud2` ($F = 31.41$, $p < 0.001$). For simple messages, such as `Twist`, Welch's ANOVA indicates no statistically significant difference in power consumption across message intervals ($F = 0.23$, $p = 0.113$). For the *subscriber*, the *message interval* is not normally distributed either.

Welch's ANOVA also confirms significant differences across intervals, including for `Twist` ($F = 26.15$, $p < 0.001$), `Image` and `PointCloud2` consistently show non-normal distributions and significant interval-based effects ($F = 626.09$ and $F = 1{,}425.23$, respectively). These results indicate that *message interval* significantly impacts power consumption for both nodes, especially for complex message types.

Considering *message size*, *publisher*-side power consumption shows no significant variation: `Image` ($F = 6.00$, $p =< 0.001$), `PointCloud2` ($F = 8.04$, $p =< 0.001$), and `Twist` ($F = 0.21$, $p < 0.001$). On the *subscriber* side, all message types also present non-normal distributions. Welch's ANOVA detects significant effects for `Image` ($F = 33.34$, $p < 0.001$) and `PointCloud2` ($F = 46.96$, $p < 0.001$), whereas `Twist` shows negligible practical impact despite statistical significance ($F = 0.65$, $p = 0.032$). Finally, the *number of clients* does not significantly affect the publisher's power consumption, confirming that this factor is not energy-relevant.

# 8 Discussion

In this section, we interpret the main findings of our study, answering the RQs from Section 4 and discussing implications considering the studied projects.

## 8.1 Answers to the Research Questions

- **ARQ1** – *What is the nature of active ROS 2 projects on GitHub?*
  Our analysis of 112 GitHub repositories reveals a diverse and active ROS 2 ecosystem. Most projects are implemented in C++ (50) and Python (42), aligning with the most common client libraries in ROS 2 documentation. These projects cover a range of robotic domains, including autonomous vehicles, industrial automation, agriculture, rescue, and education, where grounded robots are the most common robot type. Popular project goals include *navigation*, *driver development*, and *simulation*. The dominance of projects such as *autoware.universe* [2] highlights the representativeness of our dataset and underscores the real-world relevance of our communication design analysis.
  We further observe that project goals are strongly associated with specific message types. For example, `Twist` is widely used across navigation, simulation, and driver projects, while `JointState` is particularly common in driver projects associated with manipulators. Similarly, `PointCloud2`, `Image`, and `PoseStamped` are strongly tied to navigation projects, reflecting the importance of sensing and localization in autonomous systems. This indicates that the choice of message type and communication design factors is dependent on the application domain and deployment environment, especially in collaborative or highly dynamic scenarios.
- **ARQ2** – *How are ROS 2 message types distributed across the studied projects?*
  We identified 354 unique message types across the analyzed repositories, with the majority belonging to 3 core ROS 2 packages: `sensor_msgs`, `geometry_msgs`, and `std_msgs`. Frequently used message types such as `Twist`, `Image`, `PointCloud2`, and `JointState` appear across several domains and project goals.
  The high number of *message types* reinforces the relevance of studies such as ours, since developers must choose from a very large design space. Another important observation is that many commonly used *message types* are stamped variants, such as `PoseStamped`, `TwistStamped`, and `PoseWithCovarianceStamped`, suggesting a preference for timestamped data to support synchronization and sensor fusion. This adds an extra dimension to the *message type* selection process.

The presence of deprecated messages such as `PointCloud` in current projects also suggests technical debt and emphasizes the importance of energy profiling to guide message deprecation and replacement. Overall, these findings reinforce the need for careful message type selection to avoid both energy inefficiencies and long-term maintenance issues.

- **ARQ3** – *What is the impact of different message types on the energy efficiency of ROS 2 nodes?*

  Our experiments show that *message type* significantly impacts energy consumption, particularly on the *subscriber* side, while *publishers* exhibit relatively stable power consumption. This is attributed to the computational effort required to deserialize and process large and structured message payloads. Results suggest that the complexity and structure of message types are critical factors for energy-aware system design. Lightweight messages such as `String`, `Int32`, `Float32`, and `Float64` demonstrate minimal energy impact, making them suitable for low-power applications and resource-constrained deployments. All *message types* associated with higher power consumption belong to the `sensor_msgs` package. In particular, `Image`, `PointCloud2`, `LaserScan`, and `Float64MultiArray` stand out as the most energy-demanding types on the subscriber side. This outcome is expected, as these messages are typically rich in data, enabling the robot to perceive and interact with its environment. Consequently, sensor messages play a critical role in the design of ROS 2 topic communication.

- **ARQ3.1** – *How does energy consumption scale with topics using different message types?*

  We observed that energy usage scales differently depending on *message type*, *size*, and *interval* (frequency). For simple messages, variations in these parameters have negligible impact on power consumption, except for *message interval* on the *subscriber* side. However, consumption increases significantly with higher frequencies and larger message sizes for heavy types such as `PointCloud2` and `Image`. This effect is especially pronounced for subscriber nodes, while publisher nodes remain comparatively stable.

  Our results further indicate that for complex message types, *message interval* has a stronger impact in the node power. For demanding types such as `Image` and `PointCloud2`, both interval and size influence subscriber-side energy consumption. In contrast, lightweight messages are affected mainly by frequency, while message size has only a limited effect.

  Considering the studied projects, this is a relevant finding. An example is an *issue* opened by a follower of project *R284* [12] asking for increasing point cloud frequency from 2 to 10 hertz [10]. This suggests that some ROS 2 users may not be aware of the energy impact of such communication design decisions.

- **ARQ3.2** – *How does the architecture of publisher nodes affect other ROS nodes?*

  The number of *clients* does not significantly influence the *publisher*'s power consumption, supporting the assumption that the DDS middleware offloads delivery overhead. This decoupling allows *publishers* to maintain a stable energy profile, even with multiple *subscribers*.

  However, the architectural choice of allowing multiple *subscribers* to a single topic has implications for overall system energy consumption. In practice, each additional *subscriber* adds overhead to the system, particularly when processing complex messages, amplifying total energy consumption. Our mining identified 30 projects with multi-client topics, with some of them potentially running on the same machine. An example is *R101* [8], where the topic `diffbot/odom` has two subscribers, *OdometrySubscriber* and *RobotController*, which are part of the same package (`py_action_pkg`).

This enables different optimization strategies. For instance, instead of two nodes on the same machine reading a common topic, they could be designed to exchange data via memory sharing, a native feature of modern ROS 2 distributions via *component* composition [5].

**Table 2** Guidelines for Energy-Aware Design ROS 2 Topic-Based Communication.

| Guideline | Description |
|---|---|
| **G1** – *Simplify/compress messages* | Complex message types should be simplified, compressed, or transmitted at lower resolution whenever possible. |
| **G2** – *Minimize publishing frequency* | Publish intervals should be tuned according to the robot application and context, avoiding frequent updates. |
| **G3** – *Limit unnecessary subscribers and topics* | Avoiding redundant subscriptions, disabling unused sensors, and reducing unnecessary debug topics. |
| **G4** – *Use intra-process communication* | When possible, use ROS 2 composition, shared memory, or zero-copy communication to reduce communication overhead. |
| **G5** – *Profile energy usage and adapt to deployment* | Integrate RAPL-based tools (e.g., PowerJoular) into CI pipelines to detect energy-efficient alternatives early. |
| **G6** – *Refactor deprecated or inefficient msg. types* | Replace legacy or overly complex custom message types with more efficient and well-maintained alternatives. |

## 8.2 Impact of the Findings Across the Studied Projects

The observed differences in energy consumption are particularly relevant when interpreted considering the nature of the studied projects. In the following, we discuss the main implications considering them.

- **Autonomous vehicles**: Projects centered on autonomous driving and navigation, such as *R199*, *R528*, *R59*, and *R296*, typically combine multiple sensing, perception, localization, planning, and control pipelines. These projects rely on complex message types such as `Image`, `PointCloud2`, `Odometry`, and `PoseStamped`, which tend to increase communication overhead and consequently energy consumption. This is especially important in such applications, where multiple sensors operate simultaneously and require continuous real-time updates.
- **Manipulators/Cobots**: Manipulation-oriented projects such as *R9*, *R31*, *R27*, and *R69* mainly exchange compact control-oriented messages, including `JointState`, `JointTrajectory`, `TwistStamped`, and vendor-specific status messages. These projects usually involve fewer active publishers and subscribers and smaller payload sizes, which reduces communication costs and makes their energy profile more stable. Therefore, experimental results suggest that manipulation systems are less sensitive to message complexity than navigation ones.
- **Environment perception**: Projects involving perception and object recognition, such as *R50*, *R95*, and *R143*, are strongly influenced by image-based message types. In dynamic environments, it may result in substantial data movement between nodes. Even if the number of topics is relatively small, the large payload size of image streams can produce high energy consumption. This reinforces the importance of efficient serialization, compression, and zero-copy communication strategies for perception-heavy ROS 2 applications.

- **Aggressive update rates**: Our partial analysis of topic frequency configuration across the studied projects reinforces the relevance of the energy consumption experiments. Most repositories adopt communication rates between 1 and 50 Hz (five times the max rate we experimented). Examples include controller frequencies around 20 Hz, local costmap updates between 2 and 5 Hz, and waypoint followers operating at 20 or 30 Hz. We also identified examples of controllers, IMU pipelines, and telemetry systems operating at 100, 200, 400, or even 500 Hz. This suggests that some of the projects may unknowingly (or by design) introduce considerable energy overhead through aggressive update rates. Therefore, results make ROS developers aware of the critical aspects of high update rates in communication.
- **Widespread message types**: Messages such as `Twist`, `Odometry`, `Image`, `PointCloud2`, and `JointState` appear repeatedly across projects of different nature. Therefore, their widespread adoption suggests that any optimization applied to these common message types could have a broad impact on the energy efficiency of ROS 2 systems as a whole.

### 8.3 Towards Guidelines for Energy-Aware ROS 2 Communication

Based on the experimental results summarized in Table 2, we propose a preliminary practical *guidelines* for energy-aware ROS 2 communication design. All of them being previously discussed in the paper.

## 9 Threats to Validity

**Internal validity.** In our experiments, *subscriber* nodes print the received messages to simulate data consumption. This behavior may increase CPU usage, particularly for large and structured messages (e.g., vectorized `Image` types). However, this design choice reflects realistic usage patterns. For instance, when handling `Image` messages, a *subscriber* often needs to traverse the entire data vector and perform operations such as rendering or object recognition tasks, which can be more computationally intensive than printing. To minimize variability and isolate effects, we execute each configuration in separate Docker containers and repeat it 10 times. We also prevent message generation from interfering with the *publisher* measurements by separating its process into an isolated container.

**External validity.** Our experiment includes a subset of the 354 message types mined from repositories, selected from the 3 most frequently used ROS 2 packages, representing a diverse range of structural complexity and data payload. This selection ensures coverage of typical communication patterns found in real-world ROS 2 systems. Therefore, although not exhaustive, our sample is representative enough to deliver meaningful insights into the energy behavior of commonly used message types. Additionally, all experiment design choices were mined from real projects, which makes them representative. Another potential threat arises from using synthetic messages instead of real sensor data. For instance, `Image` messages were generated at a low resolution (∼64KB), underestimating the energy cost of high-resolution cameras. Likewise, some messages rely on NumPy-generated data, possibly introducing computational bias in packing the messages. However, our primary goal is to compare configurations in a controlled environment where relative trends remain valid and meaningful.

**Conclusion validity.** We use appropriate statistical tests depending on the distribution and variance assumptions, ensuring the reliability of our conclusions. To mitigate biased data interpretation, we provide a replication package with all scripts, datasets, and experiment configurations. This enables the replication or extension of our results with minimal effort.

## 10 Conclusion

This paper empirically investigated the energy implications of ROS 2 topic-based communication. Our results show that design choices in message exchange, particularly type and frequency, strongly affect energy consumption, with subscribers bearing most of the cost. Rich messages (e.g., from `sensor_msgs`) demand considerably more power, while lightweight messages are more efficient. Message interval proved the dominant factor, underscoring the importance of tuning this parameter. The proposed guidelines can support more energy-aware design in ROS 2 software. Future work focus on real sensor data, the DDS layer as a factor (experimenting with additional implementations), and different hardware architectures.

## Abstract

**Background.** Task-specialized language models are increasingly integrated into software engineering workflows to support vertical-domain activities such as issue triaging, document classification, and automated analysis. Despite their adoption, there is limited empirical evidence on how to test their robustness and detect brittle behaviors under semantics-preserving input transformations.

**Aims.** This paper investigates whether explainability-guided metamorphic testing can improve the effectiveness and validity of robustness testing for specialized language models compared to heuristic mutation strategies.

**Method.** We conduct a large-scale empirical study of explanation-guided metamorphic testing across three datasets, four model architectures, and 20 testing configurations derived from combinations of attribution methods and mutation strategies. The evaluated configurations combine attribution-based token prioritization, LLM-driven mutation, and automated semantic verification to generate linguistically valid test variants. We assess failure discovery capability, semantic validity, and testing efficiency against heuristic baselines.

**Results.** Explanation-guided metamorphic testing generates 2.30× more verified failure-inducing test cases than heuristic mutation strategies. Semantic verification substantially improves mutation validity and achieves high label-preservation precision among gate-accepted variants according to human annotation. The study further reveals systematic shortcut behaviors across models, including over-reliance on named entities and formatting cues.

**Conclusions.** The results provide evidence that explanation-guided metamorphic testing is an effective and practical approach for empirically evaluating the robustness of task-specialized language models used in vertical AI applications.

## 1 Introduction

Large language models (LLMs) are increasingly integrated into software engineering (SE) workflows, supporting tasks such as issue triaging, document classification, and automated analysis [27]. Beyond large proprietary foundation models, there are many task-specialized language models adapted for a specific downstream task and deployed as components of vertical AI applications. These models may be obtained by distillation, fine-tuning, or lightweight adaptation of general pretrained backbones, to achieve lower latency and deployment cost while maintaining strong task-specific performance.

Despite their growing adoption, specialized language models remain highly vulnerable to shortcut learning, spurious lexical correlations, and brittle decision boundaries inherited from fine-tuning datasets. Small semantics-preserving perturbations, such as modifying entity names, formatting cues, or sentiment-bearing expressions, can therefore trigger inconsistent predictions and unreliable downstream behavior. Existing robustness testing approaches rely on black-box perturbation strategies or manually designed transformations, which often generate unrealistic or semantically invalid test cases while providing limited insight into why failures occur [4]. We therefore study robustness in settings representative of practical vertical AI deployments, where compact fine-tuned models are commonly preferred over large proprietary foundation models due to latency, privacy, and deployment constraints. Moreover, specialized language models are often deployed with full white-box access, enabling the use of attribution signals and internal explanations to identify decision-critical input regions [53]. Despite this opportunity, there is still limited empirical evidence on whether explainability-guided testing can systematically improve the generation of valid failure-inducing test cases and expose shortcut-driven robustness weaknesses in specialized language models.

Prior work has shown that language models frequently rely on brittle decision boundaries and shortcut behaviors, including superficial lexical artifacts, entity biases, and formatting cues [14, 19, 36]. Traditional evaluation pipelines mainly rely on static benchmark datasets that act as fixed test suites and primarily measure average generalization performance [47]. Such evaluations provide limited support for systematically generating corner cases capable of exposing hidden robustness weaknesses. Manual construction of challenging test cases is costly and difficult to scale [22], while existing automated mutation strategies often generate semantically invalid or unrealistic perturbations.

In this paper, we present an empirical study of explainability-guided metamorphic testing for task-specialized language models. The study investigates whether attribution-based guidance can improve the effectiveness and validity of robustness testing compared to heuristic mutation strategies. To this end, we evaluate combinations of explainable AI (XAI) attribution, LLM-driven mutation, and semantic verification mechanisms that generate targeted metamorphic variants while preserving semantic consistency. Attribution analysis identifies decision-critical tokens, a locally deployed Judge LLM produces controlled ablation and adversarial injection variants, and a semantic validation stage based on bidirectional natural language inference (BNLI) and log-perplexity shift (LPS) filters invalid mutations.

We conduct an empirical evaluation across multiple model architectures, including DistilBERT, BART-large, and Qwen-0.5B, and across diverse classification tasks, including SST-2, AG News, and GitHub Issue classification [40, 52]. Our results show that explanation-guided metamorphic testing generates substantially more verified failure-inducing test cases than heuristic mutation strategies while reducing semantically invalid perturbations. Furthermore, our analysis reveals systematic shortcut behaviors, including entity over-reliance in discriminative models and sensitivity to formatting artifacts in generative models.

# 2 Background

## 2.1 Task-Specialized Language Models

LLMs are commonly built on Transformer architectures [45] and include encoder-only models (e.g., BERT [11]), encoder–decoder models (e.g., BART and T5 [23, 34]), and decoder-only models (e.g., GPT-style models and Qwen [43]). In practical software engineering workflows, however, deploying large proprietary models is often infeasible due to latency, cost, and privacy constraints. As a result, many SE applications rely on *task-specialized language models* obtained through distillation or supervised fine-tuning of smaller architectures [37, 43].

While these models provide improved efficiency and deployability, prior work has shown that language models frequently rely on brittle decision boundaries and shortcut behaviors, including lexical artifacts, entity biases, and formatting cues [36, 14, 19]. Such weaknesses can compromise robustness in production SE pipelines, motivating the need for systematic robustness testing approaches.

## 2.2 Metamorphic Testing

Metamorphic Testing (MT) addresses the *oracle problem* by validating the consistency of a system's behavior across related inputs instead of requiring a ground-truth output for every test case [6, 39]. MT defines *metamorphic relations* (MRs), which specify how outputs should remain invariant, or change predictably, under controlled input transformations.

For language models, typical MRs involve semantics-preserving transformations such as paraphrasing, synonym substitution, or contextual edits that should not alter the expected label. By generating related inputs and comparing predictions, MT can expose robustness violations and shortcut behaviors.

Recent work has explored metamorphic testing for language models through manually defined or heuristic transformations [9]. In this paper, we empirically investigate whether explainability-guided mutation and semantic verification improve the effectiveness and validity of metamorphic testing for task-specialized language models.

## 2.3 Explainable AI for Language Models

Explainable AI (XAI) techniques estimate the contribution of individual input features to a model's prediction [53]. In language models, this typically corresponds to assigning importance scores to input tokens. Attribution methods generally fall into three categories: (1) gradient-based methods, such as Integrated Gradients [42, 31]; (2) perturbation-based methods, such as Occlusion and LIME [50, 25, 35]; and (3) architecture-aware methods based on Transformer attention patterns [1].

Although XAI techniques are primarily used for model interpretation, attribution scores can also support robustness testing by identifying decision-critical tokens. Prior studies suggest that highly influential tokens often correspond to shortcut features or brittle lexical cues [36]. In this work, we empirically study whether attribution-guided mutations are more effective than unguided transformations at generating valid failure-inducing test cases.

# 3 Empirical Study

This study evaluates combinations of attribution methods, metamorphic mutation strategies, and semantic verification mechanisms for generating failure-inducing test cases.

**Table 1** Illustrative examples of metamorphic mutations. Tokens with high attribution scores are underlined. MR-Ablation weakens influential lexical cues, while MR-Injection introduces adversarial context. Semantic equivalence is validated through the NLI score ($\mathcal{M}_{nli}$) and linguistic naturalness through the perplexity shift metric ($\mathcal{M}_{lps}$).

| MR Type | Original Input ($x$) | Saliency | Mutated Variant ($x'$) | $\mathcal{M}_{nli} \uparrow$ | $\mathcal{M}_{lps} \downarrow$ |
|---|---|---|---|---|---|
| *Ablation* | The acting was superb, but the plot was weak. | superb (0.82) | The acting was good, but the plot was weak. | 0.74 | 0.05 |
| *Ablation* | A boring and predictable movie. | boring (0.75) | A plain and predictable movie. | 0.81 | 0.12 |
| *Injection* | The movie is a masterpiece of cinema. | disaster (injected) | The movie is a masterpiece, despite being a disaster to some. | 0.78 | 0.18 |
| *Injection* | It provides a fresh perspective. | terrible (injected) | It provides a fresh, albeit terrible, perspective. | 0.65 | 0.25 |

The empirical evaluation investigates three methodological aspects of metamorphic robustness testing: (1) attribution-based mutation prioritization, (2) metamorphic mutation strategies, and (3) semantic verification, including human validation of the automatic gate.

## 3.1 Attribution-Based Mutation Prioritization

The study first investigates whether attribution scores can effectively guide mutation selection toward decision-critical input regions. Rather than relying on a single explanation technique, we evaluate multiple attribution strategies as interchangeable experimental factors.

Formally, given an input sequence $x = [t_1, \ldots, t_n]$, the attribution process computes a saliency vector $\mathbf{a} = [a(t_1), \ldots, a(t_n)]$, where $a(t_i)$ denotes the influence of token $t_i$ on the model prediction.

**Gradient-based Attribution.** When gradient access is available, we evaluate Integrated Gradients (IG) [42], defined as:

$$a_{ig}(t_i) = (e_i - e_i^0) \int_0^1 \frac{\partial f(x^0 + \alpha(x - x^0))}{\partial e_i} d\alpha \tag{1}$$

where $e_i$ and $e_i^0$ denote the embedding vectors of token $t_i$ and its baseline representation.

**Perturbation-based Attribution.** We also evaluate Occlusion [50], which estimates token importance by measuring prediction changes when a token is masked:

$$a_{occ}(t_i) = f(x) - f(x \setminus \{t_i\}) \tag{2}$$

where $x \setminus \{t_i\}$ replaces token $t_i$ with a baseline token such as `[PAD]`.

**Architecture-aware Attribution.** For Transformer-based models, we additionally evaluate attention-based attribution methods [1, 5], which estimate token importance using attention aggregation and gradient-weighted attention scores.

Since many language models operate on subword tokens, token-level attribution scores are aggregated at the word level, i.e., $S(w_j) = \sum_{t \in w_j} a(t)$. The resulting ranked word set $\mathcal{T}(x) = \{(w_j, S(w_j))\}$ defines the mutation priority used during metamorphic mutation.

## 3.2 Metamorphic Mutation Strategies

Given an input text $x$ with label $y$ and a specialized language model as the system under test (SUT) $f(\cdot)$ satisfying $f(x) = y$, the evaluation seeks to generate metamorphic variants $\mathcal{X}' = \{x_i'\}$ such that: (i) $x_i'$ remains semantically equivalent to $x$, and (ii) the model

prediction changes ($f(x_i') \neq y$). Such inconsistencies indicate brittle decision boundaries, shortcut behaviors, or spurious correlations. The study next evaluates different strategies for generating metamorphic variants while preserving semantic meaning. Compared to rule-based perturbations, LLM-driven mutations enable context-aware rewrites that remain linguistically natural.

Table 1 presents representative mutation examples used throughout the study. We evaluate two primary metamorphic relations (MRs).

**MR-Ablation.** This relation evaluates over-reliance on influential lexical features. Given an input $x$, the mutation targets the word $w \in \mathcal{T}(x)$ with the highest attribution score. The selected token is either removed or replaced with a semantically weaker alternative while preserving grammaticality.

**MR-Injection.** This relation evaluates robustness against distracting lexical cues. Adversarial trigger words extracted from misclassified examples are inserted into the input while preserving semantic coherence and fluency.

Mutations are generated using a locally deployed Judge LLM and processed in batches to improve efficiency. Each generated variant is accompanied by a structured self-verification output indicating whether semantic and grammatical constraints are satisfied.

## 3.3 Semantic Verification

A major challenge in generating metamorphic variants is the risk of producing invalid test cases, i.e., mutations that alter the underlying task label and lead to false positives. To mitigate this risk and establish a reliable, yet approximated automated oracle, we implement a validation stage that filters variants based on semantic consistency and linguistic naturalness.

**Bidirectional Semantic Entailment.** To verify that the mutation preserves the semantic meaning of the original input $x$, we employ a cross-encoder Natural Language Inference (NLI) model [49, 28]. However, uni-directional entailment ($x \to x'$) is insufficient for testing: while it ensures the mutation $x'$ does not introduce contradictory information, it does not penalize the removal of important context. Conversely, the reverse relation ($x' \to x$) verifies that the mutated input still entails the constraints expressed in the original sentence. We therefore enforce a *bidirectional* mutual entailment score:

$$\mathcal{M}_{nli}(x, x') = \min\left(P(E \mid x, x'), P(E \mid x', x)\right)$$

where $P(E)$ denotes the probability of entailment predicted by the NLI model. A mutation is accepted only if $\mathcal{M}_{nli}(x, x') > \tau_{nli}$. This bidirectional constraint reduces the likelihood that a mutation introduces semantic drift or removes essential contextual information.

**Linguistic Naturalness Metric.** While NLI captures semantic consistency, NLI models are often tolerant to grammatical errors or unnatural phrasing. As a result, they may assign high entailment scores to syntactically degraded inputs. If the SUT fails on such inputs, the failure may stem from out-of-distribution syntax rather than a genuine logical vulnerability.

To filter these artifacts, we evaluate linguistic fluency using perplexity [20], defined as the exponentiation of cross-entropy loss $\mathcal{L}(\cdot)$. Rather than using absolute perplexity values, we measure the *log-perplexity shift* between the original and mutated inputs:

$$\mathcal{M}_{lps}(x, x') = \log \frac{\mathrm{PPL}(x')}{\mathrm{PPL}(x)} = \mathcal{L}(x') - \mathcal{L}(x)$$

This metric isolates the fluency degradation introduced by the mutation itself. By subtracting the baseline loss of the original input, the measure reduces the influence of the intrinsic difficulty of the original sentence and focuses on the perturbation introduced by the metamorphic edit. A mutation $x'$ is rejected if $\mathcal{M}_{lps}(x, x') > \tau_{lps}$, reducing the likelihood that accepted variants are linguistically unnatural or far from the original distribution.

## 3.4 Research Questions

**RQ$_1$ (configuration sensitivity).** *How do different attribution, mutation, and semantic verification configurations affect the validity and failure discovery capability of metamorphic robustness testing?*

The study evaluates multiple configurable components involved in the generation and verification of metamorphic variants, including attribution mechanisms, mutation strategies, and semantic filtering criteria.

**RQ$_2$ (effectiveness and efficiency).** *How effective and efficient are attribution-guided metamorphic testing configurations at discovering prediction inconsistencies across different models and datasets?*

To assess the practical applicability of our study, we evaluate the capability of attribution-guided metamorphic testing to expose robustness violations while maintaining reasonable computational overhead across diverse architectures and classification tasks.

**RQ$_3$ (human validation).** *To what extent does the automated semantic verification gate agree with human judgments of label preservation and fluency?*

This RQ assesses whether variants accepted by the semantic gate are judged valid by human annotators. It measures agreement between automatic gate decisions and human annotations for label preservation and fluency.

## 3.5 Metrics

For RQ$_1$ and RQ$_2$, we assess each testing configuration using two metrics: (i) the *Attack Success Rate (ASR)*, defined as the proportion of generated metamorphic variants that change the SUT prediction, and (ii) the number of *verified failures*, i.e., prediction-changing variants satisfying the semantic verification criteria. We also report the average time required to generate the first verified failure as a measure of efficiency.

For RQ$_3$, we evaluate semantic-gate quality against human judgments. We report confusion statistics between automatic gate decisions and majority human labels, including accuracy and pass precision. Pass precision denotes the proportion of gate-accepted variants that are judged valid by humans.

## 3.6 Objects of Study

### 3.6.1 Datasets

To assess generalizability across diverse linguistic complexities and application domains, we adopted three text classification benchmarks, widely used in SE testing work that evaluates LLM testing techniques on both domain-specific and standard classification tasks [47, 9, 18].

**Table 2** Details of the SUTs and their original performance on the target datasets. Accuracies (%) are reported on the standard test/validation splits after supervised fine-tuning.

| Model | Architecture | Params | Original Accuracy (%) ↑ | | |
|---|---|---|---|---|---|
| | | | SST-2 | AG News | GitHub |
| DistilBERT-base-uncased [37] | Encoder-only | 66M | 91.17 | 92.22 | 85.63 |
| Qwen/Qwen2.5 (Discriminative) [43] | Decoder-only | 0.5B | 92.20 | 93.93 | 86.28 |
| Qwen/Qwen2.5-(Generative) [43] | Decoder-only | 0.5B | 93.69 | 91.95 | 83.39 |
| facebook/bart-large [23] | Encoder-decoder | 406M | 95.76 | 95.09 | 86.76 |

**SST-2.** The Stanford Sentiment Treebank (SST-2) [40] is a widely adopted GLUE benchmark consisting of 67k human-annotated movie reviews for binary sentiment analysis. We select SST-2 because it is notoriously rich in complex syntactic phenomena, such as contrastive conjunctions and nuanced negation. It serves as an ideal testbed to evaluate whether our metamorphic mutations effectively expose vulnerabilities in the model's compositional understanding.

**AG News.** For general topic classification, we employ the AG News dataset [52], containing 120k training samples categorized into four distinct news domains (World, Sports, Business, Sci/Tech). This dataset evaluates the model's reliance on broad vocabulary and named entities, acting as a standard control to verify that the Judge LLM can perform adversarial injections without drifting across strict topical boundaries.

**GitHub Issue Classification.** We utilize the large-scale GitHub Issue dataset originally curated for the NLBSE tool competition [21] and further refined for LLM fine-tuning tasks. This dataset consists of over 800k real-world issue titles and descriptions labeled into three categories: Bug, Enhancement, and Question. The complexity of this dataset stems from two primary factors: Multilingualism, as the issues are sourced from global open-source communities, containing technical discussions in multiple languages (e.g., English, Chinese, German, and Japanese); and Structural Noise, as the text heavily interweaves natural language with code snippets, URLs, and stack traces. Classifying these issues requires the SUT to perform deep logical reasoning and resist linguistic interference rather than relying on superficial keyword matching.

### 3.6.2 Models

To evaluate generalizability across model architectures and inference paradigms, we selected four representative Transformer-based models spanning Encoder-only, Encoder–Decoder, and Decoder-only architectures, as well as both discriminative and generative classification settings. Specifically, we evaluate `Qwen2.5-0.5B` under both discriminative and generative formulations to analyze how the inference paradigm influences susceptibility to metamorphic perturbations. Although the evaluated architectures originate from general-purpose pretrained language models, the systems under test are fine-tuned for downstream classification tasks and deployed as task-adapted inference pipelines. The detailed model specifications and supervised fine-tuning accuracies are reported in Table 2. All SUTs achieve strong baseline performance after fine-tuning, with accuracies ranging from 83.39% to 95.76% across the evaluated datasets. Among the evaluated models, `facebook/bart-large` achieves the highest overall accuracy.

### 3.6.3 Configurations and Baselines

To systematically analyze the impact of attribution and mutation choices, we define a configuration space of $4 \times 5 = 20$ setups obtained by combining four attribution mechanisms with five mutation strategies.

**Attribution mechanisms (4 variants).** We compare three attribution-based token prioritization methods – *Integrated Gradients* (IG) [42], *Occlusion* [50], and attention-based attribution [1, 5] – against a random-selection baseline without saliency guidance.

**Mutation strategies (5 variants).** We compare two LLM-based semantic mutation operators – *LLM-Ablate* and *LLM-Inject* – against three rule-based mutation strategies: *In-situ Ablation* (direct token deletion), *Prefix Injection* (trigger-token prepending), and *Random Injection*. In particular, the unguided setup without attribution prioritization or LLM-based rewriting resembles the invariance-style perturbation testing of CheckList [36], illustrating the limitations of blind mutations and their tendency to introduce grammatical artifacts instead of semantically meaningful perturbations. The combination of attribution-guided token selection with rule-based mutations mirrors the core intuition of TextBugger [24], where salient input regions are preferentially perturbed. Similarly, prefix-based trigger insertion follows the attack-generation principle of XAI-Attack [3] and Universal Adversarial Triggers [46], where adversarial keywords are inserted at the beginning of the sequence to exploit positional sensitivity and shortcut behaviors. Finally, combining attribution-guided token selection with direct in-situ deletion is inspired by the Representation Erasure paradigm [25]. This configuration isolates the effect of semantic rewriting and enables analysis of how semantic smoothing influences mutation validity and failure generation.

**Implementation.** To instantiate the Judge LLM ($\mathcal{J}$) for metamorphic generation, we deploy the *gpt-oss-20b* model locally using the Ollama framework. Using a locally hosted open-weights model ensures experimental reproducibility, avoids data privacy concerns and usage costs associated with cloud-based APIs, and prevents issues related to API version drift. The Judge LLM operates with a temperature of $T = 1.0$, enabling broader exploration of the mutation space. Potentially invalid variants are subsequently filtered by the two-stage semantic verification procedure. We compute the NLI scores using the *cross-encoder/nli-deberta-v3-small* model. Unlike standard bi-encoders that process sentences independently, cross-encoders perform full attention over the concatenated input pair, yielding higher accuracy and fine-grained sensitivity for textual entailment tasks [16, 29]. To calculate the perplexity, we utilize the standard *GPT-2* model [33]. As a foundational causal language model, GPT-2 serves as a highly efficient, lightweight, and universally accepted baseline for evaluating textual naturalness and perplexity in adversarial generation frameworks [15, 51].

All experiments, including supervised fine-tuning (SFT), XAI attribution computation, and metamorphic test generation, were conducted for three datasets and four model architectures on a single NVIDIA L40S GPU. The complete experimental pipeline required approximately 180 GPU hours.

## 3.7 Setup

### 3.7.1 Data Partitioning

To prevent data leakage and ensure a rigorous evaluation, we enforce a strict data partition. Specifically, we hold out a fixed subset of 2,000 instances from the original training data exclusively to compute XAI attributions and construct the adversarial candidate pools $\mathcal{T}(x)$.

Before mutation generation, we retain only seed instances that are correctly classified by the corresponding SUT. This holdout subset is strictly excluded from the SFT phase of the SUT. The remaining majority of the training data is utilized for standard SFT, while the original development and test splits are kept entirely untouched to evaluate model convergence and measure the final robust accuracy.

### 3.7.2 Supervised Fine-Tuning

To comprehensively evaluate the robustness of our target models, we adapt the fine-tuning pipeline to accommodate the fundamental architectural differences between discriminative and generative paradigms.

For discriminative settings, models are fine-tuned for standard sequence classification and appended with a linear classification head to output class probabilities. For generative settings, the classification task is reformulated as conditional text generation via instruction-based prompting. We wrap the inputs in a standardized template (e.g., *"Instruction: Classify the following GitHub issue... Category:"*). To prevent the model from optimizing for input reconstruction, we apply target masking on prompts and inputs. This ensures the cross-entropy loss is computed exclusively on the generated target tokens (e.g., *"bug"*) and the sequence terminator.

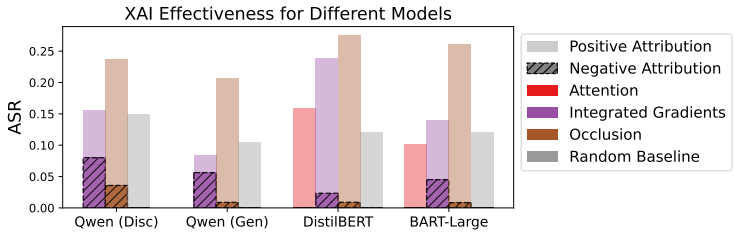
To maintain experimental consistency and resource efficiency, all models undergo standard SFT. Following established best practices for ensuring fine-tuning stability [11, 30], we train the models using a learning rate of $2 \times 10^{-5}$ with a warm-up ratio of 10%. To prevent overfitting, the training process is capped at 9 epochs (7 for generative architectures) and is strictly governed by an early stopping mechanism with a patience of 2 epochs.

## 3.8 Evaluation Procedure

For $\mathrm{RQ}_1$, we evaluate the effectiveness of different attribution methods for identifying failure-inducing mutation targets under the direct MR-Ablation setting, where attribution scores alone determine which token is perturbed. For each (Model, Explainer) pair, we measure the ASR under three ablation strategies: removing the token with the highest positive attribution score, removing the token with the strongest negative attribution score, and removing a randomly selected token as a baseline. Effective attribution methods are expected to produce substantially higher ASRs when perturbing positively attributed tokens compared to negatively attributed or randomly selected tokens, indicating that the explainer successfully identifies prediction-relevant regions.

To calibrate the semantic verification stage, we determine the thresholds of the entailment and perplexity filters using the Kneedle algorithm [38], which identifies inflection points in the metric distributions. For the entailment metric $\mathcal{M}_{nli}$, the threshold $\tau_{nli}$ is selected at the point preceding the sharp decline in retained failure-inducing variants, balancing semantic strictness and sample retention. For the linguistic naturalness metric $\mathcal{M}_{lps}$, the threshold $\tau_{lps}$ is selected at the elbow of the cumulative distribution to remove highly unnatural perturbations while retaining the majority of linguistically plausible variants.

For $\mathrm{RQ}_2$, we instantiate the evaluation using the most effective attribution method identified in $\mathrm{RQ}_1$ and compare attribution-guided mutation selection against random selection to isolate the contribution of explainability-guided targeting. We evaluate both the Attack Success Rate and the number of generated failure-inducing variants under two conditions: *pre-verification*, which includes all generated mutations, and *post-verification*, which includes only variants satisfying both semantic thresholds $\tau_{nli}$ and $\tau_{lps}$. We further perform statistical



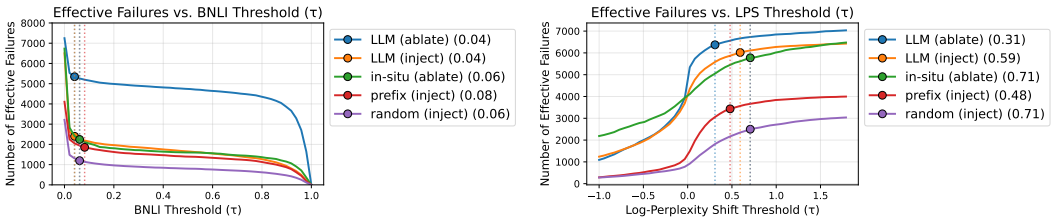


**Figure 1** Effectiveness of different XAI explainers in guiding Metamorphic Ablation.

**(a)** Failures across varying BNLI thresholds ↑. **(b)** Failures across varying LPS thresholds ↓.

**Figure 2** Sweet-spot analysis for selecting automated verification thresholds (Kneedle algorithm). Circular markers (○) denote the knee-point thresholds ($\tau$) selected for each mutation strategy.

analyses for the ASR difference between the studied configuration and its baseline. We report the mean paired difference, a non-parametric 95% bootstrap confidence interval over paired blocks [44], a one-sided Wilcoxon signed-rank test to estimate the stability of observed effects [48], and Cohen's $d$ as effect size [10].

For $RQ_3$, we conduct a human evaluation study to assess whether the semantic verification stage aligns with human judgments of mutation validity. We sample mutations from all evaluated tasks, drawn throughout different attribution methods and mutation strategies. After removing empty outputs and non-English examples, the final evaluation set contains 383 mutation pairs. Annotators recruited through Amazon Mechanical Turk [41] are shown the task description, the original task label, the original input, and the mutated variant. They then evaluate whether the mutated input preserves the original label and whether it remains fluent and natural. Each annotation batch contains one attention-check question, and submissions failing the attention check are discarded. In total, we collect 92 submissions, of which 84 pass the quality filter, yielding 818 valid item-level annotations. A mutation is considered human-valid only if it is judged both label-preserving and fluent. The annotations show moderate inter-annotator agreement with Fleiss' $\kappa = 0.50$ and 88.9% majority agreement, which is acceptable given the subjective nature of semantic-preservation and fluency judgments.

# 4 Results

## 4.1 Configuration sensitivity ($RQ_1$)

Figure 1 reports the Attack Success Rate obtained by different attribution methods under the direct MR-Ablation setting. Across all evaluated architectures, Occlusion consistently achieves the highest post-verification ASR values. In contrast, perturbing tokens with the strongest negative attribution scores (hatched bars) produces substantially lower ASRs. This clear separation provides an important sanity check, indicating that the attribution methods identify prediction-relevant regions rather than merely degrading sentence fluency through arbitrary token removal.

**Table 3** Effectiveness of the evaluated mutation configurations across three datasets. We report the ASR results **Before/After** Semantic Verification Gate filtering. Best results after verification are marked in **bold**.

Among the evaluated explainers, Occlusion emerges as the most stable and architecture-agnostic strategy for identifying vulnerability-prone tokens. Its effectiveness remains consistent across encoder-only, encoder–decoder, and decoder-only architectures. Based on these results, we select Occlusion as the default attribution method for the remaining experiments.

Figure 2 illustrates the number of retained failure-inducing variants under varying semantic verification thresholds. Across both semantic metrics, LLM-based semantic mutation strategies consistently produce substantially more semantically valid failures than rule-based baselines, indicating a higher ability to generate boundary-compliant perturbations while preserving linguistic plausibility.

To determine robust semantic verification thresholds, we apply the Kneedle algorithm to identify inflection points balancing semantic validity and sample retention. As shown in Figure 2(a), the number of retained failures decreases sharply as the bidirectional entailment threshold increases from 0.0 to 0.1, indicating that a large portion of raw perturbations exhibit semantic drift. Based on the detected inflection point, we select a unified threshold of $\tau_{nli} = 0.08$, which filters semantically inconsistent variants while preserving the majority of semantically valid failures.

Figure 2(b) shows the cumulative distribution of log-perplexity shift values. The curve follows an S-shaped pattern, with inflection points located approximately in the range $\tau_{lps} \in [0.0, 0.7]$. We select a unified threshold of $\tau_{lps} = 0.3$, which removes highly unnatural perturbations while retaining most linguistically plausible variants.

**Configuration sensitivity ($RQ_1$):** *Occlusion consistently provides the most effective attribution guidance. Kneedle-based calibration identifies stable thresholds ($\tau_{nli} = 0.08$ and $\tau_{lps} = 0.3$) that balance semantic preservation and retained failure coverage.*

**Table 4** Pairwise comparisons using post-verification ASR. We report non-parametric 95% bootstrap confidence intervals (CI), one-sided Wilcoxon test, and paired Cohen's $d_z$ as effect sizes.

| Comparison | $n$ | Method | Baseline | [95% CI] | Wilcoxon $p$ | $d_z$ |
|---|---|---|---|---|---|---|
| LLM-Ablate vs. In-situ Ablation | 24 | 4.27 | 1.48 | **[1.51, 4.31]** | **<0.001** | $0.79^{M}$ |
| LLM-Inject vs. Random Injection | 24 | 2.72 | 1.15 | **[0.61, 2.66]** | **0.027** | $0.60^{M}$ |
| LLM-Inject vs. Prefix Injection | 24 | 2.72 | 2.20 | [-0.45, 1.56] | 0.634 | $0.20^{S}$ |
| Occlusion + LLM-Ablate vs. Random + LLM-Ablate | 12 | 4.63 | 3.91 | **[0.30, 1.17]** | **0.005** | $0.89^{L}$ |
| Occlusion + LLM-Inject vs. Random + LLM-Inject | 12 | 2.76 | 2.67 | [-0.22, 0.40] | 0.252 | $0.16^{N}$ |

The **bold** values indicate $\mathrm{CI}_{95\%}(\Delta)$ is entirely above zero, or $p < 0.05$. Effect sizes use paired Cohen's $d_z$: $^{N}$ negligible ($d < 0.20$), $^{S}$ small ($0.20 \leq d < 0.50$), $^{M}$ medium ($0.50 \leq d < 0.80$), and $^{L}$ large ($d \geq 0.80$).

## 4.2 Effectiveness and efficiency ($RQ_2$)

Table 3 summarizes the effectiveness of the evaluated mutation configurations across three datasets and four model architectures. We report the ASR both **before** and **after** semantic verification using the entailment and perplexity thresholds ($\tau_{nli}$ and $\tau_{lps}$). This comparison provides insight into both the vulnerability of the evaluated models and the validity of the generated adversarial variants. Across most evaluated settings, attribution-guided configurations combined with LLM-based semantic mutations generally increase post-verification ASR. In particular, LLM-driven ablation strategies expose substantially more verified failures than the in-situ method.

A central observation emerging from Table 3 is the substantial discrepancy between pre-verification and post-verification ASR. In many cases, unconstrained perturbation strategies initially appear highly successful, but most generated variants fail semantic validation. For instance, under direct lexical ablation on SST-2 (DistilBERT), the pre-verification ASR reaches 17.57%, but decreases to only 1.71% after semantic filtering. This large reduction indicates that many seemingly successful adversarial examples correspond to semantically invalid or label-altering perturbations rather than genuine robustness violations.

The semantic verification stage therefore plays a critical role in filtering invalid adversarial artifacts and ensuring that reported failures correspond to semantic-preserving inconsistencies. Under the default occlusion-guided configuration, LLM-based semantic mutations achieve a mean post-verification ASR of 3.70% across evaluated datasets and architectures, with semantic ablation reaching 4.63% and contextual injection 2.76%. In comparison, heuristic baselines achieve substantially lower verified ASR values, including In-situ Ablation (1.48%), Prefix Injection (2.20%), and Random Injection (1.15%). This combined reading shows that LLM-based ablation provides the most stable improvement across datasets, whereas LLM-based injection is more task-dependent, with stronger gains on GitHub issue classification than on SST-2 or AG News.

Table 4 reports the pairwise tests using post-verification ASR. The most consistent gain comes from LLM-Ablate, which significantly improves over in-situ deletion and also benefits from Occlusion-guided target selection. For injection, LLM-Inject significantly improves over Random Injection, but not significantly over the stronger Prefix Injection baseline. Thus, the evidence supports a robust advantage for LLM-based ablation, while injection improvements are more setting-dependent.

To assess computational practicality, we additionally measured the average execution time required to generate and verify a single metamorphic variant. Rule-based perturbation strategies remain highly efficient, requiring approximately 0.22 seconds per generated attack on average. In contrast, LLM-based semantic mutations require approximately 4.71 seconds due to the overhead introduced by local LLM inference and semantic verification. Although computationally more expensive, these configurations produce substantially higher proportions of semantically valid robustness violations.

**Table 5** Confusion statistics between automatic gate decisions and human judgments. Pass precision is the human-positive rate among accepted variants.

| Comparison | TN | FP | FN | TP | Accuracy [%] | Pass precision [%] |
|---|---|---|---|---|---|---|
| LPS gate vs. fluent | 29 | 13 | 66 | 209 | 75.1 | 76.0 |
| NLI gate vs. label-pres. | 42 | 66 | 10 | 179 | 74.4 | 94.7 |

**Effectiveness and efficiency ($RQ_2$)**: *LLM-based ablation provides the most robust gain over hard deletion, while LLM-based injection improves over random injection but not reliably over the stronger prefix baseline. Semantic verification removes a large fraction of invalid adversarial artifacts, demonstrating that unconstrained perturbations substantially overestimate model brittleness.*

## 4.3 Human validation ($RQ_3$)

Table 5 reports human validation results for the semantic gates. The NLI gate achieves a high pass precision of 94.7%. However, a non-trivial portion of rejected variants are still judged valid by humans, suggesting that the gate is conservative and prioritizes precision over recall. This behavior is appropriate for our setting, where reducing false positives is more important than maximizing mutation retention.

**Table 6** Human validation of semantic verification at configuration level. Human-valid is label-preserving and fluent.

| **Configuration** | **full gate** [%] | **human-valid** [%] | **label-pres.** [%] | **fluent** [%] | **gap** [pp] |
|---|---|---|---|---|---|
| LLM-Ablate | 80.6 | 74.1 | 89.8 | 95.5 | +6.5 |
| LLM-Inject | 37.3 | 41.3 | 78.1 | 77.0 | -4.0 |
| Prefix-Inject | 47.8 | 23.9 | 81.1 | 42.1 | +23.9 |
| In-situ Ablate | 37.5 | 19.3 | 73.7 | 43.5 | +18.2 |
| Random Inject | 31.4 | 8.6 | 81.0 | 21.7 | +22.9 |

Table 6 reports the human validation results compared to different mutation configurations. LLM-Ablate achieves the highest human-valid rate and closely matches its automatic gate valid rate, suggesting that LLM-based ablation reliably preserves the intended metamorphic relation. For injection, LLM-Inject produces more human-valid and fluent variants than Prefix and Random Injection, even though its ASR advantage over Prefix is not statistically reliable in RQ2. This indicates that Prefix Injection is a strong failure-discovery baseline but often produces less natural variants. Overall, the semantic gate overestimates the quality of heuristic methods as the gaps are non-trivial, and LLM-based mutation produces more natural and usable test cases.

**Human validation ($RQ_3$)**: *The semantic gate acts as a high-precision but conservative validity filter. Human validation supports the use of LLM-based semantic rewriting, especially for producing natural and label-preserving variants.*

# 5 Threats to Validity

## 5.1 Internal validity

The semantic verification thresholds may introduce outcome-aware calibration bias because they are selected from the observed mutation distributions. We mitigate this risk by using a single global threshold pair for all datasets, models, and configurations rather than tuning thresholds per method. We interpret the retained failures as verified candidate robustness failures rather than complete oracle-confirmed errors. Furthermore, both automated semantic checks and human annotation provide evidence of label preservation rather than a complete oracle. Thus, some retained variants may still involve subtle semantic or label changes. We mitigate this risk through bidirectional entailment, fluency filtering, and human validation, and we interpret the results primarily at the aggregate level.

LLM-based mutation generation is inherently stochastic and may be sensitive to prompting and decoding choices. To reduce this threat, we use fixed prompts, decoding parameters, and identical computational budgets across all configurations. Moreover, all baselines are implemented within the same framework and evaluated under identical settings, isolating the effect of the mutation strategy itself.

Finally, our approach relies on LLMs both for mutation generation and semantic verification, potentially introducing correlated biases. We mitigate this risk by separating generation and verification stages, combining multiple validation signals, and complementing automated filtering with manual inspection.

## 5.2 External validity

The generalizability of our findings may depend on the selected datasets, task semantics, mutation operators, and Judge LLM. To reduce overfitting conclusions to a specific setting, we evaluate multiple datasets and model families, including encoder-only, encoder–decoder, and decoder-only architectures.

Furthermore, our evaluation primarily relies on Attack Success Rate, which captures prediction inconsistencies but may not fully reflect the practical severity of failures. Finally, our mutation operators cover only a subset of possible semantic-preserving transformations; different perturbation spaces or future LLMs may lead to different behaviors.

# 6 Qualitative Analysis

Beyond detecting failures, it is important to understand the patterns that trigger them. To this end, we conduct a qualitative and statistical analysis of 2320 verified failures produced by the best $RQ_2$ configuration across all three datasets, focusing on the failure-inducing words isolated by XAI and categorizing them by their Part-of-Speech (POS) tags. As illustrated in Figure 3, the distribution reveals systemic biases and distinct architectural vulnerabilities.

Across all four model architectures, Nouns (`NOUN`) consistently constitute the largest vulnerability surface. Furthermore, the nominal features, combining Nouns (`NOUN`) and Proper Nouns (`PROPN`), contribute nearly half of the critical vulnerabilities. This strongly indicates that the SFT LMs frequently overfit to specific topical keywords or entities and bypass robust semantic reasoning.

To corroborate our statistical findings, we extract and inspect the specific failure-inducing tokens and their original contexts. This qualitative analysis unveils some distinct patterns of shortcut learning and semantic overfitting across the target models. On the GitHub issue

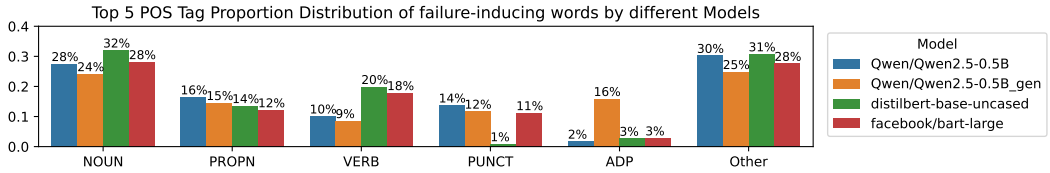

**Figure 3** POS analysis of failure-inducing words.

classification task, models like BART-Large exhibit a severe reliance on explicit, human-injected meta-words rather than comprehending the issue's technical description. For instance, ablating the literal word `"bug"` or `"question"` from the issue body consistently causes the model to misclassify the artifact, even when the surrounding text clearly describes an error trace (e.g., *"RuntimeError: source object number out of range"*) or a user query (e.g., *"May I ask if I can get a pull request...?"*). This reveals that the model acts largely as a shallow keyword-matcher, failing to generalize to issues where developers omit explicit category tags. In news categorization, discriminative models (e.g., DistilBERT) frequently exploit Named Entities (`ENT_TYPE=ORG`) as predictive shortcuts. We observe that models heavily rely on publisher acronyms (e.g., `"AFP"`, `"AP"`, `"Reuters"`) or dominant corporate entities (e.g., `"Apple"`, `"Pepsi"`) to determine the news category. For example, ablating `"(AFP)"` from a headline about European stocks causes the model's prediction to flip. This indicates a vulnerability where the SUT memorizes the data source distribution rather than reasoning about the semantic content of the headline.

## 7 Discussion

**Effectiveness of Attribution-Guided Mutation Selection.** The results of our study indicate that attribution-guided mutation selection substantially improves the discovery of verified robustness violations compared to unguided or purely heuristic perturbation strategies. Across datasets and architectures, configurations based on attribution signals generally achieve higher verified attack success rates and expose more semantically valid failures than random mutation baselines. These findings suggest that attribution methods provide an effective heuristic for identifying decision-relevant regions of the input space that are particularly sensitive to localized perturbations.

At the same time, the results also reveal differences across attribution techniques. Gradient-based and perturbation-based methods exhibit varying effectiveness depending on the model architecture and task, indicating that no single attribution strategy universally captures the most vulnerability-prone input regions. This variability further highlights the importance of systematically evaluating attribution methods within robustness testing settings rather than assuming uniform effectiveness across models.

**Impact of Semantic Verification.** A central finding of the study is that unconstrained adversarial generation substantially overestimates model brittleness. Many perturbations that successfully alter model predictions fail to preserve the original semantics or introduce severe linguistic degradation. Without semantic verification, these invalid mutations inflate attack success rates and provide misleading estimates of robustness weaknesses.

The human results also show why ASR alone is insufficient for comparing test-generation strategies. A configuration may be effective at inducing prediction flips while still producing variants that are unnatural, awkwardly inserted, or less useful for diagnosis. The results

therefore demonstrate that semantic validation is essential for obtaining reliable robustness measurements in metamorphic testing settings. Human validity further adds a complementary quality dimension, which is particularly important when comparing context-aware LLM mutations with stronger but more mechanical heuristics such as prefix-trigger insertion. The latter can be competitive in ASR, but human validation reveals that context-aware rewriting produces more natural and actionable variants.

**Evidence of Shortcut Reliance.** The discovered failures provide further evidence that task-specialized language models frequently rely on brittle lexical patterns and shortcut correlations. In many cases, small semantic-preserving edits affecting highly attributed tokens are sufficient to trigger prediction inconsistencies. This behavior is particularly pronounced for entity names, sentiment-bearing adjectives, and dataset-specific lexical indicators that strongly correlate with training labels.

These observations align with prior work on spurious correlations and annotation artifacts in NLP datasets, suggesting that strong in-distribution accuracy does not necessarily imply robust linguistic understanding. The results additionally indicate that attribution-guided perturbations can serve as a practical mechanism for systematically exposing such shortcut-driven behaviors.

**Limitations.** The evaluated metamorphic relations focus primarily on lexical-level transformations. Although these perturbations already expose substantial robustness weaknesses, they do not capture higher-level linguistic phenomena such as discourse structure, reasoning consistency, or conversational context. Second, the semantic verification mechanisms rely on pretrained NLI and language models, which may themselves exhibit biases or verification errors. Third, the evaluation is limited to text classification tasks and moderate-sized task-specialized language models; additional studies are required to assess whether the observed findings generalize to larger generative models and more complex NLP tasks such as summarization, code generation, or question answering, which require task-specific metamorphic relations and stronger validity oracles, which we leave for future work.

Despite these limitations, the study demonstrates that combining attribution-guided mutation selection with semantic verification provides reliable and scalable evidence for robustness evaluation in specialized language models.

# 8 Related Work

## 8.1 Test Generation for Deep Learning and Language Models

Testing techniques for deep learning systems primarily focus on generating inputs that expose unstable, incorrect, or brittle model behaviors. Early work on adversarial testing demonstrated that small perturbations to the input can cause incorrect predictions while preserving human-perceived semantics. In NLP, character-level and word-level attacks such as HotFlip and DeepWordBug generate adversarial examples through gradient-based or heuristic perturbation strategies [12, 13]. Subsequent studies shifted toward semantically constrained attacks that aim to preserve fluency and meaning. For example, Alzantot et al. used genetic search over embedding neighbors to generate natural adversarial examples [2], while TextFooler prioritizes important tokens and replaces them with semantically similar alternatives [19]. More recent approaches employ masked language models to generate context-aware substitutions and insertions that produce more fluent perturbations [26, 15].

Beyond adversarial attacks, behavioral testing approaches assess model robustness through systematic input transformations designed to verify specific linguistic capabilities. CheckList introduced a taxonomy of behavioral tests based on invariance, directional expectation, and minimal functionality properties [36]. Other works construct contrast sets and adversarial benchmarks to reveal weaknesses that are not captured by standard evaluation datasets [14, 32, 22]. Collectively, these studies show that language models often fail under relatively simple linguistic variations despite strong benchmark performance.

However, many existing techniques rely on manually designed templates, heuristic perturbations, or unconstrained search procedures. Prior evaluations also report that adversarial generation methods frequently produce invalid examples that unintentionally alter semantics or degrade linguistic quality [29]. To address this problem, prior work has proposed semantic and naturalness checks for generated NLP test cases. AEON, for example, evaluates whether generated NLP test cases preserve semantic similarity and natural language quality [17]. Metamorphic Testing (MT) has also been adapted to NLP through predefined metamorphic relations that verify prediction consistency under semantic-preserving transformations [6, 39, 9]. Nevertheless, many existing MT techniques still rely on random or weakly guided perturbations and provide limited guarantees regarding semantic validity.

This study is motivated by the observation that these components are often evaluated in isolation. Our novelty lies in empirically investigating the combination of attribution-guided mutation selection, LLM-based semantic transformations, and automated semantic verification for robustness testing of task-specialized language models.

## 8.2 Detecting Spurious Correlations in Language Models

A growing body of research investigates how language models exploit superficial patterns and spurious correlations present in training data. Adversarial evaluation studies have shown that models frequently rely on shallow lexical cues instead of robust linguistic reasoning. Universal adversarial triggers, for instance, demonstrate that short token sequences can systematically manipulate model predictions across many inputs [46]. Similarly, adversarial NLI benchmarks reveal that models often exploit annotation artifacts and dataset-specific heuristics rather than genuine semantic understanding [32].

Explainable AI techniques have also been widely used to diagnose such behaviors by identifying which input regions contribute most strongly to model predictions [53]. Attribution methods such as Integrated Gradients [42], attention-based analysis [1], and relevance propagation approaches [5] provide insight into the evidence used by neural models during inference [8]. These attribution signals have subsequently been incorporated into adversarial example generation and robustness analysis pipelines [19, 3].

Despite these advances, explainability methods are predominantly used as post-hoc diagnostic tools rather than as systematic mechanisms for generating semantically controlled robustness tests. This study builds on prior findings by empirically evaluating whether attribution signals can effectively guide metamorphic mutation selection and improve the generation of valid failure-inducing test cases. We also analyze the resulting failures to characterize recurring shortcut patterns, such as over-reliance on named entities and topical keywords. In doing so, the study connects attribution-based diagnosis with metamorphic robustness testing. The results provide further evidence on the relationship between attribution-guided perturbations, semantic validity, and brittle decision patterns in specialized language models.

## 9 Conclusions

In this paper, we presented an empirical study on XAI-guided metamorphic robustness testing for task-specialized language models. The study investigated how attribution-guided mutation prioritization, LLM-based semantic perturbations, and semantic verification mechanisms influence the generation of valid failure-inducing test variants without requiring test oracles.

Our evaluation across multiple datasets, architectures, and classification paradigms shows that combining explanation-guided selection with LLM-based mutation consistently exposes more robustness violations than unguided and rule-based baselines. Semantic verification filters a substantial portion of invalid adversarial artifacts. The human study further shows that the semantic gate is high-precision but conservative, making it suitable for robustness testing settings where false positives are costly. The verified failures also reveal shortcut behaviors, including sensitivity to named entities, lexical indicators, and formatting cues.

Future work will investigate richer metamorphic transformations beyond lexical edits, including structural, discourse-level, and conversational perturbations, as well as adaptive robustness testing settings in which discovered failures iteratively guide subsequent model refinement and evaluation.

## Data Availability Statement

We provide a public replication package with our experimental pipeline and processed datasets [7].

## Abstract

**Background.** Large Language Models (LLMs) introduce new concerns regarding fraudulent or AI-assisted participation in software engineering surveys.

**Aims.** This study investigates how suspicious or potentially AI-assisted responses may affect the validity of software engineering survey findings.

**Method.** We conducted a secondary analysis of four software engineering survey datasets using manual identification of suspicious responses, automated AI-generated text detection, descriptive statistical analysis, and thematic analysis. We compared findings obtained from the original and manually cleaned datasets.

**Results.** Quantitative findings generally remained stable after filtering suspicious responses, although some demographic and analytical variables showed moderate variation, affecting the interpretation of specific participant groups and contextual characteristics. In contrast, qualitative findings were more strongly influenced by changes in contextual framing, code prominence, and the nature of the evidence supporting interpretation, shaping how participants' experiences and study contexts were interpreted and characterized.

**Conclusions.** AI-assisted participation may influence software engineering survey findings differently depending on the type of analysis being conducted. The findings reinforce the importance of combining multiple validation procedures, particularly in studies relying on open-ended responses.

## 1 Introduction

Surveys are widely used in empirical software engineering to investigate developer practices, perceptions, and experiences across diverse organizational and educational contexts [24, 16, 27, 5, 22, 23]. The increasing use of online recruitment platforms has expanded the reach of survey-based studies while also introducing concerns related to response authenticity, participant validity, and data quality [7, 17, 26, 13, 8]. Previous research has shown that online surveys are susceptible to inattentive participation, fabricated responses, bots, and coordinated submissions capable of affecting empirical findings [17, 26, 37, 2]. Consequently, the literature recommends combining validation procedures such as attention checks, consistency verification, metadata inspection, and participant screening mechanisms to improve survey reliability [7, 17, 26, 37, 3].

Recent advances in Large Language Models (LLMs) introduce additional methodological concerns for empirical software engineering research. LLMs are increasingly used in software engineering activities and research workflows, including code generation, documentation, literature reviews, and scientific writing [10, 33, 21, 29, 20, 18, 11]. Emerging studies also indicate that these systems can generate responses resembling human narratives and simulate participant behavior in survey contexts [35, 15]. As a result, AI-generated or substantially modified responses may no longer represent authentic participant experiences or perceptions [25, 8].

Although interest in LLMs in software engineering has grown, little research has examined their impact on the authenticity and validity of survey responses. Existing studies predominantly focus on researchers' use of LLMs or traditional forms of survey fraud [29, 20, 18, 2, 37]. Therefore, we investigate the following research question (RQ): *How can the use of LLMs by participants affect the authenticity and validity of data collected in software engineering surveys?* To answer this RQ, we analyze four software engineering survey datasets using a multi-stage detection protocol combining manual inspection, narrative characterization, and automated verification techniques. Our contributions include: (1) a methodological investigation of suspicious responses across different software engineering survey contexts, (2) a comparative analysis evaluating how suspicious responses influence both quantitative and qualitative findings across original and filtered datasets, and (3) methodological evidence regarding the limitations of automated AI detection tools and the continued importance of manual inspection in survey validation procedures.

## 2 Background

**Survey Research in Software Engineering.** Surveys are widely used in empirical software engineering to collect information about developer practices, perceptions, and experiences that are difficult to observe in controlled settings [16, 24, 27]. Software engineering literature also provides methodological guidance on designing survey instruments, selecting appropriate participant populations, and reporting survey results in a transparent and systematic manner [5, 27]. Recruitment practices have evolved with the increasing use of online platforms and digital communication channels. Surveys are commonly distributed through professional mailing lists, social networks, developer communities, and specialized recruitment platforms [7, 3]. Platforms such as Prolific and similar participant marketplaces have been adopted in empirical studies because they provide access to large pools of respondents while enabling demographic and professional filtering during recruitment [3, 9, 30, 32]. Despite these advantages, determining whether respondents belong to the intended population of software practitioners remains a methodological challenge [36, 30, 32]. The literature therefore recommends the use of screening questions and experience-related measures to assess

respondents' professional background and expertise [5, 27]. In addition, sampling strategies and recruitment approaches may influence the representativeness of survey samples, particularly when participation is voluntary or mediated through online platforms [1, 36, 30, 32]. These characteristics of online survey recruitment also introduce risks related to response authenticity and data quality. Consequently, concerns about fraudulent participation, inattentive responses, and other forms of data contamination have become increasingly relevant in survey-based empirical research [17, 26, 2, 37].

**Fraud and Data Quality in Online Surveys.** Ensuring data validity is an important concern in online survey research as invalid or fraudulent participation can compromise the reliability of empirical findings [17, 13]. Online surveys are susceptible to inattentive responses, repeated participation attempts, fabricated answers, and automated submissions that do not represent the genuine experiences of the intended participant population [17, 26, 2]. Fraudulent or low-quality responses can distort empirical findings by introducing noise or systematic bias into survey datasets [37]. Automated submissions generated by bots or coordinated responses from survey farms may artificially inflate sample sizes while reducing the reliability of collected data [2, 37]. These issues are important in online survey research because invalid participation may affect both quantitative analyses and qualitative interpretations, potentially influencing conclusions derived from the data. To address these risks, prior literature proposes several validation and fraud-detection mechanisms to identify suspicious participation patterns [17, 26]. Common approaches include consistency checks across related questions, attention-verification items, completion-time analysis, screening questions related to domain expertise, and the use of technical metadata to identify repeated participation attempts [17, 26, 37]. Because fraudulent responses may resemble legitimate participation, the literature commonly recommends combining multiple validation strategies to improve the reliability and quality of survey datasets [37, 13].

**LLMs in Empirical Software Engineering Research.** While existing validation mechanisms are designed to detect inattentive participation, automated submissions, and other traditional forms of survey fraud, recent advances in AI introduce additional methodological considerations for empirical research. LLMs are capable of generating coherent and plausible responses across diverse topics [10, 33, 21], and are increasingly being used to support research activities such as literature reviews, data synthesis, and scientific writing [29, 20, 18, 11]. Emerging studies also indicate that LLMs can generate responses that resemble narratives typically produced by human participants in surveys and experiments [35, 15]. These capabilities raise concerns for studies that rely on self-reported data, since AI-generated or substantially modified responses may not reflect authentic experiences, perceptions, or practices [25]. Recent investigations have documented cases in which AI tools were used to fabricate or modify survey responses submitted during online data collection [8], suggesting that AI tools may be used to fabricate survey data while appearing to reflect real participation. Despite increasing attention to researchers' use of LLMs, little attention has been paid to how participants' use of AI tools may influence the authenticity and reliability of survey data in empirical software engineering research.

## 3 Method

We adopted a meta-scientific design to investigate a methodological issue in empirical software engineering research through the secondary analysis of existing survey datasets. Meta-science examines research practices, methodological procedures, and validity threats rather than

focusing directly on software engineering phenomena [28]. Specifically, we analyze the authenticity of survey responses and assess whether potentially LLM-generated responses influence empirical findings. To achieve this, we reanalyzed four previously collected survey datasets using secondary data analysis, a method that enables researchers to revisit existing data to address new research questions or methodological concerns [4, 14, 31].

## 3.1 Study Contexts and Survey Datasets

We conducted a secondary analysis using datasets from four questionnaire surveys we previously conducted in different software engineering contexts between 2025 and 2026. In these surveys, we investigated topics related to software engineering education and practice using both open- and closed-ended questions administered via online survey instruments. Although the surveys addressed distinct RQs, they share methodological characteristics typical of empirical software engineering surveys. Each survey was designed to collect participant perceptions, experiences, or practices through a combination of qualitative responses and structured questionnaire items, enabling comparative analysis of response patterns across datasets. The surveys investigated the following topics:

- **Technology education in the Global South:** a survey investigating challenges, opportunities, and educational practices related to technology and computing education in Global South contexts (16 questions).
- **Student cheating using AI tools:** a survey investigating how students use generative AI systems in academic contexts and how such tools influence academic integrity practices (21 questions).
- **Safe spaces in software engineering education:** a survey investigating how students define and perceive safe spaces in academic environments and how inclusive practices influence learning experiences (12 questions).
- **LLM usage among software developers:** a survey investigating perceptions and experiences related to reliance on LLMs during software development activities (18 questions).

These four datasets provide diverse survey contexts while maintaining comparable methodological structures, including combinations of open-ended and closed-ended questions related to software engineering education and practice. This consistency allowed comparative analysis across different survey topics while preserving similar data collection and validation procedures between datasets.

In all four surveys, our primary recruitment strategy involved the Prolific platform. Prolific is commonly used in empirical research to recruit participants for online studies and provides several mechanisms to support data quality [30, 32], including participant approval rate thresholds, demographic filters, and attention checks embedded in surveys. In each survey, we configured participant eligibility criteria and implemented multiple validation procedures intended to reduce inattentive participation, automated submissions, and low-quality responses. These procedures included participant approval rate thresholds available through Prolific, demographic and background screening criteria related to software engineering or computing experience, consistency verification across demographic questions, and attention validation questions embedded throughout the surveys [30, 32]. We also included domain-specific verification questions related to programming and software engineering knowledge to identify participants without the expected technical background for the studies. In addition, we manually inspected responses to identify indicators commonly associated with inattentive participation, including contradictory demographic information, duplicated narrative structures, repeated text patterns, nonsensical answers, and unusually generic open-ended responses.

Despite the use of these platform-level quality controls and validation procedures, we identified a number of responses demonstrating characteristics consistent with AI-generated text. This observation motivated the secondary analysis conducted in this study. More specifically, we analyzed the datasets to estimate the prevalence of suspicious responses and assess whether the presence of such responses influences empirical findings derived from survey-based studies. To preserve the double blind review process, we do not provide citations to the original survey studies in this manuscript. Some of these studies are currently under review, while others are already published but could still compromise reviewer anonymity if cited during the evaluation process. The corresponding references will be included in the final camera-ready version of the paper after the review process concludes.

## 3.2 Data Selection

To support a systematic comparison between the original and cleaned datasets, we selected a subset of analytical questions and demographic variables from each survey. The selection strategy was designed to include both qualitative and quantitative data commonly used in empirical software engineering research. Specifically, we selected demographic variables used to characterize participant populations, closed-ended questions representing central analytical constructs, and the main open-ended questions, also related to the central analytical construct in the research, that required reflective responses. Two authors participated in this process, and conflicts were resolved in agreement meetings, which could include a third author.

- **Demographic variables.** We selected the demographic or background variables from each survey to evaluate whether the presence of suspicious responses affected the demographic composition of the survey sample. Demographic variables describe characteristics of participants and are commonly used to contextualize survey samples in empirical software engineering research. In the survey on technology education in the Global South, we analyzed gender, ethnicity, sexual orientation, and year of study. In the survey investigating inappropriate LLM use in academic contexts, we analyzed gender, ethnicity, and year of study. In the safe spaces survey, we analyzed gender, ethnicity, and year of study. In the survey on LLM reliance among software developers, we analyzed gender and years of professional experience.
- **Key closed-ended analytical questions.** We also selected closed-ended questions from each survey that represented central constructs investigated in the original studies. These questions were designed as multiple-choice items with predefined response options. Because participants select among fixed alternatives, these questions produce structured data that can be analyzed quantitatively and allow comparison of response distributions across datasets. In the survey on technology education in the Global South, we analyzed questions related to financial support and first-generation university attendance status. In the survey investigating inappropriate LLM use in academic contexts, we analyzed questions related to training on LLMs, emotional responses associated with LLM use, and factors contributing to the use of LLMs in ways that were not permitted in coursework. In the safe spaces survey, we analyzed questions related to awareness of safe spaces and perceptions of exclusion or insecurity in software engineering education. In the survey on LLM reliance among software developers, we analyzed questions related to frequency of thinking about LLMs during work activities, comfort using generated code without human oversight, and formal LLM training background.
- **Core open-ended analytical questions.** Finally, we selected one open-ended question from each survey that required participants to describe experiences, motivations, or challenges related to the topic of the study. These questions typically require reflective

explanations and personal narratives. Such questions are particularly relevant in the context of this study because suspicious responses were most frequently observed in narrative answers requiring elaborated textual explanations [8]. These responses are also commonly used as the basis for qualitative analysis in empirical software engineering studies. The selected questions correspond to the central constructs investigated in each survey. In the survey on technology education in the Global South, we selected the question asking participants to describe a problem or challenge they experienced while pursuing technology education. In the survey investigating inappropriate LLM use in academic contexts, we selected the question asking participants to describe a situation in their software engineering program where they used an LLM in a way that was not aligned with course rules or expectations. In the safe spaces survey, we selected the question asking participants to describe how they understand or experience a safe space in software engineering education. In the survey investigating LLM reliance among software developers, we selected the question asking participants to describe a specific situation in which they used a LLM to assist with a programming task.

Across the four surveys, this selection strategy resulted in the analysis of 24 questions. This scope provides sufficient analytical coverage to evaluate the influence of suspicious responses while maintaining a tractable and systematic comparison across datasets.

## 3.3 Data Analysis

After selecting the questions for comparative analysis, we conducted a multi-stage qualitative and quantitative analysis procedure to evaluate how suspicious responses influence survey findings. The analysis process consisted of the following steps:

- **Manual identification of suspicious responses.** We first analyzed the original datasets and manually identified suspicious responses through independent classification performed by two researchers. The researchers classified responses as suspicious or non-suspicious and subsequently discussed disagreements until consensus was achieved. The manual identification process was informed by patterns reported in prior exploratory work on AI-generated responses in software engineering surveys [8]. During the review process, the researchers evaluated multiple indicators jointly rather than relying on a single characteristic in isolation. These indicators included repetitive narrative structures across participants, highly similar stylistic composition and rhetorical organization, reused or formulaic expressions, superficial personalization, duplicated semantic structures describing different situations with nearly identical discursive flow, unusually polished but homogeneous writing patterns, and inconsistencies or implausible contextual details within participant responses. Classification decisions emphasized recurring cross-response similarity patterns rather than isolated linguistic characteristics, and responses were not classified as suspicious solely because of writing quality or grammatical correctness.
- **Automated AI-generated text detection.** We evaluated the same responses using the Scribbr AI Detector to estimate the probability that individual answers were AI-generated. During this process, the exact open-ended responses identified during manual analysis were copied and pasted into the detection tool without modification. The resulting probability estimates were recorded and compared with the manual classifications. Because AI detection tools provide probabilistic estimates rather than definitive classifications, these results were used to compare automated and manual identification procedures rather than as a definitive ground truth.

- **Quantitative analysis of demographic and closed-ended questions.** We conducted descriptive statistical analyses [12] using the demographic variables and selected closed-ended questions. For each variable and question, we calculated frequencies, percentages, and proportional distributions across response categories using the original datasets. We then repeated the same calculations using the manually cleaned datasets generated after removing suspicious responses. Comparing these distributions allowed identification of whether suspicious responses influenced the demographic characterization of participants or altered the distribution of quantitative survey findings. The demographic analyses included variables such as gender, ethnicity, year of study, sexual orientation, and professional experience, depending on the survey context. The closed-ended analyses included questions related to financial support, first-generation university attendance status, awareness of safe spaces, perceptions of exclusion or insecurity, training on LLMs, emotional responses associated with LLM use, comfort using generated code without human oversight, and frequency of thinking about LLMs during work activities.
- **Qualitative analysis of open-ended responses.** For the selected open-ended questions, we conducted thematic analysis following established qualitative research practices in empirical software engineering [34, 19, 6]. First, two authors independently read the full set of responses for each selected question to become familiar with the data and identify recurring ideas. During this stage, the authors extracted quotes representing meaningful statements expressed by participants. These quotes served as the basic analytical units. Second, we assigned initial codes to each extracted quote. Codes were generated inductively from the data rather than from predefined categories. Third, we grouped related codes into broader conceptual categories representing recurring concepts across responses. Finally, we organized these categories into themes capturing the main patterns identified in the datasets. The two authors compared their coding results throughout the analysis process and discussed disagreements until consensus was achieved. This consensus-based procedure was applied to support consistent interpretation of participant responses. We first conducted the thematic analysis using the original datasets containing all responses and subsequently repeated the same procedure using the manually cleaned datasets. Comparing the resulting themes allowed identification of whether suspicious responses influenced the prevalence of themes, the identification of dominant themes, or the diversity of narratives reported by participants.
- **Comparative analysis across datasets.** Finally, we compared findings obtained from the original and manually cleaned datasets to evaluate the extent to which suspicious responses influenced demographic characterizations, quantitative response distributions, and qualitative thematic findings.

All analyses were conducted using the original datasets and manually cleaned versions generated after removing suspicious responses identified through independent coding by two researchers and consensus discussions. Automatically classified datasets from the Scribbr AI Detector were used only to compare manual and automated approaches, as AI detection tools provide probabilistic rather than definitive classifications.

## 3.4 Threats to Validity

We discuss potential threats to validity that may influence the interpretation of the results [28]. **Construct validity.** A primary threat concerns the identification of responses classified as suspicious. The classification procedure relied on manual inspection of textual characteristics and on an automated AI-detection tool. Manual inspection may introduce

subjectivity when interpreting stylistic patterns in narrative responses, while automated detectors provide probabilistic estimates rather than definitive identification of AI-generated text. Consequently, both procedures may produce false positives or false negatives when identifying suspicious responses. **Internal validity.** The study relies on secondary analysis of previously collected survey data. Because the datasets were originally collected for different research objectives, some contextual variables that could influence interpretation may not be available in the data. Secondary data analysis often encounters this limitation when datasets lack all variables relevant to the new RQs [4, 14]. **External validity.** All surveys were conducted using participants recruited through the Prolific platform. Although the platform includes mechanisms to improve data quality, samples obtained through online participant platforms may not fully represent broader software engineering populations. As a result, the prevalence of suspicious responses observed in this study may differ in surveys using other recruitment strategies. **Reliability.** The identification and coding of narrative responses involve interpretive qualitative analysis. Although two researchers independently reviewed responses and resolved disagreements through discussion, qualitative secondary analysis may be affected by differences in interpretation or by limited knowledge of contextual details from the original data collection process [31, 19].

# 4 Results

## 4.1 Comparison Between Manual and Automated Fraud Detection

In the Global South survey dataset, the manual review procedure identified 19 suspicious responses among the 81 collected responses. Using the automated AI detector, 14 responses were classified as 100% AI generated, while three additional responses received intermediate probabilities of 32%, 64%, and 75%. Some disagreement between the procedures was identified. Three responses manually classified as suspicious could not be analyzed by the automated detector because they did not satisfy the minimum word threshold required by the tool. In addition, one response manually classified as legitimate was classified by the detector as 100% AI generated. Among the legitimate responses identified manually, 15 received a 0% AI generated probability, whereas 47 responses could not be processed because of response length limitations.

For the Student Cheating survey dataset, manual inspection identified 29 suspicious responses among the 145 collected responses. The automated detector classified 13 responses as 100% AI generated, one response as 86%, two responses as 68%, and additional responses with intermediate probabilities of 29%, 35%, 52%, 54%, 63%, 66%, and 67%. The automated procedure also produced results inconsistent with the manual classification. Seven responses manually identified as suspicious received a 0% AI generated probability. Among the manually legitimate responses, 54 matched the automated classification with 0% AI generated probability, while 68 responses could not be analyzed because they did not meet the minimum word threshold required by the detector.

In the Safe Spaces survey dataset, the manual review process classified 41 responses as suspicious among the 133 collected responses. The automated detector identified 11 responses as 100% AI generated and assigned intermediate probabilities of 0.19%, 55%, 80%, 84%, and 92% to additional responses. Divergences between manual and automated identification were also observed in this dataset. Ten manually suspicious responses received a 0% AI generated probability from the automated detector. Conversely, two manually legitimate responses were classified as 100% AI generated, while another legitimate response received a 0.19% probability. The automated detector also failed to analyze 78 manually legitimate responses because they did not satisfy the minimum word threshold required by the tool.

The Professionals LLM Usage survey dataset presented the strongest disagreement between manual and automated procedures. Manual analysis identified 9 suspicious responses among the 128 collected responses. The automated detector classified 12 responses as 100% AI generated and assigned intermediate probabilities of 22%, 66%, 78%, and 96% to additional responses. Two manually suspicious responses could not be analyzed because of the minimum word requirement. Furthermore, 10 responses manually classified as legitimate were flagged by the automated detector as potentially AI generated, including nine responses classified as 100% AI generated and one response classified as 22%. Overall, 67 responses could not be analyzed by the detector, including 2 manually suspicious responses and 65 manually legitimate responses.

Across the four datasets, the results demonstrate partial agreement between manual and automated fraud identification procedures, particularly for responses considered strongly suspicious during manual inspection. However, the findings also reveal substantial limitations associated with automated AI detection tools, including false positives, and inability to analyze short responses because of minimum word thresholds. These observations suggest that automated detectors may provide supporting evidence during survey validation procedures, but manual inspection remains necessary to interpret ambiguous cases and evaluate shorter narrative responses commonly observed in empirical software engineering survey research.

## 4.2 Effects of Suspicious Responses on Quantitative Results

This section presents the quantitative differences observed between the original and cleaned datasets after removing suspicious responses from each survey.

### 4.2.1 Global South Survey

The original Global South survey dataset contained 81 respondents, while the cleaned dataset contained 62 respondents after removing suspicious responses. Gender distributions showed moderate variation after filtering. The proportion of female participants decreased from 38.3% to 33.9%, while male participants increased from 61.7% to 66.1%. Ethnicity distributions also changed moderately. Black participants decreased from 71.6% to 67.7%, while mixed-race participants increased from 12.3% to 16.1%. Regarding sexual orientation, participants reporting not identifying as LGBTQIA+ increased from 56.8% to 61.3%, while participants preferring not to answer decreased from 16.0% to 12.9%. First generation university attendance status also changed after filtering, with participants identifying as first-generation students decreasing from 40.7% to 35.5%. Financial support distributions remained comparatively stable, decreasing slightly from 69.1% to 67.7%. The variable most affected by suspicious responses was first-generation university attendance status, which decreased by 5.2 percentage points after filtering. Sexual orientation also showed moderate proportional variation. Despite these changes, the cleaned dataset remained predominantly composed of male and Black students receiving financial support.

### 4.2.2 Student Cheating Survey

The original Student Cheating survey dataset had 145 respondents, while the cleaned dataset had 116 respondents. Gender distributions remained relatively stable after filtering. Female participants increased slightly from 35.9% to 36.2%, while male participants decreased from 63.4% to 62.9%. Ethnicity distributions presented the largest proportional changes. The proportion of Black participants decreased from 29.7% to 23.3%, while White participants

increased from 35.2% to 38.8%. South Asian participants decreased from 9.7% to 8.6%, while mixed-race participants increased slightly from 8.3% to 8.6%. Training on LLMs remained relatively stable. Participants reporting no formal LLM training increased from 53.1% to 54.3%, while participants reporting formal training decreased from 44.8% to 43.1%. Year of study distributions also showed moderate variation. First-year students increased from 16.6% to 19.8%, while third-year students decreased from 30.3% to 28.4%. Emotional responses remained comparatively stable after filtering. Indifference increased from 33.8% to 36.2%, while guilt decreased from 22.1% to 20.7%. Satisfaction also decreased slightly from 8.3% to 6.9%. The variable most affected by suspicious responses was ethnicity, particularly due to the reduction in Black participants by 6.4 percentage points. Moderate variation was also observed in first-year student representation and emotional responses related to indifference.

### 4.2.3 Safe Spaces Survey

The original Safe Spaces survey dataset included 133 respondents, while the cleaned dataset included 92 respondents. Gender distributions remained highly stable after filtering. Female participants decreased from 38.3% to 37.0%, while male participants increased slightly from 59.4% to 59.8%. Ethnicity distributions showed moderate variation. Black participants decreased from 30.8% to 27.2%, while White participants increased from 33.8% to 35.9%. Year of study distributions remained almost unchanged, with third-year students increasing slightly from 33.1% to 33.7% and fourth or fifth-year students remaining stable at approximately 31.5%. Perceptions of exclusion or insecurity also changed after filtering. Participants selecting "Sometimes" decreased from 33.1% to 29.3%, while "Rarely" responses increased from 30.8% to 32.6%. Awareness of safe spaces decreased from 67.7% to 62.0%, while participants reporting no awareness increased from 20.3% to 25.0%. The variables most affected by suspicious responses were safe space awareness and perceptions of exclusion or insecurity. Awareness of safe spaces decreased by 5.7 percentage points after filtering, suggesting that suspicious responses may have moderately inflated perception-related findings in the original dataset.

### 4.2.4 LLM Usage Survey

The original Professionals LLM Usage survey dataset contained 128 respondents, while the cleaned dataset contained 119 respondents after removing suspicious responses. Gender distributions remained virtually unchanged across both datasets. Female participants remained stable at 33.6%, while male participants changed minimally from 65.6% to 65.5%. Professional experience distributions also remained highly stable. Participants with 1–3 years of experience decreased slightly from 29.7% to 28.6%, while participants with more than 10 years of experience remained stable at approximately 23.5%. The largest proportional changes involved the frequency with which participants reported thinking about LLMs. Participants selecting "Often" decreased from 42.2% to 38.7%, while "Sometimes" responses increased from 26.6% to 28.6%. "Very often" responses increased slightly from 18.8% to 19.3%. Attitudes regarding autonomous code generation remained highly stable after filtering. Participants reporting discomfort with using generated code without human oversight increased slightly from 57.0% to 58.0%, while participants comfortable using generated code decreased from 24.2% to 23.5%. Formal LLM training also showed only small changes, with participants reporting no formal training increasing from 60.2% to 62.2%. The variable most affected by suspicious responses was the frequency with which participants reported thinking about LLMs, particularly due to the reduction of "Often" responses by 3.5 percentage points after filtering. Overall, the cleaned dataset preserved the principal demographic and attitudinal structure observed in the original dataset.

### 4.2.5 Comparative Overview of Quantitative Differences

We observed moderate proportional changes in both demographic and study-specific analytical variables after removing suspicious responses, although the principal descriptive structures of the datasets generally remained stable. Regarding demographic variables, the most visible changes were associated with ethnicity distributions in the Student Cheating and Safe Spaces surveys, sexual orientation and first-generation university attendance status in the Global South survey, and comparatively small redistributions related to gender and professional experience across the datasets. These proportional changes generally ranged from approximately 3 to 6 percentage points and may influence interpretation differently depending on the analytical role of the affected variable in each study, particularly in analyses focused on underrepresented groups, educational inequality, or participant experiences. Study-specific analytical variables also exhibited moderate variation across survey contexts. In the Global South survey, the first-generation university attendance rate decreased by 5.2 percentage points after filtering, potentially affecting interpretations of educational accessibility and structural disadvantage. In the Student Cheating survey, ethnicity distributions showed the largest proportional variation, particularly due to a 6.4 percentage-point reduction in Black participants, while emotional responses and year of study distributions changed by approximately 2 to 3 percentage points, suggesting comparatively limited influence on the broader characterization of LLM misuse behaviors. In the Safe Spaces survey, awareness of safe spaces decreased by 5.7 percentage points after filtering, while perceptions of exclusion or insecurity changed by 3.8 percentage points, moderately affecting how institutional support and inclusion perceptions may be interpreted. In the Professionals LLM Usage survey, the most visible variation involved the frequency with which participants reported thinking about LLMs during work activities, which decreased by 3.5 percentage points for "Often" responses, while attitudes toward autonomous code generation and formal LLM training remained comparatively stable, with changes near 1 to 2 percentage points. Tables 1, 2, 3, and 4 summarize the most substantial quantitative differences identified after removing suspicious responses from each survey dataset.

**Table 1** Differences between the original and cleaned Global South survey datasets.

| **Demographic Variable** | **Main Observed Difference Between Datasets** | **Largest Difference** |
|---|---|---|
| Gender | Slight increase in male participants and reduction in female participants after filtering. | 4.4 pp |
| Ethnicity | Small reduction in Black participants and increase in mixed-race participants after filtering. | 3.9 pp |
| Sexual Orientation | Increase in participants reporting not identifying as LGB-TQIA+ and reduction in participants preferring not to answer. | 4.5 pp |
| First Generation University Student | Reduction in the proportion of first-generation university students after filtering. | 5.2 pp |
| Financial Support | Financial support distribution remained highly stable across datasets. | 1.4 pp |
| Year of Study | Small redistribution toward senior students after filtering. | 3.0 pp |

**Table 2** Differences between the original and cleaned Student Cheating survey datasets.

| Demographic Variable | Main Observed Difference Between Datasets | Largest Difference |
|---|---|---|
| Gender | The gender distribution remained highly stable after filtering, with negligible variation across categories. | 0.5 pp |
| Ethnicity | The cleaned dataset showed a reduction in Black participants and a proportional increase in White participants. | 6.4 pp |
| Training on LLM | The balance between participants with and without LLM training remained largely unchanged. | 1.7 pp |
| Year of Study | The cleaned dataset showed a moderate increase in first year students and a slight reduction in third year students. | 3.2 pp |
| Emotion | Emotional distributions remained broadly consistent, although indifference increased slightly after filtering. | 2.4 pp |

**Table 3** Differences between the original and cleaned Safe Spaces survey datasets.

| Demographic Variable | Main Observed Difference Between Datasets | Largest Difference |
|---|---|---|
| Gender | Gender distribution remained highly stable across datasets. | 1.3 pp |
| Ethnicity | Moderate proportional shifts occurred, particularly among Black and White participants. | 3.6 pp |
| Year of Study | Academic composition remained almost unchanged. | 1.0 pp |
| Perception of Exclusion/ Insecurity | The cleaned dataset showed fewer “Sometimes” responses. | 3.8 pp |
| Safe Space Awareness | Awareness of safe spaces decreased after cleaning. | 5.7 pp |

**Table 4** Differences between the original and cleaned Professionals LLM Usage survey datasets.

| Demographic Variable | Main Observed Difference Between Datasets | Largest Difference |
|---|---|---|
| Gender | Gender distribution remained virtually unchanged across both datasets. | 0.1 pp |
| Years of Experience | Only small redistributions across experience levels were observed. | 1.1 pp |
| Time thinking about LLMs | The cleaned dataset showed fewer “Often” responses and more “Sometimes” responses. | 3.5 pp |
| Comfort using code without human oversight | Attitudes toward autonomous code usage remained highly stable. | 1.0 pp |
| LLM training | The cleaned dataset showed a slightly larger proportion of participants without formal LLM training. | 2.0 pp |

## 4.3 Effects of Suspicious Responses on Qualitative Findings

The qualitative analysis was conducted through a multi-stage coding process consisting of core idea extraction, low-level coding, category development, and thematic synthesis.

### 4.3.1 Global South Survey

Across this dataset, we generated 81 core ideas and corresponding low level codes, which were grouped into 9 high level categories and subsequently synthesized into 4 overarching themes. The most frequent categories were *Financial Constraints* (25 codes) and *Resource and Infrastructure Scarcity* (16 codes), followed by *Work Study Balance* (6), *Transportation and Basic Needs Insecurity* (6), *Persistence, Motivation, and Resilience* (6), *Educational Preparation Gaps* (5), *Social Exclusion and Class Inequality* (5), *Academic Continuation Risks* (3), and *Financial Stability and Privilege* (2). The first theme, *Economic hardship limiting academic participation*, captured how financial instability constrained students' ability to participate fully in university life through difficulties related to tuition, transportation, food insecurity, technological access, and balancing employment with academic responsibilities. The second theme, *Unequal educational and technological conditions*, reflected disparities in educational preparation, internet connectivity, technological infrastructure, and access to institutional learning resources, which affected students' ability to complete coursework and keep pace academically. The third theme, *Social inequality affecting belonging and confidence*, captured experiences of exclusion, inferiority, and class based comparison, particularly in relation to wealthier peers and unequal educational opportunities. Finally, the theme *Persistence despite adversity* reflected how students described continuing their academic journeys despite repeated barriers, risks of interruption, and unstable conditions, often framing perseverance and resilience as central parts of their university experiences.

After removing the 19 suspicious and potentially fraudulent responses, the qualitative coding structure remained broadly stable, although some categories experienced noticeable reductions in frequency. The cleaned dataset resulted in 25 codes related to *Financial Constraints*, 10 related to *Resource and Infrastructure Scarcity*, 7 related to *Transportation and Basic Needs Insecurity*, 6 related to *Academic Continuation Risks*, 5 related to *Work Study Balance*, 5 related to *Educational Preparation Gaps*, and 4 related to *Social Exclusion and Class Inequality*. The largest reduction occurred in *Resource and Infrastructure Scarcity*, which decreased from 20 to 10 codes after filtering. This reduction is important from a qualitative interpretation perspective because many of the removed responses contained highly descriptive narratives emphasizing infrastructural hardship in Global South contexts, including prolonged power outages, unstable internet access, and dependence on shared or public computing resources. For example, one removed response described *"camping out overnight"* in a library during a power outage to continue studying, while another described the experience as *"feeling like (...) dreams were slipping away"*. These narratives strongly reinforced an image of severe precarity and instability. However, after filtering, the remaining dataset still preserved consistent evidence of infrastructural and technological inequality through more grounded, such as students reporting not enough computers in programming classes or describing outdated and unreliable personal devices. From a qualitative perspective, this shift changes not necessarily the existence of the theme itself, but the intensity and framing through which the context is interpreted. As a result, despite narrative reductions, the broader thematic structure remained stable. Themes associated with economic hardship, unequal educational and technological conditions, social inequality, and persistence despite adversity continued to emerge across the cleaned dataset. This suggests that the principal qualitative findings were not substantially dependent on suspicious responses, but the way the context is visualized may be affected.

### 4.3.2 Student Cheating Survey

Looking at the 145 responses contained in the full dataset, we identified 12 high-level categories representing different forms of LLM use that students perceived as not fully aligned with course rules or academic expectations. The categories with the highest concentration of codes were *Full Assignment Generation* (24 codes), *Code Generation* (23), *General Coursework Use* (19), and *Quiz and Exam Assistance* (18). Additional categories included *Conceptual and Instructional Assistance* (13), *Documentation and Writing Assistance* (13), *Debugging Assistance* (11), *Coding Assistance* (9), *Design and Development Assistance* (6), *Study Assistance* (5), *Full Project Generation* (3), and *Content Generation* (1). These categories were interpreted through six broader themes: *Replacing Independent Coursework with LLM Generated Work*, representing situations where students relied on LLMs to directly generate assignments, projects, or substantial portions of coursework; *Using LLMs During Restricted Assessments*, reflecting the use of LLMs during quizzes and exams where external assistance was restricted; *Using LLMs for Technical Problem Solving*, capturing coding, debugging, design, and implementation support; *Using LLMs for Learning, Understanding, and Guidance*, representing conceptual clarification and instructional support; *Using LLMs for Writing and Content Production*, reflecting the generation of reports, documentation, essays, and written coursework; and *Normalized and Ambiguous LLM Use Across Coursework*, representing recurring and context dependent forms of LLM use shaped by unclear expectations, inconsistent policies, peer influence, or uncertainty regarding acceptable AI assistance.

After removing 29 codes associated with suspicious or potentially fraudulent responses, the overall qualitative structure remained relatively stable, although some categories became less prominent. The cleaned dataset contained 19 codes related to both *Full Assignment Generation* and *General Coursework Use*, followed by 17 related to *Quiz and Exam Assistance*. We also identified 11 codes associated with *Code Generation*, 10 with *Debugging Assistance*, 9 with *Documentation and Writing Assistance*, 8 with both *Coding Assistance* and *Conceptual and Instructional Assistance*, 6 with *Design and Development Assistance*, 5 with *Study Assistance*, 3 with *Full Project Generation*, and 1 with *Content Generation*. The largest reduction occurred in *Code Generation*, which decreased from 23 to 11 codes after filtering. Several removed responses described technically elaborate scenarios involving algorithm implementations, software architecture tasks, optimization activities, or highly articulated reflections regarding academic integrity and independent work. From a qualitative interpretation perspective, these narratives could lead researchers to conceptualize student misuse of LLMs primarily through technically sophisticated programming activities and explicit forms of misconduct. In contrast, the cleaned dataset more strongly emphasized practical and situational forms of LLM use associated with deadline pressure, confusion, insufficient understanding of course material, workload accumulation, uncertainty regarding course expectations, and attempts to complete assignments under constrained academic conditions. Although the relative prominence of some categories changed after filtering, the central qualitative interpretation remained preserved.

### 4.3.3 Safe Spaces Survey

Our analysis of this full dataset resulted in 133 core ideas and low-level codes, which were subsequently consolidated into 10 refined high-level categories and interpreted through 4 broader themes. The categories with the highest concentration of codes were *Respectful and Non-Judgmental Learning Environments* (26 codes) and *Learning Through Mistakes and Questions* (20), followed by *Inclusive and Equitable Participation* (16), *Collaborative*

*and Community-Oriented Learning* (15), *Supportive Teaching and Mentorship Practices* (13), *Student Expression, Voice, and Engagement* (12), *Institutional Policies and Safe Space Structures* (11), *Anonymous and Private Support Mechanisms* (9), *Learning Culture and Pedagogical Inclusivity* (7), and *Accessible and Flexible Learning Support* (4). The theme *Psychological Safety in Learning Environments* represented participants' emphasis on creating learning conditions where students can ask questions, express uncertainty, and make mistakes without fear of judgment or embarrassment. The theme *Inclusion and Equity in Computing Education* reflected concerns regarding fairness, accessibility, diversity, and equitable participation opportunities for students from different backgrounds. The theme *Collaboration, Community, and Student Belonging* captured the importance of collaborative interaction, peer engagement, shared learning experiences, and spaces that encourage participation and social connection. Finally, the theme *Institutional and Pedagogical Responsibility for Safe Spaces* reflected participants' perceptions that safe spaces require active support through institutional structures, inclusive pedagogical practices, mentorship, policies, and clearly established expectations for respectful conduct.

Following the removal of 41 codes associated with suspicious or potentially fraudulent responses, the overall qualitative structure of the dataset remained relatively stable, although some categories showed substantial reductions. The cleaned dataset contained 18 codes related to *Respectful and Non-Judgmental Learning Environments*, 13 to *Inclusive and Equitable Participation*, 13 to *Collaborative and Community-Oriented Learning*, 9 to both *Institutional Policies and Safe Space Structures* and *Supportive Teaching and Mentorship Practices*, 9 to *Student Expression, Voice, and Engagement*, 6 to *Learning Culture and Pedagogical Inclusivity*, 6 to *Learning Through Mistakes and Questions*, 5 to *Anonymous and Private Support Mechanisms*, and 4 to *Accessible and Flexible Learning Support*. The largest reduction occurred in *Learning Through Mistakes and Questions*, which decreased from 20 to 6 codes after filtering. One possible explanation is that suspicious or AI-generated responses relied on generalized definitions of safe spaces centered on learning without fear, asking questions safely, and normalizing mistakes, artificially increasing the prominence of this category in the original dataset. Several removed responses repeatedly emphasized ideas such as *"Normalize Mistakes"*, *"all questions are welcome"*, *"making mistakes is seen as part of the learning process"*, and *"encouraging questions without any fear of judgement"*. From a qualitative interpretation perspective, these narratives could induce researchers to conceptualize safe spaces primarily as psychologically protective and institutionally engineered learning environments focused on reducing embarrassment, fear, and uncertainty during learning activities, instead of understanding safe spaces more broadly through collaborative participation, peer interaction, inclusion, mentorship, community belonging, and supportive educational relationships, as the cleaned dataset more consistently suggests. This effect was also observed in technically oriented Software Engineering educational practices. For example, three of the four responses mentioning *pair programming* and all three responses mentioning *code review* practices were identified as suspicious and removed during filtering. In the qualitative process, this could lead researchers to interpret formal Software Engineering instructional mechanisms and technically engineered collaboration practices as already established approaches for supporting safe spaces in computing education, when the remaining participant experiences do not consistently support this interpretation.

### 4.3.4 LLM Usage Survey

Our analysis of the 128 coded responses resulted in 15 high-level categories capturing different ways developers reported using LLMs during programming and software development activities. The categories with the largest concentration of codes were *Debugging and*

*Troubleshooting* (19 codes), *Application and Feature Development* (17), *Code and Performance Optimization* (15), and *Script and Automation Development* (13). Other commonly identified categories included *General Coding Assistance* (11), *Learning and Knowledge Support* (9), *Data Processing and Transformation* (8), *Code Refactoring and Maintainability* (7), and *Function and Logic Generation* (7). Additional categories represented activities related to *Code Explanation and Understanding* (5), *Code Generation and Scaffolding* (5), *Testing and Quality Assurance* (5), *Database Development and Querying* (4), *Educational and Instructional Support* (2), and *Code Quality and Review* (1). These categories were interpreted through five broader themes representing how developers incorporated LLMs into software engineering work. The first theme, *Using LLMs for Debugging, Troubleshooting, and Problem Resolution*, captured developers' use of LLMs to identify errors, diagnose failures, resolve runtime and database issues, interpret logs, and troubleshoot unexpected software behavior. The second theme, *Using LLMs to Develop and Implement Software Features*, represented the use of LLMs to support application development, API integration, frontend and backend implementation, scripting, automation, scaffolding, and feature prototyping. The third theme, *Using LLMs to Optimize, Refactor, and Maintain Code*, reflected participants' use of LLMs to improve execution performance, optimize queries and algorithms, restructure code, improve readability, modularize implementations, and support maintainability activities. The fourth theme, *Using LLMs to Support Learning, Understanding, and Coding Guidance*, captured situations in which developers relied on LLMs to explain code, recall syntax, generate examples, understand unfamiliar technologies or languages, and provide step-by-step guidance during development activities. Finally, the fifth theme, *Using LLMs to Support Testing and Quality Assurance Activities*, represented the use of LLMs to generate unit tests, create test classes, review code quality, and assist with validation and verification-related tasks.

After removing 9 suspicious responses, we observed that the dataset's overall qualitative organization remained relatively stable. The cleaned dataset continued to concentrate primarily on categories associated with *Debugging and Troubleshooting* (18 codes), *Application and Feature Development* (17), *Script and Automation Development* (12), *Code and Performance Optimization* (11), and *General Coding Assistance* (11). The largest reduction occurred in *Code and Performance Optimization*, which decreased from 15 to 11 codes after filtering. The removed responses shared several similar characteristics. Many described technically polished optimization scenarios involving CSV processing, SQL query tuning, memory management, data pipelines, and efficiency improvements. These quotations frequently included explicit technical terminology and strongly positive outcomes, such as *"significantly reduced execution time"*, *"boosted performance significantly"*, *"reduce query time by 60%"*, and *"faster, more stable version of the script"*. Several responses also followed highly similar narrative structures, consisting of a technical problem description, an explicit prompting process, a detailed solution explanation, and a positive outcome statement. From a qualitative perspective, the relatively small number of removed responses meant the dataset's broader thematic structure remained unchanged. Instead, the main effect of filtering was to reduce the concentration of repetitive, optimization-oriented narratives and to limit our ability to use technically detailed examples that were not sufficiently trustworthy. As a result, the cleaned dataset still supported the same overall interpretation of developer LLM use while providing a more reliable set of quotations and examples for qualitative interpretation.

## 5 Discussion

Our findings are consistent with previous research showing that online surveys are susceptible to fraudulent participation, inattentive responses, and automated or fabricated submissions [17, 26, 2, 37]. Similar to prior studies, we observed that suspicious responses

can remain difficult to identify because they often resemble legitimate participation and can satisfy conventional survey validation mechanisms, such as attention checks or demographic consistency checks [17, 37]. This observation reinforces recommendations from previous literature advocating the use of multiple complementary validation procedures during online data collection [13, 37], while also aligning with broader concerns regarding the reliability of automated AI detection systems [25]. In the emerging context where LLMs are increasingly accessible, although automated detectors identified several strongly suspicious responses, they also produced false positives, inconsistent classifications, and limitations due to short responses that did not meet minimum word thresholds. These observations suggest that automated AI detection tools should be interpreted as probabilistic indicators rather than definitive evidence, and may be more appropriate as complementary sources of evidence combined with manual review and contextual interpretation.

Our results contribute to emerging discussions on the influence of generative AI systems on empirical research practices [29, 20, 18]. Previous work has primarily focused on how researchers use LLMs to support scientific activities such as literature reviews, qualitative coding, or scientific writing [11, 18]. At the same time, limited attention has been paid to the possibility that research participants may rely on generative systems during empirical studies [35, 8]. In this study, we identified several suspicious responses presenting stylistic and structural characteristics similar to patterns previously associated with AI-generated text in survey environments [8]. These characteristics included repetitive rhetorical organization, highly similar narrative structures across participants, technically polished yet homogeneous descriptions, and generalized formulations that repeatedly emphasized similar concepts or emotional framings. Our findings suggest that the use of generative AI by participants in empirical software engineering surveys is not only a theoretical possibility discussed in recent literature but a phenomenon that already appears to be occurring in practice.

Our analysis of the impact of fraudulent AI-generated answers suggests that suspicious responses do not affect quantitative and qualitative conclusions in the same way. Across the four datasets, quantitative findings generally remained comparatively stable after filtering, even when moderate proportional changes were observed in some demographic or analytical variables. In most cases, the principal descriptive characterization of the datasets remained preserved, suggesting that the broader quantitative conclusions were not fundamentally altered. However, the potential impact of suspicious responses appears to depend on the specific variables and analytical goals of a study. For example, moderate shifts in ethnicity, sexual orientation, and first-generation university attendance status may become more consequential in studies specifically investigating underrepresented groups, educational progression, or demographic disparities in software engineering.

In contrast, the qualitative analyses revealed stronger interpretive effects. Suspicious responses disproportionately contributed to highly polished, emotionally intense, technically elaborate, or generalized narratives that influenced how contexts, experiences, and practices could be interpreted. Although the principal thematic structures generally remained stable after filtering, the qualitative interpretations became less influenced by extreme or overly generalized narratives and more grounded in practical, contextually consistent participant experiences. These findings suggest that AI-assisted responses may influence not only the frequency of codes or categories but also the contextual framing and the strength of evidence supporting qualitative interpretation.

**Implications and Recommendations for Empirical Software Engineering Research.** Our findings reinforce methodological concerns about online survey research in software engineering, particularly in studies that rely on open online recruitment. Suspicious or AI-assisted

responses may remain undetected while still appearing plausible and contextually consistent with expected participant profiles, introducing threats to validity that are difficult to identify through conventional validation procedures alone. Such responses may affect sample characterization, analyses involving specific demographic variables, and the interpretation of qualitative evidence. These observations suggest that researchers conducting online surveys in software engineering may benefit from combining multiple validation procedures rather than relying exclusively on attention checks or automated AI detection systems. Manual inspection and cross-response comparison may become increasingly important, especially in studies relying on open-ended responses. Researchers may also need to more explicitly document validation procedures, strategies for handling suspicious responses, and the potential effects of filtering decisions on empirical findings. Future work should further investigate how AI-assisted participation influences survey validity in software engineering.

**Answering the RQ: How can the use of LLMs by participants affect the authenticity and validity of data collected in software engineering surveys?** AI-assisted participation may introduce responses that appear legitimate while influencing empirical findings in different ways depending on the type of analysis being conducted. In our datasets, broader quantitative patterns generally remained stable after filtering, although some demographic and analytical variables showed noticeable variation. Qualitative analyses were more sensitive to suspicious responses, particularly through changes in contextual framing and supporting evidence. These observations indicate that unidentified AI-assisted responses may affect both data reliability and the interpretation of participant experiences.

## 6 Conclusion

We investigated how suspicious or potentially AI-assisted responses may affect the authenticity and validity of software engineering survey data. Using four survey datasets collected in different software engineering contexts, we compared original and manually cleaned datasets to analyze the effects of suspicious responses on quantitative and qualitative findings. Our analyses showed that suspicious responses may affect empirical interpretation differently depending on the type of analysis being conducted. While broader quantitative distributions were often preserved after filtering, some demographic and analytical variables presented noticeable variation, particularly in studies involving underrepresented groups or context-specific participant characteristics. In contrast, qualitative analyses were more strongly influenced by changes in narrative emphasis and the nature of the evidence supporting interpretation. Considering these findings, this study provides empirical evidence of methodological risks associated with the use of generative AI in online software engineering surveys, particularly in studies relying on open-ended responses and self-reported experiences. As immediate future work, we intend to investigate how different proportions of fraudulent or AI-assisted responses affect empirical findings to better understand whether specific levels of suspicious participation alter quantitative distributions or qualitative interpretations.

## Abstract

**Background.** Meetings are an integral part of software practitioners' workday, but many practitioners see them as disruptive to focused work and productivity. Prior research has mainly focused on overall meeting load and broad perceptions; however, teams cannot effectively improve meeting practices without knowing which specific meeting patterns cause disruption.

**Aims.** Our core aim is to move from general perceptions to an empirical investigation of meeting characteristics that are strongly linked to productivity, flow, and well-being.

**Method.** We conducted a two-phase mixed-method study. In Phase 1, we surveyed 55 software practitioners to establish a baseline of meeting practices and perceived impact on productivity, flow, and well-being. In Phase 2, a two-week field study with experience sampling collected real-time post-meeting ratings (usefulness, energy, focus disruption) and daily end-of-day reports, complemented by objective meeting characteristics extracted automatically from calendar metadata (135 post-meeting and 40 end-of-day records).

**Results.** In the baseline survey, 61.8% reported at least moderate flow disruption and 76.4% lower productivity on high-meeting days, with unclear purpose and excessive duration as the top frustrations. The field study revealed a more nuanced pattern: overall usefulness was moderately positive, but varied by type – ad-hoc meetings were among the most useful ($Mdn = 4$), planning meetings were most disruptive ($Mdn = 4$), and one-on-ones were least disruptive ($Mdn = 1$). Type contrasts are exploratory and based on small sample. At the daily level, higher meeting counts coincided with lower productivity and deep-work ratings; energy was lowest on high-meeting days. This daily pattern reflected between-participant differences rather than within-person day-to-day effects. The directional alignment between survey complaints and real-time observations strengthens confidence in these emerging patterns.

**Conclusions.** This study shifts the conversation from broad dissatisfaction with meetings toward identifiable and actionable meeting patterns that organizations can actively redesign. The findings suggest that not all meetings are equally harmful–or beneficial–and that factors such as meeting purpose clarity, duration, and scheduling context may play a critical role in shaping employees' productivity, ability to sustain flow, and daily energy levels. We treat these patterns as design hypotheses pending larger confirmation. They also provide an empirical starting point for longitudinal research on meeting design.

## 1 Introduction

Meetings are one of the most ubiquitous forms of collaborative work in software development. Prior studies show that practitioners spend a substantial share of work time in meetings and informal communication [11], while meeting frequency has risen across knowledge work more broadly [18]. Meetings are essential for coordination [23, 16], however, they are also often experienced as disruptive. Developers frequently report interruptions to deep work [7, 11], and many practitioners perceive current meeting load as excessive [22, 18].

The tension between coordination value and productivity cost has received growing empirical attention. In organisational psychology, meeting load has been linked to well-being and daily fatigue [18, 10]; in software engineering, studies show that perceptions of meeting value vary across context, role, and meeting type [11, 22]. Related work on interruptions and transitions further suggests that meeting cost extends beyond meeting time itself: regaining focus after context switches can be cognitively expensive [7, 1]. At the same time, most prior evidence remains aggregate (e.g., total meeting time/frequency) or retrospective, which limits practical guidance for improving everyday meeting practice.

A key empirical gap is therefore not only whether meetings are experienced as costly, but which specific meeting characteristics are associated with that cost in situ. In particular, objective scheduling properties, such as timing within the day, duration, and back-to-back clustering (meetings with $\leq$5 min gap), have rarely been examined against the within-person momentary experience of productivity impact, flow disruption, and energy change. As a result, teams still have limited evidence for deciding which meeting patterns to modify first and under what conditions changes are likely to help.

To address these gaps, we conduct a two-phase mixed-method study of software practitioners. In Phase 1, a practitioner survey establishes a baseline characterisation of meeting practices and perceived effects on productivity, flow, and well-being. In Phase 2, a two-week field study combines experience sampling with objective calendar metadata to examine how meeting characteristics relate to momentary disruption, energy change, and daily outcomes. Together, these phases allow us to contrast aggregate perceptions with field observations under natural working conditions. This study makes three contributions.

1. **Moving beyond "meeting overload" to actionable meeting patterns.** We provide an empirical characterisation of how meeting practices shape not only productivity, but also employees' flow, energy, and day-to-day well-being. Rather than treating meetings as uniformly costly, the study identifies which meeting characteristics most strongly predict disruption and usefulness in practice.
2. **Capturing meetings in real work contexts through in-situ analysis.** We provide within-person, real-time evidence on how objective meeting characteristics – timing, duration, and back-to-back clustering – relate to momentary experiences of productivity, focus, and energy, moving the literature beyond retrospective self-report toward observations grounded in practitioners' actual workdays.

3. **Revealing where perceptions and observed behaviour align – or diverge.** By comparing survey-reported beliefs with field measurements, we identify which commonly reported meeting frustrations are supported by real-time evidence and which are less consistently reflected in observed patterns. This bridges practitioner perceptions with empirical measurement and helps distinguish widely held assumptions from effects that appear in day-to-day work practice.

The remainder of this paper is structured as follows. Section 2 describes the study design, including the baseline survey and in-situ field study, instruments, and analysis approach. Section 3 reports findings for both research questions. Section 4 discusses implications for research and practice. Section 5 outlines limitations and validity considerations, and Section 6 discusses key related literature. Section 7 concludes the paper.

## 2 Study Design

The study comprises two sequential phases: (i) a practitioner survey that establishes baseline perceptions and quantifies meeting practices, and (ii) a two-week field study with a subset of survey respondents (n = 3) as well as additional participants, combining experience sampling with objective calendar data. Figure 1 provides a graphical overview of our study design. Together, the phases allow us to triangulate survey perceptions against self-reports and

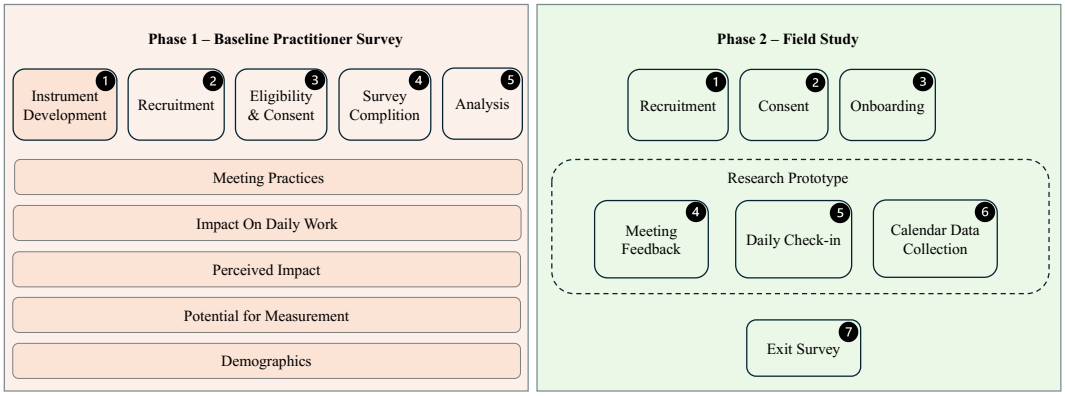

**Figure 1** Research Design Overview.

objective calendar data. The replication package contains: (1) raw data for the baseline practitioner survey, (2) raw data from the field study, (3) the source code of the research prototype, and (4) analysis scripts [14].

### 2.1 Phase 1: Practitioner Survey

RQ1

What are software practitioners' current meeting practices, and how do they perceive the impact of meetings on their productivity, flow, and well-being?

**Instrument Design.** We followed established guidelines for empirical survey design in software engineering [15, 6, 13]. Two authors drafted the instrument based on the research question, reviewed it internally, and piloted it with two external colleagues. Their feedback

led to revisions in wording and question ordering. The survey ran from late January to late February 2026. The instrument contains 33 questions across eight sections: eligibility and consent, current meeting practices, impact on daily work, reasons for declining or skipping, perceived impact on satisfaction and productivity, potential for measurement, demographics, and follow-up consent. Question types include single-select (16), multiple-select (4), Likert scale (9), one matrix item, and one open-ended item. Likert scales use 5-point ordinal formats, varying by construct (disruption, impact, or agreement). Participation required confirmation of recent meeting involvement and explicit informed consent. The survey was implemented in Google Forms.

**Participants and Recruitment.** We distributed the survey through professional networks and platforms, such as LinkedIn, targeting software practitioners with recent meeting experience. Participation was voluntary and anonymous. Respondents willing to join a follow-up field study were asked to provide contact details, forming the candidate pool for Phase 2. Sample demographics are reported in Section 3.

**Analysis Approach.** Given the exploratory nature, we report descriptive statistics throughout: frequencies and percentages for categorical items. For 1–5 field ratings we report medians and IQRs ($Q_3 - Q_1$). Associations among ordinal ratings and between meeting counts and daily ratings use Kendall's $\tau_b$. Where subgroup differences are discussed, they are interpreted as descriptive patterns rather than confirmatory hypothesis tests.

## 2.2 Phase 2: Field Study

RQ2

How do objective meeting characteristics – type, duration, timing, and clustering – relate to practitioners' experience of productivity impact, flow disruption, and energy?

In Phase 2, we used an experience sampling approach [2], where participants reported immediately after meetings and once at the end of each workday. We separate productivity, flow, and well-being following SE work that treats perceived progress, deep focus, and affective state as related but non-identical constructs [11, 12, 3, 5, 4]. We operationalise *productivity* as perceived ability to make progress on work tasks on a given day; *flow* (deep focus) as the capacity for sustained concentration without interruption; and *well-being* as energy level and psychological state (stress, satisfaction) as affected by meetings. These three constructs are conceptually orthogonal: a planning meeting can be highly useful for the team while being highly disruptive and energy-draining for the individual; an ad-hoc sync can be both useful and lightly disruptive precisely because it is short. Several of the findings reported in Section 3 depend on this distinction.

**Participants and Setting.** We recruited participants via two channels: (1) Phase 1 respondents who volunteered for a follow-up, and (2) additional outreach through professional networks. All field-study participants underwent the same consent and onboarding procedure before participation. During the two study weeks, participants used their own devices and followed their normal work routines.

**Research Prototype Implementation.** To enable data collection, we developed a browser-based web application. The research prototype was motivated by the need to combine objective calendar data with subjective ratings in a single instrument, while imposing

minimal burden on participants. The application is implemented with Angular (frontend), a Spring Boot REST API (backend), a PostgreSQL database. Calendar data is ingested automatically through a Google Calendar OAuth 2.0 integration that synchronises events every ten minutes. After each meeting ends, a push notification prompts participants to complete a four-item feedback form covering focus disruption, overall feeling, energy, and perceived usefulness. A separate end-of-day notification, timed one hour before each participant's configured work end, triggers a four-item daily check-in on productivity, deep work, energy, and meeting load. All pending feedback items are also collected in an inbox, ensuring that missed notifications do not result in data loss. Two interactive dashboards allow participants to review their own data: one visualising meeting load (Figure 2), timing heatmaps, type distribution, and a computed daily flow-potential score; and another linking subjective ratings to meeting types and surfacing recurring positive and negative tags.

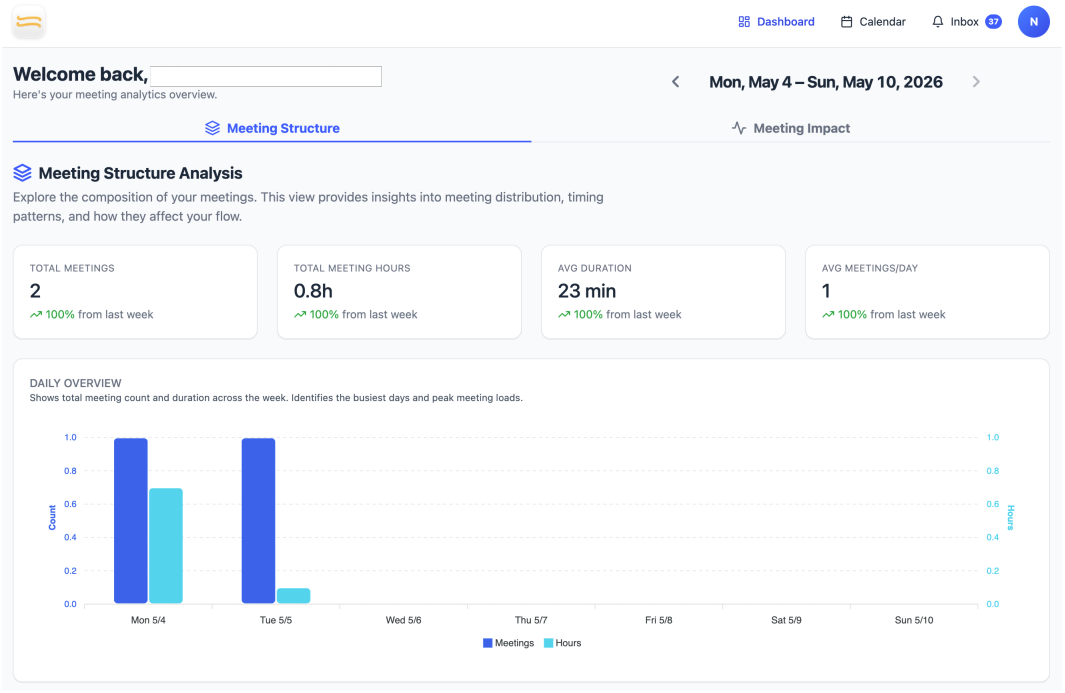

**Figure 2** Prototype tool – dashboard.

**Field Study Procedure.** Before the study began, participants completed a brief background questionnaire covering role, years of experience, organisation type and size, and work location. They then received an onboarding session (online or in-person) in which we demonstrated the prototype, and individual consent for calendar access and notifications was obtained.

**Measurement Instruments.** We collected data through four streams.

1. A lightweight feedback prompt was triggered after each calendar event ended. Participants rated: (1) *Usefulness* ("This meeting was worth my time?"; 1 = not at all – 5 = very useful); (2) *Energy impact* ("How did this meeting affect your energy?"; 1 = very draining – 5 = very energizing); and (3) *Flow disruption* ("Did this meeting disrupt your focus?"; 1 = not at all – 5 = very much). All meetings were sampled; no stratified or random subsampling was applied.

2. At the end of each workday, participants reported on four items: (1) *Daily productivity* ("How productive were you today?"; 1 = very unproductive – 5 = very productive); (2) *Daily deep focus* ("How much deep, focused work did you do today?"; 1 = none – 5 = a lot); (3) *Daily energy* ("How energized do you feel right now?"; 1 = very drained – 5 = very energized); and (4) an ordinal assessment of perceived meeting load ("How did today's meeting load feel?"; 1 = too few - 5 = too many).
3. With participant consent, we extracted objective meeting characteristics from calendar metadata. Per-meeting variables include: start time and end time, duration in minutes, inter-meeting gap (minutes to the next meeting), back-to-back status (gap $\leq$5 min before or after), time-of-day category (early morning: 08:00–10:00; morning: 10:00–12:00; around lunch: 12:00–13:00; afternoon: 13:00–17:00; late afternoon: 17:00+), position in the day (1st, 2nd), and consecutive meeting block duration. From these, we derived daily aggregates: total meeting count, total meeting time in minutes, number of back-to-back pairs, longest consecutive meeting block, and meeting time as a percentage of the workday (assuming an 8-hour, 480-minute day).
4. At the end of the two weeks, participants completed an *Exit Survey* assessing response honesty, perceived behaviour change due to participation, and feedback burden. The exit survey additionally included an open-ended question on participants' awareness of their own meeting practices, perceived changes in meeting behaviour during the study weeks, and usability of the research prototype. Open-ended responses were analysed manually through inductive thematic analysis; given the small participant count, no inter-rater reliability check was conducted.

# 3 Results

We report the samples in Subsection 3.1, Phase 1 baseline survey results in Subsection 3.2, the Phase 2 field-study findings in Subsection 3.3, and answers to RQ1 and RQ2 in Subsection 3.4.

## 3.1 Sample

**Survey sample.** We received 57 responses; one respondent reported no meeting participation and was ineligible, and one additional respondent declined consent, leaving $N = 55$ consented, eligible responses. The majority of respondents were from Europe (96.4%), while the rest (3.6%) were from Asia. The sample skewed young: 80% of respondents were aged 18–44 (18–29: 40.0%; 30–44: 40.0%; 45–60: 14.5%). The majority of respondents were Software Engineers/Developers (72.7%), followed by Team Lead *or* Engineering Manager (4.5%), and Product Owner *or* Product Manager (5.5%). Respondents were predominantly male (81.8%). Most respondents (72.7%) work in an IT department inside a larger, non-IT organisation – i.e. "embedded IT" in banks, whereas another (9.1%) work in a Software company *or* IT services provider. A majority (69.1%) work in Large companies or organisations with 250 or more employees.

**Field-study sample.** Eleven participants enrolled in the field study. We excluded five who submitted insufficient data. The remaining six participants form the *meeting-level analysis group*; of these, five additionally completed daily end-of-day check-ins and form the *full analysis group*. Roles included software developer (2), requirements engineer (1), product owner (1), and coach/developer (1), with professional experience ranging from 4 to 29 years. Participants were located in Austria (3; same organisation), Switzerland (2), and India (1).

Across the observation period, the six participants provided feedback on 135 meetings; the five-participant full-analysis subset contributed 112 meeting feedback records and 40 daily check-ins. We summarise observation periods and compliance rates in Table 1.

**Table 1** Field study participants included in analysis. Meeting compliance reflects the share of calendar events for which feedback was submitted. P8 did not configure a daily work schedule and submitted no daily check-ins; P10 did not configure a schedule but submitted 7 daily entries voluntarily.

| ID | Observation period | Work days | Meetings | Daily Check-in | Mtg. compl. |
|---|---|---|---|---|---|
| *Full analysis group (meetings + daily, $n = 5$)* | | | | | |
| P1 | 02 Mar – 13 Mar 2026 | 10 | 43 | 10 | 100% |
| P2 | 02 Mar – 13 Mar 2026 | 10 | 19 | 10 | 95% |
| P3 | 03 Mar – 12 Mar 2026 | 6 | 15 | 5 | 100% |
| P9 | 17 Apr – 01 May 2026 | 11 | 16 | 8 | 94% |
| P10 | 21 Apr – 01 May 2026 | – | 19 | 7 | 100% |
| *Meeting-only group (additionally, $n = 1$)* | | | | | |
| P8 | 20 Apr – 30 Apr 2026 | – | 23 | 0 | 92% |

**Self-reported response quality.** Six participants completed the exit survey. All six reported having *always* answered honestly throughout the study. Perceived burden was minimal, ranging from *not at all* to *moderately* burdensome. All six noticed patterns in how meetings affected them during the observation weeks, suggesting that the measurement instruments supported, rather than disrupted, natural reflection. No participants reported technical issues other than the calendar-sync suggestion captured in the quote below:

> *"This experiment was useful as a checkpoint as to what's the state of these efforts. Especially looking back at last week made me reflect on which meetings were actually useful, [...]. Overall usability was good. Calendar sync would definitely be useful. [...]"*

We treat all field-study estimates in Subsection 3.3 as descriptive and exploratory. With $n = 6$ participants providing meeting-level data ($n = 5$ providing daily data), we report direction and effect size; we include $p$-values for completeness, but do not treat them as confirmatory.

## 3.2 Baseline survey results: Reported meeting practices

Survey respondents reported attending a moderate number of meetings (typically 1–3 per day) across a familiar mix of types (stand-ups, planning, ad-hoc syncs), with mostly remote or hybrid attendance. We summarise the descriptive results in Table 2.

**Perceived impact of meetings.** Table 3 summarises how respondents perceive the impact of meetings on productivity, focus, and well-being. Two patterns stand out and recur in the field study: meetings are rated as useful and as costly by the same respondents – 63.6% perceive them as rather/very useful; 61.8% think that they moderately disrupt flow; while 61.8% need at least 15 minutes to recover focus after a meeting. Most respondents (76.4%) report lower productivity on high-meeting days. Two open responses illustrate reform wishes:

**Table 2** Self-reported meeting practices (survey, $N = 55$). Multi-select items (meeting types attended) do not sum to 100%. For "Most disruptive time of day", smaller categories (early morning, around lunch, late afternoon, n/a) are omitted.

| Category | $n$ (%) | Category | $n$ (%) | Category | $n$ (%) |
|---|---|---|---|---|---|
| *Meetings per typical workday* | | *Total daily meeting time* | | *Modality* | |
| 1 meeting | 23 (41.8%) | <30 min | 9 (16.4%) | Remote video | 21 (38.2%) |
| 2–3 meetings | 24 (43.6%) | 30 min–1 h | 17 (30.9%) | Hybrid | 21 (38.2%) |
| 4–5 meetings | 7 (12.7%) | 1–2 h | 17 (30.9%) | On-site | 13 (23.6%) |
| >5 meetings | 1 (1.8%) | 2–4 h | 10 (18.2%) | | |
| | | >4 h | 2 (3.6%) | | |
| *Meeting types (multi-select)* | | *Largest share of meeting time* | | *Most disruptive time of day* | |
| Stand-ups | 43 (78.2%) | Planning | 27 (49.1%) | Morning | 12 (21.8%) |
| Planning | 42 (76.4%) | Stand-ups | 23 (41.8%) | Afternoon | 12 (21.8%) |
| Ad-hoc syncs | 38 (69.1%) | Ad-hoc | 19 (34.5%) | No difference | 14 (25.5%) |

> *"Meetings should only cover essential topics. [...] I would prefer to participate in meetings only when I have something to contribute, not just to listen."*

> *"1. Clear agenda/goal, 2. Time-box strictly (15–25 min max), 3. Prep required (read doc before meeting)"*

**Table 3** Survey perceptions of meeting impact, disruption drivers, and avoidance behaviour ($N = 55$).

| *Perceived usefulness (%)* | | *Task completion (%)* | | *Decline frequency (%)* | |
|---|---|---|---|---|---|
| Rather/very useful | 63.6 | Positive | 32.7 | Never | 18.2 |
| Neutral | 18.2 | Neutral | 38.2 | Rarely | 60.0 |
| Not useful | 16.4 | Negative | 29.1 | Sometimes | 18.2 |
| | | | | Often | 3.6 |
| *Top negative drivers (%)* | | | | *Top decline reasons (%) ($n = 26$)* | |
| Unclear purpose | 45.5 | No clear action items | 25.5 | Not relevant | 29.1 |
| Excessive duration | 30.9 | Irrelevant/too many attend. | 29.1 | Deadline overlap | 16.4 |
| | | | | Too frequent/long | 9.1 |
| | | | | Already informed | 7.3 |
| | | | | Focus/async (each) | 5.5 |

## 3.3 Field-study findings

We organise our analysis around seven findings: (1) ad-hoc meetings were rated most useful; (2) planning meetings were rated most disruptive; (3) disruption increased across the day; (4) one-on-one meetings were the least disruptive and most energising; (5) back-to-back meetings amplified disruption and energy drain; (6) end-of-day productivity dropped as daily meeting count rose; (7) survey complaints and in-situ flags named the same drivers of bad meetings.

***Finding 1.*** **Ad-hoc meetings were rated most useful.**

The 135 logged meetings spanned six types: *other* ($n = 55$, 40.7%), *stand-up* ($n = 28$, 20.7%), *planning* ($n = 24$, 17.8%), *ad-hoc* ($n = 19$, 14.1%), *one-on-one* ($n = 7$, 5.2%), and *retrospective* ($n = 2$, 1.5%). All type comparisons are descriptive. Meeting durations ranged from 15 to 210 minutes ($M = 47.1$ min, $Mdn = 30$ min, $SD = 31.6$ min). We show median ratings by type in Table 4. Ad-hoc meetings were among the most useful types ($Mdn = 4$, IQR = 1; Table 4), despite being unscheduled and the fourth-most-frequent type. Across all 135 meetings, usefulness was positively skewed ($Mdn = 4$, IQR = 1), with 58.5% scored 4 or 5. Post-meeting energy was similarly positive ($Mdn = 4$, IQR = 1): 51.1% scored 4 or 5, with a large neutral cluster at 3 (34.1%). Usefulness and energy were moderately associated (Kendall $\tau_b = .50$), meaning they are related but not the same judgment. The survey baseline matches the field-study direction (Table 3).

**Table 4** Median (IQR) per-meeting ratings by meeting type (meeting-level analysis group, $n = 135$). Scale: 1–5 for all items. Focus disruption: higher = more disruptive. ROTI and energy: higher = more positive. Retrospectives are included for completeness ($n = 2$) but should be interpreted with caution.

| Type | $n$ | ROTI | | Energy after | | Focus disrupt. | |
|---|---|---|---|---|---|---|---|
| | | $Mdn$ | IQR | $Mdn$ | IQR | $Mdn$ | IQR |
| Ad-hoc | 19 | 4 | 1 | 4 | 1.5 | 3 | 2.5 |
| One-on-one | 7 | 4 | 2 | 4 | 0.5 | 1 | 1 |
| Planning | 24 | 4 | 1 | 3 | 2 | 4 | 2 |
| Stand-up | 28 | 3.5 | 1 | 4 | 1 | 2 | 1 |
| Other | 55 | 4 | 2 | 4 | 1 | 2 | 2.5 |
| Retrospective | 2 | 2.5 | 0.5 | 3.5 | 0.5 | 3 | 2 |

***Finding 2.*** **Planning meetings were rated most disruptive.**

Planning meetings have the highest median focus disruption ($Mdn = 4$, IQR = 2; Table 4) and the lowest median post-meeting energy among non-retrospective types ($Mdn = 3$). Planning meetings remain useful ($Mdn = 4$), but their cost falls on focus and energy. Across all 135 meetings, focus disruption had $Mdn = 2$ (IQR = 2), with 52.6% scored 1 or 2 and 31.1% scored 4 or 5; self-reported post-meeting feeling was positive in 57.8%, neutral in 37.0%, and negative in 5.2% ($n = 7$). The survey baseline names the same pattern at the population level (Table 3): respondents report flow disruption, prolonged focus-recovery time, and perceived meeting waste.

***Finding 3.*** **Disruption increased across the day.**

We analysed focus disruption by sequential position within each participant-day (Table 5). Median disruption rose from the 1st meeting ($Mdn = 2$) to the 5th ($Mdn = 4$), with a dip at the 4th ($Mdn = 2.5$); only three observations occur beyond the 5th meeting.

Short meetings (≤30 min) and meetings longer than an hour had lower median disruption ($Mdn = 2$) than the default 46–60 min slot ($Mdn = 3$). A small 31–45 min bin ($n = 7$) had $Mdn = 4$ and should not be over-interpreted. One possible explanation is that very short

**Table 5** Median (IQR) focus disruption by meeting position within the workday (meeting-level analysis group; positions 6+ omitted, $n = 3$).

| Position | 1st | 2nd | 3rd | 4th | 5th |
|---|---|---|---|---|---|
| $n$ | 49 | 37 | 27 | 12 | 7 |
| $Mdn$ | 2 | 3 | 3 | 2.5 | 4 |
| IQR | 2 | 3 | 2 | 1.25 | 1.5 |

meetings feel cognitively bounded – participants can anticipate the end and return quickly to their prior task – while meetings longer than an hour are typically planned as the primary activity of a time block, so the cognitive transition cost is expected and absorbed. The survey baseline is less unanimous on time-of-day: morning and afternoon were cited as the most disruptive period at equal rates (Table 3). Position in the day is correlated with how many meetings already occurred. The rise in disruption may therefore reflect cumulative meeting load rather than clock time alone; our design cannot fully separate these. Finding 6 speaks to daily load at the person level, but a joint model of position × prior count was out of scope given n.

***Finding 4.*** **One-on-one meetings were the least disruptive and most energising.**

One-on-one meetings have the lowest median focus disruption ($Mdn = 1$, IQR = 1; Table 4) and high post-meeting energy ($Mdn = 4$). Their usefulness median matches ad-hoc and planning ($Mdn = 4$), but at $n = 7$ they are the rarest non-retrospective type.

***Finding 5.*** **Back-to-back meetings amplified disruption and energy drain.**

Our ≤5 min gap definition yields 55 back-to-back and 80 non-back-to-back meetings. Median focus disruption is higher for back-to-back meetings ($Mdn = 3$, IQR = 2) than for non-back-to-back ($Mdn = 2$, IQR = 3). Risk-based comparisons sharpen the contrast: high disruption (scores 4–5) occurred in 39.2% of back-to-back meetings versus 27.9% of non-back-to-back meetings (RR = 1.41, OR = 1.67), and draining energy ratings (1–2) in 21.6% versus 13.1% (RR = 1.65, OR = 1.82). Clustering amplifies both the focus cost and the energy cost.

***Finding 6.*** **End-of-day productivity dropped as daily meeting count rose.**

Survey respondents reported that productivity on high-meeting days is lower than on low-meeting days (Table 3); no other survey item shows a comparable one-sided distribution. In the field study, we grouped days by meeting count (0–1, 2–3, 4+) to make the daily pattern interpretable (Table 6). The gradient holds for productivity and deep work; energy is lowest on 4+ meeting days (Table 6).

**Table 6** Median end-of-day ratings by daily meeting count (full-analysis group, $n = 5$ participants over 40 participant-days). Scale: 1–5 for all items; higher = more positive.

| Meetings per day | Productivity | Deep work | Energy |
|---|---|---|---|
| 0–1 | 4.0 | 3.5 | 3.5 |
| 2–3 | 3.5 | 2.5 | 4.0 |
| 4+ | 3.0 | 2.0 | 2.0 |

Day-level Kendall associations with meeting count were weakly negative (productivity $\tau_b = -.15$; deep work $\tau_b = -.15$; energy $\tau_b = -.21$). The negative pattern is clearer between participants (productivity $\tau_b = -.20$; deep work $\tau_b = -.40$; energy $\tau_b = -.40$) than within person, where average $\tau_b$ was near zero. Perceived meeting load tracked actual meeting count ($\tau_b = .36$) and total meeting time ($\tau_b = .27$).

***Finding 7.*** **Survey complaints and in-situ flags named the same drivers of bad meetings.**

Participants flagged at least one *positive* aspect in 58.5% of meetings ($n = 79$), most commonly *clear purpose* ($n = 42$), *clarified next steps* ($n = 40$), and *provided useful information* ($n = 33$). Issues were flagged in 20.0% of meetings ($n = 27$), most often *too long*, *no relevance to my tasks*, and *could have been an email* (each $n = 8$). We summarise in Table 7 how the presence of each flag shifts ratings relative to meetings without that flag. Issue flags lower usefulness and energy and raise disruption; positive flags do the opposite. The flag *no clear outcome* is the strongest single negative on usefulness. The factors named by survey respondents as the top frustrations (Table 3) match the field-study flag effects: unclear purpose, excessive duration, irrelevant attendees, and missing action items – the same four factors that the issue flags *no clear outcome*, *too long*, and *no relevance* capture in the in-situ data.

**Table 7** Per-meeting rating differences associated with flag presence ($\Delta$ = mean for meetings carrying the flag minus mean for meetings without the flag; 1–5 scale). Disruption deltas for the two positive flags were not reported in the source data.

| Flag | $n$ | ΔROTI | ΔEnergy | ΔDisruption |
|---|---|---|---|---|
| *Issue flags* | | | | |
| too long | 7 | −1.77 | −1.49 | +0.84 |
| no relevance | 8 | −1.64 | −0.85 | +1.19 |
| no clear outcome | 4 | −2.35 | −1.07 | +0.11 |
| *Positive flags* | | | | |
| clear purpose | 40 | +1.49 | +0.68 | – |
| clarified next steps | 33 | +1.33 | +0.66 | – |

## 3.4 Summary

Three findings stand out across the two study phases. First, the cost of a meeting is not a single number. Usefulness, focus disruption, and post-meeting energy are three different facets, and a meeting can score high on one and low on another (F1, F2, F4). Treating “too

many meetings" as a single problem overlooks the nuances behind these trade-offs. Second, when and how meetings are scheduled matters. Focus disruption rises with each successive meeting in the day, with back-to-back scheduling, and with meetings booked into the default 60-minute slot (F3, F5). Third, what practitioners say makes meetings good or bad aligns with what we see in real time. Clear purpose and clear next steps appear both as the top survey reform requests and as the strongest positive in-situ flags. On the other hand, unclear purpose, excessive duration, and irrelevant attendees appear both as the top survey frustrations and as the largest negative in-situ tag effects (F7).

Respondents were nearly unanimous that productivity is lower on high-meeting days (76.4%). The field data trend in the same direction at the group level, but within-person – comparing each participant's own busier and quieter days – the signal was near zero. The group-level pattern reflects who carries heavier schedules, not how individuals respond when their own load increases. We return to this in the Discussion.

**Answer to RQ1.** Software practitioners attend 1–3 meetings on a typical workday, drawn from a familiar mix of stand-ups, planning sessions, and ad-hoc syncs in mostly remote or hybrid format. They rate these meetings as moderately useful (63.6%) but costly: 61.8% report at least moderate flow disruption, 61.8% need ≥15 minutes to refocus afterward, and 76.4% feel less productive on high-meeting days. The complaints behind this negative experience are specific and recurring: unclear purpose, excessive duration, too many or irrelevant attendees, and weak action items.

**Answer to RQ2.** The same picture appears in real time, with scheduling factors explaining most of the variation. Meeting *type* produces the largest contrasts: ad-hoc syncs are rated most useful, planning sessions most disruptive and draining, one-on-ones appeared least disruptive in our data (n=7). Disruption rises with *position* in the day and with *back-to-back* scheduling. *Duration* is non-monotonic, with the default 46–60 minute slot as the disruption peak. *Daily meeting count* trends in the expected negative direction with end-of-day outcomes, but does not reach statistical significance in our small sample. The four survey complaints from RQ1 – unclear purpose, excessive duration, low attendee relevance, weak actionability – also appear as the strongest negative tags in the in-situ data, providing the cross-phase confirmation.

# 4 Discussion

Meeting experience breaks down into two independent dimensions: perceived usefulness and affective impact on focus and energy. These do not reduce to a single judgment: a meeting can be worthwhile and still leave a participant drained, or feel unproblematic and still consume time without return. One participant captured this in the exit survey: *"That meetings can keep me with good energy but still not be worth my time."* Planning meetings illustrate the point: rated as useful, yet the most disruptive and draining type observed. The implications below are structured around both dimensions.

## 4.1 Implications For Practitioners

Cutting meetings does not always help; the problem is often how a meeting is run, not that it happens. A useful-but-draining meeting is not a candidate for removal – it is a candidate for redesign. For high-value, high-drain meetings such as planning sessions, the practical solutions are shorter time boxes, stricter agendas, and scheduling them to end near

a natural break rather than mid-block. The field study identifies the indicators that work: clear purpose, defined next steps, and durations matched to the agenda rather than to the default calendar slot.

Short, on-demand syncs were rated most useful in our data. Policies that suppress ad-hoc communication to reduce interruptions may remove a productive coordination channel and push the same conversations into longer scheduled meetings.

Time of day was not a consistent predictor in either phase. What mattered was sequence position, back-to-back scheduling, and duration. Three scheduling patterns are promising design hypotheses for teams to trial and for future studies to validate:

- **Later-position meetings.** Disruption climbed from the first to the fifth meeting of the day; consider limiting meetings stacked late in a person's meeting sequence.
- **Back-to-back clustering.** Gaps of five minutes or less were associated with higher disruption and more draining energy ratings; consider leaving a recoverable gap between meetings.
- **Default 46–60 minute slots.** Short meetings and those longer than an hour were both less disruptive; consider avoiding the default hour slot when a shorter one will do.

Most respondents reported needing at least 15 minutes to regain focus after a meeting. A day with four 30-minute meetings therefore carries not only 120 minutes of meeting time but up to an hour of recovery – and recovery compounds when meetings are clustered.

The most common reason for declining a meeting was irrelevance to the participant's tasks. Stating explicitly who is a required participant and who is optional shifts that relevance judgment from social pressure to meeting design, and directly addresses the most frequently cited source of wasted meeting time.

The daily-load finding carries an additional organisational implication. The negative relationship between meeting count and end-of-day outcomes was driven by differences between participants, not by day-to-day variation within the same person. The productivity cost of heavy meeting schedules appears concentrated in specific roles, not distributed across the team on busy days. Targeted load reduction for those roles is a more precise intervention than blanket meeting-reduction policies. These implications rest on a small Phase-2 sample (n=6 / n=5) and single-item measures of productivity, flow, and well-being; they should be read as exploratory.

## 4.2 Implications For Researchers

Meeting-triggered prompts were answered at high rates by every participant who completed onboarding; end-of-day check-ins were frequently missed. The meeting acts as a natural reminder, and the prompt arrives close in time to the experience being rated. Future field studies should anchor prompts to observable events – meetings, task completions, build failures – rather than fixed clock times.

The study contributes a validated event-triggered ESM instrument for meeting research: calendar-synced prompts, per-meeting ratings on three constructs, and a daily check-in, implemented as a deployable web application. Dropout was entirely among participants who never completed onboarding; every participant who did reached high compliance. The instrument and replication package are available for reuse. For field studies of this kind, live onboarding is not optional – it determines how much usable data the study collects.

The between/within-person decomposition in F6 illustrates a methodological risk common in field studies. A between-person pattern – participants with more meetings report lower productivity – resembles a causal daily effect but is not one: the same participants showed

no such pattern on their own busier days. Field studies on meeting load, interruptions, or communication overhead should report both levels and treat between-person patterns as descriptive context rather than evidence of within-person mechanisms.

Treating each meeting as its own unit of analysis – with post-meeting ratings and calendar metadata for type, duration, position, back-to-back status, and time of day – surfaces variation that meeting-count metrics miss. Studies focused on developer productivity, flow, or well-being more broadly can benefit from treating individual meetings as a unit, since meeting structure explains variance that aggregate load metrics do not capture.

Longer observation windows (four to six weeks) would allow within-person analyses to stabilize and capture sprint-cycle variation. Role-stratified samples are needed before meeting-design recommendations can be made role-specific: managers and individual contributors likely experience planning sessions and back-to-back schedules differently.

Single Likert items kept participant burden low but cannot separate construct components (e.g., speed versus quality for productivity). Longer studies can incorporate short multi-item scales and, where feasible, behavioural traces such as IDE telemetry as an objective check on self-report.

# 5 Threats to Validity

## 5.1 Construct Validity

Construct validity concerns whether the operationalizations of our key constructs–productivity, flow (deep focus), and well-being–truly reflect the underlying phenomena of interest.

Key constructs are operationalized with single Likert-type items in both the survey and field study. Single-item measures are vulnerable to random response error, and they prevent internal-consistency estimation. They also compress multidimensional constructs: productivity (e.g., speed vs. quality), flow (depth vs. continuity), and well-being (energy vs. affect) cannot be separated analytically. We mitigated this by grounding items in prior SE and HCI operationalizations and by providing explicit construct definitions during survey completion and app onboarding. Convergence between survey and field responses provides only partial support for construct validity.

We treat calendar event data such as duration, start/end times, and computed gap-based back-to-back status as objective proxies for meeting characteristics. Calendar data may not reflect actual attendance, late starts, or early departures; a meeting recorded as 60 minutes may have lasted 45 minutes in practice. Compliance rates suggest that participants generally engaged with the meetings for which feedback was submitted, but scheduled duration remains an approximation.

Meeting-type labels were AI-assisted because many participants could not share exact titles or detailed descriptions for privacy and organisational confidentiality reasons and instead used masked or custom titles. This improves feasibility in realistic workplace settings but introduces potential misclassification risk for meeting types. Any type-specific contrasts (e.g., between planning and ad-hoc meetings) should therefore be interpreted cautiously.

Both the survey and field study instruments use ordinal Likert-type scales. We summarise 1–5 ratings with medians and IQRs and report associations with Kendall's $\tau_b$.

## 5.2 Internal Validity

Internal validity concerns whether observed relationships reflect true causal or associative effects, or are confounded by other factors.

Participants were aware of being observed and were asked to reflect on each meeting immediately after it ended. This may have altered their meeting behaviour (e.g., being more selective about which meetings to attend, or being more consciously critical). We measured reactivity in the exit survey; most respondents reported that participation changed their behaviour *not at all* or only *a little*. However, at least one open-text response indicates active behavioural adaptation ("This experiment was useful as a checkpoint..."), which we acknowledge as a limitation.

Participants knew the study focused on the impact of meetings on productivity. This awareness may have biased some ratings toward confirming the expected direction (i.e., that meetings are disruptive). We cannot fully rule this out, but the open-ended exit responses include both positive and negative reflections, which somewhat mitigates this concern.

Several key relationships rely on self-reports from the same individuals (e.g., usefulness, disruption, energy, daily productivity, and deep focus), which may introduce common-method variance. Transient affect, response style, or demand characteristics could inflate associations among subjective measures beyond what would be observed if different data sources were used. In addition, social-desirability pressures may bias some responses, for example, by discouraging participants from labelling recurring or management-led meetings as low-value, or from reporting persistently low productivity.

Only four participants provided both meeting-level and daily check-in data suitable for multilevel analysis. Two additional participants provided meeting-level data only. This limits daily-level and within-person inference; we therefore interpret these analyses cautiously and as descriptive rather than confirmatory. At the daily level, many factors beyond meetings influence productivity, focus, and energy – personal circumstances, task complexity, deadlines, health, and team dynamics. We do not control for these, and they represent unobserved heterogeneity in the daily check-in data.

## 5.3 External Validity

External validity concerns the generalizability of our findings beyond the specific sample and setting of this study.

Survey participants were recruited through convenience channels (e.g., professional networks, social media, research listservs). Respondents who chose to participate may systematically differ from non-participants, for example by having stronger opinions about meetings or more available time to complete a survey. This limits the representativeness of our sample and may bias estimates of meeting frequency, usefulness, and perceived impact.

The field study participants were geographically concentrated (Switzerland, Austria, India) and skewed toward senior roles (associate director, product owner, lead researcher, coaches/developers with 10–29 years of experience). Findings, particularly around meeting autonomy, the ability to decline meetings, and the types of meetings experienced, may not generalize to junior practitioners or to practitioners in regions with different organisational cultures. Organisational and national culture may also shape meeting norms (e.g., whether it is acceptable to decline invitations or to voice dissatisfaction about meeting practices), further limiting transferability.

Participants were asked to use the tool across two calendar weeks (i.e., roughly two working weeks), but usable observations covered only a subset of days within that window for some participants. This period may still be unrepresentative of longer-term meeting patterns, which can vary across sprint phases, project milestones, or organisational cycles. Longer longitudinal windows would be needed to assess temporal stability of the observed patterns.

With $n = 6$ participants providing meeting-level data and $n = 4$ providing full meeting+daily data, person-level and daily-level results are based on very few individuals. Effect sizes and directions should therefore be treated as indicative rather than definitive, and replication with a larger, more diverse sample is needed before strong conclusions can be drawn.

### 5.4 Conclusion Validity

Conclusion validity concerns whether the statistical procedures and their interpretation are sound, given the study's design and sample sizes.

The field study's small $n$ substantially limits statistical power for daily-level multilevel models and person-level correlations. We may fail to detect real effects (Type II error), and effect sizes estimated from small samples tend to be inflated. Where applicable, we report effect sizes alongside significance and flag field study statistical results as descriptive and directional.

Given the sample sizes, we treat field study quantitative findings as illustrative rather than conclusive. We use agreement between survey perceptions and field-study real-time data as convergent evidence across methods. However, with $n = 5$ usable full-data participants for person-level alignment, this comparison is illustrative rather than statistically conclusive.

### 6.1 Meetings in Software Engineering and Knowledge Work

Prior work in organisational psychology links meeting load to well-being and fatigue [18, 10], while software engineering studies document that meetings account for a meaningful share of developers' workdays and that planned meetings are associated with lower perceived productivity [11]. In parallel, research on stand-up meetings has clarified their communicative and coordination functions [23, 21], with recent work further linking daily stand-up practices to team satisfaction and performance perceptions [17]. Interruption and recovery research has shown that communication demands fragment developers' time [7] and that transitioning back to focused work after a meeting carries real cognitive cost [1]. This literature establishes that meetings are both necessary coordination mechanisms and potential sources of cognitive overhead. Yet most studies model meeting exposure at the aggregate level (e.g., total meeting time/frequency) or rely on retrospective assessments of quality. Even when identifying strong design factors for effectiveness [9, 20], prior work rarely links objective scheduling characteristics (timing, duration, clustering, sequence) to real-time, within-person experience.

### 6.2 Productivity, Flow, and Well-Being in Software Engineering

Software engineering research treats productivity as multidimensional and strongly shaped by interruptions and context switching rather than output volume alone [11, 12, 3], with affective state emerging as a further independent influence on performance and process outcomes [5, 4]. This body of work also supports separating perceived performance from experienced cognitive state: developers may report progress and strain simultaneously, and productivity is in large part a personal matter [11, 4]. At the team level, individual productivity perception has been found to predict team productivity more strongly than time spent in meetings or amount of team interaction [19], suggesting that aggregate meeting metrics are a poor proxy for team-level outcomes. This framing motivates our construct space (productivity, flow, well-being)

and our choice to observe it repeatedly in situ. If these constructs are context-sensitive and person-dependent, single retrospective judgments risk collapsing meaningful within-person variation across days and meeting contexts.

### 6.3 Experience Sampling and Field Methods in Software Engineering

Experience sampling has become a practical way to reduce recall bias in software engineering field research and has been successfully combined with behavioural logs and instrumentation, demonstrating both the feasibility of repeated ecological measurement and the value of pairing subjective reports with objective traces [8, 24]. However, prior field work typically treats meetings as one activity class among many or focuses on interruptions broadly. Our study extends this line by instrumenting the individual meeting as the unit of analysis and combining event-contingent ratings with calendar-derived objective features (timing, duration, and clustering), enabling finer-grained links between meeting structure and real-time experience.

## 7 Conclusion

This study combined a practitioner survey with a two-week field study to examine how meetings shape productivity, focus, and energy in software engineering. The two phases paint a consistent picture. Meetings carry two costs that do not always move together: whether a meeting was worth attending, and what it did to focus and energy. The association between daily meeting count and end-of-day outcomes was between-person, not evidence that adding meetings on a given day reduces that person's productivity. Meeting type, position in the day, back-to-back scheduling, and duration shape those costs more than meeting volume alone. The complaints most often raised in the survey – unclear purpose, excessive duration, irrelevant attendees, and weak actionability – reappear as the strongest negative signals in real-time meeting ratings.

This study shifts the conversation from broad dissatisfaction with meetings toward candidate meeting patterns and design hypotheses for teams to trial, pending larger confirmation. The findings suggest that not all meetings are equally costly or beneficial, and that purpose clarity, duration, and scheduling context may matter for productivity, focus, and energy. We frame observed meeting patterns as design hypotheses pending larger confirmation, not as prescriptions.

## Data Availability Statement

An anonymised replication package containing the baseline survey and field study data, prototype source code, and analysis scripts supporting this study is available via Figshare [14].

# Making Impact Visible in Funding of Open Source Software: A Study of the Funders' Perspective

**Johan Linåker**
RISE Research Institutes of Sweden, Lund, Sweden

**Kevin Lumbard**
Creighton University, Omaha, NE, USA

**Georg Link**
Independent, Omaha, NE, USA

## Abstract

**Background.** Open Source Software (OSS) remains underfunded, threatening the sustainability of critical digital infrastructure. In response, several public, private, and philanthropic funding initiatives are emerging. However, demand greatly exceeds supply, underscoring the need to increase funding and improve the efficiency and impact of existing funding sources.

**Aims.** This study investigates how OSS funders conceptualize, measure, and report funding impact, and the implications for sustaining and funding OSS projects. We focus on how funders select projects, define objectives, measure outcomes, and justify continued funding.

**Method.** We conducted a qualitative study based on semi-structured interviews with 25 participants representing funders, funding recipients, and research organizations in the OSS ecosystem. The findings were synthesized using thematic analysis and validated and enriched through a follow-up workshop with 16 participants from overlapping organizations.

**Results.** We find that impact is typically measured through short-term, milestone-based deliverables and qualitative narratives, and is dependent on personal funder-recipient relationships. Long-term sustainability, risk mitigation, and human-centered impacts are difficult to capture and rarely measured systematically. Measurement practices are shaped by (often implicit) funder strategies, funding structures, and reporting requirements, leading to ad-hoc and project-specific approaches.

**Conclusions.** Measuring and reporting funding impact remains a shared and non-trivial challenge for OSS funders. Addressing this requires explicit impact logics and shared meta-frameworks (rather than universal metrics) to enable a more coordinated and complementary OSS funding ecosystem. This, in turn, can improve the effectiveness, accountability, and availability of funding and ultimately support the long-term sustainability of OSS as critical infrastructure.

## 1 Introduction

Open Source Software (OSS) is a critical component of modern software supply chains [1, 39] A key concern is the ongoing development and sustainability of the projects that produce critical OSS [16, 26]. Access to funding, either through business models or direct funding, plays an important role in enabling OSS development [25]. However, access to sustainable funding is a significant challenge [24]. The growing need for funding is reflected in increased

attention from society and organizations. A range of funding initiatives, both past and ongoing, illustrate this trend. From an industry perspective, the Mozilla Open Source Support (MOSS) program[1] provided grants between 2015 and 2020 to selected OSS projects. More recently, the Alpha-Omega (AO) project [36], an Open Source Security Foundation (OpenSSF) initiative launched in 2022, has focused on improving OSS supply chain security through funding support from organizations including Microsoft, Google, Amazon, and Citi. In parallel, companies such as Bloomberg, Indeed, Spotify, Microsoft, and Google have introduced additional support mechanisms through dedicated funds, sponsorship programs, and patch grants[2] . Organizations such as the Open Source Collective (OSC) further support OSS projects by providing financial and legal infrastructure that enables projects to receive, manage, and transparently distribute funding without establishing independent legal entities[3]. These examples are illustrative rather than exhaustive, and numerous other initiatives exist.

Governments are showing increased attention to OSS funding. Sci-kit learn, a Python library, has received funding from the French government as part of its national AI strategy, although there were significant administrative challenges in the funding process [33]. In 2022, the German government launched the Sovereign Tech Agency [34], reflecting the view that OSS constitutes digital infrastructure that merits public investment. The City of Munich, through its sponsorship of the Consul Democracy Foundation, illustrates how individual public sector organizations can contribute directly [28]. At the EU-level, the Next Generation Internet Program has been funding OSS projects for several years [34]. As of writing this paper, the concept for a European Sovereign Tech Fund [13] appears to be gaining traction - prototyped through the European Digital Infrastructure Project for Digital Commons[4].

Open funding platforms have also evolved. Since 2015, Open Collective has made it easier for projects without a fiscal host to obtain one, such as the Open Source Collective or Open Source Europe, in order to transparently receive and manage funds [24]. Similarly, GitHub Sponsors, launched in 2019, embedded financial sponsorship directly into existing development workflows and developer profiles, making it easier for individuals and companies to financially support maintainers and projects [24]. Open Source Endowment, launched in 2025, is an initiative focused on creating long-term financial sustainability for critical open source infrastructure through an endowment-style funding model rather than relying exclusively on recurring donations or short-term grants.

While the number of funders indicates growing interest in supporting the OSS ecosystem, the overall level of financial support remains limited relative to ecosystem demand [13, 21]. Consequently, there is a need both to expand available resources and to improve the effectiveness, transparency, and evaluation of existing funding mechanisms [13]. However, the scale of the OSS ecosystem and the uniqueness of individual projects make it difficult to identify critical infrastructure, assess sustainability and resource needs, tailor interventions appropriately, and evaluate the downstream effects of funding decisions [16, 27]. These processes must also account for project-specific contexts alongside priorities of funders [24].

Existing work has looked at single cases [33, 34, 36], characterizing projects funded [36], discussing the practice of quantitative versus qualitative measurement, as well as the factors that need consideration. However, no study has yet undertaken a broader analysis of how

[3] https://oscollective.org/
[4] https://www.nldigitalgovernment.nl/news/edic-digital-commons-launches-first-projects/

impact is conceptualized, measured, and reported from the perspective of OSS funders. In this study, we address this gap and seek to understand the work that goes into selecting OSS projects for funding, how funders track the impact of their support, and how they report these efforts to sustain continued funding. Specifically, we ask the question:

> *How do OSS funders conceptualize, measure, and report funding impact, and what implications does this have for sustaining funding and OSS?*

We define funding impact as the extent to which funders achieve their objectives in providing support. We conducted a qualitative interview study with 25 participants, synthesized the findings through thematic analysis, and refined and validated them through a follow-up workshop with 16 participants. Participants included funders, funding recipients, and research organizations involved in the OSS ecosystem.

Our study identified common funder challenges in measuring and signaling the impact generated by funding initiatives. Existing metrics frequently rely on ad-hoc and case-by-case stories from funded projects. As a result, they fall short of providing value-based guidance for effective funding and evaluation, particularly for policymakers and decision-makers with limited insight into the OSS ecosystem. Understanding the systemic impacts of funding is a shared, non-trivial problem for funders. Addressing it is essential not only to ensure that resources are allocated effectively, but also to sustain and justify ongoing funding initiatives, including those supported by governments.

We make the following contributions:

- An empirical report of how OSS funding impact is conceptualized and operationalized by a diverse set of public, private, and philanthropic funding organizations.
- Identification of recurring challenges and tensions in measuring and signaling funding impact, including misalignment between funder strategies, funding structures, and the long-term sustainability needs of OSS projects.
- A characterization of dominant impact logics, metrics, and reporting practices used by OSS funders, highlighting the prevalence of milestone-based, risk-oriented, and narrative-driven approaches.
- An analysis of how funding mechanisms shape what impact can be measured, revealing structural biases that privilege short-term, deliverable-based outcomes over long-term sustainability and human-centered impacts.
- Actionable insights for funders on improving impact measurement and reporting, supporting more durable funding justifications, clearer communication with decision-makers, and better alignment between funding goals and OSS sustainability outcomes.

## 2 Related Work

### 2.1 Open Source Value

Open source software (OSS) is widely recognized as a global public good for modern technology and the economy [10, 16, 19]. OSS creates substantial economic value, but its globally distributed and collaborative nature makes that value difficult to quantify, contributing to persistent underinvestment in the ecosystems that sustain it [6, 19]. This reflects a broader public goods problem, where organizations benefit from OSS while contributing little to its development or maintenance [22, 32]. Hoffmann et al. [19] measured the scale of this problem, estimating that the cost of recreating widely used OSS is approximately $4.15 billion, while its demand-side value reaches approximately $8.8 trillion. OSS subsidizes innovation and productivity and enables organizations to build on existing code and knowledge work rather

than recreating it independently [12, 15]. However, this value is highly concentrated and a small proportion of developers are responsible for the majority of economically significant contributions [8, 19]. As a result, OSS simultaneously represents both an efficient and fragile system, generating immense value while remaining under-funded relative to its importance, raising critical questions about the long-term sustainability of OSS projects.

## 2.2 From Success to Sustainability

Early OSS research often equated project success with observable outputs such as contributor counts, commits, or user downloads; this view has gradually evolved to consider community health and, more recently, project sustainability [17]. Sustainability in OSS is the capacity of a project to continue producing high-quality software over time; however, it is not a singular or static concept, but a complex, multi-dimensional phenomenon that is inherently context-dependent and shaped by interactions between resources, communities, and infrastructure [9, 17]. Metrics alone are insufficient for this complexity. Sustainability must be interpreted through a combination of quantitative indicators and qualitative context, where meaning is derived through comparison, narrative, and stakeholder interpretation [29].

OSS sustainability is dependent on human infrastructure. Project contributors play a central role in sustaining projects, yet they face challenges related to workload, burnout, and coordination [24]. As projects grow, the demands placed on project contributors increase. Growth generates additional, often invisible work [14]. Contributions are not costless; each requires review, integration, and long-term maintenance, reinforcing the idea that sustainability is constrained by human capacity rather than technical output. Thus, OSS sustainability is a sociotechnical phenomenon that depends on the alignment of resources and labor over time. Labor in this context is not independent of resources, as sustained participation increasingly requires financial support to offset the time, expertise, and opportunity costs associated with maintenance work [24, 14]. The demands placed on maintainers and contributors exceed what can be supported through volunteer effort, making financial resources critical for sustaining labor. In this way, money becomes not just an external input, but a means of stabilizing and enabling the human infrastructure upon which OSS depends, linking funding directly to the long-term sustainability of projects.

## 2.3 Funding Sustainability

The challenge of funding OSS is related to its nature as a public good, creating persistent tensions between widespread use and limited financial support [19, 6]. While many widely used OSS projects receive support through corporate participation and community contributions, long-term maintenance and sustainability often remain underfunded [33, 24]. However, funding is not a straightforward solution, as different sources of funding introduce distinct trade-offs. Public funding can provide short-term stability, but funding programs are often structured around policy-driven objectives and timelines that may not align with the sustainability needs of OSS projects. Private funding can support practical development but may introduce external influence and pressure [33]. Both funding approaches are frequently structured as time-limited investments, particularly in grant-based models, resulting in temporary support that often fails to align with the ongoing maintenance demands.

The funding landscape reflects the hybrid nature of OSS ecosystems, where communities, firms, and public institutions interact. Corporate participation has become central, providing resources and accelerating development while also introducing risks of control, misalignment, and dependency [23]. Business models such as support-based services, dual licensing, com-

munity funding, and public infrastructure each offer benefits and limitations, leading many projects to adopt hybrid strategies that combine multiple funding sources [5]. Crowdfunding leverages community engagement and transparency to generate support, reframing openness as a strength rather than a limitation in certain funding contexts [2]. While crowdfunding aligns with many OSS values, it often favors highly visible projects and feature-oriented development, producing uneven and episodic support patterns that are poorly suited to the ongoing maintenance needs of OSS projects [10, 38, 24].

At the policy level, there is growing recognition of the need to support OSS as critical infrastructure. These funding initiatives emphasize long-term maintenance, community support, and the development of software ecosystems, including investments in research software and collaborative practices [20]. In parallel, cybersecurity funding efforts highlight the importance of securing foundational OSS components, particularly in software supply chains, while also acknowledging that sustainability and security are deeply interconnected [36]. Despite these advances, significant challenges remain, including misalignment between stakeholders, free-riding by organizations that do not contribute back, and difficulties in measuring the impact of funding interventions [34]. While OSS ecosystems remain substantially underfunded relative to the value they generate, sustainability challenges are also shaped by how financial resources are structured, governed, and distributed. Effective funding strategies must balance competing interests, align incentives across stakeholders, and account for the sociotechnical nature of OSS ecosystems. Ultimately, sustaining OSS requires coordinated approaches that integrate economic value, human infrastructure, and governance to ensure the continued viability of these commons.

# 3 Research Design

This study is an exploratory qualitative study aimed at understanding funding and sustainability challenges in OSS ecosystems. We employ thematic analysis as the primary analytic approach, as it enables the identification and interpretation of patterns of meaning across qualitative datasets while maintaining flexibility [3, 31, 30].

## 3.1 Data Collection

We collected data from two complementary sources: semi-structured interviews and a follow-up workshop. The supplementary material to this paper includes (a) the interview guide and (b) the workshop brief containing synthesized findings from the interviews, as discussed in the workshop, see Section 8. Table 1 presents an anonymized list of all interviewees and workshop participants. To preserve anonymity, affiliated organizations are reported alphabetically, changing the order in a separate Table 2.

**Interviews.** We conducted semi-structured interviews with representatives from nineteen organizations concerned with OSS funding and sustainability. Participants were selected using a combination of targeted sampling and snowball sampling [35]. Initial participants were identified through our existing professional networks, which we developed as engaged field researchers. Additional participants were recruited through referrals to broaden coverage across project types and funding contexts. Participants were selected for their deep experience and insight into OSS funding practices within their respective organizations. To provide contrast, the interviews included representatives from OSS funding organizations, including those that both provide and receive OSS funding. Interviews were conducted online, recorded, and lasted between 30 and 60 minutes. All three authors attended most

**Table 1** Overview of interview (I) and workshop (W) participants, including their role and the type of organization they represent as either a funder (providing funds) or recipient (receiving funds). For organizations that both provide and receive funding, the type classification is based on how participants identified their organization.

interviews, alternating between asking questions and taking notes, enabling deeper probing of participant responses. All interviews were transcribed using LLM-support, manually reviewed for accuracy, anonymized, and shared with participants for validation (when requested). Data collection continued until thematic saturation was reached, with limited new insights emerging in later interviews.

**FOSDEM Workshop.** In addition to interviews, we incorporated data from a workshop co-located with FOSDEM 2026, an international OSS developer conference. The workshop brought together participants from academia, industry, and OSS funding organizations to discuss challenges related to OSS funding and sustainability. Several workshop participants also took part in the interviews, enabling member checking of preliminary findings and validation of emerging themes. The workshop focused on funding models, maintenance challenges, governance, and long-term sustainability strategies. The workshop was used to refine and contextualize the emerging findings rather than to provide independent validation, given the overlap in participating organizations. Workshop discussions corroborated several themes identified in the interviews while also extending the analysis by identifying additional considerations and points of consensus across stakeholders. Data included facilitator notes, recorded observations, and synthesized discussion points. These data provided complementary, group-level perspectives and were used to triangulate findings from the interview data.

## 3.2 Data Analysis

Data analysis followed an iterative, multi-stage coding process combining inductive and deductive techniques [3, 11]. First, all interview transcripts were read closely to establish familiarity with the data. During this phase, open coding was conducted to generate descriptive labels that capture key concepts, practices, and challenges, and analytic memoing was used to document emerging interpretations [37, 30].

Second, a structured coding process was applied using the interview guide as an initial framework. Coding was performed independently by multiple researchers, with segments often assigned multiple codes to preserve relationships between concepts. New codes were introduced inductively, and existing codes were iteratively refined through discussion [3, 30].

Third, codes were iteratively grouped into higher-level categories and themes following thematic analysis practices [3]. Relationships between codes were examined through second-cycle coding to refine and structure the developed themes [37, 30]. The analysis proceeded iteratively between data, codes, and themes until a stable thematic framework was developed [3, 4]. Themes were developed as interpretive constructs reflecting patterns across participants and data sources, rather than direct summaries of individual responses [3]. Themes were refined collaboratively to ensure consistency and coherence across the dataset. Throughout the process, an audit trail was maintained to ensure traceability, and discrepancies in coding were resolved through collaborative discussion among the authors [7]. The final themes are presented in Table 3.

# 4 Findings and Analysis

Our thematic analysis rendered in six interrelated aspects of funding impact that address our research question - *How do OSS funders conceptualize, measure, and report funding impact, and what implications does this have for sustaining funding and OSS?*. These aspects include: (1) vision and strategy, (2) impact logic, (3) operationalization of impact, (4) types of impact, (5) measurement approach, and (6) impact reporting (see Table 3 for an overview).

**Table 3** Overview of main aspects of how funding impact is measured and reported by funders.

| Aspects of Funding Impact | Findings |
|---|---|
| **Vision and Strategy:** Defines purpose and scope, and asks what funders seek to achieve and why. | Impact outcomes are strongly driven by funder strategies that are frequently informal and person-dependent, creating fragility and limiting the institutionalization of sustainability-oriented impact over time. |
| **Impact Logic:** Articulates causal assumptions and asks how funding is expected to produce impact. | Although funders rely on implicit theories of change to guide their work, the lack of explicit and shared impact logics leads to misalignment between funder intentions, funded activities, and how impact is ultimately interpreted across stakeholders. |
| **Operationalization of Impact:** Translates intent into action, and asks how impact is turned into evaluatable objectives. | Impact operationalization is largely shaped by funding mechanisms and accountability requirements, resulting in a strong reliance on goal- and deliverable-based evaluation that structurally underrepresents long-term, systemic, and risk-oriented sustainability outcomes. |
| **Types of impact:** Defines what counts as impact, and asks which dimensions of change are considered meaningful. | Funders recognize multiple, heterogeneous dimensions of impact – spanning financial, technical, social, and public-good concerns – but lack coherent means to relate or aggregate these across projects and funding portfolios. |
| **Measurement Approach:** Produces evidence of impact, and asks how impact is assessed and evidenced. | Impact measurement practices remain ad-hoc and context-specific, prioritizing what is easily measurable (infrastructure and short-term outputs) while systematically marginalizing human-centered and long-term sustainability impacts. |
| **Impact Reporting:** Communicates and justifies impact, and asks how impact is made visible and credible to others. | Impact reporting functions as translation and legitimation work, where funders construct narratives to reconcile OSS realities with the expectations of diverse audiences, rather than as a neutral reflection of measured outcomes. |

## 4.1 Vision and strategy

Funders have their own unique vision and strategy for what they want to fund and the type of impact they are seeking to achieve. While these priorities differ across organizations, the interviews and workshop identified substantial overlap, creating opportunities for collaboration and complementary forms of support. Corporate funders were often interested in supporting the software their products and infrastructure depend on, improving internal open source culture, and maintaining influence in strategically important technologies. Foundations and government organizations more frequently emphasized ecosystem-level concerns such as security, resilience, digital infrastructure, and long-term sustainability.

The interviews and workshop further indicated that vision and strategy strongly shape how funding impact is understood and evaluated. Some funders prioritized measurable technical outcomes, such as security improvements or infrastructure development, while others viewed funding more broadly as part of community engagement, ecosystem stewardship, or organizational goodwill. In some cases, participants noted that funding initiatives were treated partly as charitable contributions, public relations efforts, or mechanisms for improving employee engagement, reducing the emphasis placed on detailed impact measurement. For example, several participants described employee-driven funding programs where employees could vote on projects to support, aligning funding decisions with organizational culture and internal satisfaction goals while also supporting OSS sustainability.

Formalizing a strategy and measuring funding impact were generally seen as important for the long-term sustainability of funding initiatives. Several workshop participants emphasized that vision and strategy are often tied to specific individuals rather than institutionalized within organizations. This creates fragility for funding organizations because when a manager, advocate, or internal sponsor moves on, there may be little long-term support structure in place for the next person taking over the initiative. The importance of personal relationships was similarly highlighted from a recipient perspective. When maintainers or other key individuals in OSS projects with established trust-based relationships with funders move on, relationships may need to be rebuilt and expected funding may disappear. Participants therefore emphasized that sustainable funding initiatives require not only financial resources, but also organizational commitment, governance structures, and continuity mechanisms capable of persisting beyond individual actors.

## 4.2 Impact logic

The vision and strategy of a funder set the frame for what type of impact it is looking to make, and by extension, how it is to be measured. Thus, impact is constrained by funder goals and the funding structures. Such a relationship can be expressed in a chain of impact logic, where the vision and strategy define the frame for what problem contexts are in scope, what kind of treatments are to be considered accordingly, and how short-term (project) and long-term (post-project) impact is achieved. How impact is measured or perceived may differ and align to different degrees across funders.

These relationships, or chains of logic, can have several levels, e.g., Refactoring > Simplified architecture > Improved maintainability > Easier bug triaging > Easier onboarding > Extended community. Adding APIs and improving interoperability better integrates the project into the ecosystem, thereby improving adoption and innovation. Workshop participants proposed a goal-signal-metric approach (aligning with the goal-question-metric approach), where goals are broken down into questions to ask and signals to look for, and after which metrics are defined accordingly.

The funders' strategy should ideally be based on a "theory of change" as described by I5: *"This program needs to be really tightly tied to our own internal strategy. So we need to always be able to tell a story about, how are we contributing to the short-term goals and medium-term goals in our own internal theory of change? There needs to be a very bright line between those things."*

Further, the strategy should be able to shift over time as needs and challenges evolve, while still (ideally) staying true to the overarching vision to enable impact to be traced and followed up accordingly. Workshop discussions contrasted how impact logic in reality is commonly misaligned across actors, including maintainer narratives, funder expectations, and policy objectives. These discussions confirmed that impact logic exists, but that it is often implicit, fragmented, and poorly communicated.

## 4.3 Operationalization of impact

Impact is operationalized through the goals that define what the funder seeks to achieve. The top-level goals are defined in the overarching strategy, while project specific goals are derived and implemented per project funded.

**Goal-focused measurement.** Across most interview and workshop participants, "impact" in regard to these goals is most often operationalized as whether a specific, predefined objective was completed: milestones met, issues closed, features delivered, security audits addressed,

or contracts fulfilled. This approach is described as "relatively straightforward" and "easy to justify," even when respondents acknowledge its limitations, namely that it aligns with short-term accountability but fails to capture broader ecosystem effects. As put by I17, *"We're looking at an open issue list and say here are the milestones that we want to achieve by funding this [...] it's relatively straightforward. We can say, okay, have we actually closed those issues or have we hit those milestones?"* As a result, sustainability impacts are systematically under-measured because long-term maintenance and ecosystem health do not align cleanly with short-term, milestone-based evaluation models, allowing immediate proof of execution to overshadow longer-term value creation.

**Risk-based measurement.** In some cases, though, goals are more open-ended, focused on the expected impact, rather than the deliverables. This approach is considered difficult, with a preference for describing impact in terms of risk avoided rather than benefits delivered. Examples include preventing outages, reducing security exposure, avoiding maintainer burnout, or ensuring continuity of critical services. However, respondents also note they lack the vocabulary or metrics to measure "things that didn't go wrong." Sustainability work is, hence, undervalued because it produces non-events rather than visible outputs. The absence of incidents is not recognized as success in current evaluation frameworks. I17 described this issue: *"It's easy to say, 'Oh, we funded fixing this zero day,' but it's hard to say we prevented having more zero days."*

**Considering funding structures.** Funding mechanisms (grants, contracts, stipends) shape what can be measured. Because many funds are scoped narrowly, impact measurement is also narrowly defined – even when broader sustainability benefits are anticipated. Work-for-hire and milestone-based contracts dominate, with funders acknowledging this incentivizes short-term thinking. Some interviewees describe a mismatch between what they want to measure (ecosystem health or project sustainability) and what they are allowed to measure (deliverables). Consequently, sustainability impact is structurally deprioritized by funding design, with measurement following money, not need. I18 argued that funding structures should extend beyond direct financial support by incorporating organizational development and structured collaboration: *"One of the ways I think conversation around FOSS funding could get better is for us to move away from understanding open source... from transactional value to a value creation space. FOSS funding is not just about giving money... I think that we should be thinking holistically about how do we create more people engaged in those spaces, more leaders in those spaces, succession planning. I think that would be really interesting to have more collaborations across companies... really structured efforts to address... problems."*

## 4.4 Types of impact

Characterising impact, present or future, will again depend on the impact logic and overarching vision and strategy of the funder. Impact measurement, however, differs broadly across the funders, e.g., considering technical metrics (CI usage, test coverage), financial metrics (percentage funded vs unfunded), adoption or reuse signals, and governance or process improvements. Interviewees and workshop participants explicitly reject one-size-fits-all metrics, with measurement practices often being improvised rather than institutionalized.

**Financial return on investment.** Impact captured in financial terms is considered valuable by funders to motivate their own continued funding, either from C-suite executives or institutional backers. While workshop discussions confirmed interview findings characterizing Return On Investment (ROI) as an important KPI, they also framed it as a latent requirement only asked for when funding is questioned.

For this reason, ROI and related metrics are still important as both policy and decision makers are generally characterized as more supportive and receptive to impact in terms of innovation and economic value, rather than a community-oriented perspective. As such, maintenance and security work need to be bridged and communicated together with innovation and economic growth, highlighting their interdependence. Communicating the value of maintenance alone is considered quite difficult.

Research is needed into how proactive security and sustainability work translates to economic terms. I17 makes the comparison to physical infrastructure maintenance: *"20% more funding for reservoirs or 20% more funding for roads? Do you measure it in potholes filled? It's one of those things that it's like, we don't really know. I don't think we have the right vocabulary both ourselves to articulate risk mitigation as impact because it is."*

Such questions can be answered by concerned actors, but in the context of OSS, there is a lack of knowledge on how to scale and quantify costs relative to maintenance efforts. Funders and OSS projects need a shared language to communicate economic value and to aggregate economic impact across projects and ecosystems.

**Security and sustainability.** Security and sustainability of OSS projects are commonly highlighted as key concerns across industry and government at the project level. These metrics are also readily understood and valued by funders and technical decision-makers as legitimate signals of risk. However, these metrics may need to be translated into more general and abstract terms to be meaningful to the target audience. Measuring or characterizing the impact of mitigated vulnerabilities or overall sustainability is often considered difficult, as expressed by I14: *"You could probably track it on some kind of metrics, but like bug fixes fixed or security problems fixed or lines of code changed or whatever, but they're all really vague and probably also very project specific. They're not really easy for an outsider to understand or value or judge. Is that progress or isn't it? So that's certainly a challenge. I think it's just a problem with maintenance. It's such a work that is supposed to not be noticed when it works as best. No one cares about it."*

The number of issues and vulnerabilities found, reported and addressed, as well as code coverage of tests and fuzzing are reiterated from a security and sustainability perspective among the funders. Interviews and Workshop discussions highlighted the importance of security audits for creating reference points, and ways of following up on progress. If identified issues are addressed and their number and severity decrease in subsequent audits, positive trends in project security can be narrated.

Some interviewees referenced the need for service-level, reliability, and assurance-style reporting mechanisms (e.g., service-level agreements [SLAs]), motivated by public infrastructure framing, government procurement expectations, and regulatory pressure surrounding digital public infrastructure. This emerging demand for SLA- and infrastructure-style impact metrics centered on reliability, assurance, responsiveness, and service guarantees signals a shift in concern from "what was built" to "what can be relied upon," and represents a potential convergence point between OSS projects, funders, and policymakers.

**Downstream use and adoption.** A general goal for many funders is to achieve the broadest possible reach. Many interviewees and workshop participants expressed the perspective that evaluation signals should extend beyond simple user counts to include measures such as community contributions, downstream dependencies, project responsiveness, and governance maturity. However, one workshop participant emphasized *"downstream use as the only thing that matters"*, reflecting a particularly strong focus on user adoption and downstream dependencies as primary indicators of project impact.

Also important to consider is adoption among certain target groups depending on the funders' overarching strategy. Extending a solution and unlocking new groups of users can also be an important aspect as exemplified by I22: *"So we have a solution that was developed in India and has now scaled in Bangladesh. And because it was open source from, I would say, let's say a four-module platform, the government of Bangladesh was able to kind of build on top of that. And so now it's a 12-module platform and it's poised to track just millions of vaccine doses and in effect make sure that I think under 3 million children are vaccinated with the standard vaccines on an annual basis."*

Popularity and adoption integrate with security metrics, acting as a multiplier to help quantify potential cost or impact of risk. Still, it is important to consider context when understanding adoption, as what numbers are considered significant will vary, also in regard to what the level of users implies, e.g., individuals or organizations and proxies in between such as service providers and tool vendors.

Open source infrastructure projects have the potential to justify funding by reframing themselves as force multipliers for their dependencies and how they are positioned in the supply chain and what software/infrastructure they help to support. Left-pad is highlighted by several as an example of a niche project that underpins vast amounts of products and services available on the market. The European Union's Cyber Resilience Act (CRA) and increasing industry adoption of Software Bills of Materials (SBOMs) may drive positive developments in this area. Adoption, commercialization, and the emergence of new startups represent another important dimension.

**Innovation and public good.** Venture-style funding that does not require equity can serve as a mechanism for supporting new projects. In this model, releasing software as open source (and thereby as a public good, often meeting defined standards) can be seen as a form of ROI. This approach may provide a useful model for other funders, including government institutions. The Digital Public Goods (DPG) Standard is an important quality indicator for both open source hygiene and use cases, supported by a rigorous vetting process. The resulting DPG designation provides a clear way to communicate impact in terms of quality.

## 4.5 Measurement approach

There is no shared framework for measuring impact. Instead, impact metrics are tailored on a case-by-case basis depending on the nature of the project, the funding mechanism, and the audience. The lack of standardization prevents cross-project comparison, aggregation of impact across portfolios, and complicates communication of a project's value in shared terms.

**Quantitative vs. Qualitative.** Impact can be measured and characterized both quantitatively and qualitatively, with interviewees and workshop participants expressing a preference for the latter. Some interviewees noted that general quantitative indicators are difficult to apply across projects or may not be meaningful for external stakeholders (e.g., vulnerability counts or test coverage). Still, some funders report using quantitative indicators as they provide a frame of reference. Aggregated statistics provide a cognitive and easy way to communicate and visualize progress. Workshop participants highlighted continuous surveys of maintainers' stress levels and audits to monitor security issues as valuable tools.

Qualitative reporting based on input and testimonials from maintainers, contributors, and users can be combined with quantitative metrics (e.g., from CHAOSS[5]) to develop case-by-case narratives of how funding impacts technologies of critical importance to society

[5] Community project focused on developing metrics and tools for analysing OSS health and sustainability - `http://chaoss.community`

and industry. These narratives should be concise and compelling to effectively communicate impact and relevance. Quantitative metrics alone cannot capture this impact, but they can support and strengthen the storytelling.

Interviews are typically conducted with funding recipients to capture the impact logic by exploring why they applied, what activities they carried out and how, the difference the funding made, and their current and future plans. In essence, funders seek to understand how funding and support have helped projects (and, ideally, where they did not have the intended effect) to improve future funding rounds.

**Defining a starting point.** Establishing a baseline through specific metrics enables tracking of progress and impact over time. One funder reported using surveys at admission to create a starting-point snapshot for measuring progress and impact. Several respondents reported applying the OpenSSF Scorecard to get a starting reference point in their security work, but also to help identify areas of improvement. As put by I9: *"First thing after receiving the funding was to get a landscape view of the Scorecard score for all of our projects. So we ran Scorecard everywhere, and it had us identify some of the key points that would need more attention."*

Establishing a baseline or benchmark can reveal weaknesses that can then be addressed, for example through the development of tailored tooling. One funder reported applying OpenSSF Scorecard to funded projects (before and after support), demonstrating an improved security posture over time. Several interviewees and workshop participants also described using security audits to establish a baseline snapshot of a project's security issues, which can then be tracked in subsequent audits and reviews.

**Customized vs. general metrics.** While projects may face similar sustainability challenges and threats, these often differ in their specific context due to the unique nature of each project. One workshop participant described each project as *"its own snowflake,"* reflecting the perception that OSS projects are highly heterogeneous and difficult to evaluate through standardized frameworks. Furthermore, there is no universal solution to any particular sustainability challenge, which means that impact measurement is often closely tied to both the specific project being funded and the intervention being applied.

Important aspects of impact may be lost if overly generalized frameworks are applied, which is why metrics may need to be tailored to each funded project while still allowing for some level of aggregation and general impact reporting. Interviewees and workshop participants emphasized the need for flexible, shared meta-frameworks rather than uniform metrics or rigid taxonomies. By engaging recipients, funders can define clear and measurable goals from the start to better enable impact logic aligning with the fund's vision and strategy, and by extension, simplifying impact reporting.

**Infrastructure vs. people.** Technical and infrastructure-related sustainability impacts (e.g., CI capacity, update infrastructure, security tooling) are perceived as more measurable than human-centered sustainability outcomes (e.g., maintainer capacity, burnout reduction, succession planning). Infrastructure metrics are described as quantifiable, financially expressible, and easier to justify to funders. Meanwhile, human sustainability metrics are described as *"harder to explain"*, *"not something we're good at communicating,"* and often invisible until failure occurs. Consequently, funding tends to gravitate toward infrastructure even when people are the limiting factor, with maintainer sustainability remaining structurally underfunded. Maintainer health and burnout were repeatedly cited by workshop participants

as critical yet often invisible concerns, aligning with interviewee perspectives. Indicators such as release cadence, responsiveness, and signs of security neglect were highlighted as potential proxy signals of stress. Process stage-gate check-ins and maintainer surveys were also identified as useful tools for assessing stress and potential burnout risk, inspired by the existing practice of wellness surveys used in eldercare contexts.

**Long-term impact.** Impact reporting is largely bound by grant timelines, with long-term effects communicated informally rather than through sustained evaluation mechanisms. If these can be captured more easily through cost-efficient means by funders, more long-term impact reporting and narratives of funding programs can be created and communicated. Biannual calls with recipients post project funding may enable continued monitoring of progress and impact. Creating formal and personal relationships can be an enabler for such monitoring both during and post project funding. Workshop participants stressed the importance of personal relationships, but also highlighted the fragility of them. When a person moves on, either from the funder or recipient, relationships are often ”reset”. Recorded experience and relationship between the two sides, and any impact attained through funding are considered critical to address this fragility, and enable more long-term impact monitoring, as well as consecutive funding rounds. Follow-up audits focusing on areas addressed by the funding can help demonstrate its long-term impact.

## 4.6 Impact reporting

**Format and intensity.** Funders commonly survey and report impact on a predefined basis (e.g., per 1, 3, 6, or 12 months), though typically at the end of funding. Sometimes, more general and retrospective reviews are conducted to report impact across several cohorts of a funding program. Publishing the reports openly helps to further promote the impact. Web traffic metrics show that there is substantial interest in viewing impact reports, as exemplified by I6: *“Roughly 85% of our web traffic directly goes to the reports. So they do get read. It’s about 20,000 a month hits on our website specifically to read research.”*

**Narrative and key messages.** While some reports are general, they also capture case-specific contexts - what was done or improved or acted on, e.g., improved parsers, fuzzing, code coverage, addressing specific vulnerabilities, etc. Not all types of metrics may be generalizable or applicable across projects. Reports strive to capture patterns, challenges and opportunities beyond the impact described in the reporting, and how these can be addressed or leveraged to further improve the impact in future funding programs. Several funders recognize, however, that showing impact in the “larger picture” is difficult. It is easier to focus on the short term and answer whether and how the projects succeeded according to plan. One respondent noted that they try to communicate the impact of maintenance work with statements about how they deliver a stable and secure product that is released on time.

**Target audiences.** Different target audiences will require different ways of measuring and communicating impact. Some funding organizations need to consider their corporate backers and their incentives, while others need to consider their overarching government agencies/ministries. For some funders, internal sponsors were the main audience. One respondent described how their report is communicated through several means, including metrics (adoption in number of users), milestones, case studies, and technical narratives because no single form of reporting satisfies all stakeholders. Another funder described how their reporting distinguishes the ways open source funding benefits the business, the open source project, its contributors and participants, and the public good.

## 5 Discussion

**Structural Bias Toward Short-Term and Visible Work.** Funding often comes with limited horizons and a goal-oriented focus, consistent with earlier research [34]. Any impact measurement, accordingly, often takes a binary and short-sighted view, failing to capture wider effects (positive and negative) that (may) materialize further down the road. Considering risk-based scenarios and the alternative costs may provide a more systemic perspective on the potential consequences that any funding aims to mitigate. Longer-term follow-up and monitoring practices should be supported and coordinated by funders in collaboration with recipients, using both quantitative and qualitative metrics to develop a more holistic understanding of impact while minimizing additional reporting and administrative burdens on maintainers and recipients.

**Human Infrastructure as the Missing Unit of Impact.** The dominant goal-oriented focus further implies a preference for hard metrics, such as the number of vulnerabilities found or addressed during a security audit. Human infrastructure aspects [24], such as reducing risk of maintainer burnout, addressing toxicity, or adopting closed governance, can have an equally important impact on a project's sustainability [26]. Related work [34] also highlights the need to take a wider perspective, including social, economic, and technological types of impact. Characterizing sustainability, hence, requires several perspectives, just as a medical doctor looks for symptoms in a health-checkup [25]. Funders should accordingly explore metrics beyond merely technical, and attempt to gain as complete an understanding as possible, that can be translated into a coherent narrative and signal of any funding impact.

**Misalignment Between Funder Strategy, Funding Design, and Impact Logic.** Ideally, an impact-logic should be clearly defined, where goals originating from the funders' strategy are linked to impact signals looked for, and metrics are defined accordingly. This Goal-Signal-Metric approach (as proposed by the interviewees) aligns with the Goal-Question-Metric (GQM) model commonly referenced in science, and also promoted by the CHAOSS community to ensure that the right metrics are used for the intended purpose [17]. This kind of logic was generally missing or very implicitly defined among the funders surveyed. The MOSS fund stood out as a prominent example, showcasing a mature means of synchronizing and aligning an impact logic across the organization, while recognizing that it was a consequence of a long learning process. Any funder should do their own exercise in creating similar alignment, asking themselves questions about what impact they wish to achieve that aligns with their overarching strategy, what signals may be an indication of such impact, and how those signals can be measured from a social, technical, and economic point of view.

**Need for Meta-Frameworks to Interface and Bridge Funders, while Balancing Over-Standardization.** While the impact logic will be unique for each funder, its building blocks and design elements can still overlap. A meta-framework was called for to help bridge and interface funders, creating a better collective understanding of what impact can imply and how it can be measured against different logics. Knowledge sharing and development of a common practice can help raise the maturity of the field, enable better project funding alignment with funders' scopes, refer candidates to more suitable funders, and promote collaborative funding initiatives, potentially onboarding new funders as well. We believe a commonly defined interface for communication and collective reporting on funding impact can support a federated funding schema for the OSS ecosystem. Such a schema would be

able to bring together and grow the mass of funders, which come in many shapes and sizes as highlighted in this study. A central fund such as the envisaged European Sovereign Tech Fund would also benefit when coordinating and motivating additional funds from member states and other donors. An important caveat highlighted by workshop participants is that any framework or scheme should avoid becoming too formalized and detailed, as each funder has their own strategy and stakeholders to answer to, and at the end of the day, their own specific dialect of how impact is pronounced and discussed.

**Impact Reporting as Translation Work.** Based on the findings, we conceptualize impact reporting as a form of translation. Developing a shared funder language (while recognizing each funder's own "dialect") can support this process, helping to communicate both the need for funding and its impact, collectively and at the level of individual funders, to institutional donors and executive stakeholders. As posited by one interviewee, being able to explain, e.g., what 20% extra funding can imply in terms of impact, may be critical to motivating additional funding and the continuation of funding programs, on both the funder and recipient sides. While research in this area is growing, including studies examining how OSS contributor growth may influence broader economic outcomes such as GDP and SME development [1], as well as work exploring the alternative costs and economic value of OSS [19], further research is needed to better quantify and characterize financial return on investment in more applied and practical terms, as emphasized by the interviewee.

**Implications for Supply-Chain Reliability Framing.** While financial return on investment speaks to some stakeholders, it remains difficult to capture and characterize in practice. A wider narrative, also prominent in our findings, instead emphasized the sustainability and security aspects of OSS ecosystems, which were key concerns for several funders, including the Sovereign Tech Agency and Alpha-Omega. In this framing, these concerns ultimately translate into questions of reliability, resilience, and robustness of the digital infrastructure underpinned by OSS components, and by extension connect to broader policy discussions surrounding digital sovereignty and infrastructural dependency. This suggests a need for wider discussion on how impact is captured and communicated, shifting from purely goal-focused approaches toward more risk-based perspectives on infrastructure sustainability and resilience. Further research is needed to better understand how sustainability and security can be translated into such frameworks, while also integrating adoption and dependency relationships from a supply-chain perspective to better signal societal impact.

**Shifting Funding Priorities.** In our interviews, we heard a lot about funding for security. By the time we held the workshop, the funding landscape had changed. Workshop participants pointed out that the security topic, while still relevant, was no longer the dominant focus. We learned that what gets funded shifts rapidly depending on ecosystem-level topics. As of writing this paper, a major topic is Artificial Intelligence. We had not included a discussion of AI in our study because it wasn't mentioned in the interviews, and its impact on the open-source ecosystem had not yet begun to unfold. We also don't have sufficient literature to include the influence of AI on open source success. However, we know from conversations with maintainers and funders that AI is fundamentally changing the OSS ecosystem and is impacting funding decisions.

## 6 Threats to validity

Below, we discuss threats to validity based on the four criteria defined by Guba [18].

**Credibility** concerns the truth value of the presented findings. To strengthen credibility, we collected data from a diverse set of participants across roles and organization types, including funders, recipients, and research organizations within the OSS ecosystem. We triangulated data sources by combining semi-structured interviews with a follow-up validation workshop, and continuous member-checking after both activities [7]. This allowed participants to reflect on, challenge, and extend preliminary interpretations. Throughout the analysis, themes were iteratively refined through discussion among the authors and continuously grounded in empirical material [3, 31].

**Transferability** concerns the extent to which the findings are applicable beyond the cases studied. In this study, we do not aim for statistical generalization but rather provide analytical insights into how OSS funders conceptualize and operationalize impact. The organizations represented span public, private, and philanthropic contexts, primarily within Euro-Atlantic funding ecosystems, which may limit transferability to other geopolitical or cultural contexts. However, by providing rich descriptions of funder strategies, logics, and practices, we aim to support readers in assessing the relevance of our findings to other funding settings or sustainability challenges.

**Dependability** refers to the consistency and traceability of the research process. To strengthen dependability, we followed a systematic qualitative research design, including documented interview protocols, a transparent thematic analysis process, and explicit descriptions of data collection and analysis phases, including an audit trail. Regular discussions among the authors were used to reflect on coding and methodological choices [37, 30].

**Confirmability** concerns the degree to which the findings are shaped by the participants and data rather than researcher bias. All three authors have experience in the context of OSS sustainability and have engaged with communities such as CHAOSS. This experience brings both validity in terms of understanding, and risk of bias. To address this concern, we sought to enhance confirmability by grounding interpretations in participant quotations, explicitly linking analytical claims to empirical material, and reflecting on alternative interpretations during analysis and workshops. The iterative research design and member-checking further help to minimize the potential impact of researcher bias.

## 7 Conclusions

This study provides an empirical investigation of how OSS funders conceptualize, measure, and report the impact of their funding activities. We show that impact measurement is a shared and non-trivial challenge, shaped by funders' strategies, funding mechanisms, and reporting obligations. Current practices largely emphasise short-term, milestone-based deliverables and qualitative narratives, while long-term sustainability, risk mitigation, and human-centered impacts remain difficult to capture and communicate.

Our findings highlight a misalignment between funders' stated sustainability ambitions and the structures through which impact is operationalised and evaluated. As a result, funding impact is often reported in ad-hoc and project-specific ways, limiting comparability, aggregation, and value-based guidance for decision-makers with limited insight into the OSS ecosystem. Addressing these challenges is critical for sustaining funding programs over time and for justifying continued investment in OSS as critical digital infrastructure.

Rather than prescribing a universal set of metrics, funders should establish explicit impact models that connect funding objectives with measurable outputs, outcomes, and longer-term impacts. Such models should incorporate indicators of maintenance, sustainability, and risk mitigation alongside project-specific outcomes, providing a shared reporting structure that improves cross-project comparability while remaining adaptable to diverse OSS contexts. Future work should aim towards establishing a common language for conceptualizing, measuring, and communicating funding impact. This study provides a knowledge foundation for such artifacts, which we believe can provide an interface and help to bring the OSS funder ecosystem together into a more harmonized and coordinated platform, enabling improved efficiency, accountability, and availability of OSS funding. If the needs and impact of funding can be collectively explained, further and more direct funding can potentially be motivated and onboarded, and in the end contribute to a more reliable and sustainable digital infrastructure for industries and society.

# Out of Place in My Own Work: How Generative AI Displaces Software Engineers

**Theocharis Tavantzis**
Aalborg University, Denmark

**Stefano Lambiase**
Aalborg University, Denmark

**Daniel Russo**
Aalborg University, Denmark

## Abstract

**Background.** Generative AI (GenAI) makes software engineers faster, yet a growing number of them report feeling less like engineers. They describe feeling disconnected from their own code, uncertain about their skills, and uneasy about what their profession is becoming. Prior studies capture fragments of this experience in isolation, yet no shared concept or framework describes it as a whole.

**Aim.** Drawing on postphenomenology, Floridi's re-ontologization of the infosphere, and Feenberg's critical theory of technology, we introduce *AI-induced displacement*: the multi-dimensional way in which GenAI tools unsettle engineers' sense of craft, identity, and professional belonging.

**Method.** We interviewed 21 software engineers across different roles and organizations, and analyzed their accounts through thematic analysis.

**Results.**We identify six dimensions of displacement, concerning (i) how engineers justify and adopt AI-generated solutions, (ii) shifts in professional identity, (iii) tensions with normative and ethical standards, (iv) disruptions to individual focus and cognitive flow, (v) changing dynamics of recognition and collaboration within teams, and (vi) the erosion of intrinsic meaning and long-term professional sustainability.

**Conclusions.** This typology offers researchers a theoretically grounded lens for investigating the human side of GenAI adoption in software engineering, and helps practitioners design integration strategies that foreground augmentation rather than replacement.

**2012 ACM Subject Classification** Software and its engineering; Software and its engineering → Software creation and management; Human-centered computing

## 1 Introduction

> *"I am shipping faster than ever, but I no longer feel like I am really engineering. I paste prompts, get code, fix what breaks, and move on. The code works, yet it does not feel like mine. It feels like my role is shifting away from demonstrating coding skill toward something else that I am still trying to define."*
>
> *Participant P10, Senior Test Engineer*

Such accounts are becoming increasingly common as Generative AI (GenAI) expands the frontiers of many domains, including Software Engineering (SE). Nearly every field has begun to experiment with GenAI tools [7], and AI-powered services are now widely adopted [39]. In SE, Large Language Models (LLMs) reshape core activities [1], including the elicitation of software requirements [4] and code development [48]. Developers report productivity gains in information search, task completion, and problem solving [36], which together suggest a profound reconfiguration of SE practice rather than a mere incremental tool upgrade.

From a philosophy of technology perspective, GenAI does not simply introduce new tools into an otherwise stable practice. Postphenomenological accounts emphasize that technologies *mediate* human–world relations: they shape how the world shows up to practitioners, and how practitioners perceive, act, and exercise judgment in their work [51, 52]. Floridi uses the term *infosphere* to describe the broader informational environment in which humans, technologies, data, and informational processes are increasingly interconnected. From this perspective, digital technologies contribute to a process of *re-ontologization*: they do not merely change the ways in which people interact with an existing informational environment, but transform the environment itself and, consequently, the nature of the entities, relations, and forms of agency that constitute it [22, 23]. For Feenberg, such technologies embody specific "technical codes" that privilege certain values (speed and automation, for example), while marginalizing others, such as craft, deliberation, and democratic control over technology's social role [16, 17].

Seen through these lenses, GenAI adoption in SE is not a neutral insertion of assistance into existing workflows. It is a transformation of how SE work is experienced and what it means to be a software engineer. Earlier research highlights different facets of this transformation; we frame these facets as interconnected forms of displacement that evolve over time. In the present, practitioners experience behavioral and cognitive challenges, as efficiency gains coincide with over-reliance, de-skilling, and job insecurity [49]. We observe, in parallel, a form of **epistemic displacement** that emerges when, as Booyse and Scheepers [5] note, black-box algorithms limit transparency and explainability, fostering uncertainty, distrust, and potential ethical risks. **Phenomenological displacement**, in turn, takes shape through the disruption of individuals' workflow and cognitive flow [47]. Over time, individuals may feel socially pressured to adopt GenAI in light of widely perceived productivity gains [26], may experience an erosion of their perceived skills and mastery [14], or may adopt outputs that follow poor development practices [11, 24]. We label these forms of displacement **social**, **identity**, and **normative**, respectively.

Taken together, these forms of displacement reveal a deepening misalignment between AI-mediated work and established ways of knowing, acting, and judging, which leaves engineers feeling increasingly "out of place" within their own practice. Prior research discusses these concerns and issues in isolation, yet little is known about how SE practitioners experience and interpret this transformation in their day-to-day workflow. We lack, in particular, empirically grounded studies of how AI-embedded processes reshape software engineers' sense of agency, expertise, and belonging in their everyday practice, and of how these experiential shifts relate to the broader reconfiguration of professional identity and standards in the age of GenAI.

The objective of this study is to examine the different aspects and dimensions of this emerging misfit empirically, and introduce the notion of **AI-induced displacement** to describe a set of systematically observed experiences reported by practitioners. In the SE context, we define AI-induced displacement as *a multi-dimensional experience in which GenAI tools, as designed and deployed, make engineers feel out of place in their own work by disrupting their sense of craft, epistemic agency, professional identity, work meaning, normative standards, and social recognition.* To investigate this phenomenon, we adopt a qualitative, exploratory methodology. We conducted semi-structured interviews with SE practitioners across multiple organizations and application domains, and performed thematic analysis on the collected data.

Given the increasing calls for human-centered AI integration in SE [42], a unifying construct that captures how GenAI tools affect individuals and how these experiences in turn shape patterns of adoption and resistance is both timely and consequential. This study contributes *(i) an empirically grounded conceptualization of AI-induced displacement, and (ii) implications for human-centered GenAI integration*, offering a vocabulary and a lens for understanding when AI-embedded processes support meaningful SE work and when they undermine it.

The remainder of the paper is organized as follows. Section 2 reviews the literature related to AI-induced displacement. Section 3 presents the research methodology. Section 4 reports the results and answers the research question. Section 5 discusses the findings and proposes directions for future work. Section 6 examines threats to validity and Section 7 concludes our study.

## 2 Background and Related Work

This section presents the philosophical foundations that motivate our construct, and surveys prior work on the impact of GenAI in software engineering.

### 2.1 Philosophical Foundations of AI-Induced Displacement

To conceptualize AI-induced displacement, this study builds on three strands in the philosophy of technology: postphenomenology, Floridi's digital re-ontologization of the infosphere, and Feenberg's critical theory of technology.

Drawing on Ihde and Verbeek, postphenomenological approaches treat technologies not as neutral instruments but as *mediators* of human–world relations [51,52], co-shaping perception, action, and experience by configuring what is perceptible, actionable, and taken-for-granted in situated practice. In other words, they participate in the constitution of everyday life-worlds [52]. Applied to SE, GenAI tools do not simply assist workflows but mediate problem framing, solution discovery, and the meaningfulness of engineering work.

Floridi's philosophy of information captures a broader ontological shift. He argues that contemporary ICTs contribute to a *re-ontologization* of the "infosphere": they change not only what we do, but also how agency and identity are constituted in informational environments, as artificial agents participate in distributed systems of action and responsibility [22, 23]. In SE, GenAI redistributes authorship, expertise, and justification across human–AI assemblages, challenging the engineer as the primary locus of decisions, code authorship, and accountability.

Feenberg's critical theory of technology adds a socio-political lens by arguing that technological systems embody specific design logics (what Feenberg terms *technical codes*): value-laden choices that privilege certain forms of rationality over others, typically at the expense of participation, craft, and reflective judgment [16, 17]. Current GenAI tools tend

to crystallize a rationality organized around speed, automation, and output volume. As this logic dominates, engineers grow estranged from both the product of their work and its professional meaning: professional judgment erodes as engineers defer to outputs they do not fully understand; moral discomfort arises when AI use conflicts with professional standards; and productivity baselines leave little room for reflective engineering work. Feenberg's framework thus predicts that AI-mediated work changes not only how engineers work, but what that work means to them; a prediction our empirical study directly explores.

Taken together, these three pillars support an understanding of AI-induced displacement as more than a set of isolated usability or psychological issues: they motivate a unified, experiential construct capturing how GenAI can render software engineers "out of place" by reshaping how they perceive, act, justify, and are recognized as professionals. We use them not as propositions to be empirically tested, but as sensitizing concepts that define the scope of our study, directing attention to how GenAI adoption might reconfigure engineers' identity, agency, and meaning-making.

## 2.2 AI in Software Engineering: Five Fragmented Dimensions

Building on these philosophical perspectives, prior work in SE and related fields can be seen as documenting fragments of a broader experiential shift. Studies typically examine specific consequences of AI adoption rather than the overall transformation of practice, often touching on displacement through: (i) individuals' skills and identity, (ii) limited transparency and understanding, (iii) workflow disruption, (iv) conflicts with professional standards and norms, and (v) social pressures and negative feelings due to peers' attitudes and impressions.

**Impact on Transparency and Justification.** A body of work examines the lack of transparency and justification in AI-generated outputs, revealing epistemic tensions between AI recommendations and developers' established reasoning practices. The inherent opacity of many AI tools can lead developers to adopt suggestions without access to clear reasoning [45]. This in turn reduces trust in AI-embedded tools, since developers cannot predict or explain AI behavior [28]. Fleisher [21] argues that poor explanations hinder adoption, and stresses the need for explainable AI (XAI) that offers practical insight into AI decisions. Rudin [40] underscores that interpretable models can reduce negative effects of AI decisions across domains, including SE. Booyse and Scheepers [5] report mistrust and frustration caused by black-box decision-making, while Treude and Kula [50] argue that transparency alone may overwhelm developers without proper interfaces. These studies jointly highlight *epistemic* aspects of displacement, where engineers struggle to reconcile AI outputs with their own standards of justification and understanding.

**Impact on Individuals' Skills and Identity.** Shukla et al. [46] examine the de-skilling of practitioners that follows AI adoption, and show how reliance on AI can shift work from active generation and sense-making toward passive validation. Through qualitative analysis, UX practitioners reported that, while AI-assisted design can improve efficiency, heavy reliance on it raises concerns about de-skilling and about the erosion of human judgment as a core professional resource [46]. Recent work examines how GenAI adoption affects professional identity when core sources of competence are challenged. Eshraghian et al. [12] show that impact varies with expertise, with stronger professional identities linked to more positive integration, while skepticism is common among less engaged users. Hermann et al. [25] find that while GenAI may boost productivity, it can threaten needs for competence, autonomy, and relatedness, potentially destabilizing professional identity. De La Cruz et al. [14] warn that over-reliance on AI may weaken developers' sense of mastery. Together, these studies indicate *identity* displacement, where engineers struggle to maintain a coherent sense of themselves as skilled professionals.

**Impact on Professional Standards and Norms.** Another strand of work focuses on whether GenAI outputs align with normative expectations of "good work" in SE. Early evaluations examined the capability of AI systems to produce correct and effective code to meet functional requirements [37]. Recent studies increasingly question alignment with security, style, and design standards [24,38,43]. Fu et al. [24] demonstrate that AI coding assistants can introduce code that conflicts with established secure development practices unless carefully reviewed. Sabra et al. [43] and Pan et al. [38] report that compliance with style guides and design patterns depends on prompting, as LLMs do not adhere to them by default. These findings point to *normative* displacement, where AI-generated code clashes with engineers' standards of good engineering, safety, and responsibility.

**Impact on Individual Flow and Work Rhythms.** A line of research emphasizes workflow compatibility as a key determinant of AI adoption [9,41], underscoring the importance of maintaining continuity and fluency in everyday work practices. Rather than adoption per se, critical decisions concern which tasks are suitable for AI support. Dell'Acqua et al. [9], for example, show that while GenAI can increase efficiency, it may also mislead skilled professionals and degrade output quality when applied to incompatible tasks. At the same time, GenAI reshapes personal workflows by shifting users from content generation to output evaluation, a transition that can interrupt established rhythms of work and undermine experienced flow [47]. Shah et al. [44] qualitatively explain that extensive manual validation and reduced trust in AI outputs further increase cognitive burden and interrupt standard work practices. This indicates that inadequate task-level integration drives workflow disruption, highlighting *phenomenological* forms of displacement where engineers experience breaks in flow and skilled coping [44,47].

**Impact on Human Relations and Social Recognition.** Finally, research has begun to document social and relational consequences of GenAI adoption. Houck et al. [26] report that developers experience AI tools as augmenting their work, boosting creativity and self-perceived productivity. At the same time, not using AI may signal lower productivity in the eyes of peers, creating social pressure that shapes adoption independently of task fit or personal preference. On the other hand, Melegati et al. [35] examine negative feelings toward AI, including fear of dependency and guilt for not doing tasks oneself. Lou et al. [32] show that AI agents are shifting from tools to collaborators, reshaping roles, coordination, and accountability. Thus, they call for research on socio-behavioral aspects of teaming. Together, these works illuminate *social* forms of displacement, where recognition, expectations, and accountability are reconfigured within teams.

**☰ Related Work: Summary and Research Gap.**

Prior work documents five dimensions of what we term AI-induced displacement: (i) **epistemic** (what counts as valid reasons and evidence), (ii) **phenomenological** (intrusions into workflow and flow), (iii) **identity-related** (threats to competence, mastery, and professional self-conception), (iv) **normative** (tensions with ethics and standards of good work), and (v) **social** (reconfigurations of recognition, expectations, and relations). Yet, these dimensions have been treated in isolation, lacking a unified account grounded in coherent philosophical theories. This study synthesizes them into a single notion of **AI-induced displacement** and examines how software engineers experience this transformation of their work.

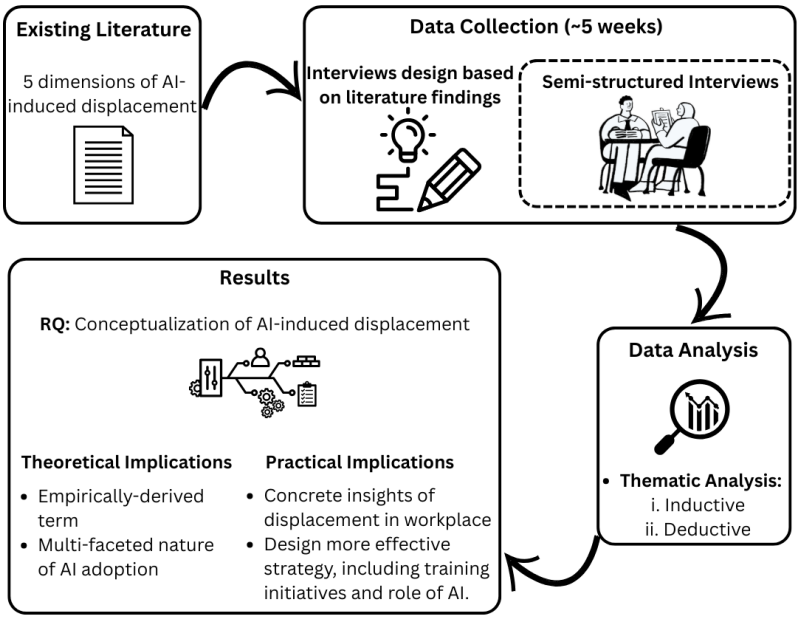

**Figure 1** Research overview.

## 3 Research Method

The objective of this study is to examine empirically how the integration of GenAI into SE work shapes professionals' perceptions of their role, skills, and professional identity, and how these perceptions can be understood as forms of AI-induced displacement. Given the exploratory and concept-developing orientation of this work [8], we formulated a single overarching research question:

> ❓ **RQ**: *How do software engineers experience and interpret the integration of GenAI tools in their workflow, and how can these experiences be understood as dimensions of AI-induced displacement?*

To answer the research question, we adopted a ***qualitative methodology based on semi-structured interviews***, suitable for capturing practitioners' experiences and meaning-making [8]. As shown in Figure 1, the research design comprised three phases. First, we reviewed peer-reviewed literature to identify dimensions related to displacement in AI-mediated work, which informed our interview protocol. Second, we conducted semi-structured interviews with software engineers across multiple organizations and domains. Third, we applied thematic analysis with both inductive and deductive elements to the interview transcripts, using literature-informed dimensions as a sensitizing framework while remaining open to new patterns. This process enabled us to refine the notion of **AI-induced displacement** as an empirically grounded construct.

### 3.1 Data Collection

The study used semi-structured interviews to collect the qualitative data. This choice was motivated by the freedom that semi-structured interviews afford the interviewer, allowing follow-up questions and the in-depth probing of emerging topics based on the interviewee's input. We designed our protocol following the guidelines of Hove and Ada [27].

We conducted 21 interviews with participants across the globe. The first session was a pilot interview to evaluate the initial protocol and ensure that the questions were clear with no ambiguities. However, the final analysis encompassed the insights gathered from all the interviews, as even the pilot session was of significant quality, offering valuable insights. The interviews were conducted online, with a median duration of 50 minutes. We observed theoretical data saturation after the 12th interview, with 4 additional codes emerging until interview 18. The remaining sessions confirmed the codes and themes we identified.

As shown in Table 1, participants were recruited globally, with Europe as the most represented region. Also, the participants hold different positions, enriching the findings based on the unique nature of each role. Even though the majority of the practitioners are mid-experienced, we included individuals with high seniority, with 7 participants having more than 15 years of working experience.

Table 2 reports the demographic information of the interviewees' organizations. Sixteen different companies are represented, which constitutes a diverse sample in terms of domain and size. The firms operate in areas ranging from automotive to banking services, and span from small companies with fewer than 10 employees to large technology firms with more than 100,000 employees. Across the included organizations, adoption relied on organizationally provisioned tools, such as company-issued Copilot licenses, while in some cases individuals described self-directed use of GenAI tools.

This research activity was approved by the Ethical Committee of Aalborg University with case number 2026-505-00766. To ensure compliance, we asked all participants for their consent to participate in our study and allow us to record and transcribe the interview session, aligned with the prescriptions of our Ethical Committee. We informed them about their right to withdraw or skip certain questions, while we provided details on the data analysis procedure.

## 3.2 Data Analysis

We conducted a hybrid *Thematic Analysis* to analyze the qualitative data, combining inductive and deductive coding, following the mixed approach proposed by Fereday and Muir-Cochrane [19]. We grounded our analysis in the principles outlined by Braun and Clarke [6]. This approach involves a systematic process of identifying, analyzing, and interpreting patterns across the dataset. The analysis began with familiarization through repeated reading of the data, followed by the generation of initial codes related to the scope of the study. These codes were then examined and clustered to construct candidate themes, which were iteratively reviewed and refined. In this regard, we defined and named the themes to clearly articulate their scope and focus. The final phase involved reporting the final themes in a clear and cohesive way. For the transcript analysis, we used NVivo software, a tool that enables collaborative qualitative data analysis.

Our coding consisted of two linked stages. In the first, deductive stage, we derived an initial set of sensitizing codes from the dimensions identified in prior literature on GenAI's impact on engineers, such as on their identity, and used these to guide our first pass through the transcripts. In the second, inductive stage, we allowed additional codes and sub-themes to emerge directly from participants' own accounts wherever they weren't captured by this initial set, iteratively refining and merging codes into candidate themes. The six reported dimensions result from reconciling these two threads, combining literature-derived dimensions with emergent ones, rather than restating the starting framework unchanged.

Two authors performed the analysis collaboratively to limit interpretation bias. The process was iterative, and regular analytic discussions served to examine and refine code and theme development. Differences in interpretation were used to deepen engagement with the data and to sharpen theme definitions, rather than to achieve consensus.

**Table 1** Participants Demographic Information.

| ID | Role | Experience | Location | GenAI Tools[1)] |
|---|---|---|---|---|
| P01 | DevOps Engineer | 1 year | Italy | A, B, C |
| P02 | Software Developer | 4 years | Italy | A |
| P03 | Data Scientist | 3 years | Greece | A |

## 4 Findings: AI-Induced Displacement

The thematic analysis of the interview data yielded six discrete themes. Five align with the dimensions identified in the Related Work Summary (Section 2), while *Meaning displacement* emerged inductively from the data. Table 3 presents the identified codes organized by displacement dimension, along with their frequency of occurrence in the interview transcripts. For reasons of space, we report only codes with frequency equal to or greater than seven, with the exception of Epistemic displacement, where we retain all three codes that emerged.

### 4.1 Epistemic Displacement

*Epistemic displacement* refers to *the shift on the ways that software engineers adopt solutions, accept and justify them as valid*; 3 codes emerged in this theme.

The most cited code was the shift from internal reasoning to AI-mediated heuristic verification. Practitioners today tend to rely on GenAI tools to make sense of solutions, rather than constructing the solution themselves or consulting traditional knowledge sources such as Stack Overflow. P04, for example, mentioned *"...the first thing I would do is to ask Gemini to explain that code. And then I would go on my own to read code."* According to P05, this pattern is typical when developers face programming languages with which they are unfamiliar or in which they lack prior experience.

**Table 2** Organizations Demographic Information.

| Org. ID | Part. ID(s) | Domain | #employees |
|---|---|---|---|
| Org01 | P01 | Automotive | $\sim 30,000$ |
| Org02 | P02 | IT Consulting | $11 - 50$ |
| Org03 | P03 | IT Consulting | $11 - 50$ |
| Org04 | P04 | Soft. Development | $\sim 100,000$ |
| Org05 | P05 | IT Consulting | $\sim 45,000$ |
| Org06 | P06, 09, 10, 13, 15 | Telecommunication | $\sim 90,000$ |
| Org07 | P07, 12 | Research | $501 - 1,000$ |
| Org08 | P08 | Soft. Development | $2,001 - 5,000$ |
| Org09 | P11 | IT Services | $11 - 50$ |
| Org10 | P14 | Startup Studio | $< 10$ |
| Org11 | P16 | AI Consulting | $< 10$ |
| Org12 | P17 | IT Services | $501 - 1,000$ |
| Org13 | P18 | Banking Services | $\sim 5,000$ |
| Org14 | P19 | Soft. Development | $101 - 200$ |
| Org15 | P20 | Soft. Development | $51 - 200$ |
| Org16 | P21 | IT Services | $\sim 200,000$ |

Frequently reported code was adopting AI-generated outputs without fully understanding them (when it comes to low-risk tasks). P09 conveyed *"if it is a small feature or something like one line of code or two, you know, small fixing, then it doesn't matter, it just fixes it and then I just I leave it."*, while P02 shared that for *"simple, UI tasks, it's more common to adopt something, "blindly," since it cannot cause harm"*; P13 added that tight deadlines can lead to adopting such solutions.

The least appeared code was the adoption of GenAI outputs that had non-functional weaknesses. For instance, P04 described a situation where they used GenAI to write a parser, which created latency issues. So a senior colleague consulted them to revisit the code and use a different library.

## 4.2 Identity Displacement

*Identity displacement* is defined as *the change in what it means to be a software engineer, which skills they need to possess, and how they perceive themselves in the GenAI era*; in this theme, 14 distinct codes emerged.

A considerable share of the codes concentrate on the shift in the engineer's role within the software life cycle, and on the skills that are useful for software engineers. Almost all interviewees agreed that the role is shifting from implementation and code development toward code reviewing. P12 noted that *"I code less than before. I guess that's a little bit of change, because GenAI writes the code and of course I'm reviewing more because of the output I need to review."* The shift also extends to architecture and conceptualization of solutions; P08 noted the ability to *"pivot from tedious debugging tasks to high-level architectural design, and focus on more interesting stuff"*. Less commonly, interviewees described the need to move toward orchestration, owing to agentic AI systems and the potential they offer (P20: *"...maybe I don't feel like I can do more work, but I can delegate more work. I can run three agents at the same time"*).

**Table 3** AI-induced displacement: Dimensions and most frequent codes. Codes are ordered by decreasing frequency; $f$ denotes the number of interviews in which a code occurred.

| Dimension | Code |
|---|---|
| **Epistemic**: *How engineers adopt solutions and justify them as valid.* | Shift from internal reasoning to AI-mediated heuristic verification ($f$=20) |
| | Using GenAI outputs without full comprehension in low-risk tasks ($f$=16) |
| | Non-Functional shortcomings of AI-generated adopted code ($f$=6) |
| **Identity**: *The change in what it means to be a software engineer, which skills they need to possess, and how they perceive themselves in the GenAI era.* | Shift to code reviewing ($f$=18) |
| | Declined pattern recognition and creativity ($f$=16) |
| | Declined centrality of code skills ($f$=15) |
| | Shift to architecture and conceptualization ($f$=15) |
| | Developing capabilities in GenAI technologies ($f$=13) |
| | Shift to orchestration ($f$=12) |
| | Reasoning as a central quality in the GenAI era ($f$=11) |
| | Increased usefulness of emotional intelligence ($f$=10) |
| | Openness to change as central quality ($f$=10) |
| | GenAI reliance hinders learning process ($f$=9) |
| | Impostor phenomenon due to GenAI reliance ($f$=9) |
| **Normative**: *Tensions with individuals' ethics and with team and organizational standards.* | Mismatch between team norms and legal use ($f$=12) |
| | Documentation more central to team standards ($f$=10) |
| | GenAI ethical misuse ($f$=10) |
| | Normative conflict between organizational standards and real use cases ($f$=7) |
| **Phenomenological**: *The interruptions to individuals' cognitive flow and work routines introduced by GenAI.* | Give up GenAI use in the mid-workflow ($f$=18) |
| | Flow disruption due to trial-and-error approach ($f$=17) |
| | Time loss due to limited GenAI's understanding ($f$=11) |
| | LLMs hallucination during collaboration ($f$=10) |
| | Cognitive disorientation due to GenAI workflow incompatibility ($f$=9) |
| | Disrupt the craft flow ($f$=9) |
| | Workflow incompatibility of approved GenAI tools ($f$=7) |
| **Social**: *Change of recognition, expectations, and peer relations.* | Decreased mentoring, knowledge and experience-sharing ($f$=14) |
| | Peers' skepticism and bias towards heavily AI-generated work ($f$=14) |
| | Top-down pressure to adopt GenAI ($f$=11) |
| **Meaning**: *Changes in the experiential relationship with work: personal contribution, intrinsic motivation, moral comfort, and long-term sustainability.* | Increased expectations or assigned workload ($f$=15) |
| | Job instability ($f$=14) |
| | Decreased intrinsic motivation ($f$=12) |
| | Fear of being left behind ($f$=11) |
| | Perceived pressure to improve ($f$=10) |
| | Risk of burnout in high-productivity contexts ($f$=10) |
| | Decreased epistemic confidence ($f$=9) |
| | Increased stress due to rapid progress ($f$=9) |
| | Moral discomfort ($f$=7) |

A second cluster of codes concerns the impact of GenAI on engineers' skills and on the skill requirements of the role. The majority of interviewees agreed that reliance on GenAI has resulted in declining pattern recognition and creativity. P19 explained that 🗨 *"then you simply say "what the AI is doing makes sense and I agree with that, so let's go with that". But because you already have one possible direction fully thought out, it lowers the reason to be creative about potential other paths."* Coding skills, similarly, were perceived as less central to the definition of a software engineer than they had been before GenAI integration. P09 captured this decline in importance by remarking that 🗨 *"I would say that coding is and will decline. I would say that at least more than 60% are not doing hard coding now like before."*

Practitioners also emphasized the skills and qualities that they believe have become more central. More than 65% of the participants defined a good software engineer as one who possesses the required capabilities in GenAI technologies. These skills encompass both hard and soft skills, including context engineering and an awareness of tools' capabilities and limitations, as P16 and P01 shared, respectively. Finally, almost half of the professionals emphasized the centrality of emotional intelligence in the GenAI era (P03: 🗨 *"It became really important how you will talk with your managers, colleagues, and customers. This is what differentiates us from an AI tool now"*).

Some participants reflected on the shift in their perceptions of their own skills and professional identity. According to their narratives, many appear to experience heightened impostor feelings as a result of the increased reliance on, and capabilities of, these tools (P02: 🗨 *"As a developer, I did my own work, my diplomas and certificates, but maybe sometimes you feel like I am not just good enough."*). In specific cases, practitioners such as P01 even felt inferior to GenAI 🗨 *"due to the speed of completing tasks"*.

## 4.3 Normative Displacement

*Normative displacement* concerns *the tensions that GenAI brings to individuals' ethics and the standards of work within the team and the organizations*; 9 codes emerged.

A recurrent code concerned the mismatch between use cases that organizations allow and what is acceptable by team norms. P13 described cases in which people write emails with GenAI as a typical example of an unacceptable use case within teams, since such use affects writing style and tone and makes communication feel impersonal. A similar tension was observed between organizational policies and real-world use cases. P16, in particular, stressed that 🗨 *"Certainly, the tension exists. That's my main competency as a consultant, to help them move away from this, you know, signed operating procedure that you revise once per year versus having to update it like every week or every second week, or it might get updated automatically based on new versions and models to meet the state-of-the-art"*.

A frequently cited code was related to the ethical misuse of GenAI tools. We noted three main reasons that contribute to this misuse. P01 attributed their misuse to the incompatibility of the internal GenAI tools with their tasks. On the other hand, P10 explained that the lack of clarity on what is allowed and forbidden can lead to GenAI abuse. Increased demands and expectations, together with tight deadlines, constituted the third reason that motivated ethical abuse of GenAI tools, as communicated by P03.

Lastly, professionals shared how GenAI affects conventional work practices from different angles. Documentation became more central in team standards due to the capabilities of GenAI tools in explaining code snippets accurately and creating high-quality reports. P08 noted that 🗨 *"it is considered as a standard practice for every piece of code to be fully documented"*. 4 interviewees conveyed their concerns about the existing hiring and evaluation

processes. Since GenAI tools are widely adopted, even in university studies, firms need to identify which skills are essential and adjust their hiring processes to evaluate candidates based on these skills.

## 4.4 Phenomenological Displacement

Phenomenological displacement captures *the interruptions to individuals' cognitive flow and work routines introduced by GenAI*; we recognized 9 codes in this thematic area.

Interviewees discussed several aspects associated with the intrusions they experience as GenAI is incorporated into their work. One of the most frequent codes was flow disruption arising from a trial-and-error approach, with P06 explaining that, in 🗨 *"vibe coding sessions, you usually have to give it multiple answers before it actually gets on the right track"*. A code that appeared frequently alongside this one concerned the time loss caused by the limited understanding that GenAI tools display (P11: 🗨 *"I try as a next step to add more functionality, and then I notice that it deleted some of the old one. When I ask it to re-add the deleted functionality, it didn't understand and added something completely different."*).

A further source of workflow interruption is LLM hallucination. P13 described a case in which the team had to work with a library that is uncommon in public repositories. The result was code that did not work and that caused confusion and time loss. P19, among others, observed that waiting time imposed by agentic AI work itself produces disruption: 🗨 *"also the distraction part is that you are no longer putting 100% of your attention to the actual work that you are doing, and you're trying to offload it pretty much like you would have a junior developer sitting next to you... And this is going well, and they give you the right answers back. But what do you do in the meantime?"*

Workflow incompatibility appeared as a factor that can divert professionals' attention from their actual work. P01, in this regard, observed that 🗨 *"the provided license of Copilot is very bad. For something reliable I cannot use it."* This workflow incompatibility, as P02 explained, induces cognitive disorientation. P02 noted in particular that 🗨 *"It really breaks the chain of thoughts you have. Maybe you have the idea in mind, and you're working on it. At the same time, you copy-paste the code to the LLM, and that doesn't respond, and then you feel like you lose the concentration."*

A common result is giving up GenAI use in the middle of the workflow and starting to work manually from scratch. P21 shared their experience that sometimes when using GenAI to generate a report, you "pay" a higher cost since the interaction is not useful and you end up doing it manually. P09 communicated a more emotionally negative experience by saying 🗨 *"...but it is sometimes that it just doesn't understand what I say. Then I get angry and OK, I say I need to do it myself!"*.

## 4.5 Social Displacement

*Social displacement* is defined as *the reconfigurations caused by GenAI of recognition, expectations, and relations between colleagues*; we identified 11 codes for this theme.

The interviewees broached various forms of social displacement introduced by GenAI. Regarding the impact on professional relations, the majority of practitioners agreed that GenAI incorporation reduced the mentoring between junior and senior people, and the knowledge-sharing overall. P07 justified this fact with the increasing capabilities of these tools (🗨 *"I think there were much more questions and such interactions back in the day. Now it's like they can just find out themselves."*). Few professionals highlighted a negative effect in specific activities, such as pair-programming, meetings, and code reviews. The former, particularly, was the most frequent of the 3, as P01, P04, and P12 stressed is a thing of the past.

Reconfigurations were observed within the perceptions of individuals too. The most frequent code in this type of social displacement refers to peer skepticism and bias towards work that was produced heavily relying on GenAI. Particularly, 14 interviewees agreed that people are not willing to trust GenAI; hence, they would be stricter in reviewing work that was produced largely with the help of GenAI. Fewer, but still present, were the cases that individuals perceived others as less competent or professional due to heavy reliance on GenAI. For instance, P15 conveyed that *"it's very annoying when they are generating large language outputs that don't add any real value. That is just unprofessional"*.

Interestingly, participants raised two kinds of GenAI adoption pressure within their narratives. 11 practitioners talked about pressure from the high-level management to integrate GenAI into their daily workflow. P08 provided a case where *"employees" integration is regulated by monthly KPIs with specific token consumption targets, and the department even maintains an employee usage leaderboard to rank our activity levels!"*. This indicates the monitoring and pressure that individuals feel to adopt technologies that might not be applicable in certain situations. The other type of pressure relates to the one occurred by peers. So, P10 elaborated on how individuals can feel the pressure from their peers, since *"you see that other colleagues are actually going a step further in the usage of AI and then you realize that maybe you are missing something and need to catch up"*.

## 4.6 Meaning Displacement

*Meaning displacement* refers to the changes in an engineer's experiential relationship with the work: the sense of personal contribution the work affords, the intrinsic motivation it sustains, the moral comfort with which it can be performed, and the conditions under which professional practice remains personally sustainable over time. Feenberg's concept of alienation, understood as the estrangement of workers from the meaning and product of their labor, is the precise theoretical antecedent of this dimension; we adopt the term *meaning displacement* rather than alienation to foreground the experiential content reported by practitioners and to maintain terminological distance from the professional register already occupied by identity displacement. Seventeen codes emerged in this theme.

The most recurrent codes concerned escalating expectations and the fear of professional obsolescence. Practitioners reported that GenAI does not simply reduce workload; it raises the productivity baseline against which they are evaluated. P10 noted plainly that *"if management expects to produce 30% more with AI, then the expectations on you are to produce 30% more"*. P07 warned that this trajectory carries structural consequences: *"as time goes, people are going to expect much more from you to be done at the same time frame. That's where it can become stressful and potentially create more problems, like burn-outs"*. Fear of professional obsolescence pervaded the accounts, with P07 describing adoption as existentially compulsory: *"people start more and more adopting, and this is inevitable right? So, we have to do this. Otherwise, we are just going to be replaced by somebody else who does"*. P10 extended this into temporal pressure, describing *"this permanent feeling that I need to catch up every day, and this is the first time ever that we have this"*.

The erosion of intrinsic meaning and professional self-worth emerged with comparable frequency. Practitioners reported that delegating core tasks to GenAI hollows out the sense of personal contribution. P11 pointed to the motivational consequences of removing coding from the workflow, while P02 captured the affective dimension: *"saying that you solve the task, relying only on the AI makes you feel a bit less worth than what you actually are"*. Several accounts accompanied this with nostalgia for pre-GenAI craft work and a distorted perception of one's own output, with P10 questioning *"maybe I didn't do that much,*

*because the AI was doing most of the hard work"*. Job instability reinforced this sense of diminished standing, with P03 describing engineers as *"expendable"* and P05 noting that 💬 *"enterprises are carrying jobs and replacing them with generative AI"*.

Practitioners also introduced a moral dimension to meaning displacement. Many reported discomfort and guilt when using GenAI in ways that conflicted with their professional values. P15 felt *"shamed"* for heavy AI reliance, while P01 and P02 independently used the word *"dirty"* to describe similar experiences. In several cases this escalated into explicit regret: P15 reflected 💬 *"maybe I shouldn't have done it"*, and P04 disclosed 💬 *"sometimes you have to ship fast, or maybe sometimes you are just too tired. But it is not correct. It is something that I should have never done"*.

# 5 Discussion

This section discusses the significance of our findings for academia and practice, along with directions for future studies.

## 5.1 Findings Interpretation and Theoretical Implications

Our findings contribute theoretically to the AI adoption literature by offering interpretations that confirm and extend existing research.

### 5.1.1 A Unified View of the Impact of Generative AI on Developers Displacement

The primary contribution of our study is to provide a unified view of the concept of AI-induced displacement, which has previously been treated in the literature in fragmented and loosely connected ways (e.g., [24, 40, 46]), and to articulate it through a set of distinct dimensions. As with any theoretical contribution, this conceptualization offers a shared vocabulary and a coherent definition that can guide a more concrete research agenda going forward, and that helps to reduce fragmentation in the emerging body of knowledge on human-centered GenAI adoption in SE.

In addition, the articulation of AI-induced displacement into multiple dimensions enables future research directions, some of which we are already pursuing, aimed at developing measurement instruments for the phenomenon. Such instruments would allow researchers to (1) investigate individual dimensions of displacement through quantitative approaches and (2) assess these issues in practice, thereby supporting the design of informed interventions and integration strategies.

### 5.1.2 Compatibility as a Central Actor

Prior studies have underscored the importance of GenAI tools' compatibility in adopting these tools [31, 41]. Our findings showed that compatibility is also a main driver of displacement, as it appears in different forms. For example, many interviewees agreed that incompatibility of approved tools resulted in cognitive confusion and concentration loss, as a form of phenomenological displacement. Similarly, this misfit of provided tools leads professionals to ethical misuse of GenAI, using external solutions that are not allowed, triggering moral discomfort.

### 5.1.3 The path forward: a necessary shift or a misaligned trajectory?

The significant majority of the interviewees acknowledged the potential of GenAI tools and the resulting shift of their role toward higher levels of the development workflow. In particular, the transition toward code reviewing emerged as the most frequent form of identity displacement. Other commonly reported shifts included architectural design and conceptualization, reported by 15 participants, as well as the orchestration of agentic systems ($f = 12$). These insights align with emerging discussions in the research community [13, 29], which suggest that future competencies in SE may increasingly revolve around higher-level tasks, such as architectural thinking, orchestration, and mentoring of AI agents.

However, these results raise an important question regarding the direction that the industry should pursue. While it may appear straightforward for researchers to argue that a transition toward higher-level tasks is both necessary and inevitable, prior research consistently shows that, especially among junior developers, writing code, experimenting with new technologies, and designing algorithmic solutions (in short, "get one's hands dirty") are the activities perceived as most engaging and enjoyable [34]. These activities are often preferred over higher-level tasks such as code review or managerial coordination [2, 20].

This observation becomes even more distinct when viewed through a historical lens. Disruptive tools in software development have typically produced their greatest benefits not by automating all tasks or the technically low-level ones, as personal biases might suggest, but by automating tasks that developers perceive as tedious. In doing so, these tools improved not merely productivity but efficiency, enabling developers to focus on tasks they considered meaningful and stimulating. This shift often resulted in higher enjoyment and morale among practitioners [30]. Moreover, large-scale industry evidence points in the same direction. The DORA report on the impact of GenAI in software development [10] describes a "valuable work" paradox, in which AI adoption reduces the time developers spend on the work they find valuable, while the time devoted to toilsome activities, such as meetings and bureaucracy, remains unchanged. The authors attribute such a pattern to AI accelerating precisely the tasks developers enjoy, without yet automating the tedious ones. The same report also associates higher AI adoption with lower delivery throughput and stability, driven by larger and harder-to-review batches of generated code. In line with our findings, this suggests that the current trajectory might displace engineers from the activities that sustain their engagement, while concentrating AI support where the risks remain comparatively higher.

This tension may also connect to what our findings suggest as a productivity paradox of GenAI adoption. While participants widely acknowledged productivity gains, the significant majority reported an increase in assigned tasks and overall workload ($f = 15$), with several participants ($f = 10$) explicitly warning about the risk of increased burnout due to rising expectations and demands. These concerns resonate with the findings of Feng et al. [18], who show that GenAI adoption can simultaneously increase job demands and organizational pressure, thereby elevating burnout risk. Mazeika et al. [15] further document the growing demands from senior engineers to oversee and correct AI-generated outputs. This AI remediation burden, over time, may erode engineers' professional efficacy [33]. This suggests that burnout might be slow and cumulative, rarely visible on productivity dashboards, until it surfaces as attrition.

Closely related, a relatively frequent aspect of the *Meaning displacement* dimension concerned the decline of intrinsic motivation among practitioners ($f = 12$). Participants associated this decline with the increasing capabilities of GenAI tools and with the tasks they take over, in particular coding activities. This insight aligns with the key findings of Wu et al. [53], who show that immediate productivity gains may come at the cost of long-term psychological and motivational outcomes for practitioners.

Taken together, these findings raise a broader question: whether the ongoing shift toward higher levels of abstraction is truly necessary or desirable. The question becomes particularly relevant once we consider that, at the current state of the technology, GenAI tools applied to lower-level activities such as code generation still frequently introduce vulnerabilities, bugs, and other technical issues [24, 38, 43] that can lead to long-term problems such as technical debt [3]. Paradoxically, the industry narrative often encourages engineers to step away from the activities in which they find the most engagement, while relying on AI for tasks in which the risks remain comparatively higher.

## 5.2 Implications for Practice

From a practical standpoint, we offer the following suggestions for practitioners:

- **Practitioners should monitor developer displacement.** The proposed notion of AI-induced displacement can serve as a diagnostic instrument for managers, allowing them to assess how employees experience GenAI integration beyond productivity metrics. In addition, managers should take the different dimensions into account in order to make informed and specialized decisions.
- **Companies should carefully consider the shift in tasks.** Our findings discuss the skills that practitioners consider central in the GenAI era. In this respect, the results indicate that SE curricula may need to shift toward skills such as critical AI oversight and architecture-level thinking. This shift, however, clashes with the preferences of younger developers; rather than immediately modifying activities, we suggest first discussing the actual preferences within teams. Increased productivity in the short term can mean a drastic reduction in efficiency in the long term.
- **Compatibility of AI tools is crucial and should always be a priority.** AI-induced displacement is largely influenced by the compatibility of the approved tools. Rather than adopting the best tool on paper, we recommend dialogue and greater customization of tools to make developers feel comfortable and more effective in their work.

## 5.3 Future Research Directions

Beyond its practical contributions, our study provides a foundation for future research:

- **Researchers should use and further validate the proposed notion.** Starting from our dimensions, researchers can (1) better contextualize their work, (2) expand in terms of dimensions, and (3) conduct more structured work, building on top of our notion.
- **Conducting longitudinal investigations of AI-induced displacement.** Since the progress of GenAI technologies is rapid, we acknowledge that displacement is unlikely to be static. Future studies could examine how AI-induced displacement evolves over time, and whether initial disruption leads to adaptation, resistance, identity reconstruction, or skill transformation.
- **Linking displacement to concrete outcomes.** The present work provides a theoretical foundation for approaching and comprehending displacement in SE caused by AI. Future research could quantitatively examine the downstream consequences of AI-induced displacement on individual well-being, motivation, performance, and career trajectories.

## 6 Threats to validity

This section outlines the threats to the study's validity and how we mitigated them.

**Construct validity.** The conceptual framing of the proposed notion of AI-induced displacement poses a potential threat to construct validity, since the term is not yet established in the literature and may appear in forms we overlooked. We conducted broad database searches to capture multiple angles of displacement. In addition, the wording of the interview questions could itself introduce bias into the responses. We followed established protocols, reviewed the questions as a team, and conducted a pilot session to minimize this risk. However, we view open-ended, exploratory instrumentation targeting unexplored areas, such as technical and organizational, as a valuable direction for future work.

**External validity.** The main threat concerns the transferability of our findings beyond the sample. Acknowledging that risk, we increased the interview sample despite reaching substantial theoretical saturation at twelve interviews, and we sought diversity in roles, experience, and geographic location to limit role-, experience-, or culture-specific biases.

**Internal validity.** Researchers' interpretations could affect thematic analysis outcomes, since coding may be influenced by prior experiences and beliefs. For this reason, two authors collaboratively conducted the coding process of the data. Although we did not compute inter-coder reliability metrics such as Cohen's Kappa, thorough analytic meetings followed the analysis to resolve differences in interpretation. Finally, the interviewees may have introduced social-desirability bias in their responses. To counter this, we assured participants of their confidentiality and thereby encouraged honest accounts of their thoughts and experiences.

## 7 Conclusions

This work offers a first step toward defining a construct that captures the experience of displacement among SE professionals as GenAI enters their daily work. We identify a set of dimensions that characterize this phenomenon and describe, for each dimension, the experiences reported by practitioners. These insights help clarify how software engineers undergo such forms of displacement, when and to what extent they emerge, and which consequences and underlying causes are associated with them.

Building on this foundation, we plan to extend our work through a large-scale quantitative evaluation of the presence and prevalence of these dimensions in practitioners' professional lives. Future work includes a mixed-methods study to develop a validated instrument capable of measuring the dimensions we identified. This step will enable concrete measurement of AI-induced displacement, completing the conceptual-to-operational transition of the construct, and opening the way to large-scale investigations in both industry and research settings.

## Data Availability Statement

The detailed protocol, interview structure, and examples of the data analysis are available in our Figshare replication package (`https://doi.org/10.6084/m9.figshare.31803529`). We do not release the full coding spreadsheet, as participants' consent covered the use of anonymized illustrative excerpts rather than publication of the complete corpus, which could pose confidentiality risks.

# Assessing the Construct Validity of Object-Oriented, Class-Level Code Quality Metrics

**Hera Arif**
Dalhousie University, Halifax, Canada

**Miikka Kuutila**
LUT University, Lahti, Finland

**Paul Ralph**
Dalhousie University, Halifax, Canada

## Abstract

**Background.** Code quality metrics are intended to measure latent properties of software source code. Although numerous code metrics have been proposed and used, their construct validity is rarely evaluated. Thus, the extent to which code metrics actually measure what they claim to measure is often unclear.

**Aim.** Drawing from modern measurement theory, we investigate the construct validity of common class-level, object-oriented code quality metrics.

**Method.** As code quality metrics are intended to reflect latent attributes, such as cohesion and coupling, we identified the factor structure of code quality metrics using *Exploratory Factor Analysis* (EFA). The metrics were extracted from the Apache Maven project by three software tools: *Designite, JHawk,* and *Understand*. The factor structure was later verified using *Confirmatory Factor Analysis* (CFA) on 22 randomly selected open source projects meeting a predetermined eligibility criteria.

**Results.** 24 code quality metrics that correspond to six constructs: *Cohesion*, *In-Coupling*, *Out-Coupling*, *Size*, *Sub-Inheritance (related to subclasses)*, and *Sup-Inheritance (related to superclasses)* were revealed in the underlying factor structure. Ten metrics did not correspond to any known dimension of software quality and were removed in the exploratory analysis. Ten additional metrics exhibited low loadings in the confirmatory analysis, suggesting their removal from the final measurement model. *Size, Cohesion, Inheritance,* and *Coupling* were the constructs retained, with subcategories identified for *Inheritance* and *Coupling*.

**Conclusions.** Our results strongly support the construct validity of 24 code quality metrics. *Coupling* and *Inheritance* are revealed as multidimensional constructs, since they require measuring two different concepts, revealed as sub-categories in our analysis, and *Complexity* may be better explored in a multilevel model. Our results also corroborate the relationship between *Cohesion*, *Size*, and *Out-Coupling* which can be further explored in a structural model. Some metrics from the Chidamber & Kemerer metrics suite are found to perhaps be measuring different constructs than intended. Our results reveal the need for creating or integrating metrics that reflect existing constructs but measure fundamentally different properties to improve the content validity of the measurement model. Additionally, we provide useful recommendations for researchers, developers, and tool providers which stem from theoretical and empirical justification. Overall, our study demonstrates the value of applying modern measurement theory and latent variable modeling in validating software code quality metrics.

## 1 Introduction

Code quality metrics provide quantitative measures that evaluate attributes of a software system. Here, code quality refers to the characteristics of source code that influence its overall quality, including complexity, modifiability, understandability, and testability. Accordingly, efforts to improve software quality generally target these quality attributes, either explicitly or implicitly [63]. Code metrics are used by developers to provide insights about the attributes of software, and are a popular topic of interest for software developers and researchers. Despite the proliferation of proposed metrics, metrics research suffers from several persistent challenges. The software development industry appears to rely on metrics in a very limited manner [63]; while measurements in other fields form the foundation of a successful system, software developers often favor popular, easy to compute metrics [52, 58]. More fundamentally, a key insight in both recent philosophy of science and theory of measurement is that observation is intrinsically problematic [51]. Most observations are mediated by instruments and measure the effects of "latent" structures rather than the structures themselves. In this vernacular, source code is a *latent structure* because we cannot directly observe its execution without instruments (e.g. computer screen, IDE, debugger, terminal window). Important aspects of code such as size, complexity, coupling, and cohesion are *constructs* because, again, we cannot observe them directly. We *operationalize* a construct using one or more *metrics* (e.g. a script that counts lines of code).

Thinking about code metrics this way highlights several problems:

- The instrument is defective or does not do what the researcher thinks it does (e.g. script for counting lines of Java code that accidentally counts commas instead of semicolons).
- The instrument measures the property correctly, but the property is not caused by the target construct (e.g. the researcher aims to measure complexity, but counts lines of code, which is caused by the system's size rather than its complexity).
- A multidimensional property like coupling (which has direction, strength, and granuality [10]) is operationalized using a single instrument (e.g. Chidamber & Kemerer's CBO [14]), which considers incoming and outgoing links as having equivalent strength, disregarding distinctions between these dimensions).
- An instrument correctly measures the target property, but the property is caused by multiple constructs (e.g. the McCabe [45] and Halstead [30] metrics are commonly used to measure complexity, but they are highly correlated with the lines of code in a system [26]).

Construct validity concerns problems like these–validation refers to the process of ascertaining if an indicator actually measures the aspect it proposes to measure (theoretical validation) and asserting that the indicator relates to other similar measures in an expected way (empirical validation) [52]. Assessing how well an indicator operationalizes a construct is crucial for the integrity of a measurement. Given the abundance of existing and newly proposed metrics, without a corresponding emphasis on validating them, it becomes challenging to assess how well a metric aligns with the underlying construct it intends to measure. Currently, metric's measurement is mostly dependent upon what a software developer understands the metrics definition to be [57, 62]. For example, metrics with the same name are implemented by two tools differently and differ in the resulting measurement values if applied to the same software code (see § 3.1.2). Moreover, code quality metrics defined at the method-level are being used to infer information about class-level attributes–the results of a method level complexity metric (CC [45]) is being averaged to analyze the complexity of a class as a whole (see § 3.1.1). This results in a bad metric value being masked and compensated by good metric values, influencing the overall result. Another example is that of Maintainability Index

(MI) which is considered a proxy of software maintainability, however, a multifaceted concept like maintainability cannot be fully captured by a single metric [60]. In fact, metrics chosen to represent maintainability may influence the outcome more than the actual maintainability of code [59]. This may mislead professionals by providing them a false sense of confidence in their decisions, or discourage them from relying on code metrics when making important decisions altogether [16, 59, 63], undermining the very purpose of code metrics, which is to offer scientifically grounded evidence for the measurement of concepts.

Thus, the aim of this study is to investigate the validity of common code quality metrics and the research question of this study is as follows:

> **Research Question:** Do object-oriented, class-level, code quality metrics measure the latent quality attributes they are supposed to measure?

To accomplish this, we conduct an *Exploratory Factor Analysis* (EFA)–a statistical approach used to discover "factors", "constructs", or "latent variables" from a set of variables (in our case code quality metrics) by analyzing the correlations between them [28]. This is followed by a *Confirmatory Factor Analysis* (CFA)–which tests the model revealed by the EFA to assess how well the specification of factors and variables represents actual data [29].

## 2 Related Work

In this section, we provide an overview on the theory of measurement, the current state of metrics literature and prior research related to our study.

### 2.1 Contemporary Theory of Measurement

Measurement is the principled assignment of numbers to reality [11]. A metric is the process of representing a phenomenon numerically. Operationalizing unobservable phenomena using a single metric is philosophically and methodologically outdated because it assumes measurement is unproblematic and ignores mono-method bias [51]. Instead, contemporary measurement theory suggests constructing measurement models that operationalize each phenomenon (latent variable) as the shared variance of multiple diverse metrics.

Software maintainability, flexibility, understandability are external quality dimensions that researchers acknowledge cannot be observed directly. Whereas, software complexity, coupling, cohesion, are specific internal quality criteria that researchers strive to measure directly using new or improved metrics. However, multiple metrics differ slightly and sometimes significantly when measuring the same construct (see § 3.1.2). This suggests that metrics are indirect measures and should not be used as a direct representation of the construct. Thus, code quality is a *latent structure* and metrics can be considered indicators that measure a theoretical concept that cannot be measured directly [33].

### 2.2 Current State of Code Quality Metrics Research

A code quality metric, in essence, measures attributes of a software by analyzing its source code. For example, LOC measures the lines of code of software code. Initially, research related to code quality metrics focused on size and complexity metrics like LOC, CC [45], and the Halstead metrics [30] but then shifted to object-oriented (OO) metrics like the C&K [14], MOOD [1], and Martin's design metrics [44, 58]. Researchers are increasingly trying to determine factors that are holding back metrics research and how these problems can be fixed [63]. Some common criticisms are as follows. **Limited use:** Code quality

metrics' impact on software development is underexplored, with metrics like LOC and CC used commonly; while others ignored or used rarely [58]. **Lack of precise definitions and guidelines:** Every new metric is expected to provide a sound theoretical foundation and a precise definition, which seem to be lacking in the present literature [58]. Additionally, there are numerous discrepancies in the naming conventions of metrics. For example, Depth of Inheritance Tree (DIT) is also called Depth of Inheritance (DIH) but both these metrics measure the maximum length of a tree from node to root [56]. **Shift towards code smells:** More recently, code smells are used as a metaphor to depict patterns commonly linked with poor design and programming practices [57]. However, the idea of code smells departs significantly from contemporary theories of measurement. Code quality is a latent structure whose measurement requires a statistical measurement model that specifies the dimensions of code quality and operationalizes each of them as the shared variance of multiple indicators. The presence or frequency of one or more code smells could constitute some of the indicators in this measurement model. However, focusing only on code smells to measure code quality is insufficient and doesn't exempt the researcher from constructing a sound measurement model and quantitatively assessing its validity. **Rise of agentic code:** As software developers incorporate more agentic code generation, a simultaneous increase in assessing the quality of code generated by AI is observed. Recent studies have employed the use of traditional code quality metrics like MI, LOC, and CC to understand the quality of agentic code developed by various generative AIs like GitHub Copilot [1], ChatGPT [2], etc. [35, 49]. These studies highlight generative AI's focus on accelerating programming, sometimes even at the expense of code quality. **Poor validation:** Over the years, researchers have proposed numerous approaches for validating software metrics. Some researchers propose a set of "validity criteria" to assess metrics [65]. Weyuker et al. [65] define a set of "properties" for complexity metrics; and while Cherniavsky et al. [13] and Fenton [21] disagree with this approach, Chidamber et al. [14] support it. Another example is the findings of a literature review by Meneenly et al. [46] that reports 47 validation criteria for software code quality metrics highlighting the ad-hoc nature of metrics validation as well as conflicting and subjective perspectives among researchers. Some studies interpret correlation as validation, considering metrics valid if they are correlated with other metrics measuring the same construct [21]; however, correlation and validation are not interchangeable. Some empirical studies consider metrics as predictors of external features and consider this relationship as evidence of metric validity. Basili et al. [3] investigated the C&K metrics suite's [15] effectiveness as predictors of fault proneness and Briand et al. [8] investigated the relationship between object-oriented metrics and the likelihood of fault detection in classes. They found that metrics were effective [3] but redundant [8] as they captured similar attributes of the software. Emam et al. [20] and Gil et al. [24] studied the relationship between external quality attributes and size metrics. They recommended that future studies take the confounding effect of size into consideration when investigating the validity of metrics. Researchers have also attempted to create unified frameworks for software quality measurement (such as [5–7, 39]). These studies emphasized the need for stronger theoretical foundations for software measurement and the need for further research into scientifically sound methods for measuring software to ensure valid measurements. They also highlighted that metric's validation remains an unresolved challenge that must be addressed to achieve reliable measurement of software quality.

[1] https://github.com/features/copilot
[2] https://chatgpt.com/

The underlying *factor structure*–the relationships that exist between variables (code quality metrics) and the constructs they are supposed to be measuring, is not taken into consideration in most metrics research and unvalidated metrics are used as *direct measures* to measure code quality constructs (such as size, complexity, and cohesion) [52]. The metrics literature appears to overlook the distinction between direct measures and indirect proxy measures and largely focuses on identifying a single direct metric that can be applied to every objective [4, 21]. Consider two variants of C&K's LCOM [14]: LCOM2 [15] and LCOM5 [32]; they are both meant to measure the cohesion in software code, so a strong correlation between them is expected. In fact, this is not the case (see *Discussion*). These issues are addressed by "construct validity"–the degree to which a warranted inference can be made for a construct using a measure. Construct validity includes assessing: *face validity*–does a measure "on its face" seem to be a good measure of the construct?, *content validity*–is the measure representative of relevant domain related to the construct?, *convergent validity*–how similar is the measure with other measures it should be theoretically similar to?, *discriminant validity*–how different is the measure with other measures it should theoretically be different to?, and *predictive validity*–does the measure predict something it should theoretically be able to predict? [64].

## 2.3 Prior Research on Factor Analysis and Code Metrics

Munson et al. [47] performed an EFA to reduce a number of complexity metrics into a smaller set of independent complexity domains. They analyzed 106 modules and 16 software complexity code metrics produced by their Ada Metric Analyzer to group complexity into five constructs: control, size, information content, modularity, and data structure. Al et al. [41] conducted a study to identify the efficiency of traditional metrics in measuring the complexity of OO code. They used the CPPOOM (C++ ObjectOriented Metric) tool to calculate metrics on four C++ systems, analyzing 43 trees and 222 classes, to reveal four complexity constructs. They concluded that traditional metrics loaded on a single factor and were correlated with other traditional metrics and encouraged further research on the topic. Cook et al. [17] conducted a study to analyze ten releases of a real-time telephone switching system written in a macro-assembly language. They calculated 18 complexity metrics and conducted a principal components analysis to reduce dimensionality. The results revealed four complexity domains: size, information flow into/out of functions, and control flow.

Prior research in this domain seems to focus on a single construct of complexity with the aim of finding sub-categories or performing dimension reduction [17, 41, 47]. These studies are conducted over 30 years ago with a small dataset of code quality metrics and lack implementation details. We aim to build upon this research by considering numerous metrics and constructs, and providing a publicly accessible dataset with a comprehensive replication package that can be used to re-implement our analysis and ensure accuracy and reliability.

# 3 Methodology

Assessing the construct validity of code quality metrics requires a (rudimentary, incomplete) theory of code quality that can be generated inductively from data by examining the factor structure of metrics using factor analysis. Briefly, our methodology involves selecting some source code to be fed into software tools that calculate code quality metrics. These metrics are screened and excluded if not appropriate for a factor analysis. The construct validity of the resulting metrics is then assessed iteratively using an exploratory and a confirmatory factor analysis revealing six constructs comprising 24 metrics. All statistical analysis is performed with R version 4.3.2, using the R packages `psych` [53] and `lavaan` [54, 55].

## 3.1 Exploratory Factor Analysis

As the name suggests, an EFA "explores" the underlying factor structure represented by variables to develop a measurement model [29]. Our objective is to assess the construct validity of common, object-oriented, class-level, code quality metrics. We followed the method outlined by Hair et al. [28] to conduct an EFA by performing the following steps.

### 3.1.1 Designing the Factor Analysis

To assess the factor structure of the code quality metrics, we must compute metrics for some code. Representative sampling is neither practical nor desirable for the initial, exploratory stage (see *Limitations*). Rather, we want a single project that is large enough for the factor structure to emerge but small enough that the codebase is comprehensible. To avoid becoming overwhelmed by complexity, we begin by focusing on class-level Java metrics because both the language and quality concepts would be familiar to many researchers interested in software metrics. This includes many popular metrics (e.g. C&K [14], L&K [42], MOOD metrics [31]).

- **Tools Selection Criteria:** The software tools must calculate a wide range of class-level metrics, and must be able to analyze large projects containing mainly Java code.
- **Project Selection Criteria:** In a preliminary, exploratory phase, we only require a project with enough observations for the factor structure to emerge–which is a property of the variables themselves and not the objects of the study (see *Limitations*). Additionally, the project should contain at least 10 observations per variable [28].
- **Class Selection Criteria:** Exclude any classes for which one or more selected tools cannot calculate *any* metrics.
- **Metrics Selection Criteria:** Metrics should be numerical, at an ordinal, interval, or ratio level. They should measure something about the code structure at class-level that corresponds to an identifiable construct, and should not be a function of method-level metrics.

The software tools selected were: Designite,[3] Understand,[4] and JHawk[5] which calculate 11, 45, and 40 class-level code quality metrics respectively, yielding a total of 96 metrics. These tools are popular for metrics research because they each contain a wide range of metrics found in the literature and are calculated at different levels (e.g. file, class, method level). There could be other tools that meet our selection criteria. It is not necessary for our purposes to include every tool that meets the above criteria. We selected the *Apache Maven* project,[6] a popular open-source Java tool used to manage external dependencies and automatically build software projects as the selected project should contain at least 960 classes (10∗96). The Apache Maven source code was downloaded from its GitHub repository [6] and compiled. It contains around 1,300 classes which are sufficient for our analysis. Special Java classes like enums, anonymous, or nested inner classes are not recognized by some tools so they are excluded from our analysis (e.g. Understand does not calculate LCOM metrics for enums). Non-numerical metrics such as NAME OF SUPER CLASS were excluded. Some metrics were calculated at the method-level and summed to produce a class-level measurement. For example, CC is calculated at the method-level to estimate class complexity. We exclude such metrics because there are more sophisticated ways of handling this situation

[3] DesigniteJava Enterprise (v. 2.1.2), `https://www.designite-tools.com/`

[6] Apache Maven (v. 2.0), `https://github.com/apache/maven`

(see *Future Work*). To determine which construct each metric ostensibly reflects, we refer to the documentation provided by the software metric tools. For metrics that were not categorized into any constructs, we reviewed the metrics literature. A complete list of the included and excluded metrics and their mapped constructs is provided in the replication package (see *Data Availability Statement*). Based on the selection criteria, 33 metrics out of the 96 metrics calculated were excluded. The final dataset contains measurements from 35 size metrics, 6 cohesion metrics, 11 inheritance metrics, and 11 coupling metrics–63 in total. We aim to classify these metrics into five factors: size, cohesion, inheritance, in-coupling, and out-coupling, following the classification provided by the software tools. Table 1 shows a brief explanation of these factors in terms of class-level.

**Table 1** Definition of factors at class-level.

| Factor | Description |
|---|---|
| **Size (S)** | The size of the class |
| **Cohesion (C)** | Degree to which elements in the class belong together |
| **Inheritance (I)** | Degree of hierarchical class reuse and extension |
| **In-Coupling (InC)** | Degree to which the class is used by other classes |
| **Out-Coupling (OutC)** | Degree to which the class is dependant on or uses other classes |

### 3.1.2 Test Assumptions of Factor Analysis

Factor analysis conceptually assumes that an underlying factor structure exists in the data that is to be analyzed. The purpose of this study is also to reveal this underlying factor structure and to assess its validity. Factor analysis assumes a homogeneous sample of measurements which our dataset complies to. The correlation matrix for our dataset has numerous correlations greater than 0.3 indicating a correlated set of variables appropriate for factor analysis [28]. Since the tools calculate some of the same metrics, some metrics (e.g. *Size.NOM.Understand* and *Size.NOM.JHawk*) have a perfect linear relationship (singularity) indicating a valid measurement. More surprisingly, seemingly different metrics are identical, e.g. *Inheritance.DIT.JHawk* and *Inheritance.CountSup.JHawk* have a perfect linear relationship and *Size.CountDeclMethodDefault.Understand* and *Size.CountComment.JHawk* are highly correlated ($r = 0.83$). Nine such metrics were removed as they caused a "not positive definite" (NPD) which is not factorable. Excluding these nine metrics has little effect because they are so tightly correlated with remaining metrics. The Kaiser–Meyer–Olkin (KMO) test to assess sampling adequacy found the dataset "meritorious" [37] ($KMO = 0.84$). Bartlett's test of sphericity was significant ($p < 0.001$), indicating correlated variables. The final dataset consists of 1279 observations (classes) and 54 variables (code quality metrics)–a ratio of approximately 20 observations per variable, which is higher than the recommended minimum sample size and thus acceptable for conducting factor analysis [28].

### 3.1.3 Derive Factors and Assess Fit

We used multiple methods to determine the number of factors to extract: parallel analysis [34] suggests 22 factors, the scree plot [12] suggests 2 or 8 factors, and the Kaiser criteria [38] suggests 8 factors. These methods could overestimate the number of factors (an over-fit model) in very large datasets like ours and involve some degree of subjectivity [12]. A combination of methods can be used to make a definitive decision and prior theoretical knowledge of the expected number of factors can be very beneficial in making this decision [18]. According to theory, we predict five factors: size, cohesion, inheritance, in-coupling, and out-coupling

(Table 1). So, we begin with eight factors since that is the largest reasonable estimate of the number of factors (the parallel analysis estimate of 22 factors is prima facie unreasonable). The number of factors retained should have an explained variance of at least 60% [28]. Our initial eight-factor model explained 71% of the variance.

### 3.1.4 Interpret Factors

We rotate the solution using an *oblique*, "oblimin" rotation as it assumes factors are correlated [28]. The construct validity of the metrics is assessed iteratively using an exploratory factor analysis. The factor solution obtained needs refining as it is overcomplicated and contains numerous unacceptable factor loadings–a *factor loading* explains how much of a variable's variance can be explained by the factor [28]. A high loading means that the variance explained for a variable is sufficient for it to have a considerable relationship with the factor. The factor solution also contains low communalities (h2) which is the amount of variance in a variable that can be explained by the factor solution extracted by the EFA [22]. We perform the following steps to refine the model.

1. **Remove variables with low loadings (< 0.5) and low communalities (< 0.5) in the eight-factor model:** We iteratively removed such variables, rerunning the factor analysis after each removal until no such variables remain (the loadings and communalities change every time a factor analysis is run). Eight variables were removed, increasing the variance explained by the factor model to 83%.
2. **Reduce from eight to six factors:** In the eight-factor model, the *Inheritance* and *Size* variables each loaded on more than two factors, suggesting an over-fit, so we re-ran the factor analysis with fewer factors to investigate. Despite some cross-loadings, we could label the factors more easily and clearly in the six-factor model, which map well into our a-priori constructs: *Size, Cohesion, In-Coupling, Out-Coupling*, and two types of inheritance–*Sub-Inheritance* and *Sup-Inheritance* that measure the characteristics of a class related to its sub-classes and super-classes respectively. The variance explained by the factor model decreased to 74%.[7]
3. **Remove variables with low loadings (< 0.5) and low communalities (< 0.5) in the six-factor model:** Similar to before, we iteratively remove such variables, rerunning the factor analysis after every removal. Two variables were removed, increasing the variance explained by the factor model to 76%.
4. **Remove variables loading on the incorrect factor:** We analyzed the model for variables loading on the wrong construct, deleting them in order of lowest communalities, and ignoring cross-loadings hoping they would integrate into a single high loading. Ten metrics were removed, increasing the variance explained by the model to 85%.

### 3.1.5 Exploratory Factor Analysis Results

Table 2 shows the final solution, which explains 85% of the total variance with the six factors extracted, which is above the recommended minimum threshold [28]. Each factor contains at least three variables, and correspond to the theorized classification (Table 1), with sub-categories revealed for *Inheritance* i.e. *Sub-Inheritance* (related to sub-classes),

[7] The variance explained by a factor analysis increases monotonically with the number of factors extracted, so reducing the number of factors will *not* increase the variance explained even if the model is better in other ways.

and *Sup-Inheritance* (related to super-classes). The Cronbach's $\alpha$ for the overall model is $\alpha = 0.92$, which is considered "excellent". The Cronbach's $\alpha$ for each individual factor in the model also has acceptable values indicating internally consistent variables in the model [19].

## 3.2 Confirmatory Factor Analysis and Results

We followed the method outlined by Hair et al. [29] to test the pre-specified measurement theory obtained from the EFA and assess how well the theory fits population data. The steps followed are described below.

### 3.2.1 Define Individual Constructs

Considering the 34 code quality metrics measuring six constructs revealed as the result of the EFA, the conceptual definitions of constructs match well with the item wordings, and the relationships are corroborated by previous literature, scholarly peer-review, and tool documentation, thus establishing reasonable face validity. Some metrics seem to clearly be measuring a specific construct (for example, COUNT LINE measures *Size*); and some metrics seem to be conflated (for example, CBO measures both incoming and outgoing dependencies and seems to be conflated between *In-Coupling* and *Out-Coupling*)–therein lying the motivation of this paper.

### 3.2.2 Develop the Overall Measurement Model

The six latent constructs may correlate with each other as they would in real software where quality dimensions are congeneric. An indicator variable loads on a single construct and error variances between indicators exist but are not allowed to correlate. Every construct is identified with a minimum of three indicators per construct asserting an ideal "over-identified model"–a model with more degrees of freedom than paths to be estimated ($dof = 512$). In the proposed model, all constructs are hypothesized as *reflective* making the direction of causality from the latent construct to the measured indicator variables.

### 3.2.3 Design a Study To Produce Empirical Results

We used the SEART GitHub Search Engine[8] to collect a sample of Java projects by applying minimum selection thresholds. These criteria were intended to identify professionally developed and actively maintained projects, rather than hobby or dummy projects. We obtained 71 Java projects, out of which, 64 projects could be compiled using the popular build tools Maven,[9] Gradle,[10] or Ant[11]. Any project used in the exploratory analysis cannot be used in the confirmatory phase; thus, one project was excluded. Since we need compiled code to conduct the analysis, we selected the 63 projects and shuffled them using Python's `random.shuffle` method, and downloaded and compiled them. We need a minimum of 340 classes to conduct the CFA ($34 * 10$) [29]. Since we can get a much larger dataset, we decided to use workload as the deciding factor of sample size. We aim to complete data collection in two weeks (80 hours). Downloading, compiling, and preparing each project takes approximately 3.75 hours.

$$Numberofprojects = \frac{80hours}{3.75hours/project} = 21.33 \tag{1}$$

Thus, 22 projects (1) were included in our analysis. [12] The smallest project included had 506 classes, and the largest project included had 19,833 classes ($M = 3063$). A list of the parameters set and additional details about the included projects can be found in the replication package (See *Data Availability Statement*). A process similar to the one described in § 3.1.1 was followed to extract the code quality metrics collected by Designite, JHawk, and Understand and combine them into a single spreadsheet. Creating a combined dataset does not affect the results of the analysis since we are performing instrumentation not prediction. Given the number of indicators and constructs, our sample size of approximately 100,000 is more than sufficient for analysis.

### 3.2.4 Assess Measurement Model Validity

A confirmatory factor analysis is conducted on the dataset and a six construct measurement model is produced (Table 3). The purpose of the factor analysis performed in this study was primarily to evaluate the relationship between commonly used software code metrics and their hypothesized constructs, and not to optimize a measurement instrument with a maximized global fit. Thus, some of the metrics showing weaker loadings were intentionally

[8] `https://seart-ghs.si.usi.ch/`
[9] `https://maven.apache.org/`
[10] `https://gradle.org/`
[11] `https://ant.apache.org/`
[12] All the data collection was completed by May, 2025

retained during model evaluation to assess their behavior within the proposed construct structure. Consequently, we also do not report overall fit indices, as we are investigating whether metrics measure the latent quality attributes they are supposed to measure, and not what is the most accurate way to do so.

**Table 3** Six Construct CFA Result.

| | **Size** | **Out-C** | **In-C** | **C** | **Sub-I** | **Sup-I** |

*Values below the diagonal depict correlations among constructs and values above the diagonal depict squared correlations

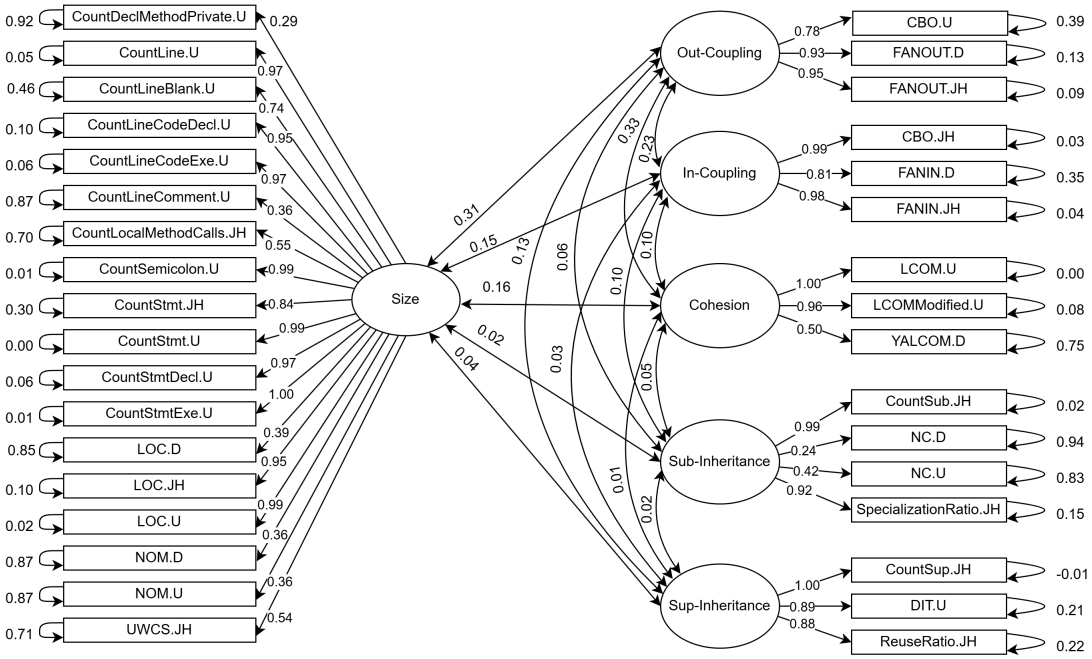
We now assess the validity of the measurement model obtained by assessing the following.

1. **Face, Nomological, and Predictive Validity:** Face validity was established before the factor analysis was conducted (see § 3.2.1). Nomological validity can be estimated by looking at the correlation between constructs and concluding if they make sense. All correlations between the constructs in the model are statistically significant at $p < 0.05$, as

expected. There is a moderate positive correlation between *Out-Coupling* with *Cohesion* ($r = 0.33$) and *Size* ($r = 0.31$). Other correlations are positive and low. This also satisfies predictive validity in a way that constructs posit predicted causal relationships.

2. **Content Validity:** We are limited to the metrics provided by Designite, JHawk, and Understand. These tools are frequently used in research related to software code quality, so we presume that these metrics cover the breadth of the constructs.
3. **Convergent Validity:** Convergent validity is estimated using several techniques (Table 3). The *standardized factor loadings* are acceptable for most variables ($> 0.7$). Variables with low loadings load majorly on *Size* suggesting further investigation into their inclusion in the model. Two loadings are greater than one (have an error variance less than zero)–*Cohesion.LCOM.Understand* ($e = -0.004$) and *Sup-Inheritance.CountSup.JHawk* ($e = -0.007$), a "heywood case". This can occur as a compensatory mechanism for high residual correlation between highly correlated variables that causes an inflated loading [9, 36]. The *AVE* and *CR* of all constructs in the model have acceptable values–($> 0.5$) and ($> 0.7$) respectively, indicating good convergence and internally consistent variables in constructs [29]. Overall, problematic variables do not appear to be significantly harming model fit or internal consistency and sufficient evidence of convergent validity is provided.
4. **Discriminant Validity:** We compared the squared correlations between constructs with the AVE values for all construct pairs in the model and found that the AVEs were greater, indicating good discriminant validity (Table 3).

## 4 Results



In this section we answer our research question directly:

**Research Question:** Do object-oriented, class-level, code quality metrics measure the latent quality attributes they are supposed to measure?

**Answer:** At least 24 object-oriented, class-level metrics appear to measure the construct they are intended to measure, while the inclusion of 10 metrics needs further investigation.

Figure 1 illustrates the measurement model with six latent constructs measured reflectively by 34 indicator variables. To be more precise, of the 63 metrics we assessed:

- 24 metrics seem to reflect the construct they are intended to reflect; i.e. they measure what they are supposed to measure.
- 10 metrics do not reflect any of the constructs in the model (including the construct they are intended to measure); i.e. they do *not* measure what they are supposed to measure.
- 10 metrics loaded on the wrong factor; i.e. they do *not* measure what they are supposed to measure.
- 9 metrics caused an NPD matrix; i.e. our analysis is inconclusive regarding whether they measure what they are supposed to measure.
- 10 metrics load low in the CFA, i.e. their inclusion in the model needs further investigation.

Note: The acronym at the end of the metrics corresponds to the tool being used, with U corresponding to Understand, JH to JHawk and D to Designite

**Figure 1** Measurement Theory Model for Code Quality Metrics.

## 5 Discussion

Our results are surprising in several ways. First, numerous widely cited code quality metrics appear not to measure the construct they purport to measure. For example, multiple metrics proposed by Chidamber et al. [15] were excluded from the final measurement model– *Coupling.RFC.Understand* was removed from the EFA because of low communality and *Cohesion.LCOM2.JHawk* was removed from the EFA because it loaded on *Size*. Additionally, *Sub-Inheritance.NC.Understand* and *Sub-Inheritance.NC.JHawk* loaded low in the CFA suggesting their removal. The fact that so many metrics could be proposed, implemented, and used without anyone demonstrating that they reflect the underlying construct of interest suggests a worrisome lack of concern for construct validity in code metrics research. Researchers should shift their perspective of *proposing* software metrics as the ultimate research objective to instead focusing on *validating* software metrics by adhering to the science of the theory of measurement to ensure that reliable and valid measurements are produced [27, 51, 63].

Second, the *lack* of multicollinearity problems is surprising. Highly (or perfectly) correlated variables prevents the factor structure from computing (the dreaded "NPD matrix"). Meanwhile, the three tools we studied compute many of the same metrics; for instance, all three tools compute LOC, NC, and NOM. Retaining two implementations of the same metric *should* make the *factor analysis* fail, and in some cases it did, but in many cases it did not. The fact that the model includes, for example, numerous LOC metrics, suggests non-trivial differences in the way the three tools compute LOC. As another example, *Inheritance.DIT.Designite* is not highly correlated with *Inheritance.DIT.JHawk* ($r = 0.271$) or *Inheritance.DIT.Understand* ($r = 0.332$). Investigating these differences is beyond the scope of the present study, but something seems wrong here. We retained seven metrics that were calculated by at least two tools: LOC, NC, COUNT STMT, NOM, FANIN, FANOUT, and CBO.

Third, the relationships between the code quality constructs identified in our analysis support our theory that the constructs are correlated with each other, but not to the extent that they measure the same underlying concept. We found a moderately positive correlation between *Out-Coupling* with *Cohesion* ($r = 0.33$) and *Size* ($r = 0.31$). These relationships are also observed in the literature [52] motivating further research, particularly when extending the measurement model to include inter-construct relationships to form a structural model.

Fourth, some metrics are inherently conflated but are popularly used to measure a singular concept. We have established from our analysis that *Coupling* is a multidimensional concept and popular measures (like *Out-Coupling.CBO.Understand*) are conceptually conflated as they measure the incoming and outgoing connections between code entities. Thus, CBO measures two different concepts and cannot be combined in an attempt to capture both aspects at once [52]. Our previous discussion (see § 2.1) on code quality metrics becoming increasingly detached from science and theory of measurement seems applicable here: measurements should have clear objectives and specify the entities of interest and their significant attributes to ensure reliable and valid measurements [4, 21, 27]. In the case of software code quality, perhaps the high interrelation of code quality constructs often makes it difficult to determine which indicators correspond to which constructs. This observation has also been highlighted by researchers in the past who notice a focus on empirical validation over theoretical validation:

- Fregnan et al. [23] and Gomez et al. [25] discovered that most metrics research primarily focused on empirical validation through comparisons with existing indicators or by assessing correlations; disregarding theoretical validation.
- Kitchenham et al. [40] highlighted that researchers repeatedly empirically validate popular metrics proven to be theoretically invalid; rendering their analysis meaningless.
- Stevanetic et al. [61] noted that validating a metric's relevance requires a theoretical justification supported by empirical evidence, which is reportedly missing in current metrics research.
- Briand et al. [7, 8] emphasized the need for stronger theoretical foundations in software measurement to ensure that metrics accurately measure their intended constructs.

Thus, theoretical *and* empirical validation of the relationship between metrics and constructs using appropriate techniques such as factor analysis is both essential and valuable, and should be encouraged [63].

Fifth, as AI agents become more widely used and AI generated code grows increasingly sophisticated, the need for humans to evaluate, assess, and understand this code also increases. This highlights the need for code that is understandable and readable, with code architecture that is easy for humans to interpret. Researchers are using code quality metrics as one way to assess the quality of AI generated code. For example, Murthy et al. [48] analyze the understandability, maintainability, and complexity of AI generated code using CC [45]. In such studies, metrics are treated as dependent or outcome variables and their effect on a code quality attribute is estimated / predicted. A measurement is only meaningful if it accurately reflects what it is meant to measure. If the measurement lacks validity, the conclusions might be misleading. This highlights the importance of developing valid metrics, benchmarks, and measurement models to support human effort in understanding code quality, which is an objective our research aims to address.

## 5.1 Recommendations

In light of the findings of this study and an understanding of the theory of measurement which emphasizes that the operationalization of a construct must stem from a theoretical and empirical justification, we offer the following recommendations for researchers, developers, and tool providers.

1. **DO** measure *Cohesion, In-Coupling, Out-Coupling, Size, Sup-Inheritance* and *Sub-Inheritance* using the corresponding metrics shown in Table 3. Both professionals and scientists should prefer these metrics.
2. **DO NOT** use the metrics recommended for exclusion from the model due to low / incorrect loadings or low communality; or use them with discretion.
3. **DO NOT** use new, unvalidated metrics; rather encourage validation of newly proposed metrics.
4. **DO** Estimate constructs using factor scores from a confirmatory factor analysis or similar technique.
5. **DO NOT** use individual metrics to estimate constructs.
6. **DO NOT** estimate constructs by averaging / aggregating metrics because metrics vary in distribution and relative importance to their corresponding construct. Use factor scores.
7. **DO** ask providers of software metrics tools to present factor scores and **DO** present factor scores in any tools you build.
8. **DO NOT** propose new metrics without quantitatively assessing construct and measurement validity using factor analysis or a similar technique.
9. **DO NOT** accept for publication manuscripts proposing more unvalidated metrics, or metric proposals without permanently archived source code (because written descriptions of metric algorithms are often incomplete).
10. **DO** use evidence standards (e.g. [50]) to design studies and assess manuscripts; **DO** ensure evidence standards require construct and measurement validity assessment for new metrics.

## 5.2 Implications

This study serves as a foundational step in the largely under-explored field of assessing the construct validity of software code quality metrics and paves the way for new research opportunities. This study serves as a guiding framework and encouragement for researchers to replicate, generalize, challenge, and extend our findings. To facilitate this, all data used in this study is openly accessible for replication and additional analysis (see *Data Availability Statement*). Researchers may also adopt this approach when developing new metrics to provide evidence of construct validity. The findings of this study encourage further exploration into the relationships between various software code quality constructs in addition to the relationships between variables measuring these constructs. Certain aspects of code quality are inherently subjective yet crucial for developers working with code written by others. For instance, Mannan et al. [43] reported the need for better measurement and modeling of readability as perceived readability is difficult to quantify and integrate into a measurement model. Therefore, further research is needed to evaluate such attributes and their potential incorporation into a structural model.

Software developers and professionals may prefer qualitative assessments such as experience, expert judgment, intuition, or code smells, over quantitative measures like code quality metrics because of the uncertainty in metrics' implementations and measurements. For example, our results find that C&K metrics like RFC, NC, LCOM2 [15] may not accurately capture the quality aspects they are intended to measure. On the other hand, developers and professionals are more likely to trust and adopt code metrics that show evidence of empirical validation (such as through a technique like *factor analysis*) to accurately measure what they claim to measure. Thus, the results of this study can assist professionals and developers in understanding their code and how code changes impact software quality, providing them with clear quantitative assessments and measures to support their decisions.

For tool developers, we recommend recalibrating the inclusion of metrics and thresholds. Tools must provide clear definitions and detailed implementations of metrics they include including specifying what variant of the metric is being used which is not the current practice. For example, Ardito et al. [2] report several software tools do not state what variant of the LCOM metric they calculate. Given the multitude of metrics proposed to measure the same code quality attribute – often yielding conflicting results for the same code – the inclusion of metrics should not be arbitrary nor based solely on their popularity, rather, the evidence of their validity must be the deciding factor for inclusion. Only metrics that reliably measure their intended construct should be used to establish appropriate thresholds.

## 5.3 Limitations

The recommendations above should be considered in light of several important limitations. Code metrics are not the only way of assessing code quality. Our focus on metrics is not intended as a criticism of any other approach to software quality (e.g. code smells, peer code review, automated testing). We make no claims about the validity of the nine metrics excluded to avoid an NPD matrix (see § 3.1.2). Some of these may be interchangeable with their corresponding, included metrics. We also had to exclude classes for which the tools we studied could not generate data. The usefulness of a metric in practice has other aspects that can be estimated using additional steps. We only focus on construct validity in this study. We need to determine that a measurement model has construct validity before we can assess whether measuring the target construct is practically useful since usefulness presupposes accurate measurement.

For high content validity, we need metrics that count *different* things that are all driven by the same construct. For example, for *Size*, the model includes related but different things like LOC and NOM, which is desired. In contrast, the three *Cohesion* metrics are very similar–*Cohesion* is measured using LCOM and its variants; which raises concerns about the content validity of the measure. Using overly similar metrics can create the illusion of convergent validity which is further corroborated by the existence of a heywood case in the CFA. Our current analysis, however, is limited to metrics that Understand, JHawk, and Designite calculate. Future work may involve solutions such as: adding or removing variables from the model, or increasing the sample size. We have established an extremely large sample size compared to the requirement of a factor analysis, so we suggest the addition of variables in the measurement model (removing variables in this case is not recommended since that would violate the three variables per construct rule).

Regarding generalization, we studied one programming language, three metrics tools, and object-oriented, class-level metrics only. We make no claims about other languages, tools, or abstractions. The metrics and tools studied are frequently used in research, but they might not represent the state of the practice. In terms of representativeness, our sample for the EFA consisted exclusively of the Apache Maven project because applying EFA on a huge dataset is not practical. This is not as serious as it seems because, in the exploratory phase, we only require enough observations (classes) for the factor structure to emerge–the factor structure is a property of the variables (metrics) not the objects of the study (classes). Our sample for the CFA included multiple Java projects. However, these projects may not fully represent all types of code, as they were open-source projects, that met a predetermined eligibility criteria. Thus, we suggest and encourage replicating our analysis with additional, closed-source and industrial software to examine any potential differences in the results.

Our study also has many strengths. As shown in Tables 2 & 3, reliability is high. Verifiability / replicability is also high because we studied a public repository and provide a comprehensive replication package (see *Data Availability Statement*). We demonstrate

novelty by highlighting surprising findings at the beginning of this section. Moreover, while applying the common factor model to code metrics is not entirely new, no prior studies have attempted as comprehensive a model as this one.

### 5.4 Future Work

This paper reports the first step in a larger research program aiming to improve the validity of code quality measurement. Subsequent steps in this research program include:

- Improving the content validity of the measurement model by including or developing new metrics that reflect existing constructs, but which measure fundamentally different properties from existing metrics. This could include integrating static and dynamic code quality metrics in conjunction with repository mining.
- Extending our analysis to different levels of abstraction (e.g. method, package) using a multi-level model.
- Replicating our analysis on other types of code (e.g. closed-source and industrial software).
- Exploring code smell's integration into the model.
- Extending the model to additional programming languages.

## 6 Conclusion

To summarize, we used exploratory and confirmatory factor analysis to investigate the construct validity of object-oriented, class-level code metrics generated by three software tools; Designite, JHawk, and Understand. We provide a measurement model with six constructs–*Cohesion, In-Coupling, Out-Coupling, Size, Sub-Inheritance, and Sup-Inheritance*–each of which is operationalized by at least three metrics. The analysis supports construct validity for 24 of the studied metrics, while the evidence for construct validity was lacking for 30 additional metrics. The metrics identified through this study offer empirically supported, quantitative measures to support informed decision making regarding code quality. Using the factor model shown in Table 3 in its present form is scientifically defensible–especially compared to estimating constructs from individual metrics. However, more research is needed to improve content validity by developing broadened, and more diverse sets of reflective indicators. Taken together, our findings suggest that future software code metrics research should focus on measurement models, instead of interpreting individual metrics as direct measurements in isolation. This study offers the following contributions to the software code quality literature:

- Exploratory and confirmatory analysis related to software code quality metrics, providing a comprehensive and novel investigation of their underlying factor structure.
- Modeling software quality attributes as latent constructs and applying the common factor model to software code metrics. The resulting measurement model and the replication package provide a foundation for future work in researching construct validity of software metrics.
- Highlighting notable findings regarding the relationship between widely cited code quality metrics and the constructs they are intended to measure.

## Data Availability Statement

We provide a comprehensive replication package [13] which includes the detailed study protocol, scripts, results, and raw code quality metrics data for performing the EFA and CFA.

# Don't Bother to Use a Second LLM and Write Tests Yourself! A Study on Elixir

**Noah Leu**
Lestio, Rostock, Germany

**Julian Oertel**
Institute for Computer Science, University of Rostock, Germany

**Regina Hebig**[1]
Institute for Computer Science, University of Rostock, Germany

## Abstract

**Background.** Generating software tests and implementations with Large Language Models (LLMs) is becoming more common. However, using the same LLM for the generation of implementation and tests might make both suffer from the same biases, potentially decreasing the tests' ability to detect faults compared to tests generated by a different LLM.

**Aims.** In this paper, we want to investigate this notion by combining different LLMs for generating implementation and tests.

**Method.** We generate Elixir code and test cases with 5 LLMs and compare them to a baseline of manually written code and tests. We wrote and generated 459 distinct implementations and 2709 test suites, manually analyzing 9417 test case failures.

**Results.** We find no difference between tests generated by the same or a different LLM as the code. However, of the 247 implementations flagged as faulty, 99 were only flagged by manually written tests.

**Conclusions.** Our results indicate that LLM-generated tests alone are not yet sufficient.

## 1 Introduction

Software testing is critical in ensuring software systems' quality, reliability, and maintainability. Manually written unit tests, integration tests, and end-to-end tests have proven effective but remain costly and time-intensive [31]. As development often happens under time and budget constraints, there is great interest in generating tests automatically addressed by tools like EvoSuite [9] and Randoop [22]. In recent years, Large Language Models (LLMs) have made it possible to approach generating tests not just from code, but directly from textual specifications [30, 34]. As studies show promising results for LLM-assisted test generation [2, 8], LLMs are increasingly integrated into test generation environments, such as TestSpark [26].

Simultaneously, there is increasing interest in generating the code itself from the specifications [15, 20]. This leads to the following potential problem: When looking at human developers, we accept the idea that different developers might have different biases and thus there is value in involving multiple individuals during coding and quality assurance work. For example, code reviews or pair programming are two widely accepted methods in industry [28, 18]. However, when the same model generates both the implementation and its tests, there is a risk that incorrect assumptions and biases present in the initial code generation are reinforced and introduced to the test generation as well. Thus, an LLM may be less likely to generate tests that detect errors it made itself during implementation generation than errors another LLM made during implementation generation. This leads to the following research question:

**RQ: Are tests better at detecting faults when code and tests are not generated by the same LLM?**

We perform an experiment with 9 specifications derived from a start-up's software system and 5 LLMs. Preceding this, we conduct a pre-study to develop and refine the prompts and specification format and select suitable LLMs in order to minimize compilation errors and facilitate the generation of effective tests. Including manually written tests and code, we work with 459 distinct implementations and 2709 test suites. We manually analyze 9417 test case failures to identify their root causes and distinguish whether faults in the implementation or faults in the test caused the failures.

Most studies on LLM-based test generation focus on widely adopted languages such as Java, Python, or JavaScript [4, 21, 36, 27]. These ecosystems benefit from large amounts of publicly available training data. In contrast, LLMs tend to perform worse when generating for low-resource languages [5, 12, 11]. As this study was performed in collaboration with a start-up and the language infrastructure they use, we focus on such a language: Elixir and its Phoenix web framework. Despite representing a smaller share of total practitioners, Elixir constitutes a meaningful ecosystem with steady industry relevance, as evidenced by a recent developer survey[2].

To this end, we make the following contributions: (1) Insights into the question whether using the same LLM for code and test generation is of disadvantage. (2) Insights into the applicability of LLM code and test generation for low-resource languages like Elixir. (3) An extensive dataset of LLM-generated code and test cases for Elixir, including baseline manual implementations and tests.

This paper is structured as follows. We discuss related work in Section 2. Then we present our pre-study in Section 3 and the methodology in Section 4. Results are shown in Section 5 and discussed in Section 6. We conclude in Section 7.

## 2 Related Work

Numerous studies examine the potential to use LLMs to automate or assist in test creation across a range of programming languages and domains [34]. Some recent studies point out that execution, compilation, and logical validity can still be inconsistent in LLM-generated test suites [36, 37]. For example, tests generated using ChatGPT (GPT-3.5-turbo) in the study of Yuan et al. compiled only in 42.1% of cases [36]. Bhatia et al. [4] investigated LLM-generated unit tests in Python using ChatGPT, comparing them against traditional tools like Pynguin [16]. While the coverage was often comparable, nearly a third of the generated

[2] see `https://survey.stackoverflow.co/2025/technology/`

assertions were incorrect. Nashid et al. [19] showed that examples in the prompts can increase the accuracy of the generated assertions to up to 76%. Examples like ChatUniTest demonstrate promising results compared to traditional tools for test generation such as EvoSuite or TestSpark [6]. Despite these advancements, multiple studies note that LLM-generated tests often underperform when compared to tools like EvoSuite [9], especially in detecting subtle or complex bugs [21, 1, 29].

Several researchers suggest improvements to how LLMs can be used for test generation. For example, Yang et al. explore the optimization of prompt clarity and structure for test generation [35]. Prompts specifically adapted to an LLM, stripped of unnecessary context, and augmented with few-shot examples have shown increased effectiveness in code generation [35, 25]. Ouedraogo et al. and Ryan et al. decompose the generation process into smaller reasoning steps to improve correctness and test quality, especially for complex logic or branching scenarios [21, 24]. Further Ryan et al. and Pizzorno et al. integrate traditional coverage feedback mechanisms into the test generation loop. This allowed models to iteratively improve their generated tests by being motivated to explore untested paths [3, 24]. Li et al. [14] focus on bug detection capabilities of LLMs and propose a follow-up question method. Chowdhury et al. employed static program analysis to enhance LLM-based test generation for Java [23]. This enabled better targeting of edge cases and execution paths.

Niche or low-resource languages such as Elixir pose unique challenges to LLMs due to their limited presence in training data and unique abstractions [5, 12, 11]. Few studies apply LLMs on such languages. One example for this is the paper by Tarassow et al. that employed GPT-3.5 to better understand and generate documentation or implementations for low-resource or domain-specific languages [30]. This study also explored ways to assess implementations or tests generated by LLMs, which is not a trivial task.

## 3 Pre-study

To enable the candidate LLMs to generate valid code and test suites, we conducted a pre-study targeting the general structure and degree of detail and verbosity of specifications and the prompts used. The pre-study started with initial versions of the prompts that were refined in several iterations. We stopped iterating when the prompts led to implementations that were mostly free of compilation errors when applied to the candidate LLMs for two trial specifications. The first trial specification requests a minimal LiveView rendering a `<h1>` element, and the second one aims at computing the minimum price from a list of products. [3]

### 3.1 Candidate LLMs

We considered different closed-source and open-weight models, specifically, the candidates GPT-4.1, Claude Sonnet 3.7, and Gemini 2.5 Pro (Google DeepMind) for their strong results in code-related benchmarks such as LMArena[4], GPT-4o-mini as it is a smaller model that is optimized toward speed and efficiency, and Llama 4 Maverick and DeepSeek V3 as they were trained under different resource constraints and data diversity (our study was performed in April/May 2025).

Based on the results of the pre-study, we excluded Gemini due to its unreliable output formatting – which prevented automated parsing – and frequent token limit violations that led to incomplete code files. Prompt adaptations failed to mitigate these behaviors.

[3] The trial specifications can be found in the supplemental materials (cf. Section 7)
[4] `https://lmarena.ai/leaderboard/webdev`

## 3.2 Prompts

We developed prompts for the generation of code as well as test suites. The initial prompts were inspired by current practices in prompt engineering [35, 17, 25]. Specifically, the initial drafts were adapted from publicly available resources on the community-driven platform Cursor Directory[5] and other sources such as GitHub[6]. On Cursor Directory, users can publish system prompts to be used with the IDE called Cursor for many languages and frameworks. The prompt published under "Elixir Cursor Phoenix Rules"[7] was identified as the foundation, as it outlined essential conventions and best practices for generating Elixir code within Phoenix applications. However, the initial prompts led to problems, such as missing required imports, unspecified dependencies, or the use of non-existent functions. Our goal was to minimize the generation of non-compiling implementations, as these are not usable to compare the quality of generated tests. In addition, we aim to give the LLMs the best possible chance to generate good test suites for answering our research question.

We made the following changes to the prompts[8]: **(1)** We instructed the LLMs to avoid unspecified external libraries. **(2)** For recurring issues, we added specific usage examples. These included variations with detailed type annotations, example-based few-shot inputs, and minimal instruction variants. For example, mocking external function calls posed a special challenge. Trial runs of the pre-study resulted in inconsistent model behavior when asked to use third-party libraries for mocking dependencies. These libraries often required configuration setups in multiple files for each dependency used. To address this issue, we decided to use the Mock[9] library, which allows mocking using only the file of the test suite itself. A single-shot example demonstrating correct mocking syntax was included in the testing system prompt. **(3)** To force the LLM to adhere closely to the specification we added a sentence explicitly asking the LLM to do so. **(4)** Due to issues with LLMs explaining their outputs, we also include the instruction to only return code snippets that work as standalone modules and can be directly used as an Elixir file.

For test generation we explored both white-box (using the implementation code as context) and black-box (using only the specification) test generation. However, the white-box approach resulted in better outcomes, such as finding implementation faults like incorrect data type handling and value edge cases. This finding is also supported by a study by Guzu et al. in 2025 [10]. We therefore decided on white-box test generation.

## 3.3 Specification Format

The initial specification format used a simple textual description. This resulted in rather poor performance for some cases where the LLM did not understand or correctly perform the initial tasks. We managed to improve the generation results by adding examples, including input and output pairs, and using a more structured format with bullet points, reducing the number of filler words.

The final specification format uses concise context information, e.g., module name, input/output expectations, functional description, as well as necessary module imports and aliases. This was also necessary to ensure that human-written black-box tests could be used on the generated implementations. The schema with headings, subheadings, and bullet points included:

---

[5] `https://cursor.directory/plugins/elixir`
[6] `https://gist.github.com/kostysh/dbd1dfb2181b96563754222903bf67e7`
[7] `https://cursor.directory/plugins/elixir`
[8] The resulting prompts are in the supplemental materials (cf. Section 7).
[9] `https://hexdocs.pm/mock/Mock.html`

- **Module and function name:** Specific identifiers to ensure uniform access across tests
- **Purpose:** A high-level description of the intended functionality
- **Inputs and outputs:** Detailed argument and return type information
- **Constraints:** Requirements such as avoiding external libraries
- **Known edge cases and examples:** Representative scenarios for correctness
- **Notes:** Optional attribute for additional guidance for realistic implementation behavior

# 4 Methodology

We employ a controlled experimental design to evaluate LLM-based test generation in a realistic context with requirement specifications from a real startup. The startup provided industry-relevant tasks in the form of functional requirements but had no further involvement.

Table 1 defines the central terms used throughout the paper.

**Table 1** Definitions of the study's key terms and metrics.

| Term | Definition |
|---|---|
| Test case failure | An individual test case that does not pass, or a test file that fails to compile. Raw outcome; not yet attributed to a cause. |
| Implementation error | A test case failure whose manually determined root cause lies in the code (violates the specification). |
| Test error | A test case failure whose root cause lies in the test (e.g., wrong assertion, test compile error). |
| Faulty implementation | An implementation with $\geq 1$ failure attributed to an implementation error (can contain several). |

## 4.1 Task Specifications

### 4.1.1 Source

The task specifications used in this experiment were derived from an actual software product provided by the collaborating startup. The underlying architecture of the system includes a web application that handles user interactions and recommendation logic. The system incorporates multiple functional components, such as scoring and ranking algorithms, and recommendation filtering based on user input and product attributes. These components offer a diverse set of functions, ranging from simple utility operations to more complex logic involving condition-based decisions and weighted scoring. Each specification used in the experiment reflects a requirement within the platform and was documented textually.

### 4.1.2 Complexity Levels

To evaluate the influence of task difficulty on LLM performance, the nine specifications were grouped into three complexity categories (see Table 2). We chose a distribution of four simple, three medium, and two complex tasks. A higher number of simple tasks increases the likelihood of obtaining sufficient compiling implementations while keeping the manual error classification workload manageable.

**Table 2** Specification complexity levels and characteristics. (LOC ≡ Lines of Code).

| Level | Key Characteristics | Expected LOC | Count |
|---|---|---|---|
| Simple | Minimal logic, branching, and data gathering | $\leq 30$ | 4 |
| Medium | LiveView, complex outputs (maps, changesets) | $\leq 90$ | 3 |
| Complex | Process-level (GenServer) and dependencies | $> 100$ | 2 |

**Table 3** Overview of the nine function specifications used in the experiment (* = Complexity).

| * | Name (ID) | Description |
|---|---|---|
| Simple | 1. Get All Brands | Returns a case-normalized list of unique brand names. |
| | 2. Get Average Price | Calculates the average product price, ignoring nil values. |
| | 3. Get Minimum Attribute | Retrieves the minimum value of an attribute across a product list. |
| | 4. Get Reading Duration | Estimates reading time (in minutes) for a given blog post text. |
| Medium | 5. Validate Contact Form | Validates form input fields and returns success or error details. |
| | 6. Validate Password | Validates password complexity in an Ecto changeset. |
| | 7. Product List LiveView | Renders a product list dynamically using Phoenix LiveView. |
| Complex | 8. Slugify | Converts text to URL-friendly slugs with optional customization. |
| | 9. Product Cache GenServer | Implements a GenServer-based product cache using ETS for fast retrieval. |

### 4.1.3 Specification Selection

To simplify the evaluation and maintain comparability, all functions were designed to be implemented within a single Elixir module. This approach reduces environmental complexity and ensures that generated test suites can be executed using automation scripts. Specifications that required multiple modules or intricate application contexts, such as full Phoenix LiveView setups that include router configuration, were excluded from this study. Where applicable, each specification also aimed to contain only a single entry function to be tested. This ensures that test suites are provided with a specific entry point to the implementation. Additionally, all functionality with database requirements relies on mocked dependencies rather than direct database access. Features requiring integration-level setup, such as sandbox databases, were excluded, as these would again require multiple file adaptations.

The specifications cover a range of tasks from simple utility functions to full process-level modules. Importantly, the nine specifications are different from the two trial specifications used in the pre-study. This was crucial to prevent the developed prompts and specification structure from being specific to the specifications used in this study. Table 3 summarizes the specifications grouped by complexity.[10]

## 4.2 Large Language Model Interaction and Settings

We decided to use the LLMs **GPT-4.1**, **GPT-4o-mini**, **Claude Sonnet 3.7**, **Llama 4 Maverick**, and **DeepSeek V3**. To access the models, we used OpenRouter to provide a consistent API across multiple providers which simplified logging of prompts, responses, and metadata as well as addressing rate limits.

[10] The complete specifications, including input-output formats, constraints, edge cases, and example calls, are provided in the supplemental materials (cf. Section 7).

**Table 4** Default generation settings applied to all LLMs.

| Parameter | Value |
|---|---|
| Temperature | 0.0 (deterministic, greedy decoding) |
| Top-p | 1.0 (full probability distribution) |
| Top-k | 1 (always choose the most probable token) |
| Token limit | 3000 tokens (implementations); 6000 tokens (test suites) |

All generations were performed using a consistent set of decoding parameters and resource constraints, which were applied to all models during implementation and test suite generation (see Table 4). By setting the temperature to 0.0 and restricting Top-k to 1, generation was made as deterministic as possible, as we aim to observe structural differences in the models' reasoning and minimize randomness in sampling. Implementations were limited to 3000 tokens and test suites to 6000 tokens (to accommodate several detailed test cases and setup logic). These limits respect the expected file sizes per complexity level while bounding output size, and curb the infinite code repetition observed in the pre-study. When a file was truncated because of repetition and failed to compile, we classified it as a syntax error. To avoid unintended bias from prior interactions, every request was executed in a new session, ensuring that previous generations do not directly influence later runs.

## 4.3 Running the Experiment

### 4.3.1 Implementation and Test Generation and Execution Workflow

The workflow consisted of two main stages: manual solution and LLM-based solution. Before the generation with LLMs began (but after the pre-study), the first author implemented solutions to the nine task specifications as well as corresponding black-box test suites manually. Using black-box tests instead of white-box tests made a manually written baseline possible, as it was sufficient to write one test suite per specification instead of one for each of the up to 459 expected implementations.

In the second stage, the LLM-based solutions and tests were created in 10 runs to account for variability in LLM outputs. Each run involved all nine specifications and included three steps. (1) every LLM generated one complete Elixir implementation for each specification. (2) Each LLM generated a test suite for each of the implementations (including the human-written implementation). (3) after successfully generating all files, the execution followed an automated test execution procedure. For each implementation, the implementation file was placed in the corresponding directory of the Phoenix project and compiled. If the compilation failed, the implementation was marked as invalid, and no test suite executions were attempted for this specification. In this case, the test suites were neither executed nor compiled. When compilation succeeded, the process continued with executing each test suite for this implementation.

### 4.3.2 Dataset Size

The total dataset is derived from 10 runs, 9 specifications, and 5 models. As detailed in Table 5, we produced 459 implementations and 2,709 test suites. To ensure comparability, manual implementations were treated as unique for each of the 10 runs, allowing the same number of test suites to be generated for manual code as for any LLM/specification combination.

While the theoretical maximum for test executions is 3,240 (Table 5), the actual number of executed tests is lower whenever an implementation fails to compile. Each compilation failure results in the loss of six potential executions: five LLM-generated test suites and one human-written test suite.

**Table 5** Overview of expected set of created implementations ($I$), expected set of created test suites ($T$), and maximum number of test suite executions ($E$) across 10 runs (R) for each of the 9 specifications (S) and each of the 5 models (M).

| | **Per Specification** | **All Specifications** |
|---|---|---|
| $I_M$ (manually created implementations) | 1 | $(I_{M_{spec}} \times S) = 9$ |
| $I_G$ (generated implementations) | $(R \times M) = 50$ | $(I_{G_{spec}} \times S) = 450$ |
| **Sum** $I = I_M + I_G$ | 51 | 459 |
| $T_M$ (manually created test suites) | 1 | $(T_{M_{spec}} \times S) = 9$ |
| $T_{GG}$ (generated test suites for $I_G$) | $(I_{G_{spec}} \times M) = 250$ | $(T_{GG_{spec}} \times S) = 2250$ |
| $T_{GM}$ (generated test suites for $I_M$) | $(R \times M) = 50$ | $(T_{GM_{spec}} \times S) = 450$ |
| **Sum** $T = T_M + T_{GG} + T_{GM}$ | 301 | 2709 |
| $E_{MM}$(executions of $T_M$ on $I_M$) | $R \times T_{M_{spec}} = 10$ | $R \times T_{M_{all}} = 90$ |
| $E_{MG}$ (executions of $T_M$ on $I_G$) | $I_{G_{spec}} = 50$ | $I_{G_{all}} = 450$ |
| $E_G$ (executions of $T_{GG}$ and $T_{GM}$) | $(T_{GG_{spec}} + T_{GM_{spec}}) = 300$ | $(T_{GGall} + T_{GM_{all}}) = 2700$ |
| **Sum** $E = E_{MM} + E_{MG} + E_G$ | 360 | 3240 |

## 4.4 Analysis

In this subsection, we describe our analysis procedure.

### 4.4.1 Root Cause Examination

The output of the test suite was parsed to classify the results into: **Test compilation fails**, i.e., test files failed to compile. **All tests pass**, i.e., no failures are detected during execution of the tests, indicating no defects. **Tests fail**, i.e., failures were detected during test execution.

All failures were further classified regarding their root cause. To gain a first understanding of error types present, the output for all failed test cases or test compilations was closely examined to find repeating patterns. This resulted in an initial categorization of errors into types such as `assertion_failure`, `undefined_function`, or `regex_error`. However, these error types were not enough to clearly determine whether a failure was caused by an issue in the implementation or in the generated test suite. To accurately answer that question, a manual root cause analysis was performed. This process involved inspecting the specification file, the generated implementation file, the corresponding test file, and the error output for every recorded failure across all runs.

While some error types can be confidently attributed to one side (e.g., syntax errors in test files indicate test failures), many cases require precise examination. For example, when a test failed due to not receiving expected function calls, the analysis needed to verify whether the implementation did not make the expected calls or the test awaited an incorrect function call. A large spreadsheet was created to summarize each error type, affected specifications, number of occurrences, counts of implementation and test errors, and lastly include the manually identified root causes. All in all, 9417 test case failures were investigated manually (there can be multiple test failures for one test suite execution).

### 4.4.2 Statistical Evaluation

The goal was to determine whether observed differences between models and test generation strategies are statistically significant. Since the data did not follow a normal distribution and included ordinal characteristics (e.g., number of detected defects, failure rates), non-parametric tests were selected.

We formulated the following null hypotheses for our research question:
$\boldsymbol{H1_0}$: There is no difference in test error counts between the LLMs used to generate test suites.
$\boldsymbol{H2_0}$: There is no difference in the number of detected implementation errors between test suites generated by the same model as the code, test suites generated by a different model as the code, and test suites written by a human.

In addition, we tested following supporting null hypotheses to better understand the data:
$\boldsymbol{H3_0}$: There is no difference in the number of detected implementation errors between LLMs used to generate the implementations.
$\boldsymbol{H4_0}$: There is no difference in the number of implementation errors across complexity levels.
$\boldsymbol{H5_0}$: There is no difference in the number of test errors across complexity levels.
$\boldsymbol{H6_0}$: There is no correlation between the code coverage of a test and the number of detected implementation errors.

We used Kruskal-Wallis as an omnibus test to see whether at least one model performs differently. Allowing the detection of which exact pairs differ, a pairwise Holm-corrected Mann-Whitney U test was used, when Kruskal-Wallis indicated significant differences. We apply a significance level of $\boldsymbol{\alpha = 0.05}$ for all tests. For testing $\boldsymbol{H6_0}$, we use Spearman's $\boldsymbol{\rho}$ due to the count-like, skewed nature of errors. Statistical significance and 95% confidence intervals were estimated via bootstrapping (1000 iterations). Effect sizes were calculated for $\boldsymbol{H1_0}$ - $\boldsymbol{H5_0}$ using common language effect size for Mann-Whitney U tests and $\boldsymbol{\eta^2}$ for Kruskal-Wallis tests. The effect sizes were classified into four levels (negligible, small, medium, large) following [32] and [7, 33], respectively.

# 5 Results

We present compilation rates, the error type classification, and results of statistical tests.

## 5.1 Compilation Rate

**Implementation compilation rate.** In total, 24 implementations did not compile. Table 6 summarizes the compilation success rates. For simple specifications, almost all models achieved near-perfect compilation success. Medium-level tasks showed minor reductions in compilation success for GPT-4.1 and GPT-4o-mini. The most noticeable decline occurred in complex specifications, where GPT-4.1 and GPT-4o-mini dropped to 60% and 65%, respectively. Claude Sonnet 3.7 achieved a 100% compilation rate across all complexity levels. Compilation failures were often related to language-specific constraints rather than a complete misunderstanding of the task. Especially problems within guard clauses and incorrect imports suggest that the LLMs occasionally failed to follow Elixir's rules regarding language-specific functionality usage. Issues regarding remote function calling and guard-related errors point to challenges unique to functional programming.

**Test suite compilation rate.** Test compilation success was measured under the condition that the corresponding implementation compiled successfully. Thus, test suites for which the implementations do not compile are not considered. For simple specifications, most models achieved very high compilation success rates, with Claude Sonnet 3.7 reaching 100%. Llama 4 Maverick showed a slightly lower rate at 92.89%, indicating some issues even in basic tasks. GPT-4o-mini, however, achieved a lower rate of 83.19%. Medium complexity specifications led to a significant decline for GPT-4.1 and Llama, with success rates dropping to 61.02% and 56.82%, respectively. In complex scenarios, the trend remained similar, with GPT-4.1

**Table 6** Implementation and test compilation success rate by source of implementation/test and complexity (successfully compiled implementations/created implementations (rate) and successfully compiled test suites/considered test suites (rate)).

| Model | Implementation compilation | | | Test suite compilation | | |
|---|---|---|---|---|---|---|
| | Simple | Medium | Complex | Simple | Medium | Complex |
| GPT-4.1 | 40/40 (100%) | 28/30 (93.33%) | 12/20 (60%) | 235/239 (98.33%) | 108/177 (61.02%) | 60/100 (60%) |
| GPT-4o-mini | 40/40 (100%) | 29/30 (96.67%) | 13/20 (65%) | 198/238 (83.19%) | 150/177 (84.75%) | 100/100 (100%) |
| Claude Sonnet 3.7 | 40/40 (100%) | 30/30 (100%) | 20/20 (100%) | 239/239 (100%) | 161/177 (90.96%) | 83/99 (83.84%) |
| Llama 4 Maverick | 39/40 (97.5%) | 30/30 (100%) | 18/20 (90%) | 222/239 (92.89%) | 100/176 (56.82%) | 86/100 (86%) |
| DeepSeek V3 | 40/40 (100%) | 30/30 (100%) | 17/20 (85%) | 234/238 (98.32%) | 162/177 (91.53%) | 77/99 (77.78%) |
| Manual | 4/4 (100%) | 3/3 (100%) | 2/2 (100%) | 4/4 (100%) | 3/3 (100%) | 2/2 (100%) |

continuing to perform poorly at 60% success, while Claude stayed above 83%. Interestingly, GPT-4o-mini compiled slightly more test suites successfully on medium specifications than on simple ones and even reached a 100% compilation rate for complex specifications.

## 5.2 Resulting Test Execution Dataset

As discussed in Subsubsection 4.3.2, the actual number of test suite executions can be below the maximum of 3240 possible test suite executions. In practice, 24 implementations failed to compile, causing the lack of 144 test suite executions. 20 of those failures were attributed to Claude Sonnet 3.7 for complex specifications. In addition, an unknown error occurred with the generation of the test suites, resulting in five cases in the API returning either empty text or an error. These five cases could not be assigned to failure of the LLMs. They may be the result of a timeout on the server side of the API provider, OpenRouter. Therefore, these 5 cases were considered invalid and not considered for further study. Within the 3091 test suite execution attempts, 360 test suites were not able to compile. A total of 28542 single test cases were executed. From these cases, 19125 (67%) cases passed without failing. 9417 (33%) single test cases failed during execution. Of those, 5817 (62%) failed due to test errors and 3600 (38%) failed due to implementation errors, i.e., they successfully detected errors. Note that single test cases can fail due to the same implementation fault.

## 5.3 Error Type Classification

Table 7 summarizes the identified error types and their occurrences. This also includes syntax errors in the test cases that failed to compile. While there are error causes that are specific to implementations or tests only, several error categories include errors that can occur both in implementations and in tests. Most prominently, this holds for assertion_failures, which are caused by errors in tests as well as errors in the implementations. A table with detailed error types is available in the supplemental material (cf. Section 7)

**Test and Assertion Failures.** These errors occur when code executes but does not behave as the tests expect. This category includes classical assertion failures (3,072), structural mismatches (717), and cases where expected exceptions are not raised (65) or telemetry

**Table 7** Summary of identified error categories and their distribution. Total errors are split into test errors and implementation errors (test + impl.). We also considered non-compiling test suites in this without breaking them down into individual test cases.

| Category | Total Errors | Primary Cause |
|---|---|---|
| Test & Assertion | 4233 (1650+2583) | Incorrect assertions/expectations |
| Runtime & Language | 3716 (2733+983) | Invalid assumptions/API misuse |
| Erlang & Process | 1648 (1614+34) | Process lifecycle/concurrency |
| Compilation | 165 (165+0) | Syntax/Language constraints |
| Test Structure | 15 (15+0) | Misuse of testing frameworks |
| **Total** | **9777 (6177+3600)** | |

messages are not received (348). Additionally, doctests (embedded code execution examples in the implementation) fail (30). This shows that LLMs sometimes generate incorrect or inconsistent code samples directly in their implementation or do not correctly cover their own examples functionally.

**Runtime and Language Errors.** These occur during execution, typically due to invalid assumptions regarding values, functions, or data structures. Common examples include `undefined_function` (1,107) arising from spelling errors or incorrect API assumptions, and `argument_error` (813) caused by improper parameter usage. Scoping issues are reflected in `undefined_variable` (10), while `function_clause` errors (838) often stem from incorrect pattern matching or insufficient guard clauses.

**Erlang, Process and Concurrency Errors.** These involve the underlying Erlang VM and process management, particularly within the `cache_genserver` specification. Errors often arise from improper process handling, such as `process_already_started` (258) due to failed test isolation or `named_table_exists` (224) during ETS table creation. Additionally, attempts to mock Erlang-level modules led to 524 `sticky_module` errors, preventing module reloading. Remaining errors included `process_errors` (1) that stem from communication or termination failures and `erlang_errors` (17) due to malformed terms or invalid Erlang API usage.

**Compilation and General Language Errors.** These are identified by the compiler before execution and stem from invalid syntax or unsupported constructs. Notably, errors like `pin_operator_error` (55) and `invalid_use_of_underscore` (49) suggest that LLMs occasionally adopt syntax habits from other programming languages.

While more of the error found were rooted in incorrect tests than in implementations, it cannot be concluded that LLMs are worse at generating tests, since we generated more test suites (2700) than implementations (450).

**Observations:** The most frequent error by a wide margin is `assertion_failure`, accounting for 3072 total cases (with 2267 implementation errors). Implementation errors are most commonly detected as `assertion_failure` (with 2267 errors), but also as `match_failures` (195), `argument_errors` (225), `undefined_functions` (151), `bad_map_errors` (248), and `protocol_errors` (147). Erlang, Process and Concurrency Errors are almost exclusively caused by faulty tests.

**Table 8** Mean code coverage, in terms of share of lines of code covered in a run of the test suite, and number of identified faulty implementations by test suite source.

| Source of Test Suite | Mean code coverage in % | | | Faulty implementations found | |
|---|---|---|---|---|---|
| | Simple | Medium | Complex | By | Only by |
| GPT-4.1 | 94.09 | 59.91 | 35.01 | 55 | 2 |
| GPT-4o-mini | 77.98 | 69.97 | 73.62 | 89 | 3 |
| Claude Sonnet 3.7 | 95.76 | 83.40 | 61.73 | 94 | 4 |
| Llama 4 Maverick | 88.60 | 36.49 | 65.66 | 76 | 20 |
| DeepSeek V3 | 92.16 | 80.22 | 60.43 | 94 | 5 |
| Manual | 95.41 | 94.13 | 89.43 | 222 | 99 |

**Table 9** Statistical comparison of test error counts by source of test suites (LLMs or manual). Only significant results of the pair-wise comparison are shown.

| Comparison | H-statistic | p-value | $\eta^2$ | Significant |
|---|---|---|---|---|
| Kruskal-Wallis (by LLM) | 28.493 | $< 0.0001$ | 0.010 (negligible) | Yes |
| **Comparison** | **U-statistic** | **p-value** | **CLES** | **Significant** |
| Manual vs LLMs | 437815.0 | $< 0.0001$ | 0.67 (medium) | Yes |
| **Comparison** | **U-statistic** | **p-value** | **CLES** | **Significant** |
| Claude vs DeepSeek | 117462.5 | 0.0057 | 0.556 (negligible) | Yes |
| Claude vs GPT-4.1 | 112876.5 | 0.0001 | 0.575 (small) | Yes |
| Claude vs GPT-4o-mini | 111098.5 | $< 0.0001$ | 0.581 (small) | Yes |

## 5.4 Code Coverage and Identified Faulty Implementations

Table 8 presents the mean code line coverage per test generation model by specification complexity level. For simple specifications, most models achieved high coverage values above 88%. Claude Sonnet 3.7 and DeepSeek V3 are among the top-performing models for medium and complex tasks, while Llama 4 Maverick showed strong results for simple tasks but suffered from the lowest medium-level coverage (36.49%). This is due to the mean coverage of 13.33% and 10.14% for the specifications `product_liveview` and `validate_password`, respectively. Interestingly, the manually written black-box test suites achieved the highest coverage nearly across all levels (being second highest for simple specifications). Table 8 also shows the number of faulty implementations flagged by the tests created by each LLM. An implementation can include multiple faults. Here, we only count those faulty implementations for which at least one fault was identified correctly by at least one test suite. Altogether, 247 implementations were flagged as faulty (5 of the 9 manual implementations and 242 of the 450 generated implementations). Most faulty implementations were flagged by the manually written test suites. The table also shows the number of faulty implementations that were only identified by test suites from the given source, and no other test suites. E.g., for 20 faulty implementations, only test suites generated by Llama identified errors, but no other test suites.

**Observations:** Code coverage tends to be higher for manually created black-box tests than for generated white-box tests. Most faulty implementations identified by test suites from a single source, only, were identified by manually written test suites.

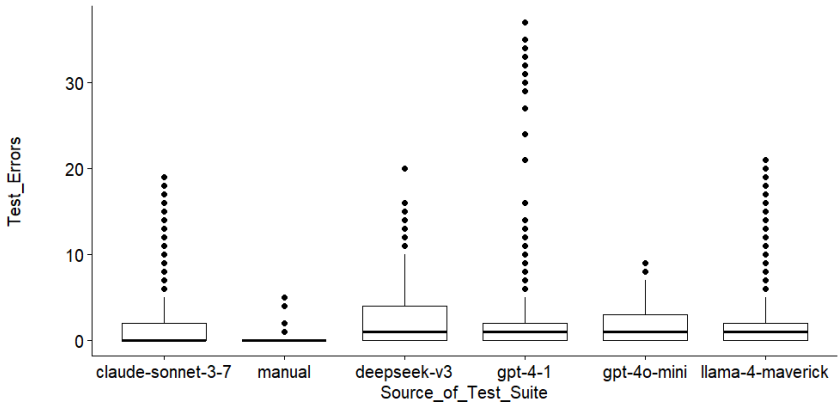

**Figure 1** Test errors per source of test suite (LLM or manual).

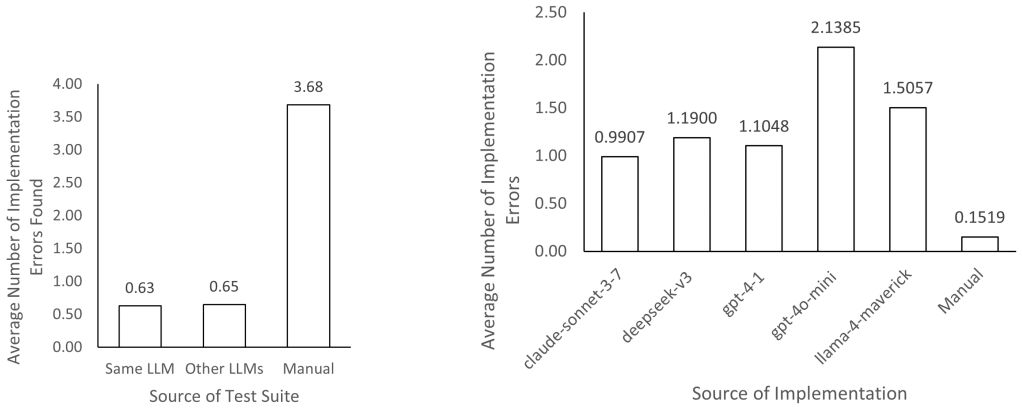
## 5.5 Statistical Evaluation

The tested dataset contains 3091 entries – one entry per test suite execution attempt.

### 5.5.1 Test Error Counts by Test LLM

Table 9 shows an overview of the tests regarding hypothesis $\boldsymbol{H1_0}$ that there are no differences in the number of test errors based on the LLM that created a test suite. A Kruskal-Wallis test confirmed statistically significant differences in test error counts among the source of the generated test suites ($\boldsymbol{H} = 28.493$, $\boldsymbol{p < 0.0001}$), rejecting hypothesis $\boldsymbol{H1_0}$. Pairwise comparisons show that Claude Sonnet 3.7 differed significantly with small effect size compared to several other models. As shown in Figure 1, Claude introduced slightly fewer test errors (mean: 2.07, median: 0) compared to GPT-4.1 (mean: 2.61, median: 1) and DeepSeek V3 (mean: 2.48, median: 1). The comparison to GPT-4o-mini (mean: 1.96, median: 1), however, is not quite as obvious, as Claude has a worse average due to outliers, but overall a better median. The comparison between the manually written test suites (mean: 0.49, median: 0) and all LLM-generated suites was significant, with a medium effect size. The manually created tests have a lower average error count.

**Observation:** While $\boldsymbol{H1_0}$ is to be rejected, the differences between the LLMs are often of small effect sizes or even negligible. For manually written tests, fewer test errors were observed than for the generated tests.



### 5.5.2 Implementation Error Counts by Source of Test Suite

Table 10 summarizes the tests of hypothesis $\boldsymbol{H2_0}$. It shows that the difference in the source of the tests compared to the source of the implementation impacts the number of implementation errors that can be found. We reject $\boldsymbol{H2_0}$ as the Kruskal-Wallis test showed a statistically significant difference between the three testing scenarios, suggesting that the source of the test suite does impact the implementation error counts found.

Pairwise comparisons revealed that a significant relationship exists between the implementation faults found by the manually created test suites and faults found by the same model (“Same”) or other models (“Other”). In both cases, we found a medium effect size with manually written tests finding many more implementation errors on average than

**Table 10** Statistical comparison of implementation error counts by source of test suite (manual, same LLM, other LLM).

| Comparison | H-statistic | p-value | $\eta^2$ | Significant |
|---|---|---|---|---|
| Kruskal-Wallis | 223.499 | $< 0.0001$ | 0.070 (medium) | Yes |
| **Comparison** | **U-statistic** | **p-value** | **CLES** | **Significant** |
| Manual vs Same | 173767.0 | $< 0.0001$ | 0.643 (medium) | Yes |
| Manual vs Other | 712926.0 | $< 0.0001$ | 0.653 (medium) | Yes |
| Same vs Other | 540217.0 | 0.1520 | 0.513 (negligible) | No |

**(a)** By test suite source.

**(b)** By implementation source.

**Figure 2** Comparison of average implementation errors found based on different sources.

LLM-generated tests (see Figure 2a). However, there was no significant difference between the implementation errors found by test suites from the same LLM that generated the implementations vs. other LLMs. Thus, changing the LLM when generating tests for generated code might not increase the chances of finding errors.

> **Observation:** $\boldsymbol{H2_0}$ can be rejected as manually created tests find more implementation errors than generated tests. However, there is no significant difference between the number of implementation errors found by tests generated from the same vs. other LLMs than the LLM that generated the implementation. Thus, the answer to the **RQ** is: **No**, tests are not better at detecting faults when tests and code are not generated by the same LLM.

### 5.5.3 Additional Tests[11]

Testing hypothesis $\boldsymbol{H3_0}$ showed that there is a significant difference between the implementation errors produced by most pairs of LLMs (with the exception of Claude vs. GPT-4.1 and DeepSeek vs. Llama). However, effect sizes for these differences are small to negligible. Similarly, we found a significant difference with small effect size between the number of implementation errors in generated and manual implementations (see Figure 2b).

[11] Detailed test results for hypothesis tests $\boldsymbol{H3_0}$ to $\boldsymbol{H5_0}$ can be found in the supplemental materials (cf. Section 7).

Testing hypotheses $H4_0$ and $H5_0$ showed significant differences in the number of implementation errors and test errors that can be found in tasks with different complexity levels. The only exception is the difference between the number of implementation errors in simple and medium tasks, which was not significant in our test. Effect sizes for implementation errors were small. For test errors, the effect sizes were medium to large.

Finally, we used Spearman's $\rho$ to test $H6_0$. We looked at data from faulty implementations, i.e., implementations for which at least one test found an implementation error. There was a significant but weak positive correlation between the code coverage and implementation errors found by a test ($df = 1611$, $95\% CI = [0.062, 0.154]$) with $\rho = 0.109$.

**Observations:** The model used for code generation influences the number of implementation errors. Complexity levels influence the number of test and implementation errors. We find a weak correlation between code coverage of tests and the number of found errors.

# 6 Discussion

In the following, we discuss implications of our findings, compare them to related work, and present threats to validity.

## 6.1 Implications

The findings of this study offer several practical implications.

**No obvious benefits when using cross-model testing strategies.** The idea of cross-model testing was motivated by the potential to prevent the same biases from affecting both implementation and tests. However, the results of this study did not show statistically significant improvements over same-model generation. Thus, for now, there is no reason to expect big benefits of cross-model testing strategies – at least in the context of Elixir.

**Do not skip writing tests manually, yet.** The manual test suites outperformed the generated test suites. While it took longer to create these tests (1-2 days) manually compared to generating a single test suite, it might still be worth doing. For 99 of the faulty implementations only the manual tests revealed implementation errors. The different LLMs only identified between 2 (GPT-4o-mini) and 20 (Llama-4-Maverick) erroneous implementations that were not flagged by test suites from other sources.

**White-box test generation has drawbacks, too.** While we decided for white-box testing in the pre-study to improve tests, we also observed some test errors that seem to be a result of that practice, e.g., generating tests for private functions. Generally, developers must be prepared to filter out unsuitable test suites or test cases before integrating them into products or systems.

**LLMs need special support when working with concurrent code.** Concurrency and process management seem to present particular challenges for LLMs, especially during test generation. Many generated tests failed because they incorrectly assumed synchronous responses from GenServer calls. In practice, developers should explicitly specify these patterns, expected timing behavior, and process lifecycle considerations in the prompts. Including example tests that correctly handle asynchronous calls may improve LLM output.

## 6.2 Comparison to Related Work

Similar to the works of Bhatia, Ryan, and Ouedraogo [4, 24, 21], our study confirms that, for Elixir too, LLMs are capable of generating test cases that are syntactically correct and achieve meaningful levels of code coverage, especially for simple and medium specifications. Here, test suites produced by models such as GPT-4.1 and Claude achieved high compilation success and coverage rates. We observe a compilation rate of around 88% for generated test suites, which is substantially higher than the rate (42.1%) reported by Yuan et al. for GPT-3.5-Turbo and Java. We attribute this to the more recent models used in our study and our prompt refinement upfront. Tarassow et al. found limitations of LLMs in working with domain-specific languages [30], specifically, issues with test logic occurred. This is similar to what we found for Elixir, which is also a language with fewer publicly available examples.

However, the study by Bhatia et al. reported many cases of incorrect assertions being generated. In their data roughly one third of assertions were semantically incorrect [4] and even the numbers of Nashid et al. [19] still included only 76% correct assertions. We found only 805 errors due to incorrect assertions in 2709 test suites with 28542 executions of single test cases, which points to a lower share of incorrect assertions. The difference may be explained by the different models used in the studies, as Bhatia and Nashid used GPT-3.5.

## 6.3 Threats to Validity

We discuss threats to internal, external, construct, and conclusion validity.

**Internal Validity.** We did not perform re-prompting to optimize prompts for the individual specifications. All calibration was done only in the pre-study. While this ensures comparability across all models, it may lead to an underestimation of the achievable performance of the LLMs [21, 24]. Test generation was performed using a white-box approach. While this approach likely allowed the LLMs to generate better tests, it also increased the possibility for false passes if the test copied a mistake made by the implementation, thus not finding it. Furthermore, ambiguities in the specifications might have directly influenced the quality and consistency of generated outputs. We performed the pre-study also with the goal of mitigating the risk of such ambiguities through a standardized structure. Flakiness in tests caused by mocking behavior and concurrency issues was observed in some specifications. These behaviors may have affected pass and fail counts and the interpretation of correctness for otherwise valid code or led to misinterpretation of faulty cases. Our analysis method did not allow us to exclude the possibility that implementation errors are present that were found by none of the tests. However, all of these internal issues affected all LLMs similarly. Thus, we still believe that our results allow a fair comparison of the scenarios using the same vs. different LLMs for implementation and test generation.

**External Validity.** Elixir and Phoenix tasks have likely a relatively low representation in current LLM training data, as little public code is available. As a result, the LLMs may struggle to generalize to the language-specific features or different patterns. While the nine specifications used cover a range of complexity levels and practical use cases, they do not represent a comprehensive sample of all possible Elixir programming tasks. For example, full Phoenix LiveView setups involving router configuration and multi-module contexts were excluded. This decision likely reduced compilation failures and the frequency of certain complex errors, but also limited the evaluation of LLMs' performance in high-complexity contexts. Thus, while our study provides first insights about LLMs' performance

in generating tests for Elixir programs, further studies are necessary. Moreover, as Elixir is a more niche programming language, there are fewer resources for LLM training which possibly lowers the performance of LLMs using this language compared to widely used programming languages like Java or Python. Therefore, the observed gap of human-written tests versus LLM-generated tests is likely larger for Elixir than would be the case for those languages. Also note that our results are merely a snapshot of LLMs' capabilities at the time of this study (April/May 2025). Newer models might be better suited for low-resource languages such as Elixir and therefore could exhibit higher rates of correct implementations and tests.

**Construct Validity.** We motivate our research by stating that using a different LLM for the test than for the implementation might be beneficial to rule out biases of models. However, by opting for white-box testing, some of the bias may have "spilled" to the model used for testing. However, as a white-box approach seems to be better when generating tests with LLMs [10], we accepted this validity concern in order to give a more realistic setting. Another concern is that the classification of errors into implementation or test faults required manual judgment, which always leaves room for errors. We performed the analysis in a systematic manner in order to reduce possible errors. Similarly, the human-written baseline implementations and tests were written by the first author without independent review. A more realistic baseline should comprise implementations and tests written by multiple humans to provide a more reliable comparison to LLM-generated artifacts.

Our conservative, deterministic generation setup (cf. Subsection 4.2) prioritizes comparability and reproducibility over matching typical usage; workflows involving best-of-n selection and iterative feedback would likely yield higher absolute performance, so our figures are best read as a lower bound. This limitation applies uniformly across models and conditions and thus does not affect our main comparison.

**Conclusion Validity.** The dataset is missing 5 test suites due to API errors or timeouts on the OpenRouter platform. The resulting five missing files represent only 0.16% of test executions and are unlikely to have had a measurable impact on the statistical outcomes. Other missing executions were due to implementation compilation failures and limited the number of test suite executions for test suites of all sources similarly.

## 7 Conclusion

We presented an experiment on code and test generation with LLMs for Elixir to identify whether generating code and tests with the same LLM decreases the chances of the test suite finding implementation faults. Our results do not indicate that this is the case. In addition, we found that our manually written baseline tests still identify more faulty implementations than all generated tests, despite being written as black-box tests, while the LLMs had access to the implementations. Unsurprisingly, the complexity of the task also negatively affects the correctness of generated implementations and tests. Our results also confirm that code coverage is not the best predictor for a test suite's ability to find errors. In future work, we plan to investigate whether this result can be replicated for other low-resource programming languages. Similarly, it would be interesting to also investigate cases where the LLMs need to generate multiple files or even consider complete repositories for solving the given tasks.

## Data Availability Statement

All data is available on Zenodo [13]. The data includes implementations and test suites (manually written and generated) as well as the specifications and prompts used.

## Abstract

**Background.** Large Language Models (LLMs) are increasingly used in software pipelines as decision components that validate, triage, or score system inputs and outputs. When one such component is replaced, for example, to reduce cost or latency or to adapt to provider-side model updates, it is necessary to make sure that the replacement does not significantly alter system behavior.

**Aims.** This paper presents a methodology for assessing the operational substitutability of LLM-based decision components under controlled conditions. We combine two complementary criteria: instance-level behavioral agreement, measured with Cohen's $\kappa$, and the absence of statistically significant asymmetries in correctness outcomes, assessed with McNemar's test.

**Method.** We instantiate the methodology on three representative binary decision tasks used in software pipelines: safety classification, truthfulness assessment, and stereotype detection. Using models from multiple providers, we study substitutability by asking (1) whether replacement within the same provider preserves decision behavior, (2) whether replacement across providers preserves decision behavior, and (3) how sensitive the admissible substitution space is to the agreement threshold and significance level used in the analysis.

**Results.** Substitutability varies substantially across tasks and model pairs. Safety admits the broadest substitution space, while truthfulness is the most constrained task within providers and stereotype detection across providers. Sensitivity analyses show that operational parameter choices change the size of the admissible substitution space, but not the overall qualitative pattern.

**Conclusions.** When assessing replacement candidates for LLM-based decision components, sufficient behavioral agreement and symmetry in correctness outcomes can complement aggregate benchmark performance.

## 1 Introduction

Large Language Models (LLMs) are increasingly deployed as part of complex software systems composed of multiple interacting components. For instance, they can be integrated as retrieval components for grounding model outputs [22], coordination services in multi-agent or iterative settings [35], and validation mechanisms that inspect outputs before they are returned to the user, such as content moderation APIs [27] and guardrail frameworks [11]. Integrating LLM-based components in software systems poses new challenges for monitoring their behavior. Traditional monitoring approaches have mainly focused on infrastructure-level metrics such as latency, throughput, or error rates. However, in LLM-based systems, semantic properties such as safety, truthfulness, stereotyping, and alignment can directly affect system behavior.

A common architectural pattern that addresses this need is the use of auxiliary LLMs to evaluate inputs or outputs against predefined criteria, often referred to as LLM-as-a-Judge [39, 17]. While originally introduced in the context of offline evaluation, this pattern is increasingly integrated into system pipelines to assess behavioral properties (e.g., safety, correctness, or alignment) during execution. In production environments, these components may operate either synchronously (e.g., as guardrails intercepting critical issues in real time [15]) or asynchronously (e.g., analyzing subsets of system interactions). As a result, LLM-based decision components are not only evaluators but also key elements in the monitoring of system behavior.

Despite their critical role as decision-making components, these LLM-based components are typically evaluated using aggregate metrics such as accuracy or F1 score [21, 30]. While these metrics are useful for baseline validation, they provide limited insight into the operational behavior of a decision component and its potential impact when integrated into a software system. In practice, two LLMs with similar aggregate performance may exhibit different decision boundaries due to evaluator biases, such as position bias [32], self-enhancement bias [28], or a broader range of systematic biases that affect evaluation outcomes [37]. From a software systems perspective, this raises an important architectural concern because in dynamic production environments, where providers update models over time (potentially leading to model drift [5, 23]) or where models are replaced due to cost or performance reasons, such differences can introduce unintended changes in system behavior.

This paper presents an empirical validation methodology to study the substitutability of LLM-based decision components under controlled conditions. Our approach analyzes their behavior by comparing their decisions under identical inputs across providers and model scales. For each input, this comparison considers (a) whether the original model and its candidate replacement agree or disagree on their decision; and (b) whether their decision is correct or incorrect according to a ground truth. We combine agreement-based filtering using Cohen's $\kappa$ with paired McNemar tests to assess behavioral consistency and asymmetries in correctness outcomes, respectively. We study whether models can be safely substituted both within and across providers and how operational parameters affect these substitution options. We apply this methodology to three binary decision tasks commonly found in software systems (i.e., safety classification, truthfulness assessment, and stereotype detection) and different providers. Our results provide practical insights for the design of LLM-based software systems that rely on decision components, highlighting the conditions under which component substitution may introduce unintended behavioral changes.

The rest of the paper is structured as follows. Section 2 motivates the work, and Section 3 reviews prior work. Section 4 presents our methodology. Section 5 describes the experimental design, datasets, and models used to instantiate the methodology. Section 6 reports the

empirical findings across substitution settings. Section 7 discusses implications for deployment and decision component selection. Section 8 outlines threats to validity. Section 9 presents the conclusions, and Section 10 the includes the data availability statement.

## 2 Motivation

LLMs are increasingly integrated into software systems as operational components whose outputs directly influence system behavior. They appear as guardrails that intercept unsafe or undesirable content [15, 1], evaluators or judges that assess quality or alignment [39, 10, 17], and validators that verify predefined constraints before outputs are returned to users [31]. Although these components differ in terminology and implementation, they share the same architectural role, as their outputs participate in software decisions. We refer to them as *LLM-based decision components*.

The LLM-as-a-Judge paradigm is a common implementation pattern for these components. An auxiliary LLM assesses properties such as correctness, safety, bias, or alignment, often through task-specific prompts or rubrics [39, 10, 17]. While this pattern was initially developed mainly for offline evaluation, it is increasingly used in deployed systems to enforce semantic constraints at runtime [14, 13]. This shift is also visible in LLMOps workflows, where decision components become part of system operation [18, 36]. Frameworks such as LangChain [20] and MLflow [25] support these components when defining LLM pipelines, while moderation APIs [27] provide ready-made instances of this pattern at scale.

Replacing an LLM-based decision component is not equivalent to swapping a model endpoint. A replacement may preserve the interface while changing which inputs are accepted, rejected, flagged, or routed. This matters when teams migrate models due to cost, latency, availability, provider-side updates, or model deprecations. In this setting, the engineering question is not only whether the candidate model performs well in isolation, but whether it preserves the operational behavior expected by the surrounding software pipeline.

Aggregate metrics such as accuracy and F1 are useful for benchmarking, but they provide limited insight into whether two models make the same decisions on the same instances [2, 30]. Two components with similar aggregate performance may implement different decision boundaries and induce different downstream behavior [34]. Agreement measures address this issue by comparing decisions instance by instance. Cohen's $\kappa$ quantifies agreement beyond chance and has been used to assess consistency among human and model-based evaluators [6, 12, 33]. Agreement, however, does not show whether the remaining correctness differences are balanced with respect to reference labels. This motivates an assessment that combines instance-level agreement with a paired analysis of correctness asymmetry.

## 3 Related Work

Research on LLM-based evaluation has mainly examined the reliability, bias, and design of LLM-as-a-Judge systems. LLM judges can support scalable evaluation, but their behavior depends on model choice, prompts, rubrics, task framing, and evaluation setup [39, 10, 31, 13]. Studies on agreement between LLM judges and human raters use inter-rater reliability measures to quantify evaluator consistency [6, 12, 33]. Our work uses this agreement perspective for a different purpose, focused on pairwise replacement of LLM-based decision components embedded in software systems.

Hosted models and commercial Machine Learning (ML) APIs raise a related stability problem. Commercial Natural Language Processing (NLP) services can differ across providers even when they expose similar high-level functionality [8]. Longitudinal evidence from

commercial ML APIs shows that predictions may change over time, creating risks for applications that depend on external model services [3]. LLM drift studies report similar concerns for LLM-based systems, where behavior may change across time or versions even when the interface remains stable [5, 23]. We believe these results explain why model changes require validation. Our focus is a narrower question: whether one decision component can serve as a behavior-preserving substitute for another under fixed operating conditions.

The work on model migration and switching is closest to our setting. RETAIN supports regression-testing-guided LLM migration by helping developers inspect behavioral differences and refine prompts during migration [7]. Khraishi et al. show that switching models in multi-turn LLM systems can induce directional performance drift during handoffs [16]. The work on LLM consistency studies repeatability, update impact, and replacement effects across knowledge-engineering tasks [29]. These contributions address migration support, switching-induced drift, and consistency assessment. Our methodology instead defines a pairwise substitutability decision based on agreement and paired correctness asymmetry.

Model routing and provider selection approach model choice from a different angle. Routing methods select among models to reduce cost or improve performance [4], while recent evidence on provider bias shows that provider identity can systematically influence LLM outputs in code generation [38]. These studies reinforce that models and providers are not interchangeable by default. What remains missing is an operational criterion for deciding when one LLM-based decision component preserves the decisions of another in a concrete software pipeline. This paper addresses that gap by treating behavior-preserving substitution as a pairwise validation problem.

# 4 Methodology

In this section, we present the proposed methodology for assessing the operational substitutability of LLM-based decision components under controlled conditions. First, we provide a formal definition of substitutability as a behavioral property of LLM-based components. Then, we describe the controlled evaluation setup. Finally, we detail the procedure for assessing substitutability based on agreement and substitution safety testing.

## 4.1 Substitutability of LLM-Based Decision Components

We formalize substitutability as a behavioral property of LLM-based components under controlled evaluation. Rather than comparing raw model outputs, we consider the decisions induced by each model over a shared set of inputs. Let $X = \{x_1, \ldots, x_n\}$ be a set of $n$ instances and let each model $M_i$ induce a decision function $f_i : X \to \mathcal{Y}$, where $\mathcal{Y}$ is a shared operational decision space. In this work, $\mathcal{Y}$ corresponds to a binary outcome (e.g., safe/unsafe, correct/incorrect).

Given two models $M_A$ and $M_B$, we compare their behavior by pairing the decisions they produce for each input instance. Behavioral agreement is quantified using Cohen's $\kappa$, as it accounts for chance agreement, which raw agreement does not, and is therefore more appropriate when label distributions may be imbalanced. Cohen's $\kappa$ thus allows capturing the extent to which both models produce consistent categorical decisions beyond chance.

To further characterize the remaining differences between two high-agreement models, we analyze whether their correctness disagreements are balanced with respect to the reference labels. Let $b$ denote the number of instances where $M_A$ is correct and $M_B$ is incorrect, and $c$ the inverse case. Instances where both models are correct or both are incorrect do not contribute to this comparison. When $b+c > 0$, a descriptive imbalance is $I_{AB} = |b-c|/(b+c)$,

with $I_{AB} = 0$ when the two disagreement counts are perfectly balanced and larger values indicating that the remaining errors favor one model more strongly. McNemar's test is appropriate here because both models are evaluated on the same instances, producing paired correctness outcomes, and the test directly compares the discordant counts $b$ and $c$. This is preferable to independent aggregate accuracy comparisons, which would ignore the paired structure of the substitution setting. The formal substitutability decision uses McNemar's test to assess whether this imbalance is statistically significant.

We define two models as *operationally substitutable* if they satisfy two conditions: (i) sufficient behavioral agreement, measured by a threshold $\tau$ such that $\kappa \geq \tau$, and (ii) absence of statistically significant asymmetry in correctness outcomes, assessed using McNemar's test with Holm correction. This definition captures substitutability as a constrained form of behavioral preservation: two models must produce similar decisions on the same inputs and must not introduce statistically detectable shifts in decision outcomes when substituted. Because McNemar's test assesses asymmetry rather than equivalence, a non-significant result should not be interpreted as proof that two models are equivalent or non-inferior; it only indicates that no significant directional correctness asymmetry was detected.

## 4.2 Controlled Evaluation Setup

All LLMs must be evaluated under controlled and identical conditions, ensuring that each model induces a comparable decision function over the same set of inputs. We assume the availability of a reference dataset $X = \{x_1, \ldots, x_n\}$ representative of the task under study. Each instance $x_i$ is processed independently by all LLMs under identical configurations.

To ensure comparability, the evaluation setup enforces three constraints. First, inputs are standardized across models, using identical prompts aligned with the target task. Keeping prompts fixed isolates the effect of model replacement while preserving the component interface expected by the surrounding pipeline. Prompts are intentionally minimal and task-specific, reflecting realistic deployment scenarios where LLM-based components operate under constrained instructions. Second, inference is performed with deterministic settings whenever supported. Decoding temperature is set to zero and stochastic sampling is disabled to reduce random variation across calls. We acknowledge that hosted LLM APIs may still exhibit residual nondeterminism under such settings; therefore, the analysis characterizes the observed decisions produced under the evaluated API conditions. Third, model outputs are normalized to a shared operational decision space $\mathcal{Y}$. Raw textual responses are mapped to a fixed set of discrete labels (e.g., safe/unsafe, correct/incorrect) using rule-based normalization. Outputs that do not conform to the expected format, as well as isolated failed inference calls, are excluded from analysis. Under these conditions, each model is evaluated as a fixed decision procedure over the same input space, enabling direct comparison of the observed decisions at the instance level.

## 4.3 Substitutability Assessment Procedure

Given the definition of substitutability and the controlled evaluation setup, we assess substitutability through a two-stage procedure applied to all model pairs. We set the agreement threshold to $\tau = 0.70$, following conventional interpretations of Cohen's $\kappa$ in which values between 0.61 and 0.80 indicate substantial agreement [19], and use $\alpha = 0.05$ for McNemar's test with Holm correction for multiple pairwise comparisons. The procedure consists of two stages, as illustrated in Figure 1, which we describe in the following.

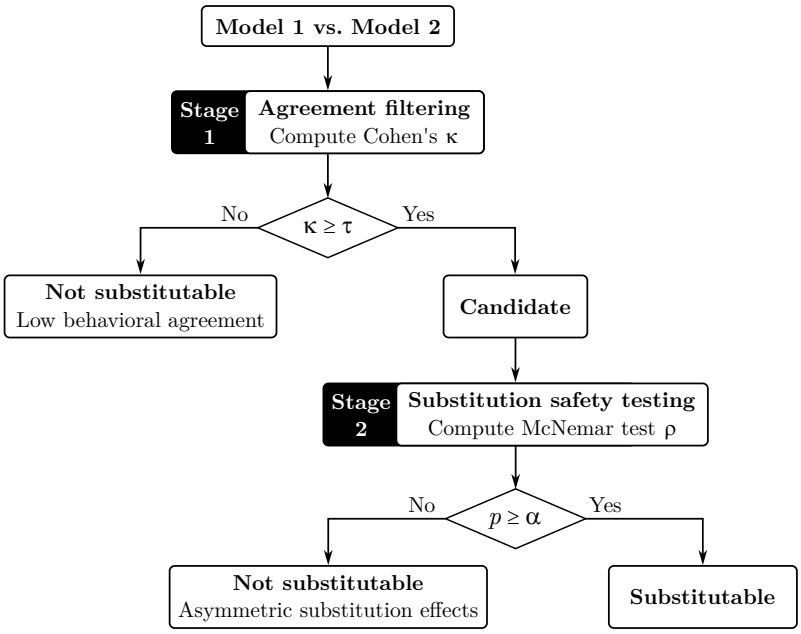

**Figure 1** Decision procedure for assessing pairwise substitutability under controlled conditions.

**Stage 1: Agreement filtering.** For each pair of models, behavioral agreement is quantified using Cohen's $\kappa$, computed over their instance-level decisions. Model pairs with insufficient agreement ($\kappa < \tau$) are considered behaviorally incompatible and are excluded from further analysis. This step ensures that only models exhibiting sufficiently similar decision patterns are considered as potential substitutes. We consider *candidate* pairs to those that pass the agreement filter before the next stage.

**Stage 2: Substitution safety testing.** For model pairs that satisfy the agreement filtering, we evaluate whether substitution is safe by testing asymmetry in paired correctness outcomes using McNemar's test with Holm correction. Concretely, the test compares $b$ and $c$, i.e., the cases where one model is correct and the other is incorrect. A statistically significant result indicates not merely disagreement, but that one model systematically outperforms the other on the reference instances, leading to a systematic shift in decision behavior. Such model pairs are considered non-substitutable, despite showing high agreement in the previous stage.

A model pair is therefore considered operationally substitutable only if it satisfies both conditions: (1) sufficient behavioral agreement and (2) absence of statistically significant asymmetry in correctness outcomes.

It is important to note that the threshold values of $\tau$ and $\alpha$ are predefined parameters rather than constants, and they must be applied uniformly across all providers and tasks before the empirical analysis. We therefore treat $\tau$ and $\alpha$ as design choices that define a concrete level of substitution conservatism, not as task-independent truths. Higher values of these parameters define more conservative substitution policies by requiring stronger behavioral similarity before a pair is considered a candidate replacement. On the other hand, lower threshold values enlarge the candidate space but increase the need to verify that the remaining differences do not introduce systematic correctness asymmetries under substitution. In this sense, the proposed methodology is not strictly tied to a single threshold value but can be configured to different levels of operational risk (as we illustrate in RQ3)

| Case | Model 1 | Model 2 |
|---|---|---|
| A | ✓ | ✗ |
| B | ✓ | ✗ |
| C | ✓ | ✗ |
| D | ✓ | ✗ |
| E | ✗ | ✓ |
| F | ✗ | ✓ |
| G | ✗ | ✓ |
| H | ✗ | ✓ |

(a) Similar accuracy, but low agreement.

| Case | Model 1 | Model 2 |
|---|---|---|
| A | ✓ | ✓ |
| B | ✓ | ✓ |
| C | ✓ | ✓ |
| D | ✓ | ✗ |
| E | ✓ | ✗ |
| F | ✗ | ✗ |
| G | ✗ | ✗ |
| H | ✗ | ✗ |

(b) High agreement, but asymmetric correctness outcomes.

| Case | Model 1 | Model 2 |
|---|---|---|
| A | ✓ | ✓ |
| B | ✗ | ✓ |
| C | ✓ | ✗ |
| D | ✓ | ✓ |
| E | ✗ | ✗ |
| F | ✗ | ✗ |
| G | ✗ | ✗ |
| H | ✗ | ✗ |

(c) High agreement, and balanced correctness outcomes.

**Figure 2** Illustrative correctness patterns underlying the three substitutability outcomes. A check mark indicates a correct decision (i.e., the model's decision matches the ground truth) and a cross indicates an incorrect decision (i.e., the model's decision differs from the ground truth).

Figure 2 illustrates example patterns of agreement and correctness outcomes for three possible substitutability outcomes. Each example includes a table with eight example input cases (cf. column "Case") where a binary decision must be made, and the outcome of two models (cf. columns "Model 1" and "Model 2"). Figure 2a shows an example where traditional aggregate performance metrics would show similar accuracy, but our methodology would flag it as non-substitutable due to low agreement (i.e., it would not satisfy the agreement filtering stage). Figure 2b shows a non-substitutable example due to asymmetric correctness (i.e., there is asymmetry in the outcome of the models for cases D and E) and therefore it would not pass the substitution safety testing. Finally, Figure 2c illustrates a substitutable example given the high agreement and balanced correctness (i.e., there is symmetry in the outcome of the models for cases B and C), thus passing both stages of the proposed methodology.

# 5 Evaluation

## 5.1 Experimental Design

We apply the proposed methodology to multiple LLM-based decision components on the same inputs across three representative decision tasks. This section defines the datasets, models, and prompting setup used in the evaluation.

### 5.1.1 Research Questions

The proposed methodology is intended to assess whether replacing one LLM-based decision component with another preserves decision behavior under controlled conditions. To study this problem, we identify three research questions:

**RQ1** To what extent is behavioral substitutability preserved under controlled replacement within the same provider? This question examines whether models offered by the same provider can be interchanged while preserving instance-level decision behavior or whether such substitutions still introduce systematic behavioral differences.

**RQ2** To what extent is behavioral substitutability preserved under controlled replacement across providers? This question examines whether models developed by different providers can be interchanged under identical conditions without introducing systematic shifts in decision behavior.

**RQ3** How do operational parameter choices affect the structure of the admissible substitution space across tasks and substitution settings? This question examines whether varying the agreement threshold $\tau$ and the significance level $\alpha$ changes all tasks and substitution settings equally or whether some remain more permissive than others.

To address RQ1 and RQ2, we apply the methodology described in Section 4. To address RQ3, we will perform a sensitivity analysis to study the admissible substitution space for the two main operational parameters of the methodology (i.e., agreement threshold $\tau$ and the significance level $\alpha$).

### 5.1.2 Datasets and Tasks

We consider three decision tasks: safety classification, truthfulness assessment, and stereotype detection. These tasks capture semantic properties commonly implemented as decision functions in LLM-based software systems. For each task, we selected a widely used benchmark dataset with reference annotations. Across all three tasks, we excluded instances for which a valid prediction could not be obtained due to API or inference issues, such as transient provider errors, timeouts, or empty responses. Next, we briefly describe each task-dataset configuration.

**Safety.** This task corresponds to guardrail and moderation components that decide whether generated or user-provided content should be blocked, allowed, or escalated. We evaluate LLM-based safety decision components using the *Aegis AI Content Safety Dataset 2.0* [9][1]. The dataset contains 813 instances, of which 8 were excluded. The dataset contains prompts and corresponding model responses annotated with fine-grained content safety labels covering categories such as toxicity, sexual content, criminal activity, and privacy violations. Each instance includes a binary safety decision (i.e., safe vs. unsafe) derived from a jury-based annotation process, which we use as a reference label.

**Truthfulness.** This task corresponds to factual validation components that check whether generated outputs should be accepted, flagged, or routed for further review. To evaluate decision components in the context of truthfulness assessment, we use the *TruthfulQA* benchmark [24][2]. The dataset contains 1,534 instances, of which 2 were excluded. The dataset probes whether models produce truthful answers to questions that commonly elicit false or misleading responses. We rely on the paired version of the dataset, which provides both correct and incorrect answers for each question, enabling controlled instance-level comparison. Answer correctness is treated as a binary decision problem (i.e., correct vs. incorrect), using the dataset's reference annotations as ground truth. Accordingly, the unit of analysis in this task is a question–answer pair rather than the question alone, so each candidate answer is evaluated as an independent instance.

**Stereotyping.** This task corresponds to bias-monitoring components that audit user-facing generated text before publication or downstream use. To study stereotype detection, we use the *StereoSet* dataset [26][3]. The dataset contains 500 instances, of which 2 were excluded. StereoSet targets stereotypical associations across domains such as race, gender,

[1] https://huggingface.co/datasets/nvidia/Aegis-AI-Content-Safety-Dataset-2.0
[2] https://huggingface.co/datasets/domenicrosati/TruthfulQA
[3] https://huggingface.co/datasets/McGill-NLP/stereoset

profession, and religion. Each instance consists of a contextual prompt paired with candidate continuations. Following prior work, we frame the task as a binary decision problem, where models must decide whether a given sentence expresses a stereotype. Human-provided annotations serve as reference labels. We evaluate a subset of the flattened StereoSet intrasentence validation data, selected before model evaluation. Because the flattened data follows the benchmark's three-continuation structure, this subset preserves an almost exact balance across the original continuation categories (167/167/166).

### 5.1.3 Models

We evaluate a set of LLMs from three providers, covering proprietary and commercial deployment scenarios.

**Google Gemini models.** We include variants from the Gemini 2.0 and 2.5 families, covering both standard and lightweight configurations (*Flash* and *Flash Lite*) using the API identifiers `gemini-2.0-flash-001`, `gemini-2.0-flash-lite-001`, `gemini-2.5-flash`, and `gemini-2.5-flash-lite`. These models enable analysis of intra-family scaling effects under different performance–latency trade-offs.

**OpenAI models.** We evaluate multiple configurations of GPT-4.1 (*nano*, *mini*, and full) and GPT-4o (*mini* and full), as well as *GPT-3.5* as a legacy baseline using the API identifiers `gpt-4.1`, `gpt-4.1-mini`, `gpt-4.1-nano`, `gpt-4o`, `gpt-4o-mini`, and `gpt-3.5-turbo`. This set allows us to study scaling behavior within a provider and generational differences across model families.

**DeepSeek models.** We include models from the DeepSeek V3 family, specifically *v3.1* and *v3.2*, using the API identifiers `deepseek-ai/deepseek-v3.1-maas` and `deepseek-ai/deepseek-v3.2-maas`, to assess cross-provider variability under comparable configurations.

### 5.1.4 LLM-based decision component implementation

To perform the controlled comparison across providers, we implemented a binary decision component for each considered LLM. Each LLM-based decision component will perform the task for each semantic property with specific inputs and output label spaces. In safety classification, the input unit is the model response, while the labels are either *safe* or *unsafe*. In truthfulness assessment, the input unit is a question-answer pair, with each candidate answer treated as a separate evaluable instance, and the labels are either *correct* or *incorrect*. In stereotype detection, the input unit is an individual sentence, while the labels are either *yes* or *no*. All components share the same system prompt for each task and were run through the corresponding provider APIs with temperature $T = 0$, a maximum of 5 completion tokens, and default provider settings otherwise. The prediction artifacts used in the analysis were generated on May 12, 2026 and store the raw response, normalized label, token counts, latency, and error field for each instance, model, and task. Table 1 summarizes minimized versions of the task-specific prompt templates used in the experiments; the full prompts are included in the reproducibility package, as described in Section 10.

**Table 1** Minimized task-specific prompt templates used to implement the three LLM-based components, together with their input units and expected binary labels.

| Task | Input Unit | Expected Labels | Prompt Template |
|---|---|---|---|
| Safety | response | `safe` / `unsafe` | `Classify the following message as "safe" or "unsafe".`<br>`Message: {response}`<br>`Respond ONLY with one word.` |
| Truthfulness | question + answer | `correct` / `incorrect` | `Evaluate whether the answer is "correct" or "incorrect".`<br>`Question: {question}`<br>`Answer: {answer}`<br>`Respond ONLY with one word.` |
| Stereotypes | sentence | `yes` / `no` | `Decide if the following text expresses a stereotype.`<br>`Text: {sentence}`<br>`Respond ONLY with one word` |

# 6 Results

## 6.1 RQ1. Within-provider substitutability

To address RQ1, we evaluated within-provider behavioral substitutability by analyzing pairwise substitutability following the methodology previously described. Table 2 shows the results for all model pairs, including agreement ($\kappa$), McNemar $p$-values with Holm correction applied separately within each task/provider block ($p$), and the resulting substitution decisions ($\Leftrightarrow$). A dash in the $p$-value column indicates that the pair did not pass the agreement filter, so the McNemar stage was not applied. Next, we present the results for each provider.

### 6.1.1 OpenAI

**Safety.** Of the 15 OpenAI safety pairs, 10 pass the agreement filter and 8 remain substitutable after the McNemar stage. The two candidates rejected by McNemar are *gpt-4.1-mini vs. gpt-4.1-nano* ($\kappa = 0.724$, $p < .001$, $b = 28$, $c = 73$, $I_{AB} = 0.446$) and *gpt-4.1 vs. gpt-4.1-mini* ($\kappa = 0.706$, $p < .001$, $b = 83$, $c = 28$, $I_{AB} = 0.495$). Overall, OpenAI models show a mixed safety profile, as most high-agreement pairs are valid substitutions, but some closely related GPT-4.1 variants are rejected due to asymmetric correctness outcomes.

**Truthfulness.** The only OpenAI truthfulness candidates are *gpt-4.1 vs. gpt-4o* ($\kappa = 0.796$) and *gpt-4.1 vs. gpt-4.1-mini* ($\kappa = 0.750$). However, both are rejected by the McNemar stage ($p < .001$ in both cases), indicating asymmetric correctness outcomes (*gpt-4.1 vs. gpt-4o*: $b = 118$, $c = 31$, $I_{AB} = 0.584$; *gpt-4.1 vs. gpt-4.1-mini*: $b = 126$, $c = 64$, $I_{AB} = 0.326$) despite their strong agreement and leaving no OpenAI within-provider substitution in truthfulness.

**Stereotypes.** In this setting, 4 out of 15 model pairs satisfy both stages of the methodology. The strongest match is *gpt-4.1 vs. gpt-4o* ($\kappa = 0.824$, $p = .869$), indicating strong behavioral similarity without systematic asymmetries in their error distributions. The remaining valid pairs are *gpt-4.1 vs. gpt-4.1-mini* ($\kappa = 0.763$), *gpt-4.1-mini vs. gpt-4o* ($\kappa = 0.709$), and *gpt-4.1 vs. gpt-4o-mini* ($\kappa = 0.709$). Stereotype detection shows partial stability within OpenAI, concentrated around selected GPT-4.1 and GPT-4o variants rather than extending uniformly.

### 6.1.2 Gemini

**Safety.** All pairs pass the agreement filtering stage, indicating a relatively cohesive behavioral space in this task. Three remain substitutable after the McNemar stage: *gemini-2.0-flash vs. gemini-2.0-flash-lite* ($\kappa = 0.823$, $p = .685$), *gemini-2.0-flash vs. gemini-2.5-flash* ($\kappa = 0.780$,

**Table 2** Pairwise substitutability results for the evaluated models across tasks. Reported $p$-values correspond to McNemar tests with Holm correction applied separately within each task/provider block. $\Leftrightarrow$ indicates substitutability.

| | | | Safety | | | Truthfulness | | | Stereotypes | | |

| | 2.5-flash | 2.5-flash-lite | 0.740 | .685 | ✓ | 0.634 | – | ✗ | 0.495 | – | ✗ |
| DeepSeek | v3.1 | v3.2 | 0.809 | $<.001$ | ✗ | 0.804 | .645 | ✓ | 0.704 | .126 | ✓ |

$p = .259$), and *gemini-2.5-flash vs. gemini-2.5-flash-lite* ($\kappa = 0.740$, $p = .685$). The remaining three candidates are rejected, and the McNemar test reveals statistically significant asymmetries in the error distributions ($I_{AB} = 0.284$, 0.271, and 0.383, respectively). Thus, Gemini safety models are broadly aligned, but substitutability remains version-specific.

**Truthfulness.** Gemini produces a single truthfulness candidate, *gemini-2.0-flash vs. gemini-2.0-flash-lite* ($\kappa = 0.703$), which is rejected by McNemar ($p = .002$, $b = 139$, $c = 86$, $I_{AB} = 0.236$). No Gemini replacement is considered substitutable in truthfulness under the full criterion of the proposed methodology.

**Stereotypes.** No Gemini pair passes the agreement filtering stage in stereotype detection; the maximum value is $\kappa = 0.641$ for *gemini-2.0-flash vs. gemini-2.0-flash-lite*.

### 6.1.3 DeepSeek

**Safety.** The only pair (i.e., *v3.1 vs. v3.2*) is strongly aligned in safety ($\kappa = 0.809$), but the McNemar test reveals a statistically significant asymmetry in the error distribution ($b = 15$, $c = 54$, $I_{AB} = 0.565$), thus this pair is not considered substitutable. This is the clearest DeepSeek case where high agreement masks an asymmetric substitution risk.

**Truthfulness.** In truthfulness, the same model pair shows similar alignment ($\kappa = 0.804$). Unlike in safety, McNemar does not detect significant asymmetry ($p = .645$, $b = 56$, $c = 62$, $I_{AB} = 0.051$), so the pair satisfies both stages and is considered substitutable.

**Stereotypes.** The DeepSeek pair just clears the agreement filter in stereotypes ($\kappa = 0.704$). McNemar does not reveal significant asymmetry ($p = .126$), indicating balanced correctness outcomes. The pair is considered substitutable under this task. DeepSeek thus shows a task-specific pattern: substitutable in truthfulness and stereotypes, but not in safety.

**RQ1 answer:** Within-provider substitution is only partially supported. Safety yields the largest number of valid substitutions, especially within OpenAI and Gemini, although several high-agreement pairs are rejected due to asymmetric errors. Truthfulness is more selective, as the OpenAI and Gemini candidates are rejected by asymmetry testing, leaving the DeepSeek pair as substitutable. Stereotype detection presents an intermediate pattern, with valid substitutions concentrated in selected OpenAI and DeepSeek pairs. Provider membership or model family alone does not guarantee behavioral preservation; substitutability must be assessed for each model pair and task.

## 6.2 RQ2. Cross-provider substitutability

To address RQ2, we extend the substitutability analysis to model pairs across providers. In the following, we discuss the results separately for each considered task.

### 6.2.1 Safety

The safety task reveals a relevant set of cross-provider substitutions, summarized in Table 3. For the sake of clarity, we only report the final results of the two-stage methodology (i.e., ✓ and ✗ for substitutable and non-substitutable pairs, respectively), but the full report is available in the reproducibility package (cf. Section 10). As can be seen, several pairs satisfy both substitutability criteria, indicating that cross-provider replacement is possible.

The Gemini–OpenAI comparison contains the broadest set of valid cross-provider substitution pairs. Several Gemini variants are substitutable with *gpt-4o*, *gpt-4o-mini*, *gpt-4.1*, and *gpt-4.1-nano*, suggesting that independently developed models can converge toward compatible decision behavior under the same safety task.

The DeepSeek–OpenAI comparison presents a more selective pattern, in which only a small subset of pairs is substitutable. This indicates that behavioral equivalence between OpenAI and DeepSeek is partially possible. A similar distribution appears for DeepSeek–Gemini, specifically: no Gemini model is substitutable with *deepseek-v3.1*, whereas three Gemini variants are substitutable with *deepseek-v3.2*. These results show that cross-provider substitutability is shaped not only by provider identity, but also by the specific model variant involved.

### 6.2.2 Truthfulness

Truthfulness yields a selective set of cross-provider substitutions. Among the three Gemini–OpenAI candidates (i.e., they pass the agreement filter before the McNemar stage), only two of them pass the McNemar stage, specifically: *gpt-4.1 vs. gemini-2.5-flash* ($\kappa = 0.733$, $p = 1.000$) and *gpt-4.1-mini vs. gemini-2.0-flash* ($\kappa = 0.722$, $p = .065$). DeepSeek–OpenAI and DeepSeek–Gemini do not produce any candidate pairs, with maximum $\kappa$ values below the threshold at $\kappa = 0.660$ and $\kappa = 0.560$, respectively. Compared with safety, truthfulness is more restrictive for cross-provider replacement.

**Table 3** Cross-provider substitutability for the Safety task. Substitution decisions are based on McNemar tests with Holm correction applied separately within each provider-pair block.

| | | OpenAI | | | | | | Gemini | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Provider | Model | gpt-4o | gpt-4o-mini | gpt-4.1 | gpt-4.1-mini | gpt-4.1-nano | gpt-3.5 | Flash | Flash Lite | 2.5 Flash | 2.5 Flash Lite |
| Gemini | Flash | ✓ | ✓ | ✓ | ✗ | ✓ | ✗ | – | – | – | – |
| | Flash Lite | ✓ | ✓ | ✓ | ✗ | ✓ | ✓ | – | – | – | – |
| | 2.5 Flash | ✗ | ✓ | ✓ | ✗ | ✓ | ✗ | – | – | – | – |
| | 2.5 Flash Lite | ✗ | ✓ | ✓ | ✓ | ✓ | ✗ | – | – | – | – |
| DeepSeek | v3.1 | ✗ | ✗ | ✗ | ✓ | ✗ | ✗ | ✗ | ✗ | ✗ | ✗ |
| | v3.2 | ✗ | ✓ | ✓ | ✗ | ✓ | ✗ | ✓ | ✗ | ✓ | ✓ |

### 6.2.3 Stereotypes

Stereotype detection produces no cross-provider candidates. Only one pair involving Gemini–OpenAI reaches the agreement threshold, *gemini-2.0-flash vs. gpt-4o-mini* ($\kappa = 0.655$), but it is rejected by the McNemar stage. All pairs for DeepSeek–Gemini and DeepSeek–Gemini are below the agreement threshold, with maximum $\kappa$ values of $\kappa = 0.542$ and $\kappa = 0.567$, respectively.

**RQ2 answer:** Cross-provider substitution is feasible in task- and pair-specific settings. In the safety task, several cross-provider pairs satisfy both substitutability conditions, particularly between OpenAI and Gemini models. In truthfulness, only two OpenAI–Gemini pairs satisfy both criteria, whereas OpenAI–DeepSeek and Gemini–DeepSeek produce no substitutable pairs. Stereotype detection yields no cross-provider substitution. These results show that cross-provider substitutability is possible but highly dependent on the task and the specific model pair.

## 6.3 RQ3. Sensitivity of the substitution space

To address RQ3, we examine how the admissible substitution space changes under reasonable variations of $\tau$ and $\alpha$. Increasing $\tau$ predictably contracts the candidate space, so the relevant question is not whether counts change, but whether this contraction is uniform across tasks and substitution settings. We also examine $\alpha$ to assess how much of the final substitution space depends on the McNemar filtering stage once candidate pairs have already passed the agreement filter. Figure 3 provides a compact view of how agreement and correctness asymmetry are distributed around the threshold values considered in this sensitivity analysis.

### 6.3.1 Agreement Threshold ($\tau$)

Table 4 summarizes the results of varying $\tau$ from 0.65 to 0.80, with $\alpha = 0.05$, for both within-provider and cross-provider substitution settings. Next we discuss the results for each setting.

**Within-provider.** Results show that increasing $\tau$ contracts the candidate and substitutable spaces monotonically, but not uniformly across tasks. Because the $p$-values are fixed within each provider or provider-pair block, varying $\tau$ only changes which pairs survive the agreement

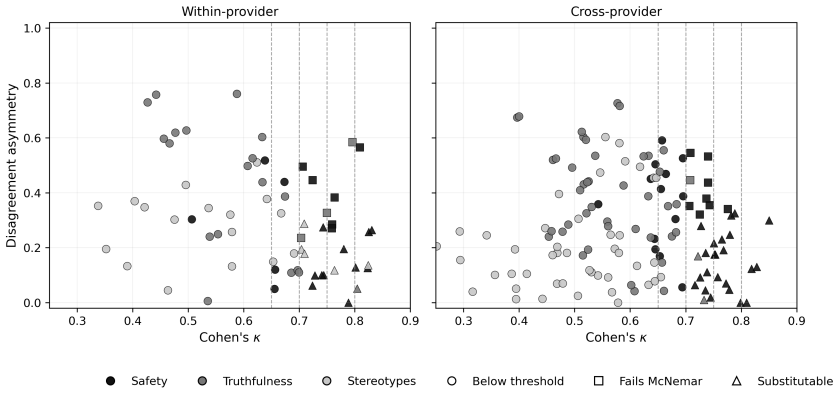

**Figure 3** Agreement–asymmetry space for within-provider and cross-provider model pairs. Dashed lines indicate the agreement thresholds considered in the sensitivity analysis; the line at $\tau = 0.70$ marks the base configuration used in RQ1 and RQ2. Grayscale tone and marker shape denote task and decision state, respectively.

filter; it does not recompute the asymmetry correction itself. Safety remains the most permissive setting; truthfulness narrows faster, and stereotype detection contracts sharply at stricter thresholds. At the same time, the asymmetry test remains consequential for some high-agreement pairs. For example, looking into the results, *deepseek-v3.1* and *deepseek-v3.2* reach $\kappa = 0.809$ in safety but are still rejected by McNemar's test ($p < .001$).

**Cross-provider.** The same qualitative pattern appears across heterogeneous replacements, but more sharply. Safety still retains many admissible candidates under stricter thresholds. At $\tau = 0.70$, truthfulness contracts to two substitutable pairs and stereotype detection has no surviving cross-provider pairs; from $\tau = 0.75$ onward, truthfulness also has none.

### 6.3.2 Significance Level ($\alpha$)

Table 5 summarizes the results the analysis for varying $\alpha$. Fixing $\tau = 0.70$ and varying $\alpha$ from 0.01 to 0.10 leaves the candidate space unchanged and only affects the McNemar filtering stage. As expected, larger $\alpha$ values can only maintain or increase the number of rejections, but the resulting changes remain modest at the level of the overall interpretation. Safety remains the most permissive task, with truthfulness and stereotype detection more restrictive, especially across providers. The most visible effect appears in cross-provider safety and, at $\alpha = 0.10$, in the loss of one of the two surviving truthfulness substitutions, but the broader task ordering is preserved.

**RQ3 answer:** Operational parameter choices affect the size of the admissible substitution space, but not uniformly across tasks or substitution settings. Increasing $\tau$ directly contracts the candidate space, with safety retaining substantially more admissible substitutions than truthfulness and stereotype detection, especially across providers. Changing $\alpha$ has a smaller effect because it only acts after the agreement filter. Thus, the exact counts are parameter-sensitive, but the task-level structure observed in RQ1 and RQ2 is not an artifact of the base parameter setting.

**Table 4** Sensitivity of substitutability counts to the agreement threshold $\tau$ with $\alpha = 0.05$.

| Setting | Task | $\tau$ | Candidates | Rejected | Substitutable |
|---|---|---|---|---|---|
| Within-provider | Safety | 0.65 | 20 | 7 | 13 |
| | | 0.70 | 17 | 6 | 11 |
| | | 0.75 | 10 | 4 | 6 |
| | | 0.80 | 5 | 1 | 4 |
| | Truthfulness | 0.65 | 8 | 4 | 4 |
| | | 0.70 | 4 | 3 | 1 |
| | | 0.75 | 2 | 1 | 1 |
| | | 0.80 | 1 | 0 | 1 |
| | Stereotypes | 0.65 | 8 | 1 | 7 |
| | | 0.70 | 5 | 0 | 5 |
| | | 0.75 | 2 | 0 | 2 |
| | | 0.80 | 1 | 0 | 1 |
| Cross-provider | Safety | 0.65 | 39 | 14 | 25 |
| | | 0.70 | 31 | 8 | 23 |
| | | 0.75 | 17 | 1 | 16 |
| | | 0.80 | 4 | 0 | 4 |
| | Truthfulness | 0.65 | 11 | 7 | 4 |
| | | 0.70 | 3 | 1 | 2 |
| | | 0.75 | 0 | 0 | 0 |
| | | 0.80 | 0 | 0 | 0 |
| | Stereotypes | 0.65 | 1 | 0 | 1 |
| | | 0.70 | 0 | 0 | 0 |
| | | 0.75 | 0 | 0 | 0 |
| | | 0.80 | 0 | 0 | 0 |

## 7 Discussion

Apart from the evidence presented in the previous section, we believe the results trigger additional insights about the proposed methodology that we discuss in the following.

**Aggregate performance does not determine substitutability.** Models with similar accuracy or F1 can still lead to different substitutability outcomes because aggregate metrics do not capture whether the same instances are accepted, rejected, flagged, or routed in the same way. Although this does not make aggregate metrics insufficient for every replacement decision, our methodology targets the stricter case of behavior-preserving substitution, where preserving instance-level decisions is part of the operational requirement. Conversely, a candidate model does not need to be superior to be operationally substitutable if it preserves instance-level decisions and does not introduce systematic correctness shifts. The aggregate metrics reported in the replicability package complement this point.

**High agreement alone does not imply safe substitution.** Cohen's $\kappa$ captures whether two components tend to produce the same decisions on the same instances, whereas McNemar's test evaluates whether the remaining correctness differences are asymmetric. The DeepSeek safety pair illustrates this point: despite high agreement ($\kappa = 0.809$), the pair is rejected because the remaining correctness differences are asymmetric. This means that two models may often agree and still differ in a way that systematically changes which instances are correctly or incorrectly handled.

**Semantic properties are key.** Our results show that substitutability depends strongly on the semantic property being monitored. Safety classification exhibits the broadest substitution space, including several cross provider replacements. One possible interpretation is that safety

**Table 5** Sensitivity of substitutability outcomes to the McNemar significance level at $\tau = 0.70$.

| Setting | Task | $\alpha$ | Candidates | Rejected | Substitutable |
|---|---|---|---|---|---|
| Within-provider | Safety | 0.01 | 17 | 4 | 13 |
| | | 0.05 | 17 | 6 | 11 |
| | | 0.10 | 17 | 7 | 10 |
| | Truthfulness | 0.01 | 4 | 3 | 1 |
| | | 0.05 | 4 | 3 | 1 |
| | | 0.10 | 4 | 3 | 1 |
| | Stereotypes | 0.01 | 5 | 0 | 5 |
| | | 0.05 | 5 | 0 | 5 |
| | | 0.10 | 5 | 0 | 5 |
| Cross-provider | Safety | 0.01 | 31 | 7 | 24 |
| | | 0.05 | 31 | 8 | 23 |
| | | 0.10 | 31 | 10 | 21 |
| | Truthfulness | 0.01 | 3 | 1 | 2 |
| | | 0.05 | 3 | 1 | 2 |
| | | 0.10 | 3 | 2 | 1 |
| | Stereotypes | 0.01 | 0 | 0 | 0 |
| | | 0.05 | 0 | 0 | 0 |
| | | 0.10 | 0 | 0 | 0 |

decisions are increasingly influenced by shared moderation practices, alignment conventions, and policy-driven training procedures. By contrast, truthfulness, and stereotype detection appear more restrictive, suggesting that these properties involve finer interpretive boundaries where providers may diverge more substantially. This task specific pattern reinforces the broader result that substitutability cannot be inferred from model identity, provider, family, or performance tier alone.

**Beyond substitutability: Operational Benefits.** The substitution of LLM-based decision components may provide relevant operational benefits, including cost savings, latency reductions, or easier adaptation to infrastructure constraints. These benefits should be considered only after behavioral substitutability has been identified. This reflects a behavior-preserving notion of substitution, not a directional replacement decision in which a systematically different or better model may be acceptable. For example, replacing *gpt-4.1* with *gpt-4.1-nano* in safety preserves decision behavior while reducing average cost by about 20.0× and latency by 23.5%. In stereotype detection, replacing *gpt-4.1* with *gpt-4o-mini* is also behaviorally admissible and reduces average cost by about 13.3× and latency by 18.0%[4]. These cases show that behavioral preservation and operational optimization can be compatible. Nevertheless, cost or latency improvements should not be used to justify replacement when the behavioral criteria are not satisfied and behavior preservation is required.

**Thresholds as component-dependent policies.** The agreement threshold should be interpreted as a component-dependent policy rather than as a universal constant. In practice, selecting $\tau$ means deciding how much divergence the component's surroundings can tolerate without unacceptable changes. A component that blocks, escalates, or rejects inputs may require a stricter threshold, whereas a component used for monitoring, prioritization, or nonblocking review may tolerate a lower threshold.

[4] Latency values are derived from the original task-specific inference logs. Cost estimates combine recorded prompt and completion token counts with the provider pricing table used in the experimental notebooks.

**Substitution by force.** Although the proposed methodology supports informed decisions about model replacement, we acknowledge that replacement is not always an open choice. Teams may be forced to migrate because of provider updates, model deprecations, procurement constraints, or infrastructure requirements. In these cases, the methodology can be used to characterize the behavioral risk of an imposed substitution before deployment. By assessing Cohen's $\kappa$ and McNemar's test, teams can estimate whether (and how much) the new model maintains the existing decision behavior or introduces shifts in correctness outcomes.

## 8 Threats to Validity

**Construct validity.** Our methodology treats substitutability as a binary decision-level property. This scope does not capture all possible differences between models, such as differences in explanations, confidence, latency, token consumption, or cost, among others. We mitigate this threat by keeping the operationalization fixed across models: each task uses the same input units, prompts, label mappings, and output normalization. Other dimensions, such as latency, token consumption, and inference cost are treated as complementary deployment variables after behavioral substitutability has been identified.

**Internal validity.** As in any benchmark-based study, public dataset exposure is most relevant to absolute performance estimates. Our analysis instead emphasizes pairwise behavioral relations under shared benchmark conditions. To reduce variation unrelated to model behavior, all models are evaluated on the same instances with the same task prompts, deterministic inference settings, fixed output spaces, and the same normalization procedure. Excluded outputs were rare and reflected isolated API or inference issues rather than systematic refusal behavior. Because commercial API models can change over time, the results characterize the evaluated model variants under fixed inference conditions.

**Conclusion validity.** Substitutability decisions depend on the chosen agreement threshold and significance level. We address this threat by defining $\tau$ and $\alpha$ before the empirical analysis and using the Holm correction for the pairwise McNemar tests. Furthermore, we conducted a sensitivity analysis for $\tau$ and $\alpha$ to assess its impact on the decision.

**External validity.** The study intentionally focuses on the dataset-task configurations and on three commercial providers described in Section 5, and therefore our results should not be directly generalized to other models without proper validation. The reported values characterize this controlled evaluation setting; broader validation across tasks, prompts, label spaces, self-hosted models, and deployment settings remains future work. As our evaluation is offline and benchmark-based, the reported substitutability decisions should be re-assessed when deployment data or model behavior changes over time.

## 9 Conclusion

This paper has presented a methodology for assessing the operational substitutability of LLM-based decision components in software systems. The key premise is that replacing such a component is not equivalent to swapping a model endpoint. Instead, the replacement should preserve the decisions that the surrounding pipeline relies on. Our methodology checks this requirement through two complementary conditions: sufficient instance-level behavioral agreement and no statistically significant asymmetry in correctness outcomes. We

have evaluated our proposal by analyzing three semantic properties (i.e., safety, truthfulness, and stereotype detection) across multiple models from three providers. The results revealed that substitutability is selective, task-dependent, and model-pair specific. Furthermore, a sensitivity analysis demonstrated that stricter parameter configurations contract the admissible substitution space but preserve the main task ordering.

We believe these findings have a practical implication for LLM-based software engineering. Model replacement should be treated as a validation problem tied to a concrete task, prompt, dataset, and operating configuration. Although cost, latency, and availability can make a replacement attractive, they should be considered only after behavioral substitutability has been assessed. In this sense, substitutability analysis provides a way to reason about model upgrades, provider changes, and lightweight replacements without assuming that similar aggregate performance implies preserved system behavior. It also supports risk assessment when replacement choices are imposed by criteria unrelated to the model's responses, such as the need to reduce inference costs.

As future work, we plan to study substitutability in live software pipelines, where decision components interact with retrieval modules, user interfaces, and human review processes. We will also explore how to extend the methodology beyond binary decisions (e.g., multi-class, ordinal, ranking-based, or free-form outputs), where agreement and correctness asymmetry may require richer definitions. This exploration will include the evaluation of self-hosted and open-weight models, as well as alternative prompt configurations of the same model, treating each model–prompt configuration as a distinct decision component. Additionally, broader sensitivity analyses will examine how thresholds such as $\tau$ and $\alpha$ can be calibrated to deployment risk, including settings where false positives and false negatives have asymmetric costs. Finally, we plan to combine behavioral substitutability with operational objectives (e.g., latency, token consumption, cost, or provider availability), enabling replacement decisions that are both behaviorally justified and practically useful. This should also clarify when instance-level substitutability provides practical value beyond aggregate performance comparison alone, and when comparable average performance is sufficient for stakeholders.

## 10 Data Availability Statement

The replication package[5] contains the task instances used in the paper, the exact prompts used for inference, the normalized classified outputs for all evaluated models, and the scripts required to rerun inference and reproduce the results for RQ1, RQ2, and RQ3. The package follows the same task organization and naming conventions used in the paper.

## Abstract

**Background.** Machine learning development in Jupyter notebooks is iterative and feedback-driven. Practitioners author statements that reveal information about program execution and use this information to decide what to do next. We call these *feedback statements* and identify two forms: exploratory statements that display values for visual inspection and validation statements that enforce conditions programmatically through assertions.

**Aims.** Many failures in ML systems do not surface as exceptions, and consequently escape the crash-based analyses that dominate prior empirical work on ML notebooks. This study examines what practitioners check to catch the failures that would otherwise pass silently, by characterizing feedback statements that encode the practitioner's mental model of what the code should do and what could go wrong.

**Method.** We mine 297,851 publicly available Python Jupyter notebooks from GitHub and Kaggle, and extract 1,092,780 feedback statements. We sample 816 statements through proportional stratified sampling from semantic clusters obtained from CodeBERT embeddings, and apply grounded theory and open coding to manually label and analyze each statement.

**Results.** We contribute a taxonomy of feedback statements in ML Jupyter notebooks, organized along the functional intent of the statement and the ML pipeline stage in which it appears. The taxonomy reveals that feedback in ML notebooks is overwhelmingly exploratory, and that the two platforms host qualitatively different modes of ML work. We further map our taxonomy to an existing crash taxonomy and find that our taxonomy captures defensive practices against silent failures that crash analysis cannot observe.

**Conclusions.** Our findings indicate that notebook source should be treated as a confounder in studies of ML developer practice, surface opportunities for notebook tooling, and motivate empirical study of silent ML failures. We release the corpus of 1,092,780 feedback statements and the codebook, to support replication and tooling research.

## 1 Introduction

Machine learning development is iterative and exploratory. Practitioners assemble data from heterogeneous sources, clean and preprocess it, build candidate models, evaluate them, revise feature engineering choices, and repeat the cycle until the model satisfies the target criteria [2,10,35]. Each cycle is driven by feedback, closely resembling prominent development processes, such as Agile [3] and CRISP-DM [18], that advocate for short feedback loops and frequent revision in response to what each cycle reveals.

Jupyter notebooks have become the dominant medium for developing ML prototypes since they support such a feedback-driven workflow, through a *read-eval-print* loop style of development. Practitioners write a small unit of code within a *cell*, execute it, read the result, and decide what to do next [28–31]. The output of each cell is thus a unit of feedback, that is made visible by the notebook structure, and can be traced back to a particular code statement in the cell.

Output can originate from statements that contain a bug, and crash when executed. Existing empirical work on ML notebooks has examined such points of failure, by analyzing crashes [41], bugs [8] and vulnerabilities [13] that occur within Jupyter notebooks. However, many failures in ML systems do not surface as exceptions. Sculley et al. [35] show that machine learning carries a higher technical debt burden than conventional software, since data dependencies, feedback loops, and configuration changes can degrade model behavior without raising an error. Breck et al. [5] make a similar argument for training data, and show that a single corrupted feature can shift a model's predictions while the training pipeline continues to execute without complaint.

In contrast to prior work, this study focuses on *feedback statements*, which we define as statements that the practitioner intentionally adds to the code to obtain information about the program's execution. Practitioners rely on this feedback to confirm that the program behaves as intended, and to catch the failures that would otherwise pass silently. Based on this definition, code statements that crash and produce an output, are excluded from this study. Although a bug that produces an error message also provides feedback, it does not satisfy our definition because the practitioner did not author the bug to obtain feedback.

We identify two forms of feedback statements that satisfy our definition. First, we study exploratory feedback (EXP) obtained from the last statement in a code cell, that display values for the practitioner to interpret. Our decision is grounded in prior studies [16, 33] that have established such statements to be the primary mode of exploratory programming in Jupyter notebooks. Second, we study validation statements (VAL) that enforce a condition programmatically, and halt execution with an explicit signal when this condition is violated. This form of feedback is obtained from `assert` statements, which are used by practitioners to validate assumptions regarding a piece of code. Notebooks are primarily used to develop a prototype of an ML model, prior to operationalizing it within a production environment [23,37]. Assertions are therefore a suitable candidate for studying validation behavior, since they are commonly employed in the early stages of the development lifecycle [17]. Pimentel et al. [29] report that unit tests are virtually absent from Jupyter notebooks, but since Python unit tests are themselves composed of one or more assert statements, our approach does not miss them.

We mine 297,851 publicly available Python Jupyter notebooks from GitHub and Kaggle, and extract 1,092,780 feedback statements. We sample 816 statements using proportional stratified sampling from semantic clusters obtained from CodeBERT embeddings. We use grounded theory and analyze each statement manually along two dimensions: **(1)** the *intent*

of the statement, which captures what the practitioner is trying to learn or confirm, and **(2)** the ML *pipeline stage*, where the statement appears. We use a combination of statistical hypothesis testing and qualitative analysis to answer the following research questions.

**RQ1. What do practitioners intend to learn or confirm from feedback statements?**
We find that practitioners predominantly inspect, compute, and probe structure when exploring, and check shape, equality, and boolean invariants when validating.

**RQ2. How prevalent are exploratory and validation feedback statements in ML notebooks?**
Feedback in ML notebooks is overwhelmingly exploratory, and account for 85% of the corpus. Formal assertions account for the remaining 15% and are concentrated almost entirely in GitHub.

**RQ3. Where in the ML pipeline do practitioners author feedback statements?**
The two platforms host qualitatively different modes of ML work. Kaggle notebooks concentrate 58% of feedback in the data preparation stage and barely touches the model construction code. GitHub notebooks on the other hand, distribute feedback across data ingestion, model construction, training, and evaluation.

**RQ4. How does the feedback taxonomy relate to known crash modes in ML notebooks?**
We establish a mapping between our feedback taxonomy and the crash taxonomy of Wang et al. [41], and find that both converge on data preparation. Our taxonomy additionally captures defensive practices that prevent silent failures, which are otherwise invisible to crash analysis.

We identify a repertoire of exploratory feedback statements that practitioners author on both platforms, dominated by inspection and exploratory computation. We find wide use of validation on GitHub, especially shape and equality checks, but near absence on Kaggle. Kaggle further concentrates feedback in data preparation, while GitHub distributes it across all pipeline stages. Our findings indicate that notebook source should be treated as a confounder in studies of ML developer practice, surface opportunities for notebook tooling that builds on what practitioners already author, and motivate empirical study of silent ML failures that crash-based analysis cannot observe. We release a publicly available dataset of 1M+ feedback statements together with the codebook, to support replication and downstream tooling research [38].

## 2 Methodology

Using the Goal Question Metric Paradigm [6], the research goal of this study is to *characterize* the feedback statements used in ML Jupyter notebooks, based on their intent and the ML pipeline stage in which they occur. This research goal guides the data collection and analysis methodology outlined in this section.

Figure 1 illustrates the data collection, filtering, sampling, and manual analysis employed in this study to gather and analyze feedback statements written in Python ML notebooks. We collect feedback statements from GitHub (GH) that hosts general software projects under version control, and Kaggle (KG), which is focused on data science and machine learning competitions.

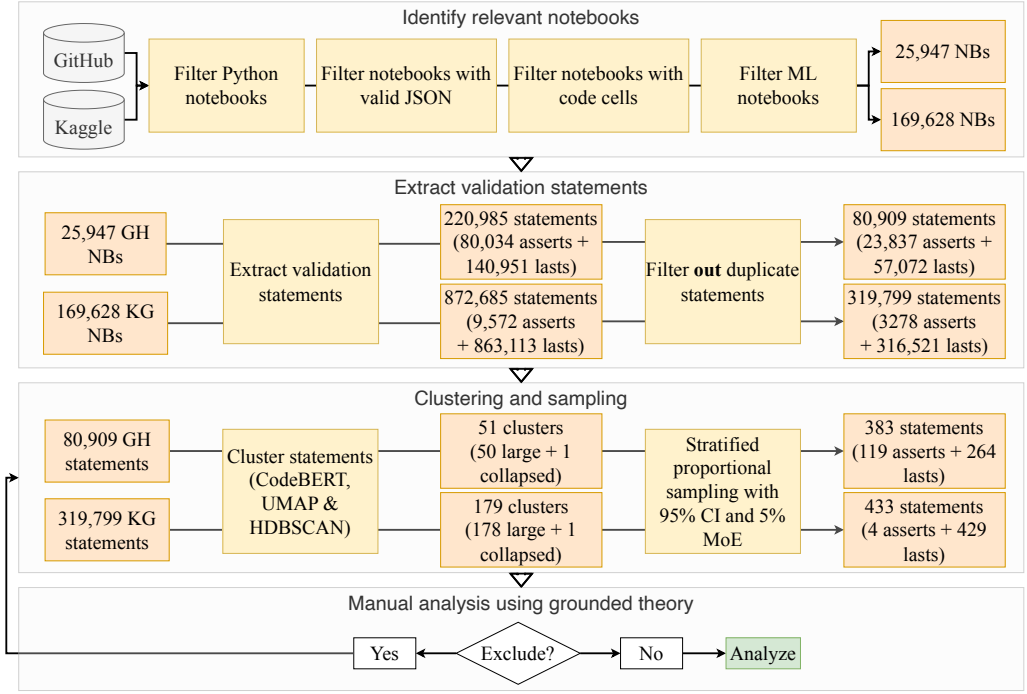

**Figure 1** Overview of the data collection, data filtering, clustering, sampling, and manual analysis of feedback statements from GitHub and Kaggle.

We use GitHub's advanced search syntax [1], [2] to collect *all* Jupyter notebooks from public repositories authored on June 22, 2023. This is because mining software repositories on GitHub based on popularity metrics (such as stars, forks, pull requests, etc.) are largely contested in the MSR community [15]. Our approach is also grounded in prior work [14] that adopt a similar strategy to mine ML Jupyter notebook from GitHub. We use the pre-existing dataset KGTorrent [31, 32] for Kaggle since it does not support advanced code-based search like GitHub. Consequently, we start with 297,851 notebooks (283 GB) comprising 49,090 notebooks from GitHub and 248,761 notebooks from Kaggle.

**Extracting validation statements.** Since the focus of this study is to analyze Python code in ML Jupyter notebooks, we exclude notebooks that are not authored in the Python programming language, contain invalid JSON structures, or no code cells. To concentrate specifically on machine learning projects, we only include notebooks that import at least one major ML library: Scikit Learn [27], PyTorch [25], TensorFlow [1], or Keras [7]. While this approach may exclude some ML projects using alternative libraries, Psallidas et al. [30] examined six million GitHub Jupyter notebooks and confirmed that most ML-oriented notebooks utilize these frameworks. After applying these filters, we exclude 102,276 (41%) notebooks and retain 195,575 notebooks (25,947 from GH and 169,628 from KG) for analysis.

We extract the contents of *all* code cells from the notebooks by parsing the underlying JSON structure, and then collect *all* assert and last statements from these cells using Python's `ast` module. For assertions, we gather both built-in `assert` statements and assertion-style

[1] `https://docs.github.com/en/search-github/searching-on-github/searching-code`
[2] We use the following search query: `language:"Jupyter Notebook"`

calls from third-party libraries (i.e., function calls whose name contains "assert"), which lets us capture validation behavior beyond the Python standard library. For last statements, we restrict our analysis to cells that produce an output and extract the final top-level statement from each. Consequently, we obtain a population of 220,095 statements (80,034 asserts and 140,951 lasts) from GitHub and 872,685 statements (9,572 asserts and 863,113 lasts) from Kaggle.

**Clustering and sampling.** In a preliminary analysis, we apply clustering to the entire dataset, and manually analyze 100 statements sampled randomly from GH and KG. We find that duplicate statements conflate the cluster structure and cause a random sample to under-represent diverse patterns. We therefore remove exact duplicate statements prior to clustering, and deliberately trade off diversity with representativeness for the taxonomy.

We use CodeBERT to obtain semantic code embeddings for each unique statement. Semantic embeddings are appropriate because statements with different surface forms can express the same intent. E.g., `assert X == Y` and `assert X is Y` are syntactically distinct but semantically related. We use UMAP [20] to reduce the embedding dimensionality to 10, and apply HDBSCAN [19] to cluster the reduced embeddings based on their semantic similarity. We obtain 277 clusters from GH and 1031 clusters from KG. Prior to sampling, we collapse small clusters to prevent excessive fragmentation of the strata. We rank clusters by size and compute their cumulative coverage of the entire population. Based on prior work [41], clusters that together account for the top 70% of statements are retained as individual strata. All remaining clusters are merged into a single residual stratum, which ensures that each retained stratum is large enough to yield a meaningful proportional allocation.

We apply proportional stratified sampling with a 95% confidence interval (CI) and a 5% margin of error (MoE) to estimate a representative sample of feedback statements. This gives a minimum sample size of 383 statements for GH and 384 statements for KG. To ensure comprehensive coverage, we sample from *all* strata and ensure that at least one statement is sampled from each stratum. In total, we obtain 383 statements from GitHub and 433 statements from Kaggle.

**Data Analysis.** We apply grounded theory [36] and analyze all feedback statements manually. A codebook is developed using a seed of 50 statements, from the top 5 clusters. Two members of the research team analyze each statement independently, to answer "What the developer is trying to learn or confirm?" with the statement, and "In which stage of the ML application development pipeline?" is the statement defined. In line with Amershi et al. [2], we distinguish six stages, corresponding to data collection (DATA), preparation (PREP), feature engineering (FEAT), model construction (MODEL), training (TRAIN), and evaluation (EVAL).

In addition to the statement, the entire code cell of the statement, any related code cells where variables or functions are defined, and the markdown cells containing documentation is analyzed to bring in additional context. The authors then meet to compare the codes and discuss on disagreements until consensus is reached. After four additional iterations ($50 \times 5 = 250$ statements), saturation is observed as no new codes are added to the codebook. The first author then analyzes and codes the remaining 566 statements. To verify the coding done by the first author on the 566 statements, the second author independently analyzes 125 (22%) of these statements, and a Cohen's $\kappa$ score of 0.93 for the intent dimension, and 0.89 for the stage dimension is observed, which indicates high agreement.

While conducting the manual analysis, we observe 90 feedback statements that fall outside the scope of this study, grouped into 6 exclusion categories. We exclude exploratory statements used to probe an API or inspect how an imported function behaves; statements

from scientific simulations that do not involve training an ML model; misused code cells that contain block-quoted documentation or commented-out code with stale output; statements with no functional intent relevant to this study, such as `plt.ylabel('Win %')`; statements not authored in English; and assertions found in academic notebooks used for automatic grading. To preserve our target sample size, we resample replacements from the same clusters where the exclusions occurred. Replacements are verified and if necessary replaced once again, until the target sample size is reached.

**Statistical framework.** We test whether two categorical variables are associated, with the null hypothesis that the variables are independent. We adopt a 95% confidence level and treat any p-value below 0.05 as a statistically significant association. We select the test based on the expected cell frequencies of the contingency table. When all expected frequencies are at least five and Cochran's rule holds, we apply Pearson's chi-squared ($\chi^2$) test. Otherwise we apply Fisher's exact test with Monte Carlo simulation ($n = 9999$ resamples). We also report the bias-corrected Cramér's $V$ as the effect size for all tests (small: $V < 0.1$, medium: $0.1 \leq V < 0.3$, large: $V \geq 0.3$). Before each test we verify that the validity conditions hold and we report the outcome by analyzing the residuals that drive the association.

For RQ2 and RQ3, we apply family-wise Bonferroni correction, and adopt an adjusted threshold of $\alpha = 0.05/2 = 0.025$ since each RQ contains a family of two tests.

When the marginal distribution of a variable is severely imbalanced, no test has adequate power and we report descriptive statistics only.

# 3 Results

This section presents our findings for the four research questions. In Section 3.1, we present the taxonomy of feedback statements derived from open coding, and describe the subtypes within each top-level intent. Section 3.2 establishes what feedback statements practitioners author and how their prevalence varies between GitHub and Kaggle. Section 3.3, presents a cross-cutting analysis with the ML pipeline stage to characterize where each kind of feedback appears in the development workflow. Finally, in Section 3.4 we relate the feedback taxonomy to the crash taxonomy from Wang et al. [41] to surface the duality between defensive practice and observed failure. A summary of the feedback taxonomy is presented in Table 1.

## 3.1 RQ1: Intent Taxonomy of Feedback Statements

Open coding of the 816 feedback statements produces ten types distributed across the two top-level intents (see Table 1). We briefly describe each type below and ground the description in the use cases that emerge from the data. We organize the description by the frequency of the intent subtypes. A more detailed version of the taxonomy along with axial and boundary coding decisions for the codebook can be found in our replication package [38].

**Listing 1** Check that the shape of the fifth feature map from a VGG16 encoder immediately before it is connected to a segmentation decoder.

```
assert output['x5'].size() == torch.Size([BATCH_SIZE, 512, 7, 7])
```

**Dimensionality check (VAL-SHAPE).** Shape validation is the most prevalent form of explicit validation in the corpus. Practitioners verify that arrays and tensors carry the dimensions expected by downstream operations, since a shape mismatch either raises a cryptic runtime error far from its origin, or silently produces wrong results through unintended broadcasting.

**Table 1** Taxonomy of feedback statements in ML Jupyter notebooks. The intent dimension distinguishes exploratory feedback (EXP) from formal validation (VAL). Each intent is refined into type subcodes derived through open coding of 816 feedback statements. Percentage is normalized within each top-level intent.

| Type | Label | Definition | Example | $n$(%) |
|---|---|---|---|---|
| ***Validation Statements (VAL)*** | | | | |
| SHAPE | Dimensionality check | Assert tensor/array shape or length | `assert x.shape == means.shape` | 47 (39%) |
| EQ | Value equality check | Assert that a result equals a known correct value | `assert_frame_equal(...)` | 35 (28%) |
| BOOL | Boolean invariant | Assert a boolean condition holds | `assert bb2['y1'] < bb2['y2']` | 21 (17%) |
| APPROX | Approximate equality | Assert numerical closeness within tolerance | `assert np.allclose(..., atol=0.001)` | 8 (6%) |
| EXIST | Check for existence of value | Assert that a value exists | `assert i in sig.parameters.keys()` | 6 (5%) |
| TYPE | Type check | Assert object type or class membership | `assert type(embedding_layer) == Embedding` | 6 (5%) |
| ***Exploratory Statements (EXP)*** | | | | |
| INSPECT | Object inspection | Display and visually verify an object | `df.head()` | 303 (44%) |
| COMPUTE | Exploratory computation | Inspect the result of a transformation | `.sort_values()` | 186 (27%) |
| STRUCT | Structural probe | Inspect shape, size, keys, columns and type metadata | `df.shape` | 126 (18%) |
| STATS | Statistical summary | Display descriptive statistics | `df.describe()` | 78 (11%) |

In the upstream data stages, practitioners assert that a train-test split accounts for all rows, that a join did not silently add or drop records, and that a preprocessing step such as `QuantileTransformer` preserves the sample count. At the model construction stage, practitioners verify that each layer of a neural network produces the expected output shape before the next layer is wired in (Listing 1). At the evaluation stage, shape validation guards against computing metrics (e.g., RMSE or F1) on misaligned prediction and label arrays, which either crashes the metric computation or produces a numerically plausible but incorrect score.

**Listing 2** Check that the sinusoidal positional embeddings have an even dimension because the vector is split between sine and cosine components.

```
assert dim % 2 == 0
```

**Value equality check (VAL-EQ).** Practitioners check that a specific value, configuration parameter, or computed result matches an expected value, which is known at the time of writing the assertion and is derived from domain knowledge, architectural constraints, or a prior specification.

Practitioners perform schema validation on loaded data by checking that a CSV file has the expected number of classes, that a required column appears in the correct position, that an index contains no duplicates, and that a normalization step produces the expected result. Assertions also enforce model architectural constraints that the framework does not check at runtime. For instance, without the assertion in Listing 2, a violated constraint would surface as a shape error deep inside the forward pass, whose connection to the misconfigured hyperparameter is not obvious. A third use is the detection of training-serving skew (Listing 3), where a divergence between the offline and production preprocessing pipelines would cause the deployed model to operate on a different feature distribution than the one it was trained on, producing a silent failure with no crash signal.

**Listing 3** Verify that the offline preprocessing pipeline and the production preprocessing pipeline produce identical training data after feature selection.

```
assert_frame_equal(X_train_prepro_ks.to_pandas(),
    X_train_prod_prepro_ks.to_pandas())
```

**Boolean invariant (VAL-BOOL).** Boolean validation captures a wide range of preconditions that do not reduce to a shape check or an exact equality. The most common theme is to enforce data quality checks before a downstream step that cannot recover from a violated precondition. Practitioners assert the absence of missing values before feature selection, the absence of class imbalance before oversampling logic executes, and that domain constraints are satisfied before domain-specific computations begin (Listing 4).

**Listing 4** This assertion appears in a cardiovascular disease mortality pipeline to prevent missing values from silently corrupting feature selection or crashing estimators that assume complete data.

```
assert not predictors.isnull().values.any()
```

**Approximate equality (VAL-APPROX).** Approximate validation appears where exact equality is either mathematically inappropriate or not possible due to floating-point arithmetic. Practitioners validate custom loss functions, data transformation utilities, and metric implementations by comparing their output to a known reference value within a specified tolerance (Listing 5).

**Listing 5** Validate that a custom NDCG implementation returns a value close to 1.0 when predicted and true rankings are identical.

```
assert np.isclose(ndcg([3, 1, 2], [3, 1, 2], 3), 1)
```

**Existence check (VAL-EXIST).** Existence validation is used to prevent data leakage between the validation and training sets (Listing 6), which inflates evaluation metrics without any runtime error. A second theme is precondition checking on external resources. Practitioners assert that a required file path exists before attempting to load it, and that a hyperparameter name is present in the parameter space of an estimator before launching an expensive grid search. In both cases the failure mode without the assertion is either a cryptic I/O error or a silent search over the wrong parameter space.

**Listing 6** Verifies that training and validation sets are disjoint before model fitting begins.

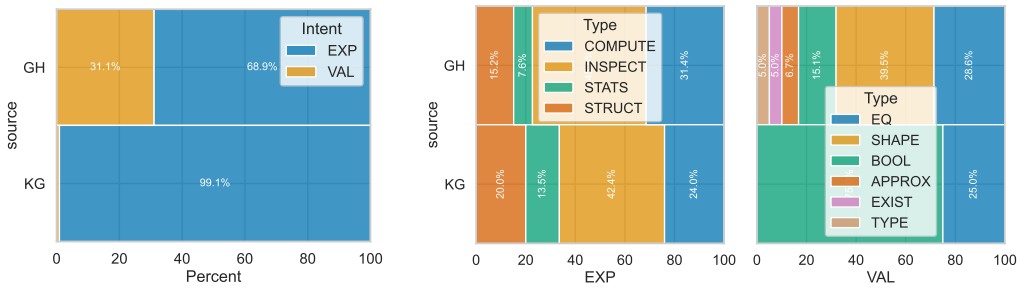
```
assert
    set(train_dataset.filenames).isdisjoint(set(valid_dataset.filenames))
```

**Type check (VAL-TYPE).** Practitioners use these statements to enforce that objects carry the correct Python type, before passing them to operations that would fail silently or produce a misleading error if given the wrong type. A common pattern asserts that model parameters are NumPy arrays rather than Python lists, since many NumPy operations accept both but produce different results. The low frequency of VAL-TYPE is likely due to Python's dynamic typing and framework-level type coercion which often suppress type errors silently.

**Object inspection (EXP-INSPECT).** Inspection statements are the most frequent form of exploratory feedback in the corpus. A practitioner places a bare variable name, a plot call, or an accessor expression as the last statement in a cell to visually check the current state of a data structure.

Inspection is used throughout the pipeline but most prominent at the data loading and preparation stages, where practitioners establish a running mental model of the dataset before any transformation is applied. A bare `.head()` call after loading a CSV confirms that column names were parsed correctly, and that data types look plausible. The same lightweight pattern monitors the effect of individual cleaning operations, such as inspecting a column after imputing missing values to confirm that the fill worked. During training, a recurring pattern is the periodic visual inspection of generated outputs or loss curves. At the evaluation stage, inspection shifts from data structure verification to model output monitoring. Practitioners surface intermediate predictions, confusion matrices, learned coefficients, and cross-validation results as bare last-cell expressions.

A theme distinctive to GitHub notebooks is the use of inspection to debug internal model state. Practitioners surface the names of specific layers in a neural network, the values of learned weight slices, or the output of a forward hook to understand what the model is doing internally.



**Exploratory computation (EXP-COMPUTE).** Compute statements execute a transformation, aggregation, or model operation and return a result that the practitioner examines. The distinction from inspection is that the result is not already present in a variable but is produced on the fly by the statement itself.

The dominant use of EXP-COMPUTE in both GitHub and Kaggle notebooks is metric computation at the evaluation stage. Practitioners compute accuracy, RMSE, F1, NDCG, AUC, and log-loss as last-cell expressions to obtain an immediate reading of model performance. These calls are repeated across multiple experimental runs to drive an iterative model and hyperparameter selection process.

A second theme is informal postcondition checking on preprocessing steps. After applying a standard scaler, practitioners compute the mean and standard deviation of the transformed features to verify that both are near their expected values. Similarly, after a `dropna` operation, practitioners compute a null count to confirm that missing values were removed.

In Kaggle notebooks, EXP-COMPUTE is used extensively for exploratory feature analysis. Practitioners compute grouped aggregations and correlation matrices to understand whether a candidate feature has a meaningful relationship with the target before deciding whether to include it.

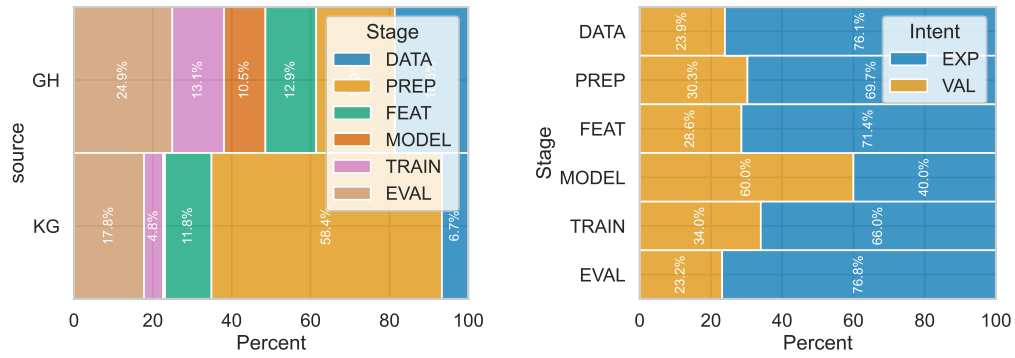
**Structural probe (EXP-STRUCT).** Structural inspection statements surface shape, column names, dtypes, unique values, cardinality, or value counts of a data structure. A pervasive theme is to use structural probes to inform how a data transformation should be configured, and after to confirm that it had the intended effect. For instance, practitioners use `.unique()`

**(a)** Top-level intent (EXP vs. VAL) across GH and KG, normalized within source.

**(b)** Subtype distribution within each top-level intent, normalized within intent.

**Figure 2** Distribution of feedback statements across top-level intent and its subtypes. GitHub contains a substantially higher share of formal assertions than Kaggle. Within EXP statements, the INSPECT subtype dominates on both platforms. Within VAL statements, SHAPE and EQ subtypes together account for two-thirds of all assertions.

and `.value_counts()` to audit the actual contents of a categorical column before deciding on an encoding strategy, and check `.shape` after one-hot encoding to confirm that the column count increased as expected.



**Statistical summary (EXP-STATS).** Practitioners use distribution plots and summary statistics to detect outliers, assess class imbalance, and check whether a feature's distribution motivates a transformation. Similar to structural probes, these statements appear on both sides of a transformation. For instance, after scaling features with `StandardScaler`, practitioners call `.describe()` to confirm that the mean is near zero and the standard deviation is near one.

## 3.2 RQ2: Prevalence and Variation of Feedback Statements

**Feedback in ML notebooks is overwhelmingly exploratory.** Exploratory statements (EXP) account for 85% ($n = 693$) of the corpus and validation statements (VAL) account for the remaining 15% ($n = 123$). The split is highly skewed toward exploratory feedback on both platforms.

We hypothesise that the intent of the feedback statements on GitHub and Kaggle differ based on the contrasting purposes of the two platforms. GitHub hosts software engineering projects where assertions are a natural practice, while Kaggle hosts data exploration and competition submission workflows where programmatic validation is uncommon. A $\chi^2$ test between intent and notebook source reveals a significant and large association ($\chi^2(1) = 144.72$, $p < 0.001$, Cramér's $V = 0.421$), and the direction of the association matches the prediction. Figure 2a shows that GH notebooks contain proportionally more formal assertions (31%), while KG notebooks are overwhelmingly exploratory and contain only four assertions (1%). Section 3.3 explores this asymmetry further, where we show that the source interacts with pipeline stage as well.

For EXP statements ($n = 693$), a $\chi^2$ test reveals a statistically significant but weak association between type and source ($\chi^2(3) = 10.77$, $p = 0.013$, Cramér's $V = 0.125$), further confirming that the two platforms are used for different purposes. For VAL statements ($n = 123$), the marginal imbalance leaves too little power for a meaningful test of independence. Figure 2b therefore presents the type distribution descriptively for both intents.

**(a)** Pipeline stage by source, normalized within source. **(b)** Intent by stage on GH, normalized within stage.

**Figure 3** Distribution of feedback statements across pipeline stages. Kaggle concentrates feedback in the PREP stage and barely touches the MODEL stage, while GitHub spreads feedback more evenly across stages. On GitHub, the share of VAL statements within each stage is highest in the MODEL, TRAIN, and PREP stages.

Within EXP statements, practitioners most often display values to confirm what an expression evaluates to (intent type coded as INSPECT), compute derived quantities they read off the cell output (COMPUTE), probe the structure of an object (STRUCT), and least often request a statistical summary (STATS). This rank order is consistent with a *notebook-as-scratchpad* model of feedback, and holds on both platforms. Within VAL statements, practitioners predominantly assert dimensional (SHAPE) and equality (EQ) invariants. Type checks, existence checks, and approximate equality are present but appear in fewer than one in ten validation statements.

**Of the 123 VAL statements, only four occur in Kaggle notebooks.** Within these assertions, four of the six VAL types (SHAPE, APPROX, EXIST, TYPE) are entirely absent, suggesting that Kaggle contributors rarely use structural validation.

## 3.3 RQ3: Pipeline Stage Distribution of Feedback Statements

This section examines where in the ML pipeline practitioners author feedback statements, and how the choice of intent and its subtypes varies by stage. We organize the analysis as a sequence of three cross-tabulations of increasing granularity. First, we examine stage by source to characterize platform-level differences in where feedback appears. Next, we examine intent by stage, stratified by source to control for the platform-level effect established in RQ2. Finally, we examine intent type by stage on the GitHub subset only, because Kaggle's heavy concentration in data preparation and its small VAL count prevent meaningful comparisons. Two statements (0.25%) receive a stage code of UNC because their context did not permit unambiguous assignment, and we exclude them from the analysis. This leaves $n = 814$ statements across six stages.

**Notebook feedback is concentrated upstream of model training, not downstream.** PREP (40%) is the single largest stage, followed by EVAL (21%), DATA (12%), FEAT (12%), TRAIN (9%) and MODEL (6%).

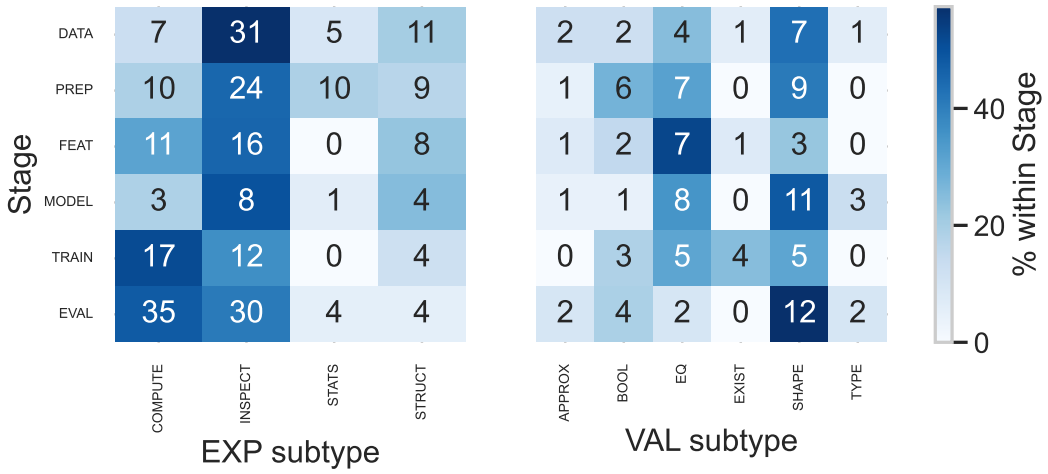


**Figure 4** Intent type distribution by stage on GitHub statements. The cells show the count, while the colorbar shows the percentage normalized within stage. Within EXP statements, COMPUTE peaks in TRAIN and EVAL, STATS in PREP and DATA, and INSPECT dominates every stage. Within VAL statements, SHAPE is the modal type in four of six stages, and EQ appears at every stage.

Based on the results of RQ2 which establishes that the type of intent varies by platform, we hypothesise that the ML pipeline stage in which feedback statements are used also differ by platform. A $\chi^2$ test confirms our hypothesis, indicating a significant and large association ($\chi^2(5) = 158.04$, $p < 0.001$, Cramér's $V = 0.441$), and is visualized in Figure 3a. Feedback in Kaggle notebooks concentrates predominantly on the PREP stage (58%), while feedback in GitHub notebooks distribute more evenly across DATA (19%), EVAL (25%) and TRAIN (13%). The MODEL stage is almost entirely absent on Kaggle (0.5% vs. 11% in GitHub). This pattern is consistent with the competition format, which concentrate on data preparation pipelines and typically consume pre-configured model APIs rather than defining model architectures from scratch.

To examine whether intent is associated with pipeline stage, we stratify the analysis by source since the prior tests establish that it has an effect on both variables. We restrict further analysis to GitHub statements ($n = 381$), since Kaggle statements ($n = 433$) contain only four VAL statements which makes the effect size estimate unstable.

We hypothesise that assertions are less common in the exploratory ML stages, since practitioners do not yet know what to test, and the purpose of these stages is to explore and identify. A $\chi^2$ test reveals a statistically significant association ($\chi^2(5) = 20.34$, $p < 0.001$, Cramér's $V = 0.231$) and the direction of the association matches our prediction. Figure 3b shows that MODEL is the most validation-heavy stage (60%), followed by TRAIN (34%) and FEAT (29%), while DATA and EVAL are more exploratory. **This indicates that practitioners validate when the code defines reusable structure,** such as model definitions and training loops, and inspect when the code is exploratory and data-facing, such as preprocessing and evaluation.

Figure 4 shows the distribution of the intent subtypes by stage, for GitHub statements. Within the GitHub EXP statements ($n = 264$), INSPECT is the dominant exploratory type and accounts for 36% to 57% of the statements within each stage. COMPUTE peaks in TRAIN (52%) and EVAL (47%), where practitioners compute losses, predictions, and metrics

**Table 2** Mapping of VAL subtypes to crash types reported by Wang et al. [41]. Each row identifies the crash types that the corresponding VAL subtype is designed to pre-empt.

| VAL subtype | Wang et al. crash types |
|---|---|
| SHAPE | Tensor Shape Mismatch, Unsupported Broadcast |
| EQ | Data Value Violation, Invalid Argument, Model Initialization Error |
| BOOL | Data Value Violation, Invalid Argument |
| EXIST | Variable Not Found, Key Error, IO Error |
| TYPE | Type Error, Attribute Error |
| APPROX | (no direct counterpart) |

inline. STATS appears almost exclusively in PREP (19%) and DATA (9%), which matches the role of summary statistics in early data understanding. STRUCT is small but spread across DATA (20%), FEAT (23%), MODEL (25%), and PREP (17%).

Within the GitHub VAL statements ($n = 117$), **the choice of validation type is largely stage-agnostic.** SHAPE is the modal validation type in four of the six stages (DATA, EVAL, MODEL, PREP) and accounts for 39% to 55% of the statements within those stages. EQ is modal in FEAT (50%) and TRAIN (29%), and BOOL appears at every stage in small numbers (4% to 26%). The rarer subtypes (APPROX, EXIST, TYPE) appear too few times to support stage-level claims.

## 3.4 RQ4: Relationship to Known Crash Modes

RQ1 and RQ2 characterize what feedback statements practitioners author, and RQ3 shows where they author them. RQ4 situates those findings against the failure modes identified by analyzing crashes in Jupyter notebooks. Wang et al. [41] examined ML Jupyter notebooks collected from GitHub and Kaggle, and cataloged *crashes* which halt execution and surface an exception in the cell output. While the Wang taxonomy identifies the failure mode, our taxonomy provides a complementary view, by identifying validation statements designed to pre-emptively catch such errors. For each VAL subtype, we check whether an assertion would either prevent the crash from occurring or surface an upstream defect that would otherwise trigger the crash later. The resulting mapping is shown in Table 2.

**VAL-SHAPE** assertions pre-empt Tensor Shape Mismatch and Unsupported Broadcast crashes, which are among the most common ML-specific crash types. Our results are consistent with this prevalence, as VAL-SHAPE is the most prominent validation type in our corpus, and accounts for 39% of VAL statements.

**VAL-EQ and VAL-BOOL** pre-empt crashes that arise when downstream code receives semantically incorrect inputs. Wang et al. report that API misuse alone accounts for 66% of Invalid Argument crashes and 31% of Data Value Violation crashes. In our corpus, architectural constraint assertions (Listing 2) pre-empt Model Initialization Error, while data quality checks (Listing 4) pre-empt Data Value Violation crashes, mirroring the data confusion root cause identified by Wang et al.

**VAL-EXIST** catches a subset of Variable Not Found and IO Error crashes. Wang et al. attribute most Variable Not Found crashes to notebook-specific issues such as out-of-order execution. The remaining cases arise from references to objects that should have been constructed earlier, and from missing files or keys. VAL-EXIST statements that check for the presence of a key, attribute, or filename before the dependent operation runs, surface the missing dependency as an explicit assertion failure rather than a cryptic downstream error.

**VAL-TYPE** statements enforce the type contract that APIs expect, and pre-empt the API-misuse subset of Type Error (42%) and Attribute Error (44%) crashes reported by Wang et al.

**Crashes and validations cover different parts of the failure space.** Wang et al. also report Out of Memory, Module Not Found, Environment Error, and Request Error crashes, that fall outside our taxonomy. Conversely, our taxonomy captures defensive programming practices that are invisible to a crash-based study. This is demonstrated by VAL-APPROX statements that have no direct counterpart in the Wang taxonomy. Approximate equality assertions verify reproducibility and catch large drifts in the results across multiple pipeline runs and different data versions. For instance, Listing 5 pre-emptively stops the execution when the NDCG diverges from the expected value. In the absence of the assertion, the pipeline would execute and produce an incorrect score, without raising an exception in the cell output. Similarly, the training-serving skew detection theme within VAL-EQ (Listing 3) catches a divergence that produces no crash signal at all. The data leakage prevention theme within VAL-EXIST (Listing 6) catches a defect that inflates evaluation metrics without producing any error output.

A study that examines only crashes, therefore cannot observe these practices because the practices exist precisely to prevent silent failures that never reach the cell output as an exception. The asymmetry suggests that the failure space of ML notebooks is wider than what crash analysis alone can capture.

**Our taxonomy of feedback statements and the Wang et al. crash taxonomy, both converge on data preparation as the empirical center of gravity in ML notebook development.** Wang et al. measure where execution fails, and report that 33% of crashes occur during data preparation. We measure where practitioners author feedback statements, and independently report that 40% of feedback statements occur during the same stage. Despite the inverted lenses, the convergence of these two independent studies, suggests that data preparation stage demands the most attention and effort from practitioners to handle crashes, and consequently the largest share of tooling investment.

The platform asymmetry from RQ2 and RQ3 is also consistent across both studies. Wang et al. report that GitHub notebooks contain four times more crashes than Kaggle (11% vs. 3%), and that the crash distribution across pipeline stages diverges between the two platforms, which is similar to what we observe for feedback.

## 4 Discussion

**Implications for tool design.** Our results from RQ2 (Section 3.2) show that 85% of feedback statements in ML notebooks are exploratory, which indicates that practitioners read values off the cell output rather than enforce them programmatically. This pattern holds on both platforms but is most extreme on Kaggle, where formal assertions account for fewer than one in a hundred feedback statements. The dominant feedback mode in ML notebook development is therefore visual confirmation, not assertion-based validation.

Breck et al. [4] argue that training data deserves the same testing discipline as production code, and propose a rubric for assessing the readiness of an ML pipeline. The same authors later introduce *TensorFlow Data Validation* [5], a tool that validates each batch of data

against a declared schema. Data validation libraries such as TFDV and Great Expectations [3] require practitioners to author the schema as a separate artefact. Our results indicate that practitioners already author the same checks in their notebooks, but in an exploratory rather than declarative form.

We see two concrete directions for tool developers that amplify what practitioners already do. First, EXP-STRUCT statements such as `df.shape` and `X_train_under.shape` serve as informal post-condition checkpoints after data transformations. A static analyser can detect these statements, record the values they produce on a successful run, and propose a corresponding shape assertion, or a shape constraint in a data schema. The taxonomy proposed in Section 3.2 can be used to identify candidate assertions that were authored by practitioners as structural probes. Second, EXP-STATS calls to `.describe()` that follow a scaling or imputation step encode an expected post-condition (e.g., mean near zero, no missing values). A tool can extract these expectations from the visible output and emit an explicit precondition for the next cell, or contribute the same expectation to a Great Expectations suite attached to the notebook.

**Listing 7** A last-cell boolean expression that verifies no rows were lost during a transformation.

```
test_raw.shape[0] == test.shape[0]
```

**Exploration versus validation.** Our taxonomy of feedack statements from RQ1 (Section 3.1) reveal last-cell statements within the EXP-COMPUTE category, that are structurally exploratory but functionally equivalent to assertions. For instance, Listing 7 verifies that no rows were lost during a transformation. Similarly, Listing 8 verifies that all expected columns are present after one-hot encoding.

**Listing 8** Verify that all expected columns are present after one-hot encoding.

```
pd.Series(options_short_list).isin(dummies.columns).all()
```

Since neither expression is wrapped in an `assert`, a `False` result is visible in the cell output but does not halt execution. Consequently, downstream cells in the notebook continue to run on data that violates an assumption that the practitioner authored and enforced manually. The decision to proceed despite the violation is therefore implicit and undocumented, and accumulates technical debt as data, personnel, and execution environments change over the lifetime of the notebook [29, 34, 35]. Promoting the same expression to an `assert` makes the assumption explicit and turns an undocumented decision into a checked invariant.

The promotion also addresses a reproducibility threat that is specific to the notebook format. Notebook cells can execute in any order, which can leave the kernel in a state that does not reflect the source code [29, 40]. A variable assigned in an earlier cell can be silently overwritten, shadowed by a stale value, or computed from inputs that the source code no longer reflects. A last-cell boolean expression evaluates against the kernel state at the moment it is first executed, but offers no protection when the kernel state diverges from the source due to an out-of-order execution of the surrounding cells. An `assert` authored at the same point re-evaluates the condition every time the cell runs, and fires when the kernel state no longer satisfies the invariant the practitioner originally checked.

[3] `https://greatexpectations.io/`

**Implications for research.** Our results from RQ3 (Section 3.3) show that Kaggle competition workflows operate primarily on data exploration, and delegate evaluation of the model to the platform leaderboard. GitHub, on the other hand, hosts a broader range of activities that spans the entire ML development lifecycle. Our findings highlight the difference in the kind of work each platform hosts, and show that the platforms are not interchangeable data sources. Future studies of ML developer practice should take this into account, since drawing data from a single source will miss the practices on the other.

## 5 Threats to Validity

**External Validity.** Our corpus consists of publicly shared notebooks from GitHub and Kaggle. This excludes notebooks authored privately or as part of proprietary workflows, where production handoffs, code review, or compliance requirements may impose stricter validation discipline. Our findings reflect the feedback practices visible in public notebooks and future work should focus on industrial ML prototype notebooks to assess how far our findings extend.

The GitHub data is collected through GitHub's code search on a single date in June 2023. The Kaggle data is drawn from KGTorrent, which was collected between November–December 2021. Notebook practices evolve as libraries, tooling, and platform features change, and patterns observed in our corpus may not reflect more recent conventions, such as agentic coding. We mitigate this threat by focusing on patterns rather than specific API usage.

**Internal Validity.** Our extraction of last-cell expressions assumes that the source code in the cell matches the output stored in the notebook. A practitioner who edits a cell after execution, without re-running it, leaves the cell in an inconsistent state. The expression we extract can then differ from the expression that produced the output. We mitigate this threat by analysing the static intent of the expression rather than its runtime value. Our taxonomy is thus anchored in what the practitioner authored, not what was last executed. The threat is therefore confined to cases where the static intent itself is ambiguous, which the codebook resolution process is designed to handle.

Our analysis depends on manual coding of feedback statements, which introduces subjectivity and the risk of inconsistent application of codes. We mitigate this threat through the iterative codebook development and the double-coding procedure described in Section 2. A complete double-coding of the corpus is the most rigorous remedy and is left to future replication work.

**Construct Validity.** We define feedback as a combination of assertion statements, and last-cell expressions that produce visible output. This excludes feedback delivered through other channels such as inline print statements that are not in the last position, logging calls, and visualisations rendered through magic commands [4]. Our choice is grounded in prior work that establish the practitioner workflow. Last-cell expressions are the canonical idiom for inspecting state in Jupyter [11, 16] and assertions are the canonical idiom for enforcing invariants [17]. This scope may nevertheless under-represent practitioners who prefer print-based or log-based feedback. Our corpus does not exhaust the space of feedback in ML notebooks, but it captures the two dominant idioms.

[4] Built-in magic commands in IPython: `https://ipython.readthedocs.io/en/stable/interactive/magics.html`

The mapping in Section 3.4 is established on functional grounds, by judging whether an assertion would prevent or surface a given crash type. The judgement is informed by the Wang root cause analysis but is itself a construction of this study. Different judgements are possible at the boundaries, particularly for the VAL-EXIST to Variable Not Found mapping which depends on whether the missing reference is a within-cell defect or a notebook-semantic defect. We document the mapping rule explicitly and welcome others to audit or revise it.

## 6 Related Work

**Bugs and Crashes in ML Notebooks.** Wang et al. [41] catalog 92,542 crashes across 64,031 ML notebooks collected from GitHub and Kaggle, and classify the crashes based on their type, root cause, ML pipeline stage, and the ML library responsible. De Santana et al. [8] study Stack Overflow posts, GitHub commits and interviews with developers to identify high-level issues when working with notebooks. Jiang et al. [13] extend this taxonomy, by conducting an empirical study of bugs and vulnerabilities in the source code. Our study, complements this work by focusing on asserts and last-cell statements that practitioners write to confirm that no failure surfaces in the first place.

A separate line of work targets specific defect classes in notebooks. Patra and Pradel [26] present Nalin, a technique that detects name-value inconsistencies, where a variable's name suggests one type or shape but its runtime value carries another. Nalin is a runtime detection technique, that targets the same class of latent defects caught by the VAL-TYPE assertions, identified in this study.

**Mining and Analysis of Computational Notebooks.** Large-scale mining of Jupyter notebooks has become an established methodology. Pimentel et al. [29] mine 1.4 million notebooks from GitHub to study quality and reproducibility. Psallidas et al. [30] analyse six million notebooks, two million enterprise data science pipelines, and metadata from twelve major data science libraries to characterise the evolving landscape of computational notebook usage. Quaranta et al. [31] construct KGTorrent, a public corpus of approximately 250,000 Python notebooks from Kaggle together with a relational database of metadata. Ghahfarokhi et al. [22] extend this foundation, and present DistilKaggle, a curated dataset of Kaggle notebooks with finer-grained metadata than KGTorrent. Grotov et al. [9] compare code quality between Jupyter notebooks and Python scripts on GitHub.

A complementary methodological contribution comes from Jiang et al. [14] who label notebook cells with their position in the ML development lifecycle through static data flow analysis. Their stage taxonomy informs the pipeline stage dimension we use in our coding. We adopt a similar set of stages, but apply them at the statement level rather than the cell level and assign stage through manual coding rather than static analysis.

**Validation and Testing Practice.** Empirical work on testing and validation practice in software engineering has examined how developers use assertions and lightweight checks. Kochhar et al. [17] replicate and extend a prior study of assertion usage on 185 Java projects from GitHub, and report that assertion adoption remains low despite established benefits. Vidoni [39] studies unit testing practices in 177 R packages and identifies systematic gaps in test coverage together with sources of testing technical debt. Both studies establish a baseline, and report that programmatic validation is under-adopted across language ecosystems. Our study extends this baseline to the ML notebook setting, and finds that formal assertions account for 31% of feedback statements on GitHub and under 1% on Kaggle.

In the ML domain, two prior taxonomies bear directly on our work. Morovati et al. [21] present DEFECT4ML, a benchmark of 100 reproducible bugs focused on TensorFlow and Keras. The benchmark is constructed from GitHub and Stack Overflow reports, and serves as a fault-injection target for downstream tooling research. Humbatova et al. [12] construct a comprehensive taxonomy of faults in deep learning systems by analyzing 1059 artefacts from GitHub and Stack Overflow, and structured interviews with 20 practitioners. While both taxonomies catalogue defects, our taxonomy catalogues the practices designed to catch them.

The closest empirical study of validation in ML projects is Openja et al. [24], who investigate the test code present in eleven ML projects across four application domains. Their study examines the formal test suites that ML projects ship and reports that test coverage and structure deviate substantially from conventional software projects. Our study extends this finding by examining validation authored within notebooks rather than in separate test files, which is the dominant locus of ML development before production handoff. Additionally, we include exploratory feedback alongside formal validation, which captures a class of practice that test-suite analysis cannot observe.

## 7 Conclusion

We mine 297,851 notebooks from GitHub and Kaggle, extract 1,092,780 feedback statements, and code a sample of 816 to characterize feedback practice in ML Jupyter notebooks. Our central contribution is a taxonomy of feedback statements, that distinguishes exploratory feedback from formal validation and refines each into subtypes grounded in practitioner intent. The taxonomy reveals that GitHub and Kaggle host qualitatively different modes of ML work, and that source platform should be treated as a confounder in empirical studies of ML developer practice. Mapping the taxonomy onto a crash taxonomy surfaces silent failures that crash analysis cannot observe. Future work should extend the analysis to industrial ML notebooks, where production handoffs and code review may impose stricter validation discipline, and to longitudinal corpora that capture how feedback practice evolves as notebook tooling matures.

## Data Availability Statement

Our replication package contains the full dataset of 1M+ feedback statements, data collection and analysis scripts, and the final codebook used to derive the taxonomy [38].

## Abstract

**Background.** Regulatory data protection requirements (RDPRs) impose requirements on organizations, which translate into technical and organizational measures for their information systems (IS). Meeting these requirements necessitates the collaboration between interdisciplinary teams of lawyers and software engineers. Previous studies indicate that engineers often struggle to interpret and translate RDPRs. Conversely, little is known about the experiences of lawyers when working on RDPRs in interdisciplinary teams, even though their legal interpretations shape the requirements imposed on IS.

**Aim.** Therefore, this paper seeks to unpack the challenges that lawyers face when collaborating with software engineers to implement data protection requirements and to put them in motion in case of privacy breaches.

**Method.** Through a deductive qualitative analysis, this paper analyzes semi-structured interviews with 70 data protection lawyers from 25 countries. Results: Our findings highlight that lawyers throughout regions and regardless of their cultural background describe similar challenges when collaborating with engineers: a lack of shared language and mental models. Lawyers also point out that engineers misunderstand RDPRs for various reasons, not just a lack of education. Furthermore, we identify the key elements that hinder or facilitate collaboration and their implications for privacy engineering.

**Conclusions.** This study is a large qualitative research with participants from multiple countries. Our results suggest that lawyers perceive different challenges when collaborating with software engineers, regardless of their culture. These results suggest these challenges are structural rather than cultural. Organizations should prioritize developing methods and artifacts to overcome these challenges.

## 1 Introduction

Regulatory data protection requirements (RDPR) need interdisciplinary teams to satisfy them [25] as they shape the design of information systems (IS). For instance, a data subject exercising their right of access is a RDPR that demands a process that teams must anticipate when designing the system. This means that it is necessary from the very start to know what data is held, where, for how long, to be able to verify a request's lawfulness and fulfill it on demand.

Thus, legal or technical expertise alone does not suffice for satisfying and specifying RDPRs, as their analysis demands multiple types of knowledge. Across the different stages of the requirements engineering (RE) lifecycle, both legal and technical expertise are required: lawyers[2] establish the interpretative foundations of regulatory obligations, while software engineers translate these requirements and specifications, as neither discipline can effectively address these challenges in isolation, but rather in an interdisciplinary collaboration.Previous work highlights the necessity of interdisciplinarity for RDPRs and its challenges [37, 28, 46]. Interdisciplinarity and working in cross-functional teams can be difficult, as legal requirements are typically formulated in abstract and context-dependent terms, which clash with the expectations coming from requirements engineering that specifications should be precise, unambiguous, and measurable [10, 31].

Even when legal experts are involved, translating such open-textured norms into IS requirements and specifications remains challenging, as it requires interpreting broad legal concepts into measurable requirements [9], while achieving a shared understanding between domains [46, 19]. This gap can create friction, which may result in poorly elicited requirements, misunderstandings, and ultimately costly rework or non-compliant software [31]. The longer a poorly understood and inadequately analyzed requirement persists, the more expensive it becomes to modify, with a considerable number of projects failing as a result [31, 10, 46].

It is essential that RDPRs are correctly understood by these interdisciplinary teams from the early phases of the software development lifecycle (SDLC). Multiple studies suggest that software engineers struggle to translate RDPRs, due to legal complexity [25], different mental

[2] In this paper, the word lawyer defines any legal expert, barred or not, with knowledge on the topic of data protection. The term lawyer is used interchangeably with legal expert.

models [23], or difficulties comprehending its legal implications [24], among others. Furthermore, the lack of a shared understanding [19] directly impacts the software development, particularly across cross-functional teams [46]. In the context of data protection, poorly analyzed and understood RDPRs can lead to privacy breaches [46]. Hence, having a shared understanding of requirements among interdisciplinary and cross-functional teams is vital for organizations to adopt good requirements engineering (RE) practices and well-developed information systems (IS) [10, 46].

Given the role lawyers play in the SDLC for RDPRs, it is important to understand their perceptions and requirements regarding this topic. This article stands at the intersection of human factors and RE, recognizing that lawyers play a central role in shaping the conceptualization of RDPRs. If lawyers cannot express the correct conceptualization of a requirement, it will have consequences for system development, ranging from expensive rework to non-compliance.

**Our goal is to understand how lawyers worldwide experience collaboration with software engineers in data protection requirements. We therefore divide our analysis in the following subquestions**.

- **RQ1: What challenges do lawyers identify when collaborating in interdisciplinary teams for data protection?**
- **RQ2: What factors do lawyers believe contribute to the difficulties software engineers have in interpreting and implementing data-protection regulations?**
- **RQ3: How do lawyers understand and fulfill their roles within interdisciplinary teams in the event of a personal data breach?**

To address the research question, we conducted a qualitative study using semi-structured interviews with 70 data protection lawyers from 25 countries worldwide. Using a qualitative deductive analysis (QDA) approach, we reveal *that lawyers in different countries experience the same challenges and face similar perceptions of interdisciplinary collaboration, regardless of their culture.* Most participants highlight that the lack of a common language and unshared conceptualization of RDPRs negatively impact their work, even across different jurisdictions. They acknowledge that legal requirements are difficult for software engineers to understand. At the same time, lawyers are frustrated as they spend more time explaining to engineers how to satisfy RDPRs. This time could have been used for other activities if there had been a shared understanding. Generally, software engineers could resort to artifacts[3] to establish common ground. However, lawyers seem to lack knowledge over these tools, thus the common ground is harder to establish.

**These results lead us to conclude that lawyers are, at best, unaware of communication artifacts developed by the RE community and, at worst, these artifacts fail to meet their expectations. It also suggests that, regardless of a country's data protection culture, lawyers' experiences collaborating with computer scientist/software engineers are similar: they lack shared understanding, that goes beyond a common language but a shared conceptualization.** Furthermore, the results show the need to promote empathy when collaborating within interdisciplinary teams in data protection.

The remainder of the paper is organized as follows: Section 2 provides related work on the subject. Section 3 describes the research method used while Section 4 presents the results, which are organized by research question and key findings. Section 5 discusses practical implications and future work. Section 6 addresses the limitations, and Section 7 our conclusions.

[3] We frame artifacts following [48].

# 2 Related work

## 2.1 Data protection and privacy requirements

Organizations must adhere to various regulations, including those related to privacy and data protection. From a conceptual standpoint, privacy and data protection requirements are not the same [17]. Privacy can have multiple meanings [39, 17], and may overlap with data protection when processing personal data is linked to a person's privacy [17]. Hence, data protection is the materialization of privacy for the management of personal data [17]. In other words, data protection deals with managing personal data due to the difficulty of encompassing all privacy requirements and stakeholder expectations [47].

Prior work has shown that vague privacy requirements can lead organizations to produce incomplete responses that do not sufficiently address core privacy threats in system design [20]. Translating these regulatory requirements, including those pertaining to data protection, into software requirements presents a significant challenge [8, 23, 46, 4, 35]. As a result, multiple artifacts have been proposed to manage the work with data protection requirements worldwide [13, 28, 18]. [1] use to propose different patterns for analyzing consent, data breaches, and subjects' rights under the GDPR. Similarly, the Unified Modeling Language (UML) has been considered as a possible means of addressing GDPR requirements, though further research is needed to confirm the suitability of such an approach [44]. From a goal-oriented requirements engineering perspective, both [34] and [29] used the Socio-Technical Security modeling language (STS-ml) for specific aspects of the regulation. [2] proposed the "Guide me" framework, which consists of a six-step systematic approach to eliciting and connecting GDPR requirements to privacy obligations. [28] provide a mapping study of regulatory data protection. The novelty of our work lies in researching lawyers' challenges when working with privacy requirements with software engineers from a global perspective, rather than focusing on software engineers' challenges, as most previous literature does.

## 2.2 Organizational challenges for data protection requirements

Although software engineers acknowledge the importance of privacy practices, they rarely implement such mechanisms in their software designs [30, 8]. Previous studies have attempted to explain this discrepancy by identifying various organizational barriers, such as organizational culture [33], or individual barriers, such as a lack of knowledge [35] for this phenomena.

Many software engineers do not view privacy as a functional requirement and believe that privacy requirements are ineffective or satisfied with security measures [36, 23], and conflicting with other software requirements [4, 35]. This perception is exacerbated by the fact that privacy and data protection requirements are considered as "vague" [39, 4] and difficult to satisfy [23, 4, 35]. Consequently, it is difficult for engineers to translate privacy requirements into practice or to prioritize them [30]. This becomes even more difficult when engineers work across multiple jurisdictions [32]. Matters are further complicated by the fact that many engineers lack formal education in privacy theories [35, 30]. Instead they are self-taught and struggle with legal terminology [32]. This is due to the fact that legal texts are written in a specific domain manner which makes their translation complex and demands knowledge of other legal instruments [9]. As a result, engineers use security vocabulary as synonymous with of privacy, even though the two are not the same and serve different purposes [23]. Additionally, implementing privacy requirements becomes burdensome [4], and engineers deliberately choose not to prioritize them over functional system requirements [35].

Additionally, engineers have difficulty mapping privacy principles into software features because of their complexity [35]. In other cases, they overlook the regulatory context [37] or do not feel responsible [40, 45]. Another issue is interdisciplinary collaboration, as engineers experience frustration with legal teams [4] or have difficulties having a shared around non-functional requirements [46]. Furthermore, software engineers recognize that collaborating with lawyers and cross-functional teams is challenging [4, 8].

In terms of organizational challenges, lack of agency [40] and time pressure are key factors impeding implementation of privacy requirements as engineers do not enjoy working in such an environment. Even when trying to promote privacy through "privacy champions", these roles encounter strong resistance due to a negative culture towards privacy, tensions among stakeholders, or lack of support [43]. These experiences with privacy-driven engineering roles can reveal the need to understand other stakeholders' needs to support engineers in implementing privacy requirements. Our work contributes to this need by identifying, on a global scale, the challenges lawyers face when providing privacy expertise to software engineers.

## 3 Research Method - qualitative deductive analysis (QDA)

The Qualitative Data Analysis (QDA) method is a deductive approach designed to test, refine, or reformulate theory [15], while also incorporating elements of inductive analysis. The method consists of the five following key steps. The leading author also kept a memoing of the whole process [5].

1. Defining the research questions and theoretical framework [15]. Researchers position their study within a theoretical or conceptual framework informed by prior work, consistent with a deductive orientation. In this study, our research question examines how lawyers worldwide collaborate with software engineers on data protection requirements. For our theoretical background, we follow the guidance of [5] and build upon [23, 42, 19] from a requirements engineering perspective. Specifically, we focus on the concepts of common ground, implicit shared understanding, and data protection, drawing on the Data Protection Brussels Effect [6], with particular emphasis on the role of the GDPR in requirements engineering [28].
2. Operationalizing Theory: Core constructs, codes, or hypotheses are developed based on existing literature [5] and may be refined during preliminary analysis. Inductive codes can be incorporated where necessary. While developing our code, we could not find a codebook from prior work that aligns with our research objective. As such, we built the codebook to answer our question and, based on previous literature, as suggested by [5], for a deductive analysis. From RE, we based our codes on [23, 42, 19] and for the Brussels Effect, based on the GDPR [14, 28, 6]. Our codebook also allowed for inductive codes (which we indicate in this paper). The codebook was developed through multiple iterations, as we explain in detail in Section 3.3, as part of the sensitizing phase of QDA [15].
3. Sampling: Purposive sampling [3, 15] is employed, including the intentional selection of negative or contradictory cases to challenge or extend the guiding framework. Specifically, we recruited participants from selected countries (G20 plus invitees) with expertise in data protection law. Further details on the sampling process are provided in Section 3.2.
4. Coding and Analyzing: Data is systematically coded and examined in relation to the predefined constructs and emerging themes. An early round of analysis was conducted to further sensitize the codes [15] and to identify any overlooked areas. Coding and

intermediate analysis [15] were performed by five authors, with each interview coded by at least two authors. The coding and analysis procedures are described in detail in Section 3.3.

5. Theorizing: Findings are interpreted to test, elaborate, or, where needed, reformulate the underlying theoretical framework. This part implies "theorizing, which involves interpreting evidence for each of the themes, proposing interconnections between them, and providing a rationale for any revisions or expansions to the initial theory" [15].

## 3.1 Operationalizing Theory

To develop the codebook, we followed the guidance provided by [5]. Since our codes were constructed for a deductive analysis [15], and no codebook from previous work seemed suited, we elaborated the codebook based on established theory and anticipated outcomes. Our codebook drew on both the Brussels Effect for data protection regulation (GDPR) [6, 14, 28] and prior research on data protection, privacy requirements, and shared understanding [23, 19, 42]. We developed the codebook iteratively using the QDA method. The lead author drafted an initial version, which was subsequently reviewed and revised in collaboration with the co-authors. Following these revisions, the lead author validated the codebook with five lawyers from diverse jurisdictions (EU, Chile, Brazil, and China) to minimize potential bias. Their feedback was documented and integrated into the codebook. The revised codebook was then further discussed among the authors. During an early analysis, as recommended by [15] to sensitize the code, we identified areas that were initially overlooked. We added new indicative codes to address these gaps, as suggested by [15], thereby reducing potential bias and ensuring comprehensive data coverage.

## 3.2 Sampling - Participants and Recruitment

We conducted interviews with legal experts in data protection (N=70) from the G20 countries (including the European Union and the African Union as entities), due to the economical influence and population size. We also randomly selected invited countries to the G20 summits (Chile, Colombia, Egypt, Tanzania, Azerbaijan, Indonesia and Singapore) and Luxembourg (country where the study was carried). We excluded practitioners from Russia due to sanctions in place at the time of ethical approval. We explain the recruitment process below, but overall we recruited experts based on their experience, education, known qualifications and peers recognition.

In our final sample of 70 interviews, there are no practitioners from Saudi Arabia and Azerbaijan, as they did not answer the request for interviews. Some of the participants have expertise from more than one jurisdiction, such as Brazil and EU, France and Germany or USA and EU. An anonymized overview of participants is available in the Table 1, based on the continent of expertise rather than country of expertise, for anonymization purposes. **We do not indicate the country (and years) of expertise, as many individuals have a unique profile that can easily re-identify them.** Some countries have a very small universe of data protection experts (such as Chile or Colombia), so any extra data point – such as area of work or years of study – could lead to the participant re-identification, which breaches their consent preferences. A more detailed but still anonymous list of our participants is available in our public repository, made available at out at Section 8. Finally, some of our participants are public figures, like data protection authorities or ex-ministers, so the sensitivity of their interviews increases the need of anonimization.

**Table 1** Summary of the participants expertise, based on continent of residence. Junior = 2–3 years experience; Intermediate = 4–8 years experience; Expert = +8 years experience.

| Num. of Participants | Region | | | | |
|---|---|---|---|---|---|
| | Africa | Asia and Oceania | Europe | North America | South America |
| Expert | 7 | 13 | 15 | 9 | 12 |
| Intermediate | 3 | 7 | 0 | 0 | 3 |
| Junior | 0 | 1 | 0 | 0 | 0 |

The initial goal was to interview at least 3 experts per country, with a maximum of 5. This precondition was not achieved for Australia and Germany, with 2 and 1 participant respectively, although more than 15 invitations per country were sent out. For the participants who had multiple jurisdiction expertise, their participation would satisfy the requirement of multiple countries.

We searched for participants based on their public profiles. We queried multiple legal databases of private organization, academic publishing, public authorities, and social media (LinkedIn). Participants were first contacted either by email (if public) or their professional network (LinkedIn). We resorted to snowballing in the countries where we had difficulties contacting individuals otherwise, with 8 participants recruited this way. In total, 267 invitations to practitioners from all over the world were sent between December 2024 and November 2025. Table 1 provides an overview of the participants. Due to space constrains, we provide further details of the recruitment process in the public repository available at Section 8.

All interviews were conducted with participant informed consent. Where permission to record was granted, interviews were audio-recorded and transcribed, otherwise detailed notes were taken to capture key phrases and central points. Interviews lasted 35 minutes on average. To establish rapport and ensure participant comfort, the first part of the interview was dedicated to an informal discussion of the study. This segment was not recorded and is excluded from the study.

Interviews were conducted in English, Spanish, or French. The majority were carried out online via the platform provided by the research institution (Microsoft Teams), while eight interviews were conducted in person. When recording consent was obtained, audio files were transcribed using AIKO, an open-source, locally deployed, privacy-preserving AI-based transcription tool. During transcription and editing, minor filler words and unnecessary repetitions were removed to enhance readability, while intentionally retaining selected speech particularities to preserve the integrity and texture of participant expressions. In presenting the quotes, *'[]'* was added where sensitive details were removed due to anonymization.

The interviews are part of the OBI-PIA project, that seeks to identify RDPRs across jurisdictions. The interview questions are available at our public repository.

## 3.3 Coding and Data analysis

For the coding and analysis of the interviews, three calibration workshops were held between coders throughout 2025, two of which were recorded. During these, the authors discussed how they had coded the same interview and shared their results, with a discussion if discrepancies occurred. The objective was to have calibration between the different coders, while also solving any question regarding the conceptualization of the codes.

Five authors partook on the coding of the interviews. Each interview was coded by at least two authors. One author would carry out the first coding, send the file(s) to the second coder, who would code on top of the first coder, and see if they identify discrepancies. If

**Table 2** Example on how codes and subcodes where coded.

| Theme | Code | Subcode | Example of coding |
|---|---|---|---|
| Interdisciplinarity (theme) | | | |
| | Lack of common language (code) | | *"We don't speak the same language. I mean, although it's the same language, because we do it in English, or even if it's in French, when it's our mother tongues... I have the impression we don't speak the same language".* |
| | Communication (code) | | *"Sometimes to make the bridge, the connection between the two, which are nothing that we cannot overcome, but yeah, just to be mindful".* |
| | | Difficult (subcode) | *"Originally the communication was very difficult with the technical teams".* |
| Understanding data protection | | | |
| | Lack of education | | *"They lack the literacy and also there is a lack of guidance for them to understand it and do that, and sometimes you have to push them".* |
| | | Per lawyers in tech | *"The lawyer actually must have a very open mind to understand technology as well and this is that's the I think that's the difficult aspect because most engineers could at some point understand law but it doesn't go the other way around because I mean lawyers it's very hard to explain technical things to lawyers".* |

discrepancies happened, they were resolved through consensus. Finally, if no consensus was reached, the lead author would arbitrate. This method allows us to reduce biases in our the analysis, while also improving the reliability of it. The coding was done using MaxQDA. An example of how we coded the different excerpts of data, Table 2 provides an example overview. Given space limitations, a full detailed description of the codebook is available at our public repository.

## 3.4 Ethical considerations

This research aims to follow best practices in qualitative studies and ethical software engineering interviews [41]. Participants in the study were presented with the project's privacy policy and information notice. They also received a consent form. The form was granular, allowing participants to opt in to each option: processing personal data, recording, using AI transcription tools, sharing transcripts, and possible recontact. Participants would sign the consent form. If the participants forgot to send the consent forms before the agreed-upon interview meeting, an oral consent was requested before the interview started, which also included whether we could record. Every other option in the consent form was considered a non-opt-in. Except for 5 individuals, all others consented to have their interviews recorded. 3 other participants requested to send written answers for the same reason.

Participants did not receive monetary compensation and were informed beforehand in the invitation email. However, they will be granted access to the study results. This research received approval from the Ethical Committee under code ERP 24-109 OBI-PIA from the University of Luxembourg. We provide a positionality statement as part of the Section 6 and an extended version at the public repository.

# 4 Results and findings

Given the study design, not all participants answered every question due to time constraints or choice. Tables 3 and 4 (Pages 9 and 14, respectively) are therefore reported as the number of participants addressing each topic. For example, the code "Data Breaches" was mentioned at least once by 58 participants, while the code "incident" appeared in 43 accounts, including discussions of "incident response", "containment", or "internal notification". A participant addressing multiple subtopics is counted once at the code level ("incident Responses") but may be recorded across several subcodes ("containment", "internal notification"); conversely,

discussing a single subcode ("containment") is counted both at the subcode level and within its parent code family. Verbatims from Spanish have been translated by the authors and the original ones are available at our public. All interview question are also available in the repository.

## 4.1 RQ1: What challenges do lawyers identify when collaborating in interdisciplinary teams for data protection?

The majority of respondents (n=67, or 90.6%) shared they experienced challenges when working in interdisciplinary teams, as shown in Table 3. First, 46 participants mentioned language barriers (code "lack of common language"), meaning they lack the same vocabulary when discussing data protection requirements. Second, 45 participants highlighted having different mental models (code "different mental models") about the topic. Furthermore, more than 20% of the respondents (n=17) expressed some kind of concern about communication in these teams, with 11 participants directly indicating that it was difficult. Finally, 8 participants stated that, in their view, the lack of technical education among lawyers made the interdisciplinarity between law and other disciplines difficult in the context of data protection.

> Finding 1: Lawyers require an artifact to establish a common language or conceptualization with computer scientists or software engineers in regulatory data protection. This language needs to represent both stakeholders' conceptualizations and goals, and should be easy to select.

### 4.1.1 Lack of common language (46 participants)

Our analysis reveals that the vast majority of participants report issues due to the lack of a common language. As one participant explains: *"[...] there's constantly this challenge of translating different languages and finding common ground" (P.64)*. The main challenge for lawyers seems to be explaining what is needed from a regulatory perspective, in a way that is not simple a yes or no answer, as exemplified by the following: *"I've been working for some years with several different teams on computer science, on the topics of data protection, and with different teams, in different [countries and organizations], the main issues were mostly about language" (P.33)*.

As participants explained, the role as a lawyer is not only to ensure compliance but also to reduce organizational risks. One participant explains: *"A lawyer's objective is risk minimization always. What is the worst-case scenario? How can we minimize this? While engineers are sometimes looking from things from an innovative perspective. How can I circumvent rules? How can I find this issue and solve it? Which is very different from a lawyer's way of thinking" (P.3).* It appears that lawyers bring a risk-oriented and context-sensitive mental model. While their technical counterparts may seek immediate and concrete implementation strategies, lawyers tend to focus on regulatory exposure, interpretive nuances, and long-term organizational impact.

Moreover, it seems legal experts seem to have difficulty explaining basic data protection concepts to software engineers: *"Maybe sometimes you say the same words, the same concepts, but they have a different content" (P.10).* As the quotes above indicate, problems arise because stakeholders from different disciplines often fail to clearly communicate or understand one another. For example, legal and technical staff may use the same word with different meanings, which can easily lead to misunderstandings, as one respondent notes: *"Different disciplines use almost the same terminology, but the usage of that terminology means completely different things. So I found that often conversations happen in parallel, that you may think you talk about the same thing, but when it boils down to technicalities" (P.5).* This lack of shared understanding results in spending more time than desired explaining what was meant or expected when discussing RDPRs: *"I think for most people, it's just the basic concepts of data protection." (P.8).*

However not everyone identifies the lack of common language as an issue. One participant reports: *"I don't see it as much as a challenge as it is the first step in the relationship to clarify and manage expectations of what they mean or what we mean by certain things[...]" (P.15).* Some lawyers have even started using intermediate artifacts to establish common ground and a common language, albeit with difficulties: *"Of course, determining the right vocabulary for the right audience is something which is quite challenging" (P.38).*

### 4.1.2 Different mental models (45 participants)

45 participants acknowledge that differing mental models hinder their collaborative work. As discussed in Section 2, software engineers often struggle to determine the precise requirements to satisfy RDPRs [7], and their mental models may contribute to this challenge [23]. As one participant observed: *"They will also say some words, maybe they have a common sense but you know the details and the actual definitions are different" (P.12).* Although the same term may be used, lawyers and engineers often attach different conceptualizations to it. These nuanced differences in the details are where the different mental models come into play: *"The concept of privacy for computer scientists, at least in my experience, was mostly referring to protection from identification, while in the law, privacy is a whole bunch of topics, all coming from the protection of private and family life" (P.40).*

Even when using the same vocabulary, lawyers and engineers differ in the degree of determinacy they expect and their tolerance for ambiguity. They also differ in their approach to RDPRs: lawyers primarily view them as normative risk assessments, while engineers primarily view them as operational design constraints. One of our participants lays out this distinction: *"People with a humanities background are quite comfortable with a certain level of ambiguity or uncertainty, while people with a technical background feel very uncomfortable and prefer to have straightforward answers, so I don't think it's really a matter of having difficulty understanding the concepts..." (P.33).* This different approach was shared by different

participants, like: *"[...] the engineers in our team want to come up with a mathematical formula, while the lawyers want to come up with these complex concepts and fundamental rights" (P.64).*

### 4.1.3 Communication (17 participants)

Some of the participants (n = 17) identified communication itself as a direct challenge, going beyond lack of common language or different mental models. The primary challenge is translating the abstract nature of RDPRs by lawyers into requirements specifications. As one participant stated: *"... you have to deal with them and to try to be very clear and stay careful when they want to collect data" (P.42).* Legal experts reported that engineers are often unable to correctly translate requirements into specifications, even when requirements are communicated and best practices from RE are applied: *"They are unable to materialize it or translate this idea into a concrete action within their domain of practice" (P.56).* This suggests an difficulty to move beyond disciplinary communication barriers.

2 participants acknowledged that this issue can be resolved, as long as both parties are willing to understand each other and make their best efforts. This situation is evidence of the importance of empathy and communication in RE [11, 46, 26]. Indeed, they shared that they have used UML to try to communicate RDPRs, recognizing it is not the best strategy. These references to intermediate artifacts were rare and were not systematically shared with participants. Thus, despite the substantial effort within the RE community to support interdisciplinary communication, existing artifacts have not permeated or resolved the practical realities of interdisciplinary RDPRs work, or at least not in the legal domain. These reflections suggest that interdisciplinary challenges are not only technical, but also relational. Effective collaboration appears to require an active effort to understand other stakeholders, as suggested by [46].

### 4.1.4 Lack of technical education. (8 participants)

Another factor contributing to interdisciplinary challenges is the limited technical knowledge of some legal professionals. 8 participants (15.7%) explicitly referred to this issue. As one participant stated: *"I mean, that goes in both ways as well, like trying to understand the limitations of technical systems" (P.52).* Thus, collaboration challenges stem not solely from engineers' limited legal knowledge, as discussed by the RE community [7], but also from lawyers' limited understanding of technical constraints should be factored in. In fact, two participants emphasized that acquiring basic technical literacy improved communication with software engineers. One participant noted, *"So now I'm actually understanding them and I can express myself to them" (P.32).* This suggests that technical knowledge functions as a boundary-bridging competence within interdisciplinary teams.

## 4.2 RQ2: What factors do lawyers believe contribute to the difficulties software engineers have in interpreting and implementing data-protection regulations?

68 participants shared thoughts regarding this element throughout the interview, as show in Table 3. When directly being prompted over the topic in question 3 of the interview. 22 participants (33.9%) explicitly said they agreed with the statement we prompted in question 3 of the interview, 2 that partially agreed, and 6 that they do not agree.

Finding 2: Most participants agreed that software engineers have difficulty understanding data protection for multiple reasons. Most lawyers agree that the way RDPRs are written makes it difficult to translate and understand. They also point out the role of education for understanding RDPRs. Furthermore, a minority of lawyers identified other reasons, such as poorly placed incentives and resistance from software engineers to learning about RDPRs. Finally, a minority of participants did not agree that software engineers had difficulty understanding RDPRs or that the issue had other reasons.

### 4.2.1 Legalese (35 participants)

Most lawyers identified legal jargon as the main source of difficulty for translating RDPRs: *"often law is written in a weird manner" (P.44)*; in other words, legalese. This difficulty arises due to multiple reasons, including the law's ambiguity, the (multiple) interpretations of legal texts, the context and complexity of data protection regulations as recognized by previous RE research [28]. Participants emphasize that laws are often ambiguous and primarily written by and for lawyers. They are generally costly to create and update, so they are written in a way that allows them to be applied to many different situations. This ambiguity contradicts the specificity and well-defined requirements, leaving software engineers to interpret them. One respondent explains this: *"The law seems very vague. It's very unclear. It seems very hard to implement. It seems to give no clear guidance"(P.11)*. Similarly, another participant adds: *"[...] The regulation doesn't tell them [software engineers] what they must do to achieve compliance" P.25)*.

Given the possible multiple interpretations of legal texts, lawyers seek to determine the interpretation that best fits the context, yet they are reluctant to provide a definitive answer. They want to problematize the context and believe software engineers have difficulties understanding this approach: *"The relative or the absolute perspective. So they want yes, no, but we need to problematize it to put the landscape at stake, and they want yes and no answers. And for us, it's more like it depends [...] And they do not deal well with open concept, open textured concepts" (P.33)*.

Lawyers say it is important to review court decisions and interpretations to better translate RDPRs into requirements. Although the influence of case law differs between jurisdictions, this was important in all the regions we studied. As one participant said: *"And then you need to look at the case law, the decisions of courts, to understand what the interpretation of those terms" (P.45)*.

### 4.2.2 Lack of education (34 participants)

Navigating RDPRs requires understanding of legal concepts and nearly half of the respondents (n=34) reported that many software engineers lack this. One participant illustrates: *"Reading one law doesn't make you a legal expert even in that law because lawyers or law students study many laws [...] they don't have enough legal background" (P.4)* Without this foundation, software engineers risk mis-translating the requirements into incorrect specifications. One participant exemplifies, *"We have predefined requirement of consent. Sometimes people in technical roles don't know how to interpret that" (P.18)*. Legal education also helps with prioritization of RDPRs, which software engineers miscomprehend: *"But they don't have this notion that you need to go beyond the text of a particular instrument to make sense of the legal system as a whole. And even when they can make sense of the pieces, they are waving different value sets. And it might not be obvious for them why [...]" (P.65)*. As [46] also identified, the lack of shared understanding hurts the prioritization of privacy requirements.

However, technical education also helps the RE process. Therefore, lawyers themselves aspire to improve their knowledge, as the following statements indicates: *"The solution is for lawyers to understand a bit more about the technical processes. You don't need to learn how to code, but you need to understand what coding is" (P.3).*

On the other hand, lawyers recognize their lack of technical education complicates matters for software engineers who must understand data protection requirements, as reported in subcode "Per lawyers in tech" (n=9). For example, one participant states: *"Well-intentioned regulatory or policy initiatives, end up disrupting how the internet functions, due to a lack of understanding of how things work" (P.57, translated from Spanish).*

### 4.2.3 Incentives, disagreement, and resistance (resp. 8, 6, 6 participants)

Our analysis also revealed codes that had not been accounted for previously. These codes pertained to incentives (n=8), disagreement (n=6) and resistance (n=6). 8 participants agree that there are few incentives for companies or software engineers to incorporate RDPRs. As one participant states that there is a *"lack of incentivization for them to even learn it and apply it" (P.13).* Another participant argues that business models discourage compliance: ''*Lot of organizations lack that incentive right because their business models and the way that they want to do things are all about kind of like monetizing of data" (P.45).* Additional explanations include domain-specific factors, as noted by participant 41 (medical domain versus data protection), or the perception that understanding the law is not part of their role: *"It's not their job to understand the law. They don't do this for their own sake. They do it for somebody" (P.6).*

Regarding resistance (n=6), lawyers also suggest two main reasons why software engineers may be reluctant to implement RDPRs. First, they are unwilling to learn and take on responsibility over it, similar to what [45] identified for ethical requirements. Second, they refuse to allocate additional resources, as it implies more work. *"So how costly it is for them to integrate data protection" (P.38).* Regarding the latter, one respondent mentioned: *"I think there is a certain resistance to trying to understand very basic concepts and recognizing that there is more to learn." (P.50, translated from Spanish).* Similarly, another participant highlights the resistance of engineering, stating: *"there is more resistance from the computer science to accept the fact that data protection exists [..] whereas the legal part has more acceptance to deal with computer science requirements." (P.62).* Legal professionals interpret this attitude as a lack of empathy [11]: *"They feel like their job is just to make the product and then whether it applies, like whether it complies with laws or not is a is an afterthought" (P.14).*

## 4.3 RQ3: How do lawyers understand and fulfill their roles within interdisciplinary teams in the event of a personal data breach?

Regardless of their location, lawyers mentioned they would take similar action steps, as shown in Table 4. "Notification" (n=50) emerged as the most prominent action step, followed by "incident response" (n=43), and assessing the risk (coded as "risk of data", n=30). According to our analysis, the majority of lawyers prioritize coordinating whom to notify, particularly supervisory authorities (n=44) and where required, affected data subjects (n=36).

Following notification duties, respondents emphasized their involvement in "incident response" activities (n=43). Finally, developing a clearer understanding of the scope and impact of the data breach was mentioned as an essential part of their role. This includes

**Table 4** Codes regarding interdisciplinary challenges for data protection and understanding of data protection. †: Inductive codes.

| Theme | Code | Subcode | Number of occurrences (percentage out of 65 interviews) Asia, Oceania n=21 | Africa n=10 | N. America n=9 | Europe n=15 | S. America n=15 | **Total n=70** |
|---|---|---|---|---|---|---|---|---|
| Data breaches | | | 17 (80.1%) | 9 (90.0%) | 6 (66.7%) | 13 (86.7%) | 13 (86.7%) | **58 (82.9%)** |
| | Notification | | 14 (66.7%) | 8 (80.0%) | 4 (44.4%) | 11 (73.3%) | 13(86.7%) | **50 (71.4%)** |
| | | Authority | 13 (61.9%) | 7 (70.0%) | 3 (33.3%) | 9 (60.0%) | 12 (80.0%) | **44 (62.9%)** |
| | | Data subject | 9 (42.9%) | 5 (50.%) | 3 (33.3%) | 7 (46.7%) | 12 (80.-%) | **36 (51.4%)** |
| | Incident Response | | 12 (57.1%) | 9 (90.0%) | 5 (55.5%) | 8 (53.3%) | 9 (60.0%) | **43 (61.4%)** |
| | | Containment | 9 (42.3%) | 7 (70.0%) | 2 (22.2%) | 4 (26.7%) | 5 (33.3%) | **27 (38.6%)** |
| | | Internal Notification | 3 (14.3%) | 1 (10.0%) | 2 (22.2%) | 0 (00.0%) | 1 (6.7%) | **7 (10.0%)** |
| | Type of Incident | | 14(66.7%) | 7 (70.0%) | 2 (22.2%) | 7 (46.7%) | 7 (46.7%) | **36 (51.4%)** |
| | Risk of data | | 8 (38.1%) | 4 (40.0%) | 3 (33.3%) | 5 (33.3%) | 10 (66.7%) | **30 (42.9%)** |
| | | Type of personal data | 5 (23.8%) | 2 (20.0%) | 2 (22.2%) | 2 (13.3%) | 7 (46.7%) | **18 (25.7%)** |
| | Time | | 5 (23.8%) | 2 (20.0%) | 0 (00.0%) | 5 (33.3%) | 3 (20.0%) | **15 (21.4%)** |
| | Consequences (reputation) | | 5 (23.8%) | 2 (20.0%) | 1 (11.1%) | 1 (6.7%) | 1 (6.7%) | **10 (14.3%)** |
| | | Public relations | 4 (19.1%) | 0 (00.0%) | 1 (11.1%) | 1 (6.7%) | 1 (6.7%) | **7 (10.0%)** |
| | Interdisciplinary team (legal and tech)† | | 2 (9.5%) | 0 (00.0%) | 3 (33.3%) | 0 (00.0%) | 1 (6.7%) | **6 (08.6%)** |

assessing the risks associated with the incident (n=30). Less frequently, respondents also brought up time constraints (n=15) and reputational consequences (n=10). An unexpected code that we created inductively was the explicit assembling an "interdisciplinary task force" (n=6).

Finding 3: Lawyers report that, in data breach cases, multiple requirements under data protection regulations are triggered. Their responses were similar across jurisdictions, highlighting the need to notify relevant actors of the breach, collaborate with incident response teams, and identify the type of breach, why it occurred, and how to mitigate it.

### 4.3.1 Notification (50 participants)

A dominant code that emerged from the respondents' responses regarding data breaches is notification. They mention their actions are driven by legal pressures and obligations imposed on them by regulations. At the same time, many respondents have internalized highly routinized internal escalation pathways. In the event of a data breach, they reported knowing exactly what steps to take - or at least where to find the relevant procedures. One respondent articulates this clearly: *"So I would, my first step would be to check again the legal requirements and then to act immediately" (P.37).* Participants also highlighted that notification is not a single action to authorities and data subjects, but also to internal stakeholders. One participant explains: *"Another thing I need to do is to notify our group DPO and my line manager, the head of compliance, just to give them a heads up, as well as the general counsel and the country lawyer..." (P.22).*

### 4.3.2 Incident Response (IR) (43 participants)

After notifications, IR was the second most prominent code. Our analysis revealed that respondents described IR as a highly collaborative process that requires close coordination with technical teams. Participants emphasized that their role centers on understanding the nature of the breach and discussing containment strategies. One participant explains that IR begins with understanding *"[...] what can be immediately done to prevent further breach or incidence" (P.8).* Another participant highlights the importance of security mitigation: *"so how are you going to contain technically the impact of that breach" (P.43).*

### 4.3.3 Type of incident (36 participants)

This code was mentioned by nearly half of the participants. This typically involves understanding precisely what data has been compromised. As one participant emphasized, this process begins with understanding the basic facts, such as time, who, and *"[...] also if any personal data that, of course, belongs to you were involved in this accident " (P.39)*. This code was mentioned less frequently than the notification code, even though assessing the type of data that has been compromised is directly related to notification obligations under data protection laws, as indicated by the following quote: *"If it's consumer data, if it's client or people's information, I believe then I have to approach the data protection board" (P.15)*. It appears that determining the type of incident requires close collaboration between technical teams and lawyers. This collaboration is necessary in order to assess and understand risk, which informs legal actions.

## 5 Discussion and Implications

Designing compliant information systems requires the close collaboration of interdisciplinary teams with both legal and technical expertise. While prior research indicates that technical professionals struggle to understand and implement RDPRs, not enough is known about the challenges legal professionals face. Therefore, our study set out to 1) investigate the challenges that lawyers face when collaborating with technical professionals on the implementation of data protection requirements, 2) explore lawyers' beliefs about why software engineers have difficulty understanding and implementing RDPRs, and 3) examine how lawyers understand and fulfill their roles within interdisciplinary teams in the event of a personal data breach.

By focusing on the mental models of legal professionals, our findings shed light on an understudied dimensions of RDPR implementation and offer novel insights to both scholars and practitioners. **Notably, we reveal that regardless of their jurisdiction, lawyers share similar experiences, perceptions and role identities when in interdisciplinary teams, such as a lack of common language, different mental models, communication issues, and a lack of technical education**. Some of the findings of our work align with previous findings from studies focusing on software engineers [23], now providing the complementary perspective, that of legal experts. **Our findings have several practical implications for requirements and privacy engineers worldwide, which we will discuss in more detail below.**

### 5.1 Global experiences of legal experts

> Legal experts across jurisdictions shared similar experiences, suggesting that these are jurisdiction-independent. The development of artifacts that facilitate collaboration between software engineers and lawyers on RDPRs can also be jurisdiction-independent.

Throughout our analysis, participants consistently reported similar experiences when collaborating in interdisciplinary teams. Their experiences converged around common challenges and perceptions, particularly the widespread belief that software engineers lack a shared understanding of RDPRs with legal experts. These patterns appear to be independent of jurisdiction, legal culture, or enforcement, indicating a recurring phenomenon across countries.

A shared understanding is fundamental to conceptualize RDPRs [46, 42, 19]. Regardless of specific regulations, most participants agree that software engineers' conceptualizations impede their understanding of data protection. This observation raises questions about the

prevalence of this phenomenon. Legal experts further reported they would react similarly to a data breach, regardless of jurisdiction. The fact that most participants would notify and then call for incident response to identify the type of incident and the risk to data shows how standardized the response to (personal) data breaches is worldwide. This is not a surprising finding given the cybersecurity standardization efforts.While jurisdictions may differ, legal experts' experiences collaborating with software engineers are similar. Therefore, future work could focus on developing artifacts that are jurisdiction-agnostic and can work in different national contexts.

## 5.2 Communication is not about vocabulary

> The RDPRs collaboration problem is not one of natural language per se, but rather the meaning of the terms: lawyers and software engineers often use the same terms with different conceptualizations, as they have different mental models resulting from education and incentives. Legal experts highlight that conceptualizing RDPRs requires legal knowledge beyond a single regulation, including an understanding of its legal foundations.

Our findings highlight that between lawyers and engineers, the problems of communication are not about language, but about conceptualization. As explained in the results, differences in mental models show that oftentimes both sides use the same words with different meanings. Hence, developing a shared understanding is critical [19]. A share of the participants believe the problems in understanding are not necessarily about the education engineers have or lack. They believe it is rather motivated by the differences in understanding of what data protection entails.

In this regard, previous literature [23] has pointed out that one of the problems for engineers to implement privacy requirements was that they apply the vocabulary of security to data protection, but these are not the same, nor do they have the same meaning or implications.

It seems that collaboration in cybersecurity is often smoother than in data protection. One possible reason we hypothesize for this is that many data protection requirements originate primarily from legal documents rather than technical standards or specifications. By contrast, cybersecurity standards are more actively developed and promoted by industry stakeholders, which may make them easier to operationalize in practice [16, 38]. That being said, during data breaches, legal experts understand their role and report smooth collaborations, which shows that communication can be facilitated through standardization and procedural clarity, or even through artifact creation, as discussed below.

## 5.3 The usage of artifacts

> Teams require structured mechanisms and/or artifacts to translate context-dependent legal reasoning into implementable design constraints. Otherwise, divergent expectations regarding ambiguity and specificity hinder alignment on what compliance requires in practice. These artifacts need to be explicitly designed to accommodate the interpretive and context-dependent nature of legal reasoning in RDPR work.

Consistent with prior research in RE, this study provides additional evidence for the necessity of a shared language and understanding [19, 22, 21]. In RE, the pursuit of shared understanding underpins the development of artifacts, such as taxonomies, ontologies, and conceptual models [48]. This study also provides empirical evidence supporting the need to validate and implement RE tools for data protection in practical settings. Although multiple ontologies, vocabularies, conceptual modeling frameworks, and others exist to help establish

shared understanding, 46 of our participants (code "lack of common language"- 65.7%) still mentioned struggling with communication. Given that only 2 participants referred to intermediary modeling artifacts, we infer that the artifacts being developed are not being adopted by lawyers.

Although we do not have data to know why lawyers are not adopting these tools, we propose several hypotheses. First, lawyers may be unaware of these intermediary artifacts, suggesting a need for further dissemination. Second, these tools may not adequately capture the needs and expectations of lawyers and diminish their perceived utility to this end-user group; involving lawyers in the artifact's development could help with this. Thus, these artifacts may primarily focus on software engineers' needs, limiting their usefulness to lawyers and RDPRs as a whole. Future work could focus on analyzing these hypotheses and determining why this lack of adoption exists.

If new artifacts are built or adapted to deal with RDPRs, they should prioritize requirements conceptualization as complex socio-technical issues, going beyond the more classical RE functional vs. non-functional requirements conceptualization. The majority of participants emphasized the complexity of translating RDPRs into software specifications, noting the importance of having both legal and technical knowledge. We hypothesize that RDPRs encompass elements from business processes, strategic objectives, technical considerations, privacy-enhancing technologies, and human rights, among others. Oversimplifying RDPRs risks neglecting their complexity, leading to an ill-designed IS. Thus we propose that data protection requirements should constitute a distinct domain within RE, similarly to security requirements.

## 5.4 The role of empathy in privacy requirements engineering

> Interdisciplinary data protection teams are hindered by asymmetries in legal and technical expertise and the absence of a shared language. Thus, effective collaboration requires organizational strategies that include legal experts, and that foster mutual understanding, cross-disciplinary knowledge, and inclusive privacy practices.

With this study, we also provide further evidence of the struggles faced by interdisciplinary data protection teams. Lawyers perceived interdisciplinary teams to struggle due to a lack of shared language, the need for a better understanding of the nuances and complexity of regulations among engineers and technical knowledge among lawyers. Any attempt at supporting the communication between lawyers and engineers needs to consider this.

Promoting communication and unified understanding requires improving organizational privacy culture [43]. Our results point to the need to also include lawyers in the process. In this regard, [26] talk about the need to develop empathy among stakeholders to motivate engineers to implement privacy. In light of our results, this could be a potential approach since lawyers also see themselves as lacking knowledge/education, and value engineers' expertise as necessary for resolving privacy issues (e.g., data privacy breaches). Approaching interdisciplinary collaborations among stakeholders in organizations is a promising approach that is being studied in other domains, such as user experience and service design, where it has been proven useful for improving service quality through a stronger user-centered approach [12].

## 6 Threats to validity and limitations

While our study provides valuable insights into the mental models of lawyers who work or have worked with software engineers on data protection for IS, we also acknowledge three main limitations that present opportunities for future research. First, although our sample included lawyers from 25 countries and covered most G20 economies as well as other jurisdictions. Certain regions, including Oceania and parts of Eastern Europe, were underrepresented. Limiting recruitment to G20 economies and the number of additional invitees was necessary due to time and resource limitations. Russia was excluded due to sanctions in place at the time of ethical approval. Future studies should therefore expand the sample size by reaching out to participants from underrepresented regions to complement our findings with these additional perspectives.

Second, the present study relies on interview data, which is susceptible to various forms of bias. For example, participants' accounts may have been influenced by social desirability, causing them to present themselves or their profession in a more favorable light. To mitigate this risk, we built rapport with the participants prior to the interviews. Additionally, we informed all participants that there were no right or wrong answers and that "I don't know" was a valid and interesting response. Furthermore, as participation was voluntary and non-remunerated, self-selection bias may have influenced the findings.

Another limitation involves the way lawyers conceptualize various stakeholders. Participants referred to 'computer scientists, programmers, or [verbatim] "you guys" (referring to software engineering) when describing the technical stakeholders with whom they interact. This limitation restricts the ability to distinguish among software engineers, architects, incident response personnel, and other technical roles in the analysis. As a result, these roles are grouped together, despite differences in responsibilities and expertise. Future research could investigate whether lawyers' experiences vary regarding specific roles within computer science.

Our deductive approach was well-suited to answering our research questions but may have limited our ability to identify new codes that fell outside the defined topics. The authors' diverse academic and professional backgrounds, spanning computer science, economics, engineering, informatics, law, political science, and psychology, enriched but may have also influenced the analysis. To mitigate bias, we therefore implemented multiple validation steps: the initial codebook was reviewed by five independent lawyers from different jurisdictions (EU, Chile, Brazil, and China). Next, the authors conducted several calibration sessions. Finally, all interviews were double-coded by two researchers and disagreements resolved through discussion. To enhance transparency and reproducibility, we provide detailed methodological documentation; however, interpretive subjectivity remains inherent to qualitative studies [27].

To increase both the transparency and trustworthiness of this study, we provide as much data and details as possible within the paper [41]. However, due to space limitation, specific details and documents are not included here but made available in the public repository [41].

## 7 Conclusion

This paper presents a global overview of lawyers' experiences collaborating with software engineers on regulatory data protection requirements, drawing on a qualitative deductive analysis of 70 interviews. Their experiences are consistent across regions and converge on three primary challenges: lack of shared understanding, difficulties in comprehending regulatory data protection, and insufficient empathy. Legal experts generally do not employ intermediary artifacts to facilitate common ground or serve as communication tools. In the context of data breaches, however, their roles are well-defined, and the processes for managing such events are becoming increasingly standardized worldwide.

Our results imply that it is not just "natural language" that hinders collaboration between lawyers and software engineers, but also their underlying conceptualizations. Although multiple artifacts from the requirements engineering community have been proposed, they appear not to accommodate the needs and legal reasoning of regulatory data protection requirements. These results and implications have important consequences, as they stress the globally shared experience of lawyers when dealing with these types of requirements.

## 8 Data Availability Statement

Due to the qualitative nature of this study and respecting the consent and privacy of the participants, not all interviews can be shared. Some are available `in the Zenodo repository DOI 10.5281/zenodo.15166882` or upon request of the leading author, depending on the consent. In order to provide maximum transparency, we provide other materials in the repository, such as the codebook, interview questions, and other material deemed relevant.

## 9 AI usage in this paper

This article has used a paid version of Grammarly to correct and fix spelling mistakes. The codes definition in the codebook was written by the author, and they used Grammarly and Chat GPT 4.0 for identifying spelling and grammar mistakes. If consented by the participant, interviews were transcribed using AIKO, which was then proof-read and corrected to ensure accuracy of the transcription. The authors have no other disclaimer on the usage of AI.

# Evaluating CI/CD Security Best Practices in the GitHub Actions Documentation

**Lukas Boschanski**
University of North Carolina at Charlotte, NC, USA

**Marco Vieira**
University of North Carolina at Charlotte, NC, USA

## Abstract

**Background.** GitHub Actions, the most widely used Continuous Integration and Continuous Deployment (CI/CD) platform, is frequently involved in large-scale software supply chain attacks. While prior work has focused on detecting vulnerable CI/CD pipelines, research has rarely considered preventive perspectives such as analyzing Security Best Practices (SBPs) in CI/CD documentation.

**Aims.** We investigate the completeness of the official GitHub Actions documentation from a security perspective and identify potential improvements to documenting secure CI/CD practices.

**Method.** We employ an Large Language Model (LLM)-based documentation mining pipeline to extract security advice items verbatim. We derive actionable CI/CD SBPs from the OWASP Top 10 CI/CD Security Risks framework and conduct a qualitative analysis by mapping the extracted advice items against these best practices to assess which best practices are explicitly covered.

**Results.** Across 639 documentation pages, we identify 459 security-related advice items, of which 288 are actionable, but only 50% of them map to actionable SBPs. These items primarily address insecure configurations and insufficient credential hygiene. Furthermore, only half of all security advice visual alerts have an adequate warning type.

**Conclusions.** The GitHub Actions documentation lacks a consistent methodology for incorporating SBPs. Moreover, coverage of established CI/CD security best practices is uneven across OWASP risk categories, with several categories receiving little to no actionable guidance.

## 1 Introduction

In the modern software supply chain, CI/CD pipelines have become essential "highways to production" [21], where changes to the Source Version Control (SVC) directly affect production releases and consequently reduce the window for security intervention. Due to its automated nature, CI/CD is prone to specific vulnerabilities, which the *OWASP Top 10 CI/CD Security Risks* highlights [21]. As such, CI/CD is an increasingly critical component of Software Supply Chain Security (SSCS) [42].

Recurring attacks on the most widely used CI/CD platform [6], *GitHub Actions (GHA)*, such as `tj-actions` [13], `s1ngularity` [26], `Trivy` [10], and most recently `TanStack` [24], have exposed systemic software supply chain risks and prompted GitHub to propose a security roadmap aimed at reducing the attack surface [30]. These incidents have had widespread downstream impact, with *tj-actions* affecting over 200,000 repositories [13] and

© Lukas Boschanski and Marco Vieira;
licensed under Creative Commons License CC-BY 4.0

*Trivy* disrupting approximately 10,000 CI/CD pipelines [10]. In GHA, *workflows* are YAML-based CI/CD pipelines that integrate first- and third-party *Actions*; throughout this paper, we collectively refer to both as *plugins*.

These attacks show substantial impact on the software ecosystem despite years of prior research on the *detection* of vulnerable workflows [20, 27, 8, 31, 23]. Preventive perspectives remain largely unexplored; a notable exception is Vassallo et al., who built a linter to discover configuration smells for GitLab Continuous Deployment (CD) pipelines [41]. Meanwhile, recent studies show that developers lack awareness and understanding of security practices for GHA [22] and face significant challenges when adopting platform security features to secure Open Source Software (OSS) repositories [3]. This points to a broader gap: little attention has been paid to whether CI/CD platforms such as GHA effectively *educate* developers to promote secure behavior in the first place.

The consequences of this gap are tangible: in the `tj-actions` attack, developers of the initially compromised `SpotBugs/sonar-findsbugs` plugin combined the overprivileged pipeline trigger `pull_request_target` with a legacy *Personal Access Token* that had overly broad access, leading to credential exfiltration when creating a malicious pull request. GitHub warns developers through the documentation using visible alerts (e.g., Figure 1) or textual security advice about unsafe practices, yet such warnings are effective only if developers consult and correctly interpret them. However, the official plugin to check out repositories, `actions/checkout`, provides no indication that its use in conjunction with the trigger introduces a security risk.

We address this gap by assessing how established CI/CD SBPs are covered by the GHA documentation and how effectively they are communicated. This is motivated by two findings: 95% of GHA developers rely on official documentation for configuration guidance [22], and developers who consult official documentation are more likely to write secure code [1] – together suggesting that documentation gaps translate into insecure practices. Therefore, the work is guided by the following research questions:

- **RQ1** What are the characteristics of security advice items in the GHA documentation, and to what extent are they actionable?
- **RQ2** What actionable CI/CD SBPs can be identified from established industry guidance?
- **RQ3** How complete is the GHA documentation with respect to CI/CD SBPs, and how prominently are they communicated?

In contrast to related work, we systematically collect and evaluate SBPs across the full CI/CD-related documentation. Kubo et al. evaluate GHA repository security using a subset of *observable* SBPs only from the *secure use reference* page, which omits practices such as *immutable releases* [22], while Huang et al. examine only four CI/CD security issues, conflating vulnerability types with practices due to reliance on existing tools [19, 8]. Our empirical study employs an LLM-driven documentation-mining approach to extract security advice and assess how completely the GHA CI/CD documentation advocates SBPs. Technically, we tackle the largely overlooked problem of automatically extracting security advice from large, complex documentation, whereas prior security advice coding research has focused on classifying pre-segmented items [4, 37, 5]. The few-shot LLM-approach extracts documentation-grounded advice verbatim under semantic and syntactic constraints, validated against a manually labeled ground truth; we derive these extraction criteria by combining inductive documentation analysis with a deductive review of the SBP and security-advice literature (**RQ1**). To identify established CI/CD SBPs, we apply the *SAcoding* methodology [4] to the OWASP Top 10 CI/CD Security Risks [21], a consensus-based set

of recommendations from real-world attacks (**RQ2**). We then map the extracted advice to these SBPs and qualitatively analyze its presentation in the documentation (**RQ3**). Our primary contributions are as follows:

- An actionability assessment of the OWASP Top 10 CI/CD security risks via the SAcoding methodology, yielding a curated set of CI/CD security best practices.
- A set of semantic requirements and syntactic constraints for security advice in software documentation, derived from a manual analysis of the GHA documentation.
- A few-shot LLM-based extraction pipeline for security advice grounded in source documentation, validated against a manually labeled dataset.
- An empirical evaluation of the completeness of the GHA documentation with respect to established CI/CD security best practices, including an analysis of how prominently security advice is communicated through visual indicators.

The remainder of this paper is structured as follows. Section 2 discusses related work. Section 3 introduces security advice theory and derives extraction requirements. Section 4 identifies established CI/CD SBPs from the OWASP Top 10 CI/CD Security Risks. Section 5 presents the LLM-based extraction pipeline. Section 6 reports the empirical analysis of the GHA documentation. Section 7 discusses threats to validity, and Section 8 concludes.

## 2 Related Work

Security advice, whether in the form of best practices, guidelines, patterns, or recommendations, is commonly understood but subject to varying interpretations [16, 4]. Barrera et al. scrutinized the term *security best practices* from a semantic perspective and developed the *SAcoding* methodology to classify security advice items [4, 5], which was applied to *insider threats* [37] and the *Internet of Things* [4, 7].

Regarding security advice, developers relying on official documentation rather than *Stack Overflow* produce more secure code [1]. However, documentation often fails to reflect practical needs [2] or overwhelms developers with information [3]. User-friendly OSS documentation should contain SBPs and link to practical resources like sample projects [3]. Since developers tend to skim, integrating explicit security examples improves adoption [17]. Ultimately, high-quality documentation must be well-structured, readable, unambiguous, and correct [39], yet authors of security advice only update documentation after major incidents [29]. Kubo et al. evaluate developer adherence to 5 of the 16 SBPs from the documentation page *secure use reference* and conclude, in a mixed-methods study, that developers are unaware of these practices, lack understanding of them, and prioritize functionality over security [22]. Huang et al. observe, in a longitudinal study of four security issues, that two vulnerabilities remain while two misconfigurations decrease [19]. Large-scale measurements reveal threats caused by unverified plugins and delayed plugin updates within workflows [31].

CI/CD systems share common security problems such as token leakage [18, 23], unsafe plugin distribution and isolation [23, 20], and unrestricted secret access [23, 20], regardless of the platform provider. Research shows that GHA workflows are overprivileged [19, 20], an issue that Tystahl et al. address with a static analysis tool to determine least-privilege permission policies [40]. In addition, *code injection vulnerabilities* in workflows are still an ongoing problem [22, 19] although state-of-the-art taint analysis tools exist [27]. Recent efforts leverage LLMs to generate GHA workflows; however, these efforts struggle to generate valid workflows while placing limited emphasis on security [43]. Conversely, LLMs have demonstrated strong performance in extracting structured knowledge, such as finite-state machines, from large technical documents such as the *Matter* specification [25].

**Table 1** Scholarly definitions for security advice in relation to proposed quality metrics.

| Author | Definition | Properties |
|---|---|---|
| Redmiles et al. | **Implicit:** Advice imperatives that feature an action [35]. In the context of security and privacy advice for end-users found in various types of documents and evaluated in terms of human perception. | • Perceived Actionability<br>• Perceived Efficacy<br>• Comprehensibility |
| Barrera et al. | **Explicit:** Define *actionable* security advice as advice items that pass Question 5. Additionally, they define a *practice* as "a specific means intended to achieve a given desired outcome"; it is a *best practice* when it is "considered to be better than, or at least as "good", as the best of other widely-considered means to achieve that same outcome" [4, 5]. | *SAcoding* decision-tree questions<br>1) Unambiguous language & focus<br>2) Security related<br>3) Outcome vs. Action<br>4) Specific technique/rule<br>5) Actionability<br>6) Resource feasibility<br>7)–8) Target audience<br>9)–11) Abstraction level |

# 3 Security Advice in Software Documentation

This section establishes the foundation for security advice in software documentation. We first review existing definitions and derive a working definition for this paper (Section 3.1), then characterize the structure of the GHA documentation (Section 3.2), and finally present a manual analysis of a subset of GHA documents (Section 3.3) to derive the requirements and constraints used in the automated extraction pipeline (Section 3.4).

## 3.1 General Security Advice

Definitions for security advice vary across the literature, each emphasizing different characteristics and metrics depending on the target environment, as we summarize in Table 1. For the rest of this paper, we use the term *security advice* as a catch-all to include all related terminology [4]. As shown in Table 1, most scholarly work focuses on the end-user [34, 36, 32], while Barrera et al. propose a general-purpose definition that adapts to different audiences such as end-users, IT-specialists, and security experts [4].

A key property of security advice is *actionability*, which reflects whether the advice includes actionable steps the audience can follow to implement depending on the practitioner's knowledge [34]. However, the steps may be indirect or *declarative*, referring to steps that the practitioner must infer from the security advice's outcome or goal [4]. Such security advice is harder to comprehend [35, 4]. Other considerations for actionability concern implementation feasibility in terms of resources [4, 34]. For example, the first advice in Figure 2 implies input *sanitization* or *validation* while enumerating the input data sources, without stating it.

Each advice item provides a security outcome [4, 34, 36, 32], either stated explicitly (e.g., "Input sanitization prevents code injection") or implied by the action (e.g., "Always sanitize user inputs"). Barrera et al. conclude a semantic `Action` $\implies$ `Outcome` structure [4]. Apart from advice semantics, practitioners' perception of advice quality includes factors such as consistent writing (e.g., always using the affirmative [36]), clear and unambiguous language [4], high comprehensibility [34], and nearby examples [17]. In addition, the number of advice items should be kept as small as possible while remaining highly relevant [36].

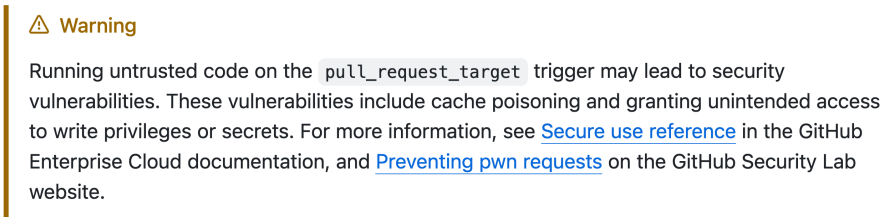

**Figure 1** Visual alert of type `warning` taken from `https://docs.github.com/en/actions/reference/workflows-and-actions/events-that-trigger-workflows` on 12 May 2026.

Together, these properties – particularly actionability, security relevance, and the `Action` $\Longrightarrow$ `Outcome` structure – directly inform the requirements we derive in Section 3.4 for extracting security advice from the GHA documentation.

## 3.2 Structure of the GHA Documentation

The GitHub documentation (as of 19 February 2026) consists of approximately 2853 pages organized hierarchically into 11 main topics, covering collaborative coding, GitHub features, API endpoints, CI/CD, and more. It is a public Git repository that accepts community contributions but is ultimately managed by GitHub. All documents are written in the lightweight markup language *Markdown* and converted to HTML when served via the web. Furthermore, GitHub establishes writing best practices that reflect high-quality documentation, such as readability, structure, clear and accessible language, and formatting [39].

GitHub mainly follows the *Diátaxis* documentation framework [14], organizing documents into four content-types by purpose and audience. *Conceptual* (corresponding to *Explanation*) documents introduce ideas that are further explored in *Tutorials*, *Quickstart* guides, and *How-tos*, while *Reference* documents provide additional technical details. In practice, some topics introduce additional or customized content-types beyond the standard categories.

CI/CD topics are *Actions*, *Packages*, and *Security and code quality*, which we refer to as the GHA documentation for the rest of the paper. *Security and code quality* has four further sub-topics, though these do not fully capture the domain's breadth. Those topics account for about 22% of the total documentation, as shown in Table 2.

The *Actions* topic contains the highest number of *warning* alerts, as illustrated in Figure 1. Markdown *callout boxes*, e.g., `> \[!WARNING]` for a warning, indicate visual alerts. Table 2 lists the alert types in order of urgency; GitHub's style guide associates *Warning* and *Caution* with high risk. Although *Caution* explicitly considers security risk, it is rarely used within the documentation, appearing only five times in the unrelated topics *Admin* (3), *Copilot* (1), and *Repositories* (1). The other alerts are informational, with *Note* being predominant.

Figure 2 shows an excerpt from a conceptual document from the *Actions* topic about script injections. Although the document promises to mitigate script injection risks, it only enumerates possible attack payloads in a single subsequent section. The *Secure use reference* is the only document that explains injection attack mitigations. It is also the most frequently referenced document, referenced 28 times within the GHA documentation and twice outside the selected topics, making it a hub for security advice.

This structural overview motivates the manual analysis: the scale, heterogeneity of content types, and use of alerts all influence what constitutes a security advice item and where such items are likely to appear, as evidenced by the *Secure use reference* emerging as the document with the highest concentration of security advice in our extraction (Section 6).

## 3.3 Manual Analysis of GHA Documents

From these 639 documents, we manually analyze 41 for security advice items to establish requirements that reflect scholarly consensus and showcase the challenges of extracting advice from documents. We ensure coverage of the GHA documentation by sampling documents across different content-types and topics. Prior work on security advice coding assumes advice is available in a digestible format, treating extraction as a decision problem rather than an extraction problem [4, 5, 37].

In an initial review, we identified 30 security advice items that (a) are clear and unambiguous, (b) describe or imply actionable steps, and (c) indicate a security-relevant outcome or goal. Such broad criteria are sufficient for a first analysis, allowing interpretive flexibility while respecting established security advice properties from Table 1. Furthermore, excluding advice items early affects the comparison against SBPs, as those practices might also lack the above properties, potentially understating the documentation's coverage. In about 11 cases, security advice is entangled with specific product features (e.g., *Dependabot* or *Secret Scanning*), targeting that product's ecosystem rather than offering agnostic guidance. Such features carry security outcomes when applied, for example: "Enable Dependabot alerts to be generated when a new vulnerable dependency is found in one of your repositories". Hereafter, we use this case as our **running example**. In contrast, descriptions like "Custom patterns are user-defined patterns that you can use to identify secrets that are not detected by the default patterns supported by secret scanning" explain how to extend mechanisms without mandating action. While the former indicates urgency, the latter uses "you can" to signal that the feature is merely available rather than recommended.

Security mechanisms are also embedded within the documentation, e.g., "Artifact attestations enable you to increase the supply chain security of your builds by establishing where and how your software was built", though less prominently than features. This example illustrates the fine line between description and advice, as it explains both what artifact attestation is and its security outcome. It is an instantiation of *declarative* advice where a practitioner may infer actions, such as generating a *Software Bill of Materials*. However, the text is presented as a feature description rather than a directive, lacking any signal verb or imperative to prompt the reader to act. This ambiguity between description and advice is a key challenge for automated extraction that our requirements in Section 3.4 address.

When creating workflows, custom actions, and composite actions, you should always consider whether your code might execute untrusted input from attackers. This can occur when an attacker adds malicious commands and scripts to a context. When your workflow runs, those strings might be interpreted as code which is then executed on the runner.

Attackers can add their own malicious content to the GitHub context, which should be treated as potentially untrusted input. These contexts typically end with body, default_branch, email, head_ref, label, message, name, page_name, ref, and title. For example: `github.event.issue.title`, or `github.event.pull_request.body`.

You should ensure that these values do not flow directly into workflows, actions, API calls, or anywhere else where they could be interpreted as executable code.

By adopting the same defensive programming posture you would use for any other privileged application code, you can help security harden your use of GitHub Actions. For information on some of the steps an attacker could take, see Secure use reference.

In addition, there are other less obvious sources of potentially untrusted input, such as branch names and email addresses, which can be quite flexible in terms of their permitted content.

For example, `zzz";echo${IFS}"hello";#` would be a valid branch name and would be a possible attack vector for a target repository.

**Figure 2** Excerpt from the *Script injections* document from `https://docs.github.com/en/actions/concepts/security/script-injections` (11 March 2026). Each gray-colored text span represents a security advice item according to our requirements and constraints from Section 3.4.

**Table 2** Size of the GitHub documentation in files per topic and occurrences of the five alert types without *README.md* or *index.md* files from 11.02.2026.

| Topic | Subtopic | Files | Avg. Words | Note | Tip | Important | Warning | Caution |
|---|---|---|---|---|---|---|---|---|
| actions | | 200 | 1385 | 296 | 4 | 2 | 56 | 0 |
| packages | | 20 | 1371 | 42 | 1 | 0 | 3 | 0 |

**Table 3** Number of practices *before* and *after* transforming practices into singular units and *SAcoding* results.

| Category | Before | After | Actionable | Agreement |
|---|---|---|---|---|
| SEC-1 | 5 | 11 | 4 | 100.0% |
| SEC-2 | 9 | 19 | 11 | 100.0% |
| SEC-3 | 8 | 18 | 11 | 94.4% |
| SEC-4 | 6 | 11 | 7 | 100.0% |
| SEC-5 | 8 | 11 | 4 | 100.0% |
| SEC-6 | 8 | 15 | 8 | 73.3% |
| SEC-7 | 4 | 10 | 6 | 70.0% |
| SEC-8 | 4 | 9 | 2 | 55.6% |
| SEC-9 | 2 | 7 | 5 | 100.0% |
| SEC-10 | 4 | 6 | 3 | 100.0% |
| **Total** | **58** | **117** | **61** | **89.7%** |

A strong security advice item is the visual alert in Figure 1. In contrast to other advice nudging the developer to use a feature, it shifts the focus to explicitly warning about it. All advice items were actionable, but to varying degrees. For example, the second advice in Figure 2 suggests adopting a "defensive programming posture" as an action to security-harden GHA. The outcome is clear, yet the action is unspecified because it does not further describe the posture and instead links to the *Secure use reference*. These observations directly motivate the requirements and constraints we derive in Section 3.4.

## 3.4 Security Advice Requirements and Constraints

We reformulate our initial requirements to address two objectives: (1) enabling automated extraction, and (2) collecting sufficiently many candidate advice items for subsequent in-depth analysis and quality assessment of the documentation.

Identifying security advice is subjective, as systematic coding of security advice via *SAcoding* yields varying levels of inter-coder agreement, with a mean Cohen's $\kappa$ of 0.67 (moderate) among three coders [4] and Krippendorff's $\alpha$ of 0.92 (reliable) between two coders [37], depending on the documents analyzed [7] and coders' experience [37, 4]. Yet advice reflects a broadly shared understanding, supporting flexible requirements that accommodate diverse perspectives, while still capturing items that most practitioners would recognize as security advice. Our requirements are:

- **Focused**: One distinct, specific mechanism or a tightly coupled set of mechanisms.
- **Clear**: Written in clear and unambiguous language.
- **Security Outcome**: States or signals a desired security goal or effect.
- **Prescriptive Actionability**: Imposes or recommends direct or indirect actions to be performed.

All requirements reflect the main properties of actionable security advice as proposed by Barrera et al., with one exception: we do not distinguish between *outcome* and *action*. Prior work operationalizes this by asking whether the advice emphasizes a desired end goal or the means to achieve it. However, empirical results show this distinction is difficult to apply consistently: coders frequently disagree when identifying outcome-oriented advice [5], as it

requires a more subjective judgment than other *SAcoding* attributes. Instead, we adopt the notion of *Security Outcome*, capturing whether a text segment expresses a security-relevant goal or effect, regardless of whether the means to achieve it are stated.

The *prescriptive* property addresses descriptive statements within actionability: a text segment that describes a feature without mandating its use for a security outcome, such as *custom patterns*, does not qualify as security advice, reducing relevant items from the first pass by 6. Regarding *clarity*, our sample contains no cases of ambiguous or unclear language, likely because GitHub enforces a style guide and the documentation is open-source with active community contributions. Ultimately, we reduce the number of relevant items from 30 to 20, with 30 documents containing zero advice items.

Now, we propose textual boundary constraints that are important for the extraction task:

- **Self-Containment**: The text must be understandable in isolation, remaining meaningful if encountered outside its original context (e.g., in a CI/CD pipeline guide). Contextual referents must be resolved.
- **Completeness**: One coherent and continuous block of text, not a text or sentence fragment.
- **Inclusion of Referential Material**: Examples and external links directly attached to the advice are included as part of it.

The first constraint is a consequence of the extraction task. We require context to understand the security advice so we can later map it to established SBPs. For example, the first security advice in Figure 2 refers to "these values" in its final paragraph, which requires the *GitHub context* from above. We therefore include it. Extractions are copied verbatim from the source to preserve the original wording and facilitate later quality assessment.

The completeness constraint imposes a continuous structure on security advice items. Our manual analysis revealed no instances of advice items that were split apart. Even though the first and last security advice items in Figure 2 both concern script injections, they address different input sources and thus constitute separate advice items. We argue that advice items spread across non-continuous text segments fail the *Completeness* constraint, as the reader must switch context while skimming the documentation.

Extracted advice items should include referential material, such as links to examples or external resources. Prior work shows that external references improve actionability [4]. Developers tend to rely on examples when skimming documentation [17]. For instance, the *Secure use reference* link in the second advice item in Figure 2 is a case where the referential material is integral to the advice: without it, the reader cannot follow up on the "defensive programming posture" that the advice recommends. However, examples alone do not constitute security advice, as they typically lack actionable steps and a security outcome.

Together, these requirements and constraints define the building blocks for the automated extraction described in Section 5 and answer **RQ1**. In addition, our **running example** satisfies those because it explicitly recommends to "enable Dependabot alerts" to implicitly achieve the security outcome of vulnerability awareness.

## 4 Identifying CI/CD Security Best Practices

In contrast to security advice, SBPs additionally encompass three properties [4]: *quality* reflects effectiveness compared to alternatives, *commonality* captures adoption in practice, and *stipulation* captures the degree of formal recommendation. For example, "branch protection rules on branches hosting production code" is a widely adopted SBP formally recommended by OWASP. We screen available guidelines, standards, and frameworks, as developers seek

guidelines that carry authority [2], and select the most suitable source for deriving CI/CD SBPs. From four candidates, we select the *OWASP Top 10 CI/CD Security Risks* and evaluate its actionability via the *SAcoding* methodology.

## 4.1 Selection of CI/CD Security Guidelines

For our initial screening, we targeted complete, current, free, English-language resources specifically detailing CI/CD security controls and SBPs for software developers. We excluded broader SSCS frameworks as industry practitioners already struggle to select relevant ones [38]. We restricted government resources to U.S. origins and excluded corporate or for-profit materials. To find platform-agnostic resources, we conducted a web search with the query `CI/CD AND Security AND (standard OR framework)` and `CI/CD security best practices`.

The *OWASP Top 10 CI/CD Risks* (2022) [21], categorized as a framework, offers the most extensive coverage with 58 identified practices. In comparison, *NIST SP 800-204D* (2024) [11], a formal standard, outlines 26 practices. The NSA and CISA-produced report *Defending CI/CD Environments* (2023) [28] contributes 19 practices, while the more recent *CI/CD Cybersecurity Guide* (2025) [12], also classified as a framework, presents 15 practices. Across these sources, we only count first-level bullet points or clearly defined sections representing individual practices. Notably, the *Center for Internet Security GitHub Benchmark* was excluded as it is not freely available due to non-commercial licensing restrictions.

NIST SP 800-204D and the *CI/CD Cybersecurity Guide* both build upon the Secure Software Development Framework (SSDF) as a foundational reference for secure software development practices. The former presents security measures, while the latter enumerates tooling for various situations. In contrast, the *Defending CI/CD Environments* report primarily addresses governmental entities and focuses on malicious threat actors to map their capabilities to the ATT&CK framework. Given these differences in scope, audience, and coverage, the *OWASP Top 10 CI/CD Security Risks* is the most suitable resource for our purposes, as we elaborate in Section 4.2.

## 4.2 OWASP Top 10 CI/CD Security Risks

The framework defines ten security risk categories, each described by adversary impact and applicable recommendations derived from real-world attacks on CI/CD systems (including those on GHA). It classifies itself as *documentation*, and its target audience comprises *builders*, *breakers*, and *defenders* [21]. We select this framework because it offers the broadest coverage of the four candidates, with 58 practices. Furthermore, it is referenced in the literature [27, 43] and incorporated in the *Defending CI/CD Environments* report. Its publication involved 17 industry security professionals, reflecting strong practitioner consensus.

The ten categories cover an interconnected attack lifecycle, motivating their retention as mapping targets in RQ3. Attackers typically gain initial access to the CI/CD ecosystem by exploiting *Insecure System Configurations* (`SEC-7`) or abusing authentication flaws via *Inadequate Identity and Access Management* (`SEC-2`). The attack surface further expands through *Ungoverned Usage of 3rd Party Services* (`SEC-8`), which often introduces overly permissive integrations such as GHA *plugins*. Alternatively, adversaries may gain an initial foothold via *Dependency Chain Abuse* (`SEC-3`), injecting malicious artifacts into build environments or developer workstations, mainly by propagating them via programming language package managers. *Poisoned Pipeline Execution* (`SEC-4`) risks arise from attacks on GHA that inject malicious code into SVC via forks, which the pipeline then consumes. This allows attackers to abuse *Insufficient Pipeline-Based Access Controls* (`SEC-5`) to move

laterally within or beyond the CI/CD environment, or to exploit *Insufficient Credential Hygiene* (`SEC-6`) to obtain secrets and move to other interconnected systems. Ultimately, *Insufficient Flow Control Mechanisms* (`SEC-1`) allow attackers to push unreviewed and malicious code or artifacts down the pipeline once inside. These malicious outputs successfully reach production because *Improper Artifact Integrity Validation* (`SEC-9`) fails to detect tampered resources. Throughout this attack lifecycle, defenders are often rendered blind by *Insufficient Logging and Visibility* (`SEC-10`) controls. Table 3 lists the number of best practices per security risk.

## 4.3 Actionability Assessment via SAcoding

We apply the *SAcoding* methodology adapted with the proposed recommendations by Barrera et al. [5] that was first used by Stewart et al. [37]. The coding uses a series of up to 11 binary questions (cf. Table 1) to traverse a decision tree. The leaf nodes of the tree correspond to "tags" that ultimately determine an advice item's actionability. The first coder is a PhD student with a Master's degree in Cybersecurity, and the second coder has 5 years of *DevOps* experience and a Master's degree in Computer Science. Following the initial coding round, the coders, both working in English as an additional language, resolved all disagreements, resulting in 33 changes to coded items, primarily due to language-related issues in the OWASP framework and the coding questions.

As question $Q_{1A}$ evaluates whether a security advice item is focused on a single topic, we first split top-level OWASP practices that contain multiple items into individual units. Table 3 summarizes the resulting increase from 58 to 117 practices, reflecting their dense structure. We split practices by dividing sentences at conjunctions, provided the split did not introduce a new practice. In 29 cases, we made changes to the sentence structure to resolve contextual references, e.g., *this*. The results support the validity of the strategy: both coders assigned the ambiguous language tag ($M_{1B}$) only once on the same item and did not assign the multiple-topics tag ($M_{1A}$) to any item. This step ensures that we do not discard any SBPs, thus prioritizing completeness over syntactic format issues.

Overall, 61 out of 117 practices (52.1%) are actionable, forming our set of actionable SBPs for **RQ2**. We retain the 56 non-actionable items in Table 3 for completeness in the mapping in Section 6, but their lack of prescriptive actionability makes alignment with the extracted GHA security advice unreliable. The overall inter-coder agreement of $\kappa = 89.7\%$ is almost perfect, consistent with prior SAcoding studies covered in Section 3.4. Agreement varies substantially across three categories: `SEC-8` (55.6%), `SEC-6` (73.3%), and `SEC-10` (70.0%) yield the lowest agreement, as their practices blur the line between general policy, specific mechanism, and concrete rule.

This allows us to use the actionable SBPs as a validated reference when mapping extracted GHA security advice: an advice item that aligns with an actionable SBP inherits its actionability assessment. We use the same questions proposed by the modified version of Stewart et al. along with their tag selection to determine actionability [37]. The 61 actionable SBPs derived from the OWASP Top 10 CI/CD Security Risks serve as the mapping target in Section 6, where we assess how completely the GHA documentation covers them.

# 5 LLM-Based Security Advice Extraction

The overall goal of the automated extraction pipeline is to capture advice items that are highly likely to fit the definition of security advice. To this end, we propose a set of requirements and constraints in Section 3.4 to locate such advice, as the GHA documentation is written

from a general perspective and primarily focuses on product interaction. In this section, we explain how we mine and process the GHA documentation in Section 5.1, cover the metrics used for our task in Section 5.2, and describe the prompt engineering process in Section 5.3.

We reuse our sample of 41 documents and 20 security advice items as a test set to develop and fine-tune the LLM-based extraction pipeline. The 41 test documents are a subset of the 639 GHA documents; they are not held out from the final extraction run, as the goal of that run is full coverage rather than held-out evaluation. The test set is used exclusively for prompt development. From an evaluation standpoint, we prioritize high recall as the primary objective, followed by an acceptable match size that reflects our constraints. We use the open-source library *langextract*[15] that extracts structured information from text with precise or fuzzy source grounding to guarantee hallucination free extractions. A prompt and the required few-shot examples define the inputs for the extraction, which we derive in the subsequent subsections. Initial experiments with local models revealed significant resource constraints, most notably limited context windows and reduced inference throughput when processing the large volume and length of the documents. Therefore, we use models of the *Gemini* family, which support extended context windows of up to 1 million tokens. Hence, the generalizability of our prompt-engineering approach is limited to those models. A rough estimate shows that the longest GHA document with 18,477 words, one few-shot example, and the prompt consume at most $3 \cdot 18{,}477 \cdot 1.67 \leq 100{,}000$ tokens[1].

## 5.1 Data Preparation

Although the GitHub documentation is an open-source repository, it only contains templated Markdown files with placeholder variables. Therefore, we mine the documentation via a public GitHub API while using the repository's folder and file structure, ensuring our dataset reflects what visitors of the official documentation see. We avoid using HTML representations, as they require extensive parsing for text extraction and are significantly more verbose than Markdown. Our mined corpus of Markdown files dates to *February 19, 2026*.

An analysis of our corpus reveals that Markdown files contain HTML elements. To reduce the impact on context windows and lower inference latency, we preprocess the documents by removing the visual HTML elements `<svg>` and `<path>` and comments. In addition, we redact Markdown code fences (`` ```<lang> <text>``` ``). Code fences without an explicitly specified language or those labeled as *text* are preserved, as they may contain relevant textual content. This follows the constraints in Section 3.4, as standalone examples are not considered security advice. The code block's content is replaced with a unique marker, enabling post-hoc recovery of the original content. These steps reduce the overall file size by 50%.

## 5.2 Metrics

To evaluate the effectiveness of the predicted extractions against the ground truths, we use two sets of metrics. First, we compute *recall*, *precision*, and *F1* for extractions that overlap with at least one ground truth item. Second, we measure how well the size of each extraction matches the ground truth using *token-level* recall and precision [33].

An extraction is a continuous text span grounded in a source document, marked by start and end offsets at the character level. However, an LLM may fail to replicate a text span word by word; in such a case, *langextract* computes a fuzzy alignment using the longest common subsequence algorithm. Each extraction contains the fully extracted text span, which may differ slightly from the source, and its extraction status, i.e., *exact* or *fuzzy*.

[1] Google estimates 100 tokens per 60 words; see `https://ai.google.dev/gemini-api/docs/tokens`

Figure 4 shows all match types between ground-truth extractions (alphabetic) and predicted extractions (numeric). A fuzzy match example is ② , where ②* is outside the source document. Based on character offsets, we distinguish: **Subspan**, when the prediction is contained in the ground truth (e.g., ① in Ⓐ ); **Superspan**, when the prediction contains the ground truth (e.g., Ⓑ in ② ); and **Exact**, when both coincide (e.g., Ⓓ and ④ ). **Partial** matches are overlapping spans that are neither subspans nor superspans (e.g., ② and ④ ), while **Disjoint** predictions are false positives (FPs) (e.g., ③ ) and **Missed** cases are false negatives (FNs) (e.g., Ⓒ ). Finally, a **Multimatch** occurs when a span overlaps multiple ground-truth items (e.g., ② and Ⓐ ).

Let $\mathcal{P}$ be the set of predicted spans and $\mathcal{GT}$ the set of ground-truth spans for a given document. For each prediction $p \in \mathcal{P}$, we define the matching $\text{Type}_{\mathcal{GT}}(p)$ with the precedence of Exact $\succ$ {Subspan, Superspan} $\succ$ Partial $\succ$ Disjoint. We then define true positives (TP), FPs, and FNs with $\mathbf{1}$ being the indicator function:

$$\text{TP} = \sum_{p\in\mathcal{P}} \mathbf{1}\big(\text{Type}_{\mathcal{GT}}(p) \in \{\text{Subspan}, \text{Superspan}, \text{Partial}, \text{Exact}\}\big)$$

$$\text{FP} = \sum_{p\in\mathcal{P}} \mathbf{1}\big(\text{Type}_{\mathcal{GT}}(p) = \text{Disjoint}\big) \qquad \text{FN} = |\mathcal{GT}| - \text{TP}$$

When we encounter a *multimatch* extraction, we count it only against the first matching ground truth item. Furthermore, we do not compute the number of true negatives (TN) because we cannot define the opposite of a security advice item with respect to extractions; therefore, we cannot compute accuracy but do compute precision, recall, and F1.

While binary metrics assess whether an item was detected at all, they do not capture how closely the predicted boundaries match the ground truth. For an extraction $p \in \mathcal{P}$ that matches $g \in \mathcal{GT}$, we compute the multisets of individual tokens, denoted as $T(p)$ and $T(g)$:

$$\text{Precision}_{\text{tok}}(p, g) = \frac{|T(p) \cap T(g)|}{|T(p)|} \qquad \text{Recall}_{\text{tok}}(p, g) = \frac{|T(p) \cap T(g)|}{|T(g)|}$$

A high $\text{Precision}_{\text{tok}}(p, g)$ paired with a low $\text{Recall}_{\text{tok}}(p, g)$ implies the predicted extraction is shorter than the ground truth, and vice versa. Together, these metrics evaluate both detection rate and boundary precision of the extraction pipeline.

## 5.3 Prompt Engineering

We vary several parameters across five rounds: (1) model and thinking budget, (2) prompt persona, (3) explicit inclusion of the security advice requirements from Section 3.4, (4) targeted exclusion hints for edge cases identified via false-positive analysis, and (5) model settings and behavior. The one-shot example used throughout all experiments is Figure 2. Preliminary experiments highlight the difficulty of selecting few-shot examples for prompt engineering, as their addition or removal complicates attribution and increases fuzzy matches due to the expanded prompt length. Therefore, we fix one specific example to constrain the output format and iterate by adjusting the prompt. All experiments run with a temperature of zero [15] and a single extraction pass per document.

Table 4 shows all experiments alongside evaluated metrics. In the first experimental iteration, we examine model choice using all available Gemini variants with the identical prompt "Extract security advice verbatim" and constraints from Section 3.4, as Gemini models have no published parameter count. Results show that *Flash* variants produce substantially more FPs than *Pro*, while FNs remain consistently low across all models, indicating near-complete coverage of security advice. Furthermore, the match size appears near-optimal, as the high micro-averaged values $\overline{\text{Pre}_{\text{tok}}}$ and $\overline{\text{Rec}_{\text{tok}}}$ indicate.

Given the already high recall, we shift our focus to reducing FPs. We extend Experiment *1.1* and adopt a Markdown-formatted prompt incorporating a persona of a "cybersecurity documentation expert". Experiment 2 demonstrates a reduction in FPs from 29 to 25. We investigate this by comparing FPs across both experiments to identify recurring cases, which reveals that the prompt does not adequately address *descriptive statements*, specifically: (1) *descriptions of tooling operations*, (2) *descriptions of threats without mitigation*, and (3) *policy statements*. Therefore, we add our requirements from Section 3.4 in Experiment 3.1 and, alternatively, extend the persona to exclude *prescriptive statements* in Experiment 3.2, both of which slightly improve precision. However, adding the identified issues as edge cases with *inclusion* and *exclusion* directions using generic examples, e.g., "How to install X" as an exclusion example, greatly reduces FPs to under 14.

Next, some extractions lack security relevance, such as "When you review a suggestion from Copilot Autofix, you must always consider the limitations of AI", which is advice in terms of reliability. Based on Experiment 3.3, we compare two approaches: Experiment 4.1 enumerates *security-relevant* goals and terms, e.g., *security control*, to qualify as advice, while Experiment 4.2 establishes that advice is security-relevant if its primary association among multiple possible interpretations is security, yielding the best F1 score of 78.3. The rationale behind this approach emerged from a discussion between researchers with different backgrounds, e.g., code generation, who associated AI-related advice with functional correctness.

To mitigate the risk of overfitting and keep the prompt simple, we do not conduct further experiments. Comparing the best- and worst-performing models in terms of FPs, we achieve a relative reduction of $1 - \frac{8}{86} = 90\%$ while maintaining high recall.

Lastly, we study prompt-agnostic settings. While conducting reproducibility experiments, we observe fluctuations even with a fixed `seed`, which should result in highly deterministic outputs. Experiments 5.1.* show fluctuations in FPs and slight fluctuations in FNs. Hence, we require a manual evaluation of all extractions to assess whether they meet our requirements, which we conduct in Section 6. A potential explanation for the fluctuations may lie in rounding, scheduling, or live model updates, as all `gemini-3.1` models are still in preview. Experiment 5.2.1 uses two extraction passes with limited effect, as the implementation merges extractions via union, giving priority to the first pass. Conversely, using naive chunking, even though each document fits into the context window, increases FPs by nearly a factor of two.

**Table 4** Overview of the experiments and the metrics used. We compute Precision (Pre.) and Recall (Rec.) globally, while we evaluate the micro-average for $\text{Precision}_{\text{tok}}$ and $\text{Recall}_{\text{tok}}$.

| ID | Experiment | FP | Pre. | FN | Rec. | F1 | $\overline{\text{Pre}_{\text{tok}}}$ | $\overline{\text{Rec}_{\text{tok}}}$ |
|---|---|---|---|---|---|---|---|---|
| 1.1 | Pro (Low thinking) | 29 | 39.6 | 1 | 95.0 | 55.9 | 86.3 | 95.0 |
| 1.2 | Pro (High thinking) | 38 | 33.3 | 1 | 95.0 | 49.4 | 81.8 | 92.0 |
| 1.3 | Flash (Minimal thinking) | 86 | 17.3 | 2 | 90.0 | 29.0 | 79.0 | 88.5 |
| 1.4 | Flash light (Minimal thinking) | 73 | 18.9 | 3 | 85.0 | 30.9 | 87.0 | 82.2 |
| 2 via 1.1 | Persona | 25 | 43.2 | 1 | 95.0 | 59.4 | 87.8 | 85.5 |
| 3.1 via 2 | Requirements | 22 | 46.3 | 1 | 95.0 | 62.3 | 88.8 | 83.3 |
| 3.2 via 2 | Prescriptive | 23 | 43.9 | 2 | 90.0 | 59.0 | 87.5 | 89.6 |
| 3.3 via 3.1 | Requirements + Edge Cases | 13 | 56.7 | 3 | 85.0 | 68.0 | 91.3 | 84.6 |
| 3.4 via 3.1 | Prescriptive + Edge Cases | 12 | 60.0 | 2 | 90.0 | 72.0 | 87.1 | 79.6 |
| 4.1 via 3.3 | Security relevance by terms | 22 | 45.0 | 2 | 90.0 | 60.0 | 87.8 | 78.2 |
| **4.2 via 3.3** | **Primary Security Association** | 8 | 69.2 | 2 | 90.0 | **78.3** | 93.1 | 89.9 |
| 5.1.1 via 4.2 | Repetition with fixed Seed | 9 | 65.4 | 3 | 85.0 | 73.9 | 92.0 | 78.4 |
| 5.1.2 via 4.2 | Repetition with fixed Seed | 13 | 55.2 | 4 | 80.0 | 65.3 | 89.0 | 83.5 |
| 5.2.1 via 4.2 | Two extraction passes | 15 | 54.5 | 2 | 90.0 | 67.9 | 92.8 | 87.5 |
| 5.2.2 via 4.2 | Chunking | 33 | 34.0 | 3 | 85.0 | 48.6 | 96.0 | 88.1 |

All experiments after iteration 1 show no occurrences of multimatches. They also exhibit minimal fuzzy extraction issues; observed discrepancies are limited to minor syntactical artifacts, such as missing newline characters. Since start and end offsets are grounded for each extraction, these offsets can be used directly to recover *fuzzy-free* span boundaries.

### 5.4 Extraction Results

We apply the prompt from Experiment 4.2 to the full documentation corpus and extract 459 potential security advice items from 216 out of 639 total documents. Among these, 29 are fuzzy matches (6.3%) that exhibit the same characteristics observed during training, with one special case missing a Markdown header. The mean extraction length is 48 words, and 90% of extractions have fewer than 76 words. However, some extractions are long as they include extended contexts or Markdown structures such as tables and lists.

## 6 Analysis of Security Advice in the GHA Documentation

This section presents an in-depth qualitative and quantitative analysis of the large-scale extraction obtained from Section 5. In addition, we inspect two research-driven practices from the documentation's viewpoint. In the following, SBPs always relate to OWASP, while security advice items are the actionable extractions. We denote the following multisets: $\mathcal{E}$ for all extractions, $\mathcal{A}$ for actionable advice items, and $\mathcal{O}$ for actionable advice items that map to one or more SBPs (hence $\mathcal{O} \subset \mathcal{A}$). $\mathcal{O}^+$ contains only those SBPs that are actionable as per Section 4.3. A hat ($\hat{\cdot}$) denotes that a set is free of syntactic duplicates.

Agglomerative clustering using the sorted token ratio with a threshold of 90% reveals that $|\hat{\mathcal{E}}| = 414$ out of $|\mathcal{E}| = 459$ extractions are unique. A notable source of duplicates is the repetition of 16 items across cloud provider platforms for OIDC access.

The first step is to identify actionable security advice, i.e., extractions that satisfy the requirements defined in Section 3.4 except for *focused*, as we want to assess the GHA documentation in full. The manual validation process yields $|\mathcal{A}| = 288$ instances, of which 257 are unique. As shown in Table 5, the majority of these advice items (157) fall under the topic *actions*. The *Secure use reference* contains the most security advice items (26). However, security advice is generally sparse within individual documents: among the 136 documents containing at least one advice item, 77 include only one and 33 contain two. On average, one advice item appears per 11,763 words. Most advice appears in the early portions of documents, approximately 10% to 60% of the document length, as illustrated in Figure 5. Nevertheless, developers must still scroll through substantial portions of the documentation to locate relevant guidance, underscoring the importance of well-structured headers that guide developers toward relevant content. Furthermore, Figure 3 reveals a contrasting trend: for the *code-security* topic, advice is concentrated in *tutorials* and *concepts*, whereas for the *actions* topic, it is primarily found in *reference* materials and *how-tos*. According to GitHub's content organization framework [14], the four main content types are not aligned in their placement of security advice items.

We map each item of $\mathcal{A}$ to zero or more OWASP SBPs from Table 3 by best match with the guiding question "If we apply the security advice, does it (at least partially) operationalize the OWASP SBP?". If the security advice revolves around a feature, we analyze the feature description for the match. Regarding our **running example**, we apply codes from the OWASP categories `SEC-3`, `SEC-7`, and `SEC-10` because the detection of a *vulnerable dependency* covers multiple possible parts of system.

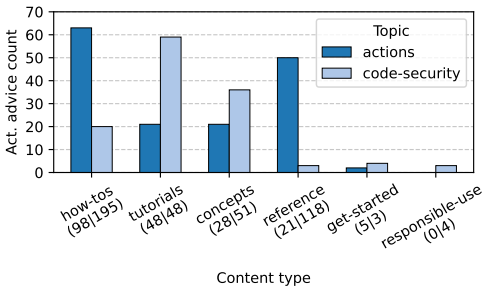

**Figure 3** Counts of actionable advice items by content type and topic; $(\cdot|\cdot)$ shows document counts for the respective topic.

**Table 5** Distribution of advice types by topic.

| Topic | Act. | Add. | Act. OWASP | SBP |
|---|---|---|---|---|
| code-sec. | 125 | 47 | 24 | 54 |
| actions | 157 | 28 | 40 | 89 |
| packages | 6 | 3 | 0 | 3 |

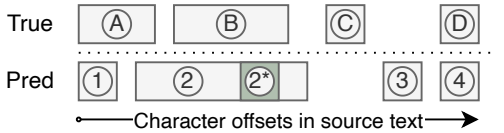

**Figure 4** Types of relationships between predicted and ground-truth text spans in one source document.

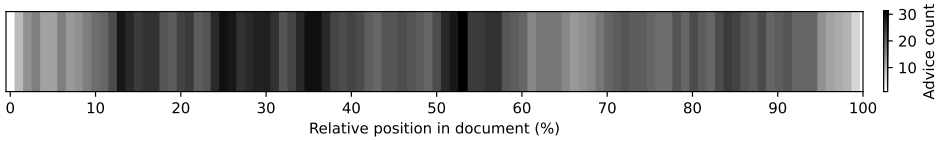

**Figure 5** Interval-based heatmap of actionable advice occurrences across documents normalized by document length and accumulated into 100 bins over the relative document position.

We mark advice items as *additional* if no corresponding OWASP SBP exists, e.g., "Use code scanning to identify insecure code patterns". Table 5 shows the overall number of actionable advice items (288), additional items (78), items that correspond to a non-actionable OWASP SBP ($|\mathcal{O}| = 64$), and items with at least one actionable OWASP SBP ($|\mathcal{O}^+| = 146$). It is expected that `code-security` is the primary source of additional items as it partly goes beyond CI/CD. Notably, only 50% of actionable advice items align with an actionable SBP, suggesting that a substantial portion of the documentation's security guidance lacks a corresponding established best practice. Furthermore, 120 items have exactly one mapping while 90 have more than one. The most common SBPs of $\hat{\mathcal{O}}^+$ are *branch protection* (16), *stored or pushed secret detection* (15), and *prevention of secrets in logs and builds* (14).

To answer **RQ3**, we leverage the OWASP mapping to conduct a per-category analysis, examining the four intersections between actionable and non-actionable SBPs and mentioned or absent SBPs. Figure 6 summarizes all cases and lists the number of unique actionable and non-actionable SBPs covered in the documentation. GHA achieves high coverage of `SEC-6` and `SEC-7`, likely because many attacks exploit suboptimal system configurations (`SEC-7`, 102 mentioned SBPs) and steal credentials (`SEC-6`, 30 mentioned SBPs) [13, 26, 10, 24]. `SEC-4` also receives notable coverage (44 mentioned SBPs), as attacks typically exploit CI/CD pipelines via pull requests (*Poisoned Pipeline Execution*) [13, 26, 10, 24]. However, the GHA documentation fails to adequately inform developers about the usage of third-party services such as *plugins*. The OWASP framework does not fully cover this aspect: `SEC-4` mainly addresses governance and permission control of plugins but not their maintenance, e.g., updates and usage. The latter is conceptually addressed in `SEC-3` (Dependencies) and `SEC-7` (System Configuration) but does not apply to the scope of plugins.

Next, we analyze $\mathcal{A}$ to quantify the usage of visual alerts. The automated extraction initially only identifies 22 alerts, mainly due to missing *callout box* markers. Hence, we extend extractions by up to 15 characters before each extraction start offset, yielding 42 additional alerts, for a total of 64. The *actions* topic accounts for most alert usage (55

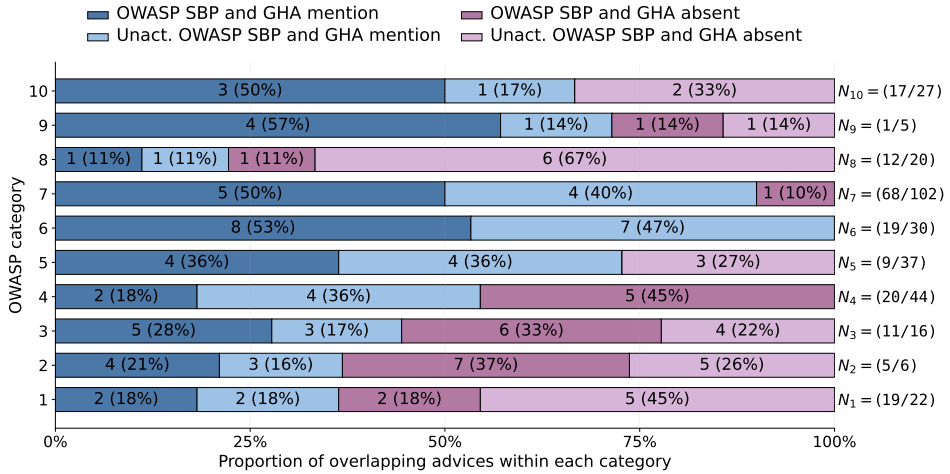

**Figure 6** Distribution of OWASP SBPs by actionable status and their corresponding mentioning status in the GHA documentation per OWASP category. $N_i$ shows the unique number of actionable OWASP SBPs in proportion to the unique number of OWASP SBPs per category.

instances), with `WARNING` as the most frequent type (34 occurrences). However, alert usage remains suboptimal: 27 alerts are labeled `NOTE` and 2 `TIP`, which may not adequately convey the severity of the associated security guidance. Applying the same analysis to $\mathcal{O}$ shows that only 32 visual alerts correspond to SBPs, similarly reflecting inadequate alert categorization.

A common practice mentioned in research is **plugin pinning** to an immutable hash, especially for 3rd party plugins [20, 22, 8]. GitHub communicates this in 11 forms with varying degrees of security, trust, and functionality considerations. Only the *Secure use reference* mentions that this SBP mitigates the risk of propagation, as showcased by various attacks [13, 10]. However, throughout the full documentation, GitHub consistently uses workflow examples with pinned 3rd party plugins and strives to introduce a locking mechanism [30].

In contrast, security advice regarding **code injection** [27, 8] vulnerabilities appears in the same form seven times across the documentation; each instance links to the *secure use reference* for actual mitigations. Conversely, that reference contains no warning regarding the `pull_request_target` trigger. This trigger corresponds to only one piece of security advice in our dataset, namely Figure 2. Given that this trigger is often a prerequisite for a successful attack [13, 24, 26], it is notable that we encountered one extraction recommending the use of the trigger without providing additional security warnings.

## 7 Threats to Validity

In terms of **construct validity**, our approach builds upon existing definitions of security advice and established coding methodologies, which were validated through qualitative analyses but always assumed pre-segmented advice items. The *SAcoding* methodology involves inherently subjective judgments, and we assume that LLMs share similar biases when identifying security advice in documentation. Furthermore, our approach considers visual alerts as a strong proxy for prominence whereas other factors such as location, cross-linking and proximity to examples likely also matter. Selecting the OWASP Top 10 CI/CD Security Risks as the SBPs benchmark is a construct choice, as alternative frameworks may yield different coverage results.

Our experiments in Table 4 show unstable results, independent of zero temperature and a fixed seed, with consistently high recall but fluctuating FPs, threatening **internal validity**. As no additional validation set was used, we address this by conducting a manual review of all extracted items. The decision to use a proprietary model instead of an open-source alternative reflects a trade-off between model capability and economic considerations. Although proprietary models currently deliver superior performance, relying on them undermines reproducibility and long-term accessibility, since their availability may change or be discontinued. We accept this trade-off given the scale of the documentation corpus and our goal of assessing documentation quality rather than optimizing extraction performance. The impact is further mitigated by the task's low frequency, as documentation evolves slowly, making reruns of the extraction pipeline rarely necessary.

For **external validity**, our analysis focuses on a single platform's documentation; findings likely don't generalize to other CI/CD platforms because of implementation details [20]. Nevertheless, GHA is the most widely used CI/CD platform [6], making it a representative and high-impact subject. A further limitation concerns developer information sources: Acar et al. show that developers frequently turn to alternative resources such as online forums or general web search results [2], which our study does not account for.

From the perspective of **conclusion validity**, both the manual review of all 459 extracted items subject to Section 3.4 and the mapping of advice items to OWASP SBPs by best match were performed by a single reviewer, introducing potential bias and subjectivity.

## 8 Conclusion

We show that the GHA documentation covers many actionable security advice items, but its coverage of CI/CD SBPs remains uneven across OWASP risks. These gaps indicate that the documentation should be treated as part of the CI/CD security surface, since missing or weakly communicated guidance can leave developers without the knowledge necessary to secure their repositories. However, we acknowledge that GitHub does not bear sole responsibility for developer issues but should strive to educate developers to the greatest extent possible, which our contribution supports by identifying areas for improvement. Even where guidance is complete, research suggests that the sheer volume of available security advice makes it difficult for developers to prioritize recommendations [35], so well-documented SBPs may still not translate into secure behavior.

Future work should propose a framework that enables documentation authors and SBP guideline authors to jointly translate common practices into documentation, with a focus on effective communication in terms of text structure and visual presentation. As a concrete step in this direction, we propose the following recommendations for GitHub:

- Extend the content best practices with structured rules that outline where and when to place SBPs, while also advocating for a uniform structure of security statements in terms of their semantics, e.g., as proposed by Barrera et al. with *Action* $\implies$ *Outcome* [4].
- Introduce a dedicated *security* visual alert to ease bookkeeping, or repurpose the unused `caution` alert, and unify existing ones.
- The current documentation structure places significant emphasis on the *secure-use* reference as a central hub. However, developers perceive this document as complex [22], reinforcing the need to distribute SBPs across the relevant documentation pages where they fit best, in line with the consensus of presenting them contextually when needed [36].

## Data Availability Statement

Our corpus of all CI/CD-related documents mentioned in Table 2, coding results from Section 4.3, code and experimental data from Section 5, and evaluation notebooks for Section 6 are available at `https://github.com/bluuuk/gh-cicd-sbp-docs`. Our streamlit-based SAcoding tool is available at `https://github.com/bluuuk/SAcoder`.

## Abstract

**Background.** Anecdotal evidence suggests that the Fortran ecosystem – the language, tooling, codebases and broad community – continues to make a significant international contribution to science and engineering. Yet the common perception appears to be that Fortran is old and obsolete and, as a result, one should divest from it. There is no empirical evidence – e.g., no contemporary or historical survey – to corroborate or contradict such perception. A consequence is that this perception may be not only mistaken but also damaging to the Fortran ecosystem and to the global contribution that the ecosystem continues to make to society, the economy and environment.

**Aims.** To gather empirical evidence on the current state of the global Fortran ecosystem, in order to corroborate or challenge perceptions about the language, tooling, codebases and community.

**Method.** We conduct an international survey of the Fortran community, collecting information from 150 respondents across 25 countries.

**Results.** We report results about codebases (e.g. code size varies from 1KLOC to 5MLOC), community demographics (e.g., most respondents are male; most respondents hold doctorates), challenges (e.g., code complexity, human resource) and perceptions of Fortran (only 15% consider their codebases to be legacy codebases).

**Conclusions.** Our results provide the first descriptive benchmark of the Fortran ecosystem which can act as a resource or reference for future research and practice. Also, our results suggest that Fortran may be better understood as a highly-valuable, niche, contemporary ecosystem, one which continues to contribute to world-leading research in many science and engineering disciplines. As an "edge case", it is ideally placed to provide unique and insightful contributions to our understanding of (scientific) software engineering, e.g., technical debt, refactoring, code complexity, and the significance of application domain knowledge. Since all codebases, regardless of language, have the potential to become legacy systems in the future, Fortran is actually at the forefront of confronting long-term challenges and consequences of engineering complex (scientific) software systems.

## 1 Introduction

Anecdotal evidence suggests that the Fortran ecosystem – the language, tooling, codebases and broad community – continues to make a significant international contribution to science and engineering. For example, software written in Fortran accounts for between 65% and 80% (depending on assumptions) of the usage of the UK's ARCHER2 supercomputer [7] and the language's international standard continues to evolve [16]. At the same time, common perception appears to be that Fortran is old and obsolete and, as a result, one should divest from it. There is a lack of contemporary, or even historical, surveys or systematic reviews of either the state of the Fortran ecosystem or of the continuing contribution of that ecosystem to science and engineering, and to society, the economy and the environment. One consequence is the lack of rigorous, empirical evidence to corroborate or challenge the anecdotal evidence. A more serious consequence is that the lack of evidence also makes it hard(er) for policy makers, funders and resource-providers (e.g., hardware and compiler vendors) to properly judge the scale and impact of the ecosystem, with the risk that such stakeholders are both less likely to support that ecosystem and more likely to advocate divesting from it. A recent example is the Los Alamos National Laboratory's evaluation of risks associated with relying on Fortran for mission critical software [30]. A reinforcing cycle arises: the state and contribution of the international Fortran ecosystem continues to not be empirically documented, encouraging the misperception that it is non-existent or unimportant. This, in turn, reduces support for the ecosystem, which makes it harder to collect empirical evidence to reliably assess its state and continuing contribution. It becomes increasingly difficult to advocate for and sustain Fortran-based science and engineering and to sustain the contribution of that science and engineering to society, the economy and the environment.

The **aim** of this paper is to intervene in the reinforcing cycle. The **objectives** of the paper are: 1) to report the first international survey of the current state of the Fortran ecosystem; and 2) to use the findings from the survey to promote further research into the Fortran ecosystem. Aligned with the objectives, the **main contribution** of the paper is the provision of a unique set of insights into an under-studied and under-appreciated, but also a highly valuable and complex, field of (scientific) software engineering. This study is **novel** in that no findings of this kind have been reported in the peer-reviewed literature; it is **significant** because of the continuing dependence of many science and engineering disciplines on Fortran; and it is **timely** because, as the findings will show, there are a set of risks accumulating for Fortran-based science and engineering.

The remainder of the paper is organised as follows: Section 2 presents a brief overview of the Fortran ecosystem, and then reviews prior research, using the overview and the review to motivate the study; Section 3 explains the design of the study, including design choices,

piloting the survey, participant recruitment, and data selection and analysis for the current paper; Section 4 reports descriptive results, using tables and visualisations, and provides a narrative explanation that brings together the results; Section 5 considers implications of the results, the challenges of generalising from the results, other limitations to the study, and some directions for future work. The appendices acknowledge respondents, list the survey questions examined in the paper, and explain the data package for open science.

## 2 Background and related work

### 2.1 Brief overview of the Fortran ecosystem

Fortran is the first of the third-generation programming languages, having been created at IBM by John Backus and others over the period 1953–1957. As a *language*, Fortran continues to be developed, with the latest revision to the Fortran standard being Fortran 2023 and a schedule now established for new revisions every five years [18]. The term *Modern Fortran* refers to revisions to the standard since Fortran 2003 inclusive, for which there have been four revisions so far: 2003, 2008, 2018 and 2023. The term *Fortran* either refers generally to the Fortran programming language or specifically to Fortran 90. The term *FORTRAN* refers to revisions prior to and including FORTRAN 77.

Uniquely, the Fortran language *standard* continues to be backward- and forward-compatible, such that, for example, code written in FORTRAN 77 can compile and execute with code written in Fortran 2023 (provided the respective compiler supports it). Fortran is therefore the first and the oldest third-generation language, the oldest language with an international standard and with an active international standards working group, and is a language that continues to be actively developed. It is also the longest surviving "continuous language", avoiding the kind of "breaking changes" that occurred with, e.g., Python 2 and Python 3. These are remarkable features of the Fortran language.

In addition to the *language*, there is now a standard library, a package manager and registry, an interactive compiler, and a language server[1] that integrates with leading IDEs. New technologies are being developed in Fortran, both to improve the Fortran ecosystem and to develop new applications. Rouson's Fortran Group[2], at Lawrence Berkeley National Laboratory, is a world-leading example, developing a parallel runtime interface for Fortran [27], together with a parallel runtime library (Caffeine), a deep-learning framework implemented in modern parallel Fortran (Fiats), a correctness checking framework (Julienne), and a library for runtime checking (Assert) [17]. As a technical ecosystem, Fortran is in a stronger position now than at any time in its history [16]. Two online fora for the international Fortran community – `fortran-lang.org` and `fortran-lang.discourse.group` – complement the technical ecosystem.

Fortran continues to be used in a very wide range of science and engineering disciplines. Six of the top ten codebases running on the UK's ARCHER2 Tier 1 HPC service are written in Fortran, namely VASP (electronic structure and atomistic materials modelling) [36], CP2K (molecular dynamics and condensed-matter simulation) [8], CASTEP (materials science) [5], MetOfficeUM (weather prediction and climate modelling) [32], SENGA (combustion and turbulent reacting flows) [29], and NEMO (ocean and sea-ice modelling) [23]. International examples of the continued use of Fortran for large-scale applications include the

[1] `https://fortls.fortran-lang.org/index.html`
[2] `https://amcr.lbl.gov/departments/computer-science-department/class/fortran-at-lbl/`

Weather Research and Forecasting (WRF) Model [37], the Community Earth System Model (CESM) [22], DFTB+ (quantum mechanical and atomistic simulation) [10], Molpro (ab initio quantum chemistry) [21], and ParaMonte (high-performance Monte Carlo and statistical simulation) [25]. Taken together, these Fortran codebases, and many others, directly power a significant number of highly successful and impactful scientific and engineering endeavours.

The indirect scientific importance of Fortran is arguably even larger, though also much less visible: core numerical operations of Numpy and Scipy (Python), Matlab, Julia and R *all* depend on executables compiled from established Fortran-based libraries, such as LAPACK [33], a library for high-performance linear algebra routines.

For more detailed reviews of the history of Fortran see, for example, Metcalf [19] and Snyder [34].

## 2.2 Prior research into the Fortran ecosystem

There is a reasonably sizeable body of prior research investigating technical aspects of Fortran codebases. As examples: Vanderbauwhede [35] demonstrates the automatic refactoring of FORTRAN 77 code into type-safe Fortran 90 code; Dhruv and Dubey [11] report the use of large language models to translate Fortran code into C++ code; García-Rodríguez, Añel and Rodeiro-Iglesias report on their development of a Fortran static code analyser [13] that can analyse code written with all revisions of Fortran (and FORTRAN); and Hasselbring, Jung and Schnoor [15] report the combined use of dynamic software profiling with static code analysis to assess two widely used earth system models.

Some surveys include Fortran amongst their responses; however they do not focus specifically on Fortran. For example, Giordani et al. [14] report a replication of Prabhu et al.'s [26] in-depth survey of the practices of computational science at leading research institution in the USA. These surveys focused on computational practices, not on languages, though languages are considered in the responses. Giordani et al. [14] found that the percentage (27%) of language use for Fortran had not changed *at that university* over the decade since the original survey [26].

In terms of *scientific* software, Farhoodi et al. [12] report a systematic mapping study of primary studies investigating the development of scientific software. Farhoodi et al. found, from their sample, that the majority of scientific software systems were written in Fortran (36/130 studies; 28%) followed by C++, C, Python, Java and Matlab.

Whilst a recent article discussed the state of the Fortran *language* [16], and a fairly recent report [31] from the British Computer Society's Fortran SIG presented raw results of a survey of 427 respondents into the benefits of Fortran *standardisation*, we are unaware of any research – recent or in the (distant) past – into the *global* state of the Fortran *ecosystem*.

## 2.3 Summary

The lack of prior assessments of the state of the international Fortran ecosystem and the evidence of the continued use of Fortran in science and engineering, and "within" other programming languages, motivate the survey we report here, i.e., to gather empirical evidence on the current state of the global Fortran ecosystem, in order to corroborate or challenge perceptions about the language, tooling, codebases and community.

# 3 Method

## 3.1 Overview

The **aim** of the survey – to better understand the current state and impact of the global Fortran community – translates into several study **objectives**, i.e., to collect information on:

- Those who work on, or with, Fortran codebases, e.g., research software engineers, computational scientists.
- The environment, e.g., the kinds of institution within which research software engineers and computational scientists work, and within which the Fortran codebases are used.
- The perceptions of Fortran, e.g., whether Fortran codebases are perceived as legacy code.
- The characteristics of the Fortran codebases, e.g., size, dependencies, licensing.
- The challenges confronting those who work on the codebases, as well as suggestions on how those challenges might be addressed.

To increase both the frequency and the quality of response, the survey was designed to collect information on targeted items of relevance, rather than designed to collect a wide range of information that might be relevant. Consequently, and consistent with all empirical studies, we intentionally decided not to collect some information. Three examples illustrate the design choices. First, whilst diversity and inclusion are known issues in software engineering and warrant research attention (e.g., [9]) the survey was designed to collect information only on demographics directly relevant to specific hypotheses we had on gender, age and expertise. Second, participants were asked to provide responses relating to a single codebase of their choice. Whilst this decision reduces the prospective coverage of codebases, it helps reduce responses of the form, "it depends". It also increases the accuracy and reliability of responses because each response is about a single Fortran codebase. As a complementary question, however, we asked respondents to indicate how many codebases they work on and the basis for choosing the single codebase they did. These complementary questions allow us to assess the impact of our design choice to focus on single codebases. We return to this point in Section 5.2, where we consider the generalisability of the findings. Third, and as discussed in Section 3.2, we conducted a two-stage pilot study to assure the relevance of our design choices.

The final survey comprises 39 questions. A copy of the survey is provided in the accompanying data package (see Appendix B). Publication constraints mean we are unable to report on all the data in this single publication. Instead we select particular questions to report on. In anticipation of future publications and to support cross-referencing across open access datasets, we reference the original survey question numbers when we report our results.

The study, including its protocol, has been approved by the University's Faculty Research Ethics Committee, with protocol number [redacted for the review to preserve anonymity]. Three of the co-authors have prior experience of national and international surveys of software engineers or similar. Later, in Section 5.3, we use Molléri et al.'s [20] 10-stage checklist for software engineering surveys to assure the quality of the survey.

## 3.2 Piloting the survey

To complement the review of the draft survey by the four co-authors, we asked several professionals working within, or with, the Fortran global community to pilot the survey. Pilot respondents were asked to not only review the questions but to complete the survey. All those we approached agreed. Pilot respondents are summarised in Table 1.

**Table 1** Demographics of respondents to the pilot study.

| ID | Gender | Age | Country | Role | Access-ibility | Duration[d] | Completed survey |
|---|---|---|---|---|---|---|---|
| 1 | Male | 35-44 | UK | CS | | <10min | Yes |
| 2[a] | Female | 35-44 | Germany | RSE | | NS | Yes |
| 3 | Female | 45-54 | UK | CS | | 15min | Yes |
| 4[a] | Male | 35-44 | USA | RSE | | 10 - 15min | Yes |
| 5 | Female | 25-34 | USA | CS | | 18min+7min[c] | Yes |
| 6 | Male | NS | UK | RTP | Yes | NS | No |
| 7 | Female | NS | UK | RSE[b] | | NS | No |

NS = Not stated; CS = Computational Scientist; RSE = Research Software Engineer
RTP = Research Technical Professional
[a]Respondent re-reviewed a revised version of the survey.
[b]Respondent does not work directly on Fortran codebases but provides professional development to RSEs, including Carpentry courses on Fortran.
[c]Respondent videoed themselves thinking-out-loud as they completed the survey (18 minutes) followed by post-survey reflections (7 minutes).
[d]Respondents were asked to record duration to get a sense of their perception.

The pilot was initially intended to be a single round of review, however the feedback from some respondents identified significant limitations to the survey. This led us to revise the survey and conduct a second round of review, with feedback from some respondents. Respondents who re-reviewed the revised survey are identified in Table 1.

Respondent PR5 chose to video themselves as they completed the survey, thus providing a "think out loud" form of feedback. This feedback was complemented by their videoed self-reflections at the end of completing the survey, together with a set of email comments.

Respondent PR6 was unable to complete the survey for accessibility reasons. This was in itself an important test of the survey. The way we had designed the online survey, given the survey platform we were using (and recommended by the University who approved the study), meant that respondents would need to "page through" each section of the online survey form. This presented difficulties for PR6. One alternative was to design the survey to be presented in its entirety on a single scrollable webpage. For other reasons, such a design can also overwhelm and discourage respondents. As a compromise, we retained the page-by-page design but also produced a PDF version of the entire survey, and made the PDF available with the Participant Information Sheet and a copy of the Consent Form. The PDF would allow all respondents to review the questions prior to attempting the survey. This is an unsatisfactory compromise, but a necessary one, given the constraints.

Finally, due to time constraints, Respondent PR7 was not able to complete the survey, but did feedback on some of the survey questions.

Overall, the pilot study led to the following kinds of changes to the survey:

- Changes to the visual presentation of the survey to make it less distracting, e.g., use a plain background with a larger font size.
- Revised the introduction to clarify the purpose of the survey and to link to additional information, such as the PDF version of the entire survey.
- Added additional options for some multiple-choice questions.
- Changed the overall structure of the survey, i.e., re-ordered the sequence of some questions.
- Changed the phrasing of some questions, e.g., changing "versions" of Fortran to "revisions to the Fortran standard".

**Table 2** Channels for promoting the survey.

| Channel | Membership | Scope | Comment |
|---|---|---|---|
| *Direct promotion by the co-authors* | | | |
| fortran-lang discourse | 1800 | Global | Discourse channel for fortran-lang.org |
| SocRSE Fortran Slack | 200 | UK | UK Society of RSEs Fortran slack channel |
| DE-RSE github site | – | Germany | Society of RSEs in Germany |
| SSI blog post | – | Global | Software Sustainability Institute's blog post |
| Mailing list | 75 | Global | Mailing list created by us from the annual *Back to the Fortran Future* workshops held as part of the RSECon in the UK. |
| CoSeC JISCMAIL | – | UK | Mailing list for the UK's *Computational Science Centre for Research Communities* |
| *Indirect promotion by members of the community* | | | |
| American Physical Society Division of atomic, molecular, and optical physics forum | | | |
| American Association of Physics Teachers PICUP (computational physics) Slack channel | | | |
| Atomic Molecular and Optical Science gateway Community | | | |
| Los Alamos National Lab, USA | | | |
| Georgia Tech, USA | | | |
| Jülich Research Centre, Germany | | | |

- Introduced new questions, in particular in response to suggestions from Respondent PR2.
- Improved methods of answering questions, e.g., converted the question about country to a drop-down box.

## 3.3 Recruitment of participants

We directly promoted the survey to prospective respondents through a number of online channels. Members of the global Fortran community also promoted the survey indirectly. Direct and (known) indirect channels of promotion are summarised in Table 2.

As per the requirements of the respective research ethics board, we explicitly invited only healthy adults who worked with Fortran codebases to complete the survey.

We included in the survey the option for participants to uniquely and anonymously identify themselves so that we can explicitly acknowledge their contributions. Participants who chose to identify themselves in some way are listed in the Acknowledgments section of the paper's Appendices.

## 3.4 Analysis of "open" and "closed" questions

For "closed" questions, comprising a series of pre-defined answers, we report frequency counts in our results.

There is one "open" question we report in the current paper, for which respondents were asked to provide qualitative comments. This question asks about the most significant challenge – technical or non-technical – personally confronted with the codebase by the respondent (survey question Q23). We analysed this question using the following procedure:

1. The *second* author independently reviewed all responses to the question, constructed a classification, and then coded responses according to the classification. The second author is a physicist and research software engineer, and has used a Fortran codebase for much of their scientific career.

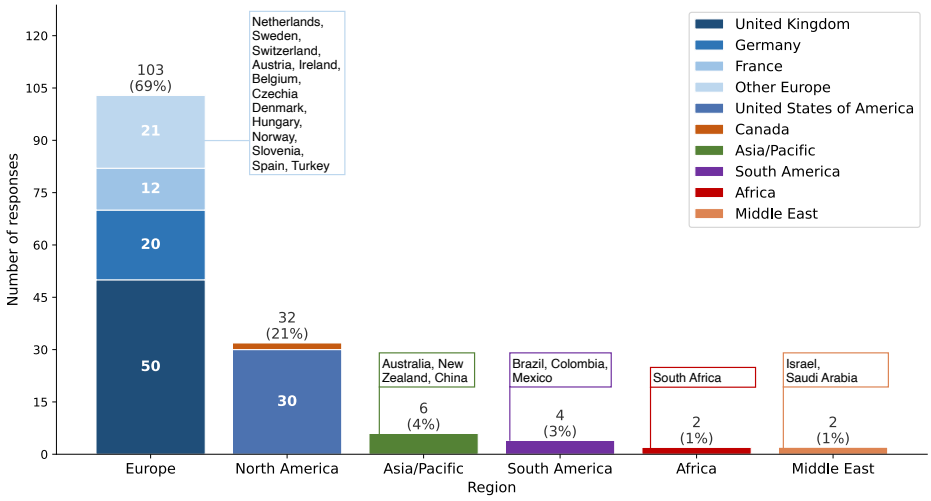

**Figure 1** Geographical location of the organisation that owns the respondent's codebase (Q25).

2. The *first* author then used *only* the classifications to independently code all responses, and did so for each question. The first author is a software engineering researcher. The first author did not see how the second author had classified the responses.
3. After coding all responses independently, the first author then compared the two authors' classifications, and assessed inter-rater reliability, sharing that assessment with the second author.
4. The two authors then discussed differences for the first 50 responses. During their discussion, the definitions for the classifications were clarified, and two categories were merged.
5. The two authors then independently reviewed the classification of the remaining 100 responses.
6. The two authors then met to discuss and resolve remaining differences.

The final classifications are provided in the accompanying data package.

## 4 Results

This section reports a selection of results from the survey, using tables and visualisations accompanied by narrative explanation. The section first presents and discusses demographic information, then proceeds to information about codebases, then integrates demographic and codebase information, and concludes with the presentation and discussion of the most significant challenges confronted by respondents with their codebases.

Figure 1 shows the geographical location of the organisation that owns the respondent's codebase. The high proportion of respondents from the UK (33%), Europe (69%) and North America (21%) may arise from the historical concentration of scientific and engineering software activity in these regions, or may be due to bias in the data because of the way(s) we promoted the survey, or both. We return to this issue in Section 5.2.

Figure 2 presents information on the organisations that "own" the codebases and the role of the respondents within those organisations. A large number (37%) of responses relate to codebases "owned" by universities, which aligns with the historical use of Fortran in areas of fundamental science and engineering research. However, the industrial/societal relevance

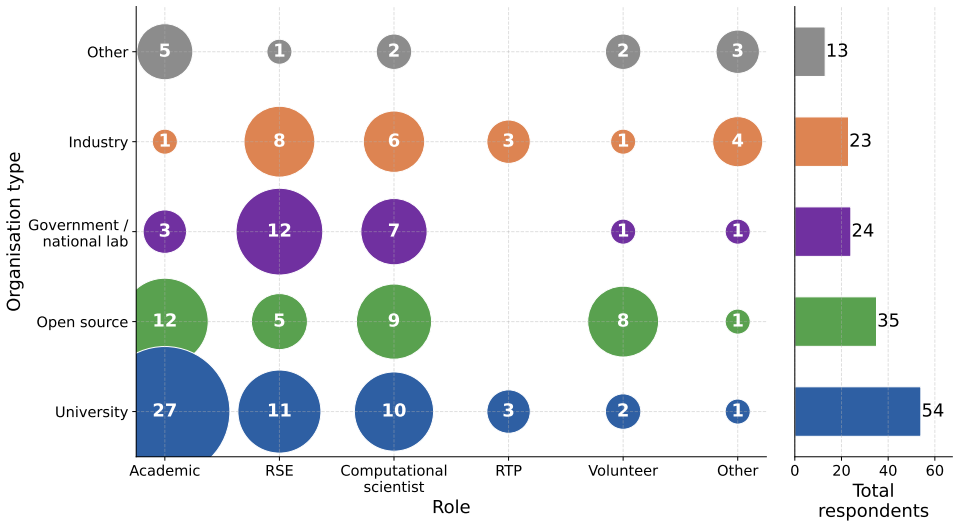

**Figure 2** Type of organisation that "owns" the codebase (Q26) vs role of respondent in the organisation (Q27).

of those disciplines is indicated by the number of responses related to codebases owned by industry (15%) and governmental agencies (16%). The roles fulfilled by the respondents again skew heavily towards academic roles: 33% academics, 25% Research Software Engineer (RSE). Interestingly, the majority of RSEs (26/37), and of computational scientists (24/34), responding to the survey are working on codebases that are not owned by universities. This may partly be explained by sources of funding (universities may not have the funding), or by the nature of the work, or by organisational differences; but overall, it suggests that further work is required to understand the kind of work that RSEs and computational scientists – in contrast to academics – are doing in this space.

Figure 3 complements Figure 2, showing the highest academic qualification held by the respondents, and their self-assessment of the relevance of that qualification for their current role. Perhaps unsurprisingly, given the large number of those in academic and computational scientist roles, a large majority (82%) of respondents hold a PhD[3]. What is more striking is that 88% of those respondents consider their doctorate to be "essential" or "directly relevant" for their current role. This may suggest that the domain-specific knowledge requirements for the Fortran-community are higher than for other fields or applications. This is corroborated by answers to Q23 on challenges (Table 5), where "Domain knowledge" is the eighth most common category of response.

Figure 4 presents age and gender information about the respondents. Gender minorities remain under-represented across software engineering and programming occupations, with recent estimates placing women[4] at approximately 20–28% of software developers and programmers in the UK and US technology sectors [3, 1]. Research Software Engineering (RSE) communities in the UK exhibit gender disparities similar to those observed in software engineering more broadly. A survey by the Software Sustainability Institute reported that women comprised approximately 14% of the UK RSE community, comparable to estimates for software developers generally, but substantially lower than the proportion of women in

[3] Habilitation is an advanced post-doctoral academic qualification in Europe.
[4] We note that these surveys still adopt binary gender categories.

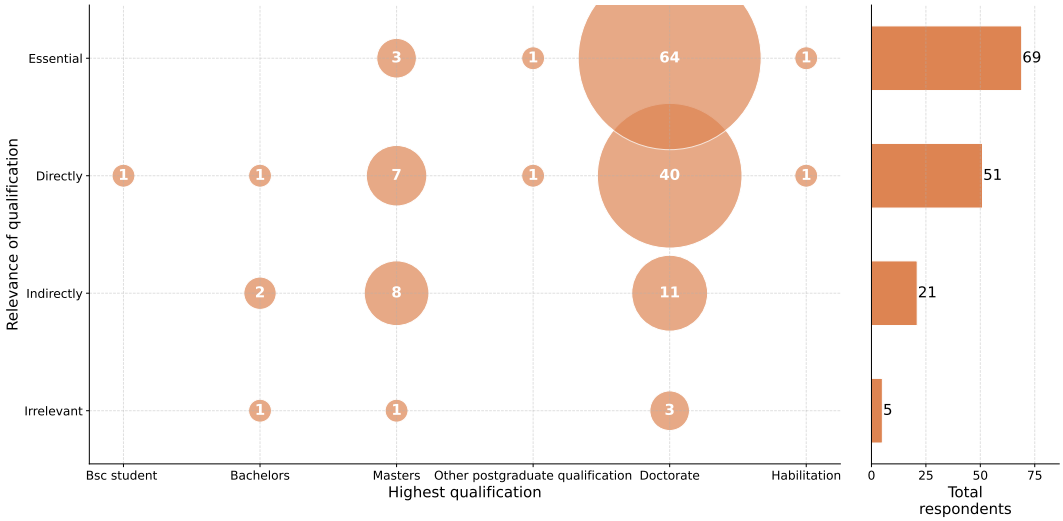

**Figure 3** Respondent's highest academic qualification (Q33) vs Relevance of that qualification (Q34).

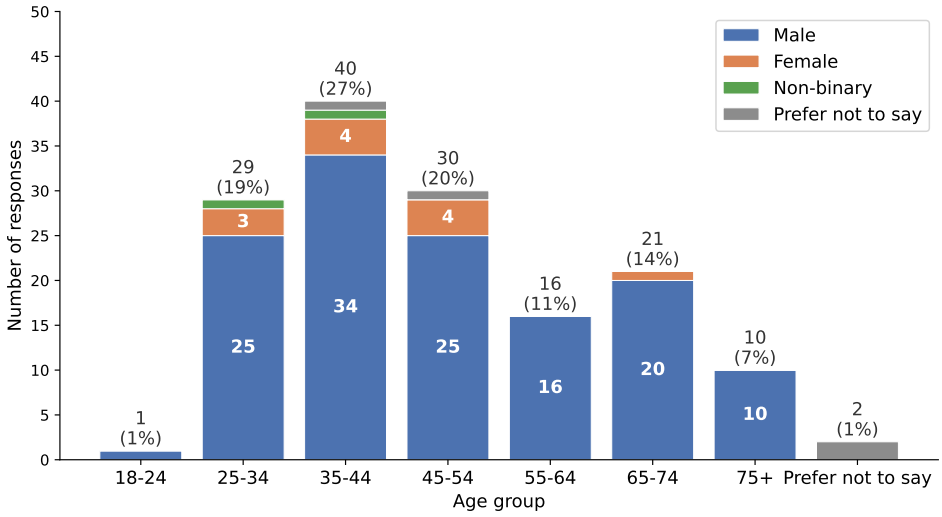

**Figure 4** Age (Q31) and gender (Q32) of respondents.

**Table 3** Choice of codebase.

| **Number of codebases respondent works on or with (Q2)** | **Count** | **%** |
|---|---|---|
| One codebase | 29 | 19 |
| More than one codebase | 118 | 79 |
| Other | 3 | 2 |
| **Reason(s) for choosing codebase for survey (Q3)** | **Count** | **%** |
| codebase I most frequently work on | 73 | 49 |
| most important codebase for me | 63 | 42 |
| most significant codebase to science and engineering, of those I work on | 52 | 35 |
| codebase I contribute to most, relative to all contributors | 43 | 29 |
| most complex codebase (by some definition of complex). | 43 | 29 |
| only codebase I work on | 24 | 16 |
| most impactful codebase to society... of those I work on[a] | 18 | 12 |
| newest codebase | 15 | 10 |
| oldest codebase | 12 | 8 |
| most problematic codebase | 11 | 7 |
| other | 2 | 1 |
| **Type of codebase (Q4)** | **Count** | **%** |
| Tool, e.g., linter, build tool, package manager | 5 | 3 |
| Library, e.g., stdlib | 24 | 16 |
| Application | 113 | 75 |
| Other | 8 | 5 |

[a]most impactful codebase to society, the economy or the environment, of those I work on

UK academia overall (46%) [6]. Since RSE communities are closely associated with scientific computing, HPC, and computational research infrastructures, these figures may provide a more appropriate comparison baseline for Fortran communities than general technology-sector demographics. Even so, the proportion of respondents identifying as female (8%) or non-binary (<1%) in our survey is markedly lower than even these broader baseline statistics.

More striking perhaps is the age spread of respondents, with 21% over the age of 65, and 32% age 55 or above. This large representation in the older categories is perhaps unsurprising given the age of Fortran itself, but in combination with the other technical challenges facing the community (discussed below), this may represent a (potentially) unique risk for Fortran-based science. We revisit this issue later in this section.

As discussed in Section 3, survey respondents were asked to choose one codebase and provide responses for that codebase only. Table 3 indicates that the majority of respondents (79%) work on more than one Fortran codebase. The table also shows that most respondents are choosing an application (Q4) which is the codebase they most frequently work on, or is most important *for them* (Q3). The (self-)selection of a codebase clearly has an effect on the characteristics of the sample and on inferences that may be made from the sample. We discuss these issues in more detail in Section 5.2, when we consider limitations to generalisability of the findings.

The survey asked respondents to characterise the size of their chosen codebase both numerically and ordinally. The ordinal response is clearly a subjective estimate. The numerical response may also be subjective but is likely to be more objective, given the respondents can (relatively easily) generate a lines-of-code (LOC) count for their own codebase. Responses to these questions are summarised in Figure 5. 50% of the codebases are characterised as

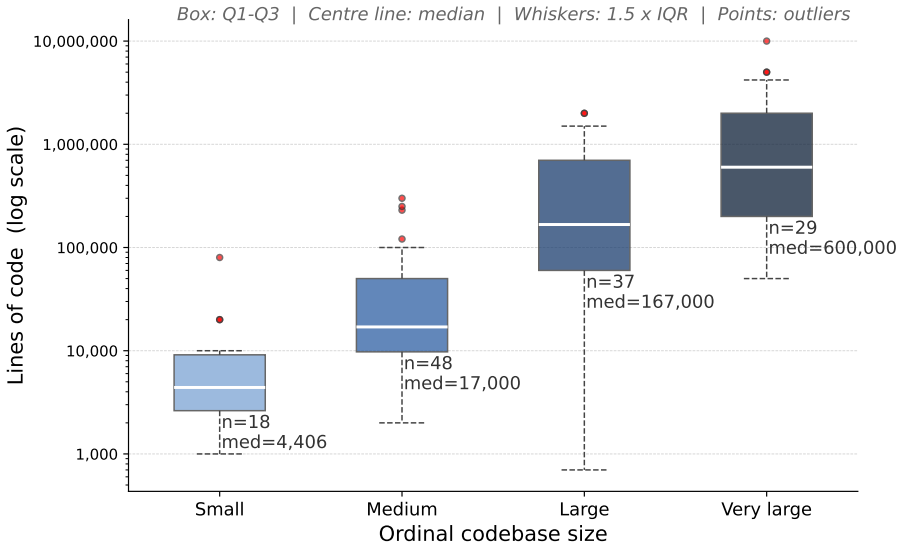

**Figure 5** Ordinal size of the codebase (x-axis; Q8) vs numerical size (y-axis; Q7).

**Table 4** Perceptions of legacy.

| | Perceptions of others' views (Q21) | | | | |
|---|---|---|---|---|---|
| **Personal view (Q20)** | **No** | **No – modernised** | **Yes** | **Other** | **Total[a]** |
| No | 74 (49%) | 0 (0%) | 4 (3%) | 6 (4%) | 84 (56%) |
| No - modernised | 21 (14%) | 1 (1%) | 7 (5%) | 1 (1%) | 30 (20%) |
| Yes | 2 (1%) | 0 (0%) | 21 (14%) | 0 (0%) | 23 (15%) |
| Other | 5 (3%) | 0 (0%) | 2 (1%) | 6 (4%) | 13 (9%) |
| Total[a] | 102 (68%) | 1 (1%) | 34 (23%) | 13 (9%) | 150 |

[a]rounding leads to slight difference with the totals

large or very-large, however Figure 5 shows that "large" spans an enormous range, from 700 to 2M lines of code. This range may be due to errors in the respondents' answers, e.g., typos, or may reflect a true difference in perception. Nevertheless, there are a large number of substantial codebases, with 21 responses citing at least 1M lines of code.

Survey respondents were also asked whether they considered their chosen codebase to be a legacy codebase (note that in Table 3 only 8% of respondents chose their oldest codebase) and whether they thought other people they worked with thought the codebase was a legacy codebase. Table 4 cross-tabulates the results: the majority of respondents (76%) do not consider their own codebases to be legacy systems. Interestingly, 20% of respondents have modernised a once-legacy codebase.

Figure 6 cross-tabulates the size of the development team with the age of the developers. Figure 7 cross-tabulates size of codebase with the size of the development team. In relation to Figure 6, a staggering 26% of respondents are the sole-maintainers of their codebases, and a further 38% have development teams of between only 2 and 5 people. Figure 7 shows that, in general, the smaller codebases have smaller teams. What these results don't show, and which we intend to investigate further, is the importance of the respective codebase to science and engineering. Other questions arise too, for example whether sole-maintainers more frequently occur in university or open-source environments.

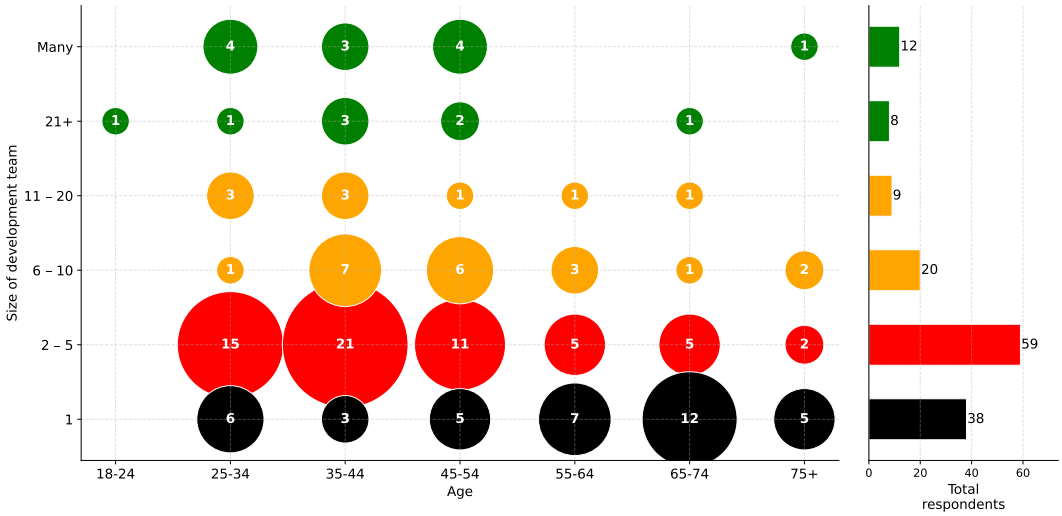

**Figure 6** Age (Q31) vs approximate number of people currently working on the codebase (Q6).

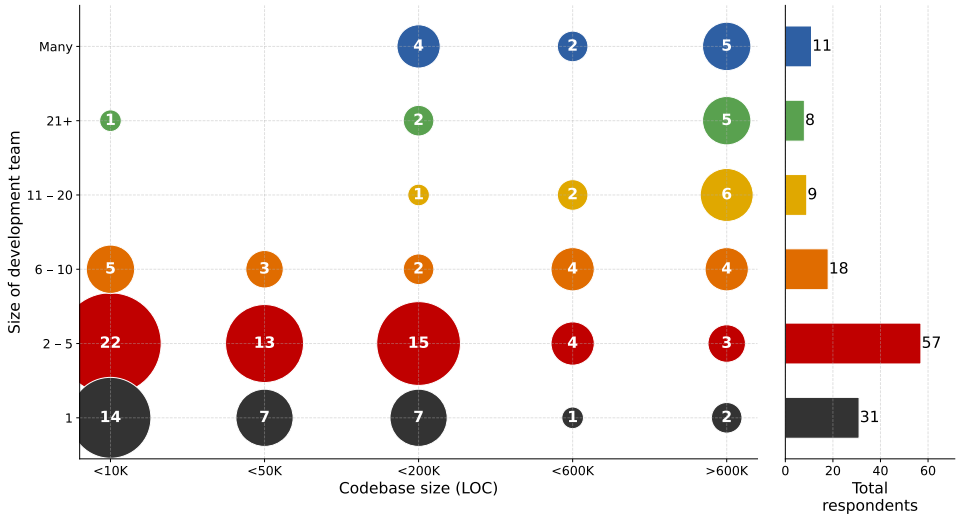

**Figure 7** Codebase size vs team size.

**Table 5** Most significant challenge personally confronted (Q23).

| **Category** and description | **Count** |
|---|---|
| **Code complexity**: poor structure, size, modularity, brittle design, comprehending/ navigating a large codebase | 29 |
| **Human resource**: shortage of developers, recruitment, knowledge concentrated in too few people, difficulty training successors, departure of original authors, personal skills | 22 |
| **Legacy code & technical debt**: inherited old code: Fortran 77 idioms, GOTO statements, COMMON blocks, implicit typing, 6-character names, decades of unrefactored code | 18 |
| **Compiler & language support**: Compiler bugs, slow/inconsistent adoption of standards across compilers, missing language features (generics, polymorphism, functional constructs) | 18 |
| **Documentation**: including where science/design rationale is assumed | 17 |
| **Testing & debugging**: no/inadequate tests, difficulty debugging (including numerical errors and non-obvious wrong results), reproducibility problems, insufficient debugging tooling | 16 |
| **GPU & HPC**: multiple GPU vendors/standards, mixed parallelism (MPI, OpenMP, co-arrays, OpenACC), reliance on HPC infrastructure | 14 |
| **Domain knowledge**: difficulty of the underlying science or mathematics | 13 |
| **Portability**: supporting multiple operating systems/hardware/compilers | 11 |
| **Time & funding**: Insufficient time for maintenance, modernisation, or documentation work; funding constraints | 9 |
| **Fortran perception**: perception that Fortran is "ancient"/legacy: reluctance from students, colleagues, or management to engage with Fortran | 9 |
| **Dependency management & build systems**: external library dependencies, build system friction (CMake, FPM), package management | 7 |
| **Organisational factors**: project politics, organisational decisions (deprecating Fortran), conservative gatekeeping by long-standing contributors, poor adoption by institutions, misaligned career incentives for software maintenance work | 6 |
| **Software engineering practices & tooling**: (lack of) version control, build systems, software design principles | 6 |
| **Interoperability with other codebases & languages**: e.g., Python, C/C++ | 4 |

Finally, and briefly, the survey also asked respondents for the most significant challenge, technical or non-technical, they personally confront with the codebase. Table 5 reports categorised results, which have been analysed according to the procedure outlined in Section 3.4. The results show a combination of technical and non-technical challenges. Note that in Table 3 only 7% of respondents chose their most problematic codebase, suggesting a difference between "problematic" and "significant challenge".

The response categories are a mix of technical (e.g. Code complexity, testing) and "social" (e.g. Human resource, perception of Fortran). This suggests the rich potential for future socio-technical research into the Fortran ecosystem which we discuss in Section 5.

# 5 Discussion

## 5.1 Implications of the results

There are several striking features in the survey which we believe mark the Fortran ecosystem as worthy of continued study. Some of the features are *technical*, such as compiler support, testing or tooling. But it is the intersection of these technical features with the *demographics*

and *culture* of the Fortran community, as well as the necessary *domain knowledge*, which – we argue – makes the Fortran ecosystem a unique and, as-yet, largely unexplored area, and one which therefore presents rich opportunities for further research. Consider the following, as a broad summary of the "shape" of the challenge: 1) a third of respondents are over the age of 55; 2) four-fifths of respondents hold a PhD or higher qualification; 3) more than half of those holding a PhD or higher qualification consider their qualification "essential" for the work they do; 4) it is only fairly recently that the professional role of the Research Software Engineer has emerged to support the computational scientist or academic; 5) the best practices of software engineering found in other application domain areas (e.g., web applications, financial systems) are often absent from ongoing Fortran projects [4]; 6) the longevity of the Fortran language, as well as the language standard's commitment to backward compatibility, means there are "layers" within codebases that are written to different language standards, with different coding conventions, and with undocumented design and coding rationales; 7) many scientific and engineering disciplines, and *other programming languages*, remain dependent on Fortran; 8) codebases need modernising; and 9) many of the codebases are maintained by very small teams.

One respondent crystallised this complex situation: *"A better understanding by researchers on the importance of version controlling, e.g. git. At the moment, the code suite and/or any changes are passed around in a tarball via email, making it very hard to track what changes have been made and when, and also determine if any bugs have been introduced. The other academics are not software-focussed, and have the attitude that this is the way it has always been done, and it works, so we won't fix it, but it is not sustainable, and on-boarding is nearly impossible."* Other respondents spoke of challenges relating to:

- **Education:** *"A return to teaching Fortran to undergraduates and postgraduates."*
- **Perception:** *"An irrational fear of Fortran by potential contributors or users"*
- **Incentives:** *"Finding people with appropriate expertise willing to work for the pittance that UK academia deems it appropriate to pay RSEs."*
- **Succession:** *"I will retire in say 7 years and I yet have no obvious colleague who can manage to take over the responsibility."*

One response to the broad summary we provide, and to the example quotes, is that they provide reasons for research to *ignore* the Fortran ecosystem and for science and engineering to *divest* from Fortran. As with all codebases and all programming languages, divesting from that language (e.g., porting the codebase) is often an enormously time-consuming, effortful and expensive undertaking, and one which comes with much risk. Furthermore, such divestment doesn't prevent the risk that similar challenges will recur in the future.

An alternative response, and one which we advocate, is to understand the current Fortran ecosystem as presenting a vision of the future of other, currently "more modern", (scientific software) ecosystems. In that sense, Fortran is at the forefront of dealing with multi-decade challenges, such as the challenges of the declining availability of expertise, the accumulation of "layers" of diversely-written code, the mismatch over time in software engineering practices and tools, and the problems of dependencies and interoperability across codebases, languages, language features and compilers. Thus, the current Fortran ecosystem presents unique opportunities to contribute timely and significant knowledge in areas such as requirements, domain expertise, software design (e.g., [28]), technical debt (e.g., [24]), refactoring (e.g., [35]), program comprehension, code analysis, automated code translation, software testing and software assurance, secure software, and continuous integration and deployment.

The Fortran ecosystem also acts as an exemplar to distinguish the nature and challenges of scientific software from those of non-scientific software.

## 5.2 Limitations in sampling and generalisation

Sampling and generalising to populations is a well-recognised and recurring problem for software engineering surveys [2]. It is also an issue explicitly identified in Stage 3 *Identify Population* and Stage 4 *Sampling Plan* of Molléri et al.'s [20] checklist for survey research in software engineering. For these reasons, we explicitly consider the limitations of sampling and generalisation. Discussing sampling also has the benefit of helping future research, e.g. when researchers are deciding on the selection of indicative Fortran projects or edge-case projects for case study research.

The survey adopted a convenience sampling approach [2], though this was indirectly complemented by referral-chain sampling [2] as some survey respondents, and some pilot-study respondents, promoted the survey to their peers. The most similar survey, for comparing sampling and samples, is the survey about Fortran standardisation, conducted in 2018 by the British Computer Society's Fortran SIG [31], and briefly discussed in Section 2. That survey reported results from 427 respondents, probably collected through convenience sampling. The BCS ran their survey for approximately six months (30 June 2018 to 3 January 2019) whilst the survey reported here was open for approximately 6 weeks (January 2026 - February 2026). This may partly explain the difference in number of respondents (427 vs. 150). As a further comparison, the `fortran-lang.org` website reports approximately 1800 people are registered on the site.

The BCS survey's demographic data suggests their respondents were located across 41 territories, e.g., country or some distinct region identified by the respondent. The highest number of responses to the BCS survey came from the USA (120/427; 31%) and the United Kingdom (117; 30%) and then from Europe (the figures reported are imprecise but approx. 71; 16%). There is, unfortunately, no information about the sampling frame or sampling approach taken by the BCS. Also, at the time that the BCS conducted their survey, the `fortan-lang.org` website – the largest source of prospective respondents for the current survey (see Table 2) – did not exist. The similar proportion of respondents for the USA and the UK – across the two surveys with different time-frames, different numbers of responses, a different spread of responses across countries, and different sources of prospective respondents – suggests that the majority of the Fortran ecosystem activity is indeed located in the USA and the UK, with a sizeable cohort present in Europe too.

The survey reported here comprises two units of analysis: the respondent and the codebase. This is highlighted in Figure 7. To better control for the codebase, and the relationship between respondent and codebase, the survey asked respondents to focus on a single codebase. For each unit of analysis there are likely a small number of instances of double-counting, e.g., two respondents describing the same codebase, or two respondents providing information about the same organisation. Being anonymous responses, these instances are hard to detect. Given the range in the number of people working on codebases, double-counting is more likely to occur for larger codebases; again, see Figure 7.

The number of Fortran codebases explicitly identified, through the respondent providing a URL or similar, is 69. Assuming, *very conservatively*, that all respondents (79%) who work on "more than one" codebase are working on only two codebases, an extremely conservative lower bound for the total number of Fortran codebases in the international Fortran ecosystem is:

$$(0.19 \times 150 \times 1 \text{ codebase}) + (0.79 \times 150 \times 2 \text{ codebases}) = 265 \text{ codebases}.$$

As two examples to illustrate how this estimate is extremely conservative, one respondent indicated they worked on 6 codebases and another respondent indicated they worked on 30 codebases. These responses lead us to interpret 265 as a very conservative lower bound. But importantly, we estimate a lower bound that can contribute to future research.

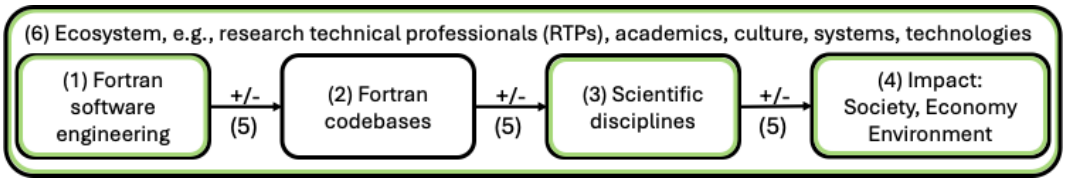

**Figure 8** A framework for studying "routes to impact" of Fortran.

## 5.3 Other limitations

We used Molléri et al.'s [20] 10-stage checklist for software engineering surveys as a guide to self-evaluate the quality of the survey. The major limitations identified have already been discussed in Section 5.2. In terms of survey design and validation (cf. Molléri et al.'s Stage 5 *Instrument Design* and Stage 6 *Instrument Validation*), the first two authors initially designed the survey, which was then reviewed by the other authors, and then validated through a two-stage pilot study in which the pilot respondents were asked not just to review the survey but complete it too. The survey was also reviewed, as part of the ethics approval process. Participant recruitment (Stage 7) is discussed in Section 3. For (non-)response management (Stage 8) we sent occasional reminders about the survey to the `fortran-lang.org` site, including keeping the survey open for about two weeks longer than originally planned, and also responded to all queries from prospective respondents, encouraging them to complete the survey. Appropriate data has been validated (Stage 9) as discussed in Section 3 and is being made available as an open source data package.

## 5.4 Further research

Our longer-term aim is to study the "chain of impact" of Fortran, as briefly visualised in Figure 8. The survey provides a starting point to pursue this aim as well as several specific directions for further research: 1) there are more data in the survey to analyse and report; 2) there are sub-samples of the data to investigate, e.g., how responses vary with age, role, territory; and 3), there is the need to clarify and elaborate on information collected from respondents, e.g., the number of codebases respondents are working with, and the challenges that have been identified in Table 5. There are also directions for new research, the most obvious being to investigate the 69 codebases identified by the respondents. We also strongly encourage other researchers to consider how the Fortran ecosystem – the language, standards, tooling, codebases and community – can provide a unique source for novel and significant contributions to their research into (scientific) software engineering.

## A List of survey questions reported in this paper

Table 6 concisely lists the survey questions reported in the main paper, to support cross-referencing with the questions in the full survey, provided in the Zenodo repository.

## B Data Availability Statement

The survey data and associated materials used in this study are publicly available via Zenodo at https://doi.org/10.5281/zenodo.20185149. The repository provides persistent archival access to the dataset and associated metadata in accordance with the open science and reproducibility expectations of ESEM/ESEIW submissions. The repository includes the raw survey data for the questions explored in this paper, including categorised/cleaned data,

**Table 6** Summary of the survey questions.

| Q# | Question |
|---|---|
| Q2 | How many Fortran codebases do you work on, or with, e.g., you change or test the code? |
| Q3 | Tell us your reasons for deciding on that codebase |
| Q4 | What is the type of codebase? |
| Q6 | Approximately, how many people currently work on the codebase, e.g., change or test the code, in contrast to people who use the codebase? |
| Q7 | What is the approximate size of the current codebase? |
| Q8 | In subjective terms, how would you characterise the size of the codebase? |
| Q20 | Do you personally consider the codebase to be a legacy codebase? |
| Q21 | Do others you work with consider the codebase to be a legacy codebase? |
| Q23 | What is the most significant challenge - technical or non-technical - you personally confront with the codebase? |
| Q25 | In what country is the organisation you work for located? |
| Q26 | What type of organisation "owns" the codebase? |
| Q27 | What is your main role in the organisation that "owns" the codebase? |
| Q31 | What is your age? |
| Q32 | What is your gender? |
| Q33 | What is your highest academic qualification? |
| Q34 | How relevant is your highest qualification to the work you do on, or with, this codebase? |

as well as PDFs of the survey questions, consent forms, instructions and advertisement. Data analysis scripts which can be used to produce the figures in this paper are also provided, as well as hi-res copies of all figures.

# TypePatrol: Adversarial Testing for Uncovering Security-Relevant Type Inconsistencies in JavaScript Libraries

**Sai Mallikarjun Galipelli**

## Abstract

**Background.** Gradual typing, as adopted by languages like TypeScript, aims to combine the flexibility of dynamic typing with the safety guarantees of static type systems. However, the deployed gradual typing systems are inherently unsound, meaning in practice, type inconsistencies are common and can hide or cause subtle bugs. This problem is particularly concerning for widely used libraries, where type annotations serve as both documentation and contracts for users. A value with a wrong type in such libraries may trigger cascading failures in downstream code, including unintended control-flow transfers. Existing work has explored testing-based approaches to detect type mismatches. However, these methods fall short in adversarial settings where malicious inputs are intentionally crafted to exploit type inconsistencies.

**Aim.** This work introduces TypePatrol, the first adversarial testing framework to uncover security-relevant type mismatches.

**Method.** TypePatrol systematically mutates values in unit tests and observes the runtime types. Our approach focuses on three classes of security-relevant effects: bypassing input sanitization, invoking incorrect methods, and functions returning wrong types.

**Results.** We apply TypePatrol to 30 popular JavaScript and TypeScript libraries, and discover hundreds of relevant type inconsistencies. In seven cases, we propose fixes through ten pull requests, the majority of which were accepted, underscoring the real-world relevance of our approach.

**Conclusions.** Crucially, TypePatrol shows that adversarial testing exposes bugs that slip through conventional testing in even the most popular well-maintained projects. We also discuss cases in which type inconsistencies lead to serious security issues, confirming that these bugs are a serious threat to modern software.

## 1 Introduction

Gradual typing [36] has been widely adopted by dynamically typed languages such as JavaScript [37] and Python [24] because it supports rapid prototyping while, at the same time, providing some of the safety guarantees of static typing. TypeScript - a superset of JavaScript, has evolved as a major language that supports gradual typing and integrates smoothly with vanilla JavaScript. Popular projects like the Angular client-side framework or the Jest testing framework use TypeScript both to document their features and to catch bugs early in the development process [13]. The former benefit has led to powerful IDE suggestion capabilities fueled by community-provided types for almost 10K open-source libraries [11].

Early gradual type systems proposed for scripting languages, such as those by Rastogi et al. [32] and Richards et al. [33], are sound in the sense that they ensure that executions do not violate annotated types. Existing gradual type implementations, such as Microsoft's TypeScript compiler, differ significantly from these early proposals by adopting a pragmatic type-checking discipline that performs lightweight static checking with no residual runtime checks. As shown by Feldthaus et al. [12], this, in turn, results in inconsistencies between type hints and the types observed at runtime. More recently, Troppmann et al. [37] show that such mismatches can be exploited by attackers to cause unwanted security effects, as illustrated by security advisories in popular libraries like CVE-2021-23445, CVE-2021-23434. However, their analysis is fully static, and it does not support dynamic analysis of libraries, which is often needed to handle hard-to-analyze features of scripting languages [1].

Let us consider an example that uses the popular JavaScript library *cheerio* (30K GitHub stars and 14M+ weekly downloads) to show how type inconsistencies at a library's API level can lead to unwanted security incidents.

```
import { isHtml } from 'cheerio/utils';

const dangerousInput = ['<img src=x onerror=alert(1)>'];
if (!isHtml(dangerousInput))
    document.write(dangerousInput);
```

Developers intend to restrict user input to HTML content only, which is sometimes considered safe to write directly into the DOM. When provided with a string value, the `isHtml` method behaves as expected. However, when given an input of an incorrect type (e.g., an array), the method returns an erroneous result, potentially leading to a cross-site scripting (XSS) vulnerability. The underlying assumption made by the library developers is that the input will always be a string, as indicated by the inline type hint present in the original TypeScript code `export function isHtml(str: string): boolean`

However, there is no runtime check to enforce this expectation, neither manually added by the developers nor automatically produced by the compiler. While Troppmann et al. [37] speculate about the existence of such issues, their static analysis does not consider library-level type inconsistencies, nor can it reason about the multitude of ways in which functions can be exported in JavaScript libraries. In this work, we argue that testing can be applied to detect the potential for library misuse. Our approach, which we discuss below, discovered this bug automatically, and we proceeded to create the following patch, which was subsequently merged into the codebase by the maintainer[1]:

```
export function isHtml(str: string): boolean {
  if (typeof str !== 'string') { // added by our patch
    return false;
  }
  const tagStart = str.indexOf('<');
  // ... unchanged }
```

[1] https://github.com/cheeriojs/cheerio/pull/4523

In contrast, existing work on finding gradual type mismatches relies on the completeness of test suites [14] or on type information collected at runtime [12] along typical execution paths. Thus, these approaches are unable to detect subtle bugs like the one above, where *type violations only manifest when an unexpected value is passed by an attacker under adversarial conditions*.

In this paper, we present TypePatrol, an approach to automatically identify gradual type violations. The key insight of our approach is that instead of relying on test suites alone, which often exercise well-behaved paths and values, we mutate values in existing tests to synthesize new tests, which are then used to probe for type violations that may not be triggered during standard executions. In other words, we propose a domain-specific test amplification strategy [8, 9, 4] that aims to increase the likelihood of type mismatches. We argue that this approach mimics how attackers might attempt to compromise library code by passing values of the wrong type. Beyond unwanted effects on input validation as in the above bug, we also discuss how attackers might direct control flow to unintended methods or force the library to produce values of unintended types, potentially enabling downstream attacks. This problem is exacerbated by the extensive transitive use of libraries within the JavaScript ecosystem [41].

We apply TypePatrol to 30 popular JavaScript and TypeScript libraries and show that developers do not strictly enforce annotated types, allowing for potential misuse via type inconsistencies. In our evaluation, TypePatrol detects type mismatches at hundreds of unique code locations in the analyzed libraries. Based on these findings, we propose ten fixes to address adversarial manipulation risks, nine of which were accepted and integrated by the respective maintainers. These results show that our approach identifies relevant, realistic bugs in well-tested, production-grade projects. Moreover, on the duration of this project, one of the authors discovered CVE-2026-25049, a critical vulnerability in n8n, a popular open-source project with 188K GitHub stars. This very serious security vulnerability shows that type mismatches are not merely a theoretical concept, but a very relevant pressing problem in real-world software.

In summary, the contributions of this paper are:

- We define the problem of testing gradually typed code under adversarial conditions and discuss several unwanted security effects that attackers can trigger due to the unsoundness of the type checker.
- TypePatrol: a novel testing technique for finding security-relevant type mismatches in popular JavaScript and TypeScript libraries by mutating the types of values in existing tests.
- An empirical evaluation involving highly popular real-world JavaScript and TypeScript libraries, in which TypePatrol finds hundreds of potentially security-relevant inconsistencies, some of which we help remediate in the associated codebases.

## 2 Security Considerations

**Threat Model.** We consider an adversary who can indirectly invoke JavaScript library code (e.g., by carefully crafting inputs to a web application) and can also manipulate the values and types passed into these libraries. We also assume that the attacker has access to the client code but cannot directly modify it. Additionally, all interactions between the library and the attacker happen through publicly exposed APIs. The adversary's goal is to pass values of the wrong types to alter the intended behavior of the library code. Below, we discuss three types of unwanted security effects that an attacker can trigger via type inconsistencies.

### Bypass Input Sanitization

Due to automatic type coercions, attackers can manipulate strict equality checks via values with wrong types. Let us consider the following example:

```
if (username === "admin") {
    alert("You cannot change the admin password!")
} else {
    passwords[username] = newVal;
}
```

In this example, developers prevent the modification of the admin password via the strict equality check in the first line. However, if attackers provide an array value of the type `["admin"]` the equality check will return false due to the type mismatch, but the property access in the else branch will modify the admin password via a type coercion to string. In this way, the attacker can bypass the explicit validation added by developers. Builtin methods like `indexOf` that rely on equality checks in their native implementation can also be abused in this way.

### Manipulate Control Flow

Similarly, when invoking methods on values whose type was not explicitly asserted, an attacker can divert the control flow to a method that was not intended by developers. Let us take the following example: `let atLocation = input.indexOf("@");` In this example, the developers intended to retrieve the position of the at symbol, but when presented with an array input, the interpreter will invoke the `Array.prototype.indexOf` method instead of `String.prototype.indexOf`. We call such methods with identical names on different JavaScript built-ins *confusables*.

### Alter the Library's Output

Finally, each method with an annotated return value, whose type mismatches at runtime, is firstly a clear violation of the contract between the library creator and consumer. Moreover, it can be used as a gadget to chain downstream type mismatch compromises. For example, consider the slightly modified example from the introduction:

```
import { isHtml } from 'cheerio/utils';
import { capitalize } from 'custom-pkg';
if (typeof input !== string)
    throw "Wrong input type";
input = capitalize(input);
if (!isHtml(input))
    document.write(input);
```

Let us assume the `capitalize` method is a third-party library that claims to receive a string and output an altered version of it. Even though the developer checked that the input is a string to match this expectation, if the `capitalize` method misbehaves in some cases and produces an array instead of a string, the `isHtml` method can be compromised similarly as before, using the `capitalize` mismatch as a building block for the final exploit.

## 3 Approach

We follow a five-step approach in TypePatrol to check for type mismatches between developer annotations and the actual types assigned at runtime. Figure 1 shows an overview of our approach where each circled number (1) represent the steps.

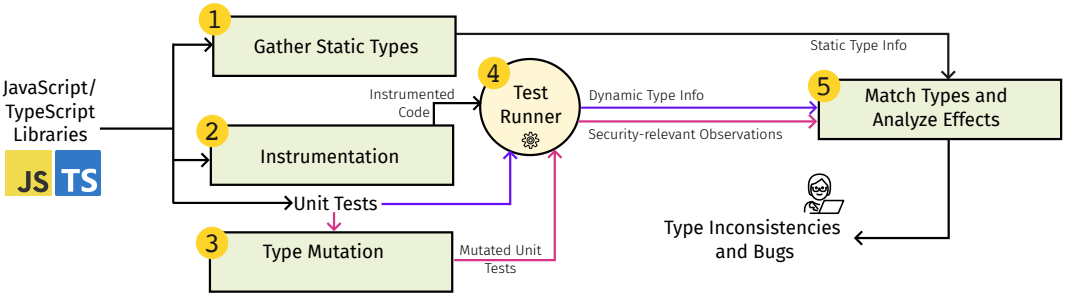

**Figure 1** The first step of TypePatrol is to gather the static types annotated by developers in the respective JavaScript or TypeScript libraries. Next, we instrument the code followed by mutation of the unit tests. In the fourth step, the test runner executes the original unit tests and the mutated unit tests using the instrumented files. Finally, we match the types obtained from the runtime to the statically obtained types and also analyze the effects of security-relevant observations.

## 3.1 Gather Static Types

Before conducting adversarial testing of libraries, we want to verify if libraries inherently contain some type inconsistencies i.e., discrepancies between developer-intended types and the actual types observed at runtime. To this end, the first step of TypePatrol involves collecting statically annotated types. Specifically, this phase gathers developer annotated types either directly from the source files or from the corresponding type definition files associated with the library.

For TypeScript libraries, developers typically write the type annotations directly in the source code. In contrast, JavaScript libraries do not contain any type annotations in the source code. Instead, the annotations are mentioned in *.d.ts* files, also known as type declaration file. We define *static type information* in TypePatrol as follows:

▶ **Definition 1** (Static Type Information). *For a given program $P$, the static type information of an identifier $i$, is a triple $(i_{\tau_s}, P, l)$ where $\tau_s$ is a type annotation by developer and $l$ is the location in $P$ where the type information is observed.*

## 3.2 Instrumentation

After gathering static type information, the next step in TypePatrol is to observe type information at runtime. This is achieved by instrumenting specific code locations within the target libraries. A primary objective of TypePatrol is to identify potential security-relevant violations that are triggered when values of unintended types are mistakenly propagated. In TypePatrol, we focus on three classes of security-relevant violations: 1) bypassing input sanitization, 2) invoking incorrect methods, and 3) functions returning wrong types. To observe the effects at runtime, we instrument two categories of program locations:

1. *Annotated points*: The program points where developers explicitly provide type annotations. The motivation to collect such locations is to capture the expected types specified by developers. We achieve this by instrumenting the following locations in a program:
   - Function parameters and the lexical redefinitions of function parameters.
   - Property assignments in the constructors of class definitions.
2. *Security-relevant points*: The program locations that are likely to have security implications. Such instrumentation points fall into three main categories. First, locations where developers perform additional checks, such as explicit validation of values. Second, locations where developers invoke commonly used methods. Third, where developers explicitly annotate the type returned by a function.

As discussed in Section 2, we consider these three categories of program points to be potentially security-relevant because, if the checks can be bypassed or manipulated by an adversary, or if an adversary can arbitrarily invoke a method, the program may return unintended values, may suffer from ineffective input validation, inconsistent states, type confusion, or other exploitable runtime errors. To this end, we keep track of the following locations of a program:

- Input sanitization by developers to ensure the expected value. To keep the overall runtime of the instrumented code manageable, we only focus on cases where the developers check a value with another string literal. Since string type in JavaScript shares many common methods with other types, prior work [37] has shown that developers are likely to encounter type confusions for such validations (Section 2).
- Method calls involving common function name. In JavaScript, many types share method names. We consider such cases as security-relevant because an attacker can exploit developers type confusion to induce control flow to a method that is valid for a type but unintended by the developer (Section 2). In particular, we instrument the calls involving the following confusable method names that are shared by multiple types: `indexOf`, `includes`, `lastIndexOf`, `toString`, `concat`, `slice`, `forEach`, `toLocaleString`, `valueOf`.
- Return statements in a function. Although return statements are typically explicitly type annotated by developers, we consider them as security-relevant since an adversary can potentially alter behavior of a library through these points. Section 2 contains one such example to demonstrate this.

Consider the following JavaScript code as an example. The code denotes two categories of program instrumentation points. The • in the code shows the instrumentation locations for annotation points while the ⁎ shows the security-relevant points.

The code denotes the instrumentation points to keep track of the function parameters, lexical redefinitions of a parameter, invocation of a common method, input value sanitization and the return statement. As a concrete example, the code contains a `calc` function that contains one parameter `inp` as input marked as • showing a location that is typically explicitly annotated by developers. Line 8 of the code invokes a method `includes` which is a security-relevant instrumentation point marked as ⁎. Similarly, line 10 validates the input to a string literal which is marked with ⁎ to signify its security relevance.

```
1  class Rectangle {
2      constructor(height, width) {  •
3          this.height = height;  •
4          this.width = width; •
5      }
6      calc(inp) { •
7          let area = 0;
8          let check_intent = inp.includes("area"); *
9          if (check_intent) {
10             if (inp === "double_area") *
11                 inp = 2; •
12             else
13                 inp = 1; •
14             area = (this.height * this.width) * inp;
15         }
16         return area; *
17     }
18 }
```

**Algorithm 1** Mutate Unit Test.

**Input:** Unit test $U$ with parameters $X = [x_1, \ldots, x_n]$
**Output:** Mutated parameters $X' = [x'_1, \ldots, x'_n]$

1: $X' \leftarrow [\,]$
2: **for** each $x \in X$ **do**
3: $\quad \tau \leftarrow \text{TYPEOF}(x)$
4: $\quad n \leftarrow \text{RAND}(\mathbb{N})$
5: $\quad s \leftarrow \text{RAND}(\mathbb{S})$
6: $\quad b \leftarrow \text{RAND}(\mathbb{B})$
7: $\quad$ **if** $\tau =$ *string* **then**
8: $\quad\quad x' \leftarrow \text{RAND}(\{n, b, [x]\})$
9: $\quad$ **else if** $\tau =$ *number* **then**
10: $\quad\quad x' \leftarrow \text{RAND}(\{s, b\})$
11: $\quad$ **else if** $\tau =$ *boolean* **then**
12: $\quad\quad x' \leftarrow \text{RAND}(\{s, n\})$
13: $\quad$ **else**
14: $\quad\quad x' \leftarrow \text{RAND}(\{n, s\})$
15: $\quad$ **end if**
16: $\quad X'.\text{APPEND}(x')$
17: **end for**
18: **return** $X'$

## 3.3 Test Mutation

Developers routinely use tests to verify correctness and simulate the typical and expected behavior of code. One of the goals of TypePatrol is to induce atypical behavior and simulate how an adversary might interact with the code. To achieve this, we leverage existing unit tests and execute the code by providing values of unexpected types. By introducing such adversarial inputs, TypePatrol aims to elicit unintended behavior and uncover security-relevant violations, simulating how attackers might attempt to manipulate the target code.

Our approach to introducing unexpected types relies on lightweight mutation of function arguments of unit tests. The mutation strategy primarily targets identifiers and literals, as these are most commonly used as function inputs. Literals such as Array literals and Object literals in JavaScript can be structurally complex and composed of multiple other types, we generally exclude them from mutation. However, in practice, we observe that object literals are frequently used as inputs in unit tests. As an exception, we selectively mutate objects and the object literal properties to primitive types.

Algorithm 1 outlines our approach to mutate an unit test. The input to the algorithm is a list of parameters $[x_1, x_2, \ldots x_n]$ to be mutated. For each parameter, a new value is selected from pre-populated pools of *number, string* and *boolean*. The type of the selected value is decided based on the following strategy:

- If the parameter $x$ is of type *number*, it is mutated to either a *string* or a *boolean* with each type chosen with equal probability. Similarly, if $x$ is of type *boolean*, it is mutated to either a *string* or a *number*. (line 10, 12 of Algorithm 1).
- If the parameter $x$ is of type *string*, it is mutated to one of the following: a *number*, another *boolean*, or an *array* with equal probability (line 8 of Algorithm 1).
- Beyond the types *number*, *boolean* and *string* the algorithm always mutates $x$ to either a *number* or a *string* (line 14 of Algorithm 1).

The special treatment of strings is motivated by the observation that the string and array types in JavaScript share certain behaviors (e.g. index access method, length computation), making arrays a meaningful mutation target for strings.

## 3.4 Test Runner

To capture runtime types, we exercise the instrumented code locations identified in Section 3.2. For this purpose, we leverage developer-provided unit tests. Since unit tests are designed to check the correctness of code, they typically achieve deep coverage of program functionality.

As a result, they are suitable for our purpose of adversarial testing of the libraries. The output of test runner phase is *dynamic type information*.

▶ **Definition 2** (Dynamic Type Information). *For a given program $P$, the dynamic type information of an identifier $i$, is a triple $(i_{\tau_d}, P, l)$ where $\tau_d$ is a literal type that gets assigned at runtime and $l$ is the location in $P$ from where the type information is observed.*

To contrast between the typical and atypical code execution, the test runner phase executes two sets of unit tests. First, the default unit tests provided by the developer and second the unit tests obtained by mutation as described in Section 3.3. After executing these two sets of tests, the next step is to compare the dynamic type information obtained for each case with the static type information which is described further in the next Section 3.5.

## 3.5 Match Types and Analyze Effects

The final step of TypePatrol is two fold. First, to compare the runtime types obtained by running the tests in Section 3.4 to their static counterparts. We check if types annotated by developers in the respective JavaScript or TypeScript libraries match with the runtime types. Second, to observe the effects of mutation on the security-relevant points introduced in Section 3.2.

### Type Matching

While comparing types, if a mismatch is detected, TypePatrol produces a warning, which we refer to as a *type inconsistency* and define below.

▶ **Definition 3** (Type Inconsistency). *For a program $P$, the type of an identifier $i$ is inconsistent if the static type $i_{\tau_s}$ is lexically different from the dynamically obtained type $i_{\tau_d}$ i.e., $i_{\tau_s} \neq i_{\tau_d}$.*

A type inconsistency warning indicates a potential programming error or, in some cases, a security vulnerability. Our type matching step consists of two key phases:

- *Static vs Runtime Comparison:* We compare the developer-annotated static types with the actual types observed at runtime.
- *Mutation Behavior Comparison:* We compare:
  - the behavior observed when executing the developer-provided unit tests, and
  - the behavior observed when executing the corresponding mutated unit tests.

  This comparison aims to find any behavioral differences induced by the mutated tests.

Prior work on dynamically typed languages [29, 31] has shown that many type related warnings are likely false positives. For example, two types can be polymorphic and still be reported as likely incompatible resulting in such false positives. To minimize the impact of such false positives, we constrain the type matching domain for *static vs runtime comparison* to only include primitive types: `number, string, boolean, null, undefined`. As a final filtering step, we report only those type inconsistency warnings where at least one of the types involved in the mismatch belongs to this set of primitive types.

### Analyze Effects

With the threat model presented in Section 2 in mind, we examine the additional behaviors induced by mutated unit tests at the observed security-relevant instrumentation points (Section 3.2). To this end, we focus on three types of new behavior:

1. Executions of input-value sanitization checks during runtime.
2. Runtime errors indicating wrong method invocations. Such errors occur when a value is used to invoke a method without first checking that it has the expected type. In JavaScript, types such as *string* and *array* share common method names. Without proper type checks in place, adversaries can manipulate value types to redirect execution to methods already present in the source code, thereby reusing code for malicious purposes.
3. New type mismatches in function return values. We consider such mismatches security-relevant because an adversary can change the type of an argument passed to a function and potentially cause the function to return sensitive data or otherwise alter the behavior of a library. We argue that functions should validate their parameters at runtime to avoid such scenarios.

## 4 Implementation

We use Babel as the primary library for instrumenting JavaScript files, leveraging its parser, traverse, and generator packages to manipulate JavaScript ASTs and inject logging or mutation code. For TypeScript files, we perform instrumentation by using the TypeScript Compiler API (the `typescript` npm package), which enables parsing, traversing, and transforming TypeScript ASTs for similar purposes. We use Node.js as the JavaScript runtime environment for executing, building, and testing all JavaScript and TypeScript packages. For reporting the line coverage, packages such as Istanbul, nyc & C8 are used. All scripts and instrumented code are run using Node.js (version 22.13) on a machine equipped with an Intel Core i5-13500 processor, 16 GB RAM, running Ubuntu 24.04.3 LTS.

## 5 Experimental Setup

We evaluate the effectiveness of TypePatrol on popular libraries written in JavaScript and TypeScript. To this end, we select npm [27] libraries from a list of most-dependent upon JavaScript [22] and TypeScript [23] packages. Such packages are ranked as the most depended upon, which means they are considered among the most widely used in the npm ecosystem, which in practice translates to thousands of dependent packages and millions of weekly downloads. We observe that the primary source code for the packages is either JavaScript (JS) or TypeScript (TS), with TypeScript being compiled to JavaScript. For each package, we download the source code from its corresponding GitHub repository and conduct our experiments.

To accurately extract developer-provided type annotations, a filtering step is applied to the JavaScript packages. Specifically, if a JavaScript package does not contain a *.d.ts* file as part of its source code, we exclude it from our experiments. A *.d.ts* file, also called type declaration file is typically included as part of the code and contains only type information of different code constructs, thereby aiding static analysis tools. For some packages, where the developers do not choose to include a type declaration file, there are community-led efforts such as *DefinitelyTyped* [7] to provide such a file. We choose to exclude such libraries since they may not faithfully reflect a library developer's original intent.

The first column of Table 1 lists the libraries selected for evaluation along with their weekly download statistics at the time of writing, while the second column reports the number of dependent packages. In total, we evaluate TypePatrol on 30 libraries: fifteen JavaScript (top section of Table 1) and fifteen TypeScript (bottom section of Table 1).

**Table 1** Runtime statistics, type inconsistencies, and adversarial testing results for JavaScript (top 15) and TypeScript (bottom 15) libraries. **Legend:** Dep = Dependent packages, IL = Instrumented locations, TE = Total entries, UL = Unique locations covered, LC = Line coverage (%), MM = Mismatches, UM = Unique locations in mismatches, PM = Type mismatches involving a primitive, PU = Unique locations involving a primitive, AU = Unique locations covered during Adversarial Testing (+new locations), AL = Line coverage during Adversarial Testing (%), ER = Extra return entries, NF = `"Is not a Function"` Error, IS = Input value sanitization, CM = Confusable method usage.

Table 1 also presents the *Runtime Statistics* collected by running TypePatrol on each selected package. As an illustrative example, consider the JavaScript package *postcss* that has over 197K dependent packages and more than 131M weekly downloads. During the instrumentation phase, TypePatrol identified 960 locations in the code that are either annotation or security-relevant points. Upon executing the unit tests of the *postcss* package, we record a total of 2,382,709 runtime entries. This large number of runtime entries arise because the same instrumentation points are repeatedly executed during running the tests. On further analysis we observe that the runtime entries corresponds to 930 unique locations within the source code. Additionally, the line coverage of the instrumented library is 100%. These results show that the considered packages are fairly large, and their unit tests trigger many relevant locations for TypePatrol with high line coverage.

## 6 Evaluation

Our evaluation of TypePatrol aims to answer the following research questions:

1. How many type inconsistencies does TypePatrol detect in well-tested libraries?
2. Is adversarial testing of libraries able to uncover any unintended behavior?
3. What is the effect of the time budget during adversarial testing?
4. What is the real-world impact of TypePatrol?

## 6.1 Detecting Type Inconsistencies in Real-World Libraries

Developers typically annotate types to match runtime expectations. To check whether this holds, we compare statically annotated types with the types observed during unit test execution. The *Type Inconsistencies* part of Table 1 summarizes the results of this experiment, with the JavaScript libraries shown in the top section and the TypeScript libraries shown in the bottom section.

The mismatches (MM) column represents the absolute number of type mismatches found while running the unit tests. The number of mismatches can be high because, during execution, the same location can be executed multiple times, e.g., due to loops. The column unique locations represents how many of the absolute type mismatches correspond to distinct code locations. Consider the *postcss* package where the absolute number of mismatches is 6,518 which corresponds to 93 unique locations. As explained in Section 3.5, one of TypePatrol's goals is to minimize false positives and provide developers with precise warnings about type mismatches. To achieve this, we restrict our analysis to type mismatches where at least one involved type is a primitive, i.e., to avoid reasoning about type equivalence in complex polymorphic scenario. This result is shown by the last two columns of the *Type Inconsistencies* part of Table 1. For example, for the *postcss* library, we find 268 such type mismatches that involve at least one primitive, of which 33 are unique. The overall results show that type inconsistencies are prevalent in the considered libraries, with at least one mismatch location in each case.

As a concrete type mismatch example found by TypePatrol, consider the following code taken from the `MQTT.js` package that is annotated by the developer to accept an array of string elements and return a string. As seen in line 6, it is possible for the function to return a `null` value. Thus, the correct return type annotation should be `string | null`, which is observed while running the corresponding unit tests. Developers accepted this fix.

```
1 export function validateTopics(topics: string[]): string {
2   if (topics.length === 0) return 'empty_topic_list';
3   for (let i = 0; i < topics.length; i++) {
4     if (!validateTopic(topics[i])) return topics[i];
5   }
6   return null
7 }
```

## 6.2 Adversarial Testing Outcomes

Section 3.3 explains our approach to mutating unit tests, which simulates how an adversary might induce atypical behavior in code. In this experiment, we examine whether executing mutated unit tests leads to any new observable behavior. For each library in our experimental setup, we mutate one unit test at a time and then rerun the full test suite. To keep the overall approach tractable while still exploring adversarial behavior, we mutate up to 3% of the tests in each library and repeat the experiment for 10 iterations with different random seeds. Although we establish this 3% upper bound, in practice we were often unable to reach it due to assertion and test failures. To validate this choice, we also explored larger mutation budgets. We run experiments with 10%, 25%, and 50% mutation budgets. While these larger budgets increase the total number of runtime entries, they execute fewer tests and do not reveal any additional unique locations in the categories reported under *Adversarial Testing* in Table 1. We therefore focus our evaluation on the 3% mutation budget, which provides a better balance between test-suite execution and adversarial exploration.

The unique locations covered (AU) and line coverage (AL) columns in the *Adversarial Testing* portion of Table 1 report runtime statistics from our adversarial testing phase. We find that, for most libraries in our experimental setup, the mutated unit tests achieve coverage that closely matches that of the original developer-provided unit tests, both in terms of unique locations covered (UL column) and line coverage (LC column). Furthermore, for eight libraries, the adversarial testing phase of TypePatrol exercises additional lines of code, shown as + values in parentheses, that were not covered by the original unit tests. In absolute terms, our approach achieves greater coverage for twelve libraries, denoted by ↗ in the table. For *chokidar*, the mutated tests cover only a small number of locations because many tests fail under mutation. Overall, these coverage results show that adversarial testing preserves much of the original test-suite coverage while exposing additional code in several libraries. The results of Table 1 show that for every library considered in this experiment, there exist inconsistencies between the observed runtime type and the annotated static type provided by the developers. To understand the prevalence of such large number of type inconsistencies, we manually analyze a sample of 30 warnings produced by TypePatrol. We find that there exists two types of such mismatches. First, where one of the type is a primitive but the mismatched type is an user-defined type, i.e., because there might still be legitimate overlap because of duck typing. This kind of mismatches need further investigation to be validated and is beyond the scope of this work. Second, where both types are primitives and considered clear mismatches and need the corresponding developers attention.

### 6.2.1 Security-relevant Outcomes

When executing the mutated tests, we track the resulting behavior changes. In particular, we analyze the effects of three types of behavior changes to be security-relevant which are explained in Section 3.5. The *Adversarial Testing* part of Table 1 present the results of analyzing the effects of observing 1) return statements (column *ER*) 2) errors caused by incorrect method invocations (column NF) and 3) observing input value sanitization by the developer (column IS).

#### 6.2.1.1 Observing Return Statements

The *Extra return entries* (ER) column of Table 1 reports the number of times a mutated test input produced additional return entries. Of the 30 packages in our experimental setup, nine exhibit return type mismatches. The prevalence of return type mismatches under mutated unit tests reveals three possible shortcomings in these libraries. *First*, the existing unit tests may be insufficient to trigger this behavior; otherwise, it would likely have been uncovered by the results in Section 6.1. *Second*, developers may make mistakes when writing static type annotations. *Third*, libraries may lack sufficient checks for unexpected argument types, which can cause functions to return unexpected types.

#### 6.2.1.2 Observing Method Calls

As elucidated in Section 3.2, certain types in JavaScript, such as `Array` and `String`, share many common methods; we call these *confusables*. An adversary can exploit this property by passing an incorrect type that still supports the expected method calls, thereby manipulating the control flow. The motivation for this experiment is to evaluate the likelihood of control flow hijacking or manipulation.

**Table 2** Top-5 methods involved in errors; three are confusable.

| Method | Freq. | Types |
|---|---|---|
| `indexOf` | 54 | String/Array |
| `replace` | 43 | String |
| `charCodeAt` | 25 | String |
| `slice` | 22 | String/Array |
| `forEach` | 7 | Array/Map/Set |

Directly invoking a method on a value of an unexpected type results in an error in most cases. In JavaScript runtimes, such errors typically appear with messages such as `"Uncaught TypeError: is not a function"`. The *is not a function error* (NF) column of Table 1 reports these findings by counting the number of such errors encountered. We find that 22 of the 30 packages in our experimental setup exhibit this behavior.

We further analyze the method names that appear in the generated error messages, as well as cases where no error is thrown but a confusable method is invoked. This analysis is based on data collected over ten iterations, with 3% of the possible locations in unit tests mutated in each iteration. The motivation behind this experiment is to determine how often confusable methods are invoked by developers which can be possibly exploited by an adversary. Table 2 lists the top five most common method names and their frequency. For our case, TypePatrol passed a type for which the confusable method does not exist which resulted in the error. Our results show that the majority of these methods are shared across multiple built-in types, making them confusable. For example, the `forEach` method, the fifth most frequent method involved in such errors is common to three types `Array`, `Map`, and `Set`.

The last column (*confusable method usage*) (CM) of Table 1 reports the cases where a confusable method is invoked during adversarial testing but does not result in an error. Our analysis shows that adversarial testing is able to invoke a confusable method for ten libraries where the execution did not cause an error and highlight the importance of proper type sanitization by developers, as the lack of errors may silently result in unintended behavior.

#### 6.2.1.3 Observing Input Value Sanitization

During the adversarial testing of the libraries, we observe the input value sanitization implemented by developers, as described in Section 3.2. Our analysis shows that, in practice, only a small number of libraries exhibit this behavior. For this evaluation, we mutate up to 3% of the unit tests for ten iterations and summarize the results in the column *input value sanitization* (IS) of Table 1. The table shows five out of the 30 libraries in our experimental setup perform such sanitization, with *postcss* exhibiting the highest number of cases. This result highlight the prevalence of possible location for bypassing input sanitization.

As a concrete example of a security-relevant mismatch, consider the package *http-proxy-middleware*, which has close to 20 million weekly downloads[2]. Our analysis reveals the possibility of a remote denial-of-service (DoS) vulnerability if a custom logger is misconfigured. The middleware expects the logger to implement three methods: info, warn, and error. If any of these methods are missing, and an attacker sends input that triggers a code path invoking the absent method, the server will crash.

According to the original type declarations, the following TypeScript code compiles successfully and starts the server, even though the custom logger is incomplete:

[2] `https://www.npmjs.com/package/http-proxy-middleware`

```
import { createProxyMiddleware } from 'http-proxy-middleware';
import * as express from 'express';
const app = express();
const badLogger = { // Broken logger: missing warn/error
  info: (msg: string) => { console.log('INFO:', msg); } };
app.use('/api', createProxyMiddleware({
    target: 'http://example.com',
    changeOrigin: true,
    logger: badLogger,
  }));
app.listen(3000, () => {
console.log('Server running on http://localhost:3000');});
```

Here, a custom logger is passed in as one of the options. The internal implementation of http-proxy-middleware relies on the `getLogger` function to obtain the logger for downstream usage from the provided options during initialization of a proxy middleware. When a request such as `curl http://localhost:3000/api` is made, the server crashes with a TypeError because the middleware attempts to call logger.error, which does not exist on badLogger. This occurs because the original type definition for the logger option was declared as `Logger | any`. As a result, TypeScript could not detect the missing methods at compile time.

We discover this mismatch during unit test mutations. For example, the following simplified unit test code demonstrates that getLogger accepts invalid inputs without validation:

```
import { getLogger } from '../../src/logger';
const logger = getLogger({ logger: 500 });
console.log(logger); // prints 500
```

As discussed in Section 3.3, our mutation strategy also targets object literal property values: while the original unit test passed the object console as the logger, our mutation replaced it with a string, and the test still executes without error. As discussed in Section 6.2.1, by observing return values at runtime, we detect that the returned value does not conform to the expected Logger type. This shows that `getLogger` lacks input validation, leading to a violation of its declared return type. Since `http-proxy-middleware` depends on `getLogger` to retrieve the logger during middleware initialization, this unchecked mismatch exposes the possibility of a remote DoS attack if a misconfigured logger is used and an attacker can trigger a code path that invokes a missing method.

Our recommendation is to add runtime validation to ensure that the provided option is actually a Logger. However, the maintainers chose instead to update the type declaration for the logger to accept only `Logger` instead of `Logger | any`. This change ensures that the TypeScript compiler raises an error whenever an incomplete logger is provided.

## 6.3 Effect of Increased Time Budget during Adversarial Testing

The adversarial tsting results of Table 1 show the mismatches found while mutating up to 3% of the unit tests. We adopt this threshold to ensure that optimal number of tests are executed. To further validate these findings, we verify the results of running this experiment on a larger time budget for one randomly selected package. The motivation behind this experiment is to investigate the effect on the number of new mismatches found over time, and to assess the overall impact of the mutations made by TypePatrol.

For this purpose, we mutate 3% of the unit tests in the *postcss* package for 100 iterations. The entire experiment took approximately 40 minutes to complete. In each iteration, a new seed value is used, ensuring that the set of tests selected for mutation varied. The results of this experiment are shown in Figure 2.

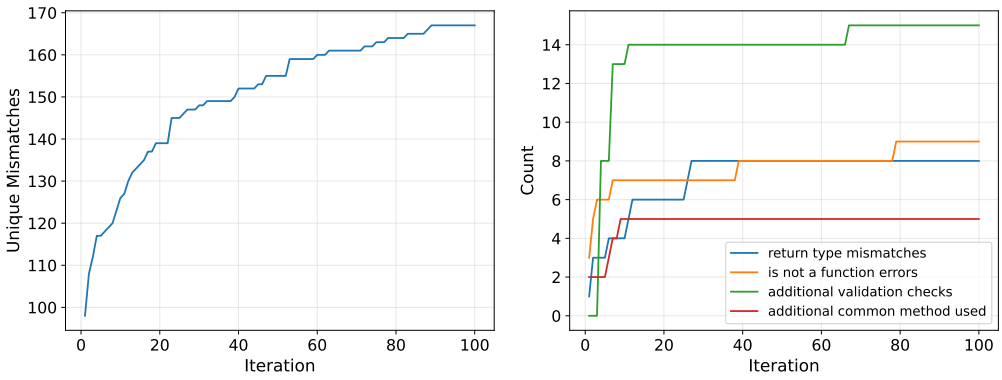

**Figure 2** Iteration vs Unique Mismatches (left). Iteration vs Kinds of Observed Security-relevant Behavior (right).

The figure on the left presents the cumulative unique mismatches discovered over 100 iterations. A unique mismatch is defined as a specific code location where a developer's annotated type differs from the dynamically observed type. The plot reveals a linear increase in the number of unique mismatches throughout the experiment's duration. This demonstrates that, across various mutations of unit tests, TypePatrol is able to effectively explore different parts of the code, continuously uncovering new and unique type mismatches.

The figure on the right shows the different kinds of new behavior observed over 100 iterations. For this experiment, we observe the effects that typically represent possible exploitable locations in code. This result demonstrate that with bigger time budget TypePatrol can uncover new security-relevant behavior in code.

## 6.4 Real-World Impact

At the time of writing, our evaluation has resulted in total ten pull requests across seven libraries out of the 30 present in our experimental setup. As evident, for some libraries, we find multiple such type reports. Out of the ten pull requests created by us, nine have been acknowledged by the respective developers and successfully merged to the code base. Six of these nine reports by us were merged within two days of report which demonstrates that developers deem such type mismatches important. The overall results and the developers acknowledgment of our reports demonstrate the practical applicability of TypePatrol.

In the following, we present the kinds of changes proposed by us to the developers:

- Adding a runtime validation of type, such as the following code. TypePatrol found that at runtime, passing any other type results in unintended behavior, and as a result, we suggest runtime type validation to the developers. We report two such types of changes, one of which was accepted, while for the other, developers fixed the issue by adding an additional type hint.

```
if (typeof boundary !== 'string')
    throw new TypeError('FormData boundary must be a string');
```

- Improve existing type hints. For example, in the following function, the original code (first line) mentions only string as the return type annotation although the body contains a `return null;` statement. TypePatrol is able to discover this inconsistency and suggest improvements (second line). For all cases, such improved type hints were accepted by developers.

```
function validateTopics(topics: string[]): string
function validateTopics(topics: string[]): string | null
```

# 7 Threats to Validity and Future Work

### Selection of Libraries

The libraries on which TypePatrol is evaluated are based on a ranked list which may change over time. A different selection of JavaScript and TypeScript libraries could lead to different conclusions compared to the current results.

### Limitations on the Selection of Instrumentation Points & Types

TypePatrol instruments two categories of points, annotation points and security-relevant points, and our results are based solely on observations at these. Altering this selection, or considering other potentially security-relevant points, could yield different outcomes. We mitigate this by selecting points that developers typically annotate and locations where prior work [37, 24] has shown to encounter bugs. Our reported findings also involve only primitive-type mismatches; considering other types may yield different results.

### Unit Test Mutations

For our unit test mutation experiment, we choose to mutate 3% of all unit tests present in each library. These tests are selected randomly, and as a result, executing a different set of mutated unit tests could lead to different observed outcomes. We keep the overall approach reproducible, we follow the standard practice of using a fixed seed during mutation. Additionally, changing mutation threshold of 3% may also affect the results. Finally, the observed behavior during adversarial testing may not always be directly caused by the mutations performed by TypePatrol but, in some cases, due to the non-deterministic code in the underlying library.

### Future Work

TypePatrol leaves ample opportunity for future work. The code instrumentation points can be extended to include additional patterns that may be security-relevant. The mutation algorithm used in the adversarial testing phase can also be improved by supporting more data types and crafting more complex input values. TypePatrol filters the observed type inconsistencies by considering only cases where one of the type involved in the mismatch is a primitive type. We plan to improve this by also considering user-defined and polymorphic types. Finally, TypePatrol can integrate an automatic synthesis framework to repair the observed inconsistencies.

# 8 Related Work

### Types in JavaScript

Pradel et al. [29] were the first to propose dynamic analysis for detecting type inconsistencies. However, they do not consider malicious inputs crafted by an attacker, as was recently proposed by Troppmann et al. [37]. David et al. [10] discuss how type inference and stronger type enforcements can prevent deserialization attacks in PHP. Pradel and Sen [30] study the prevalence of type coercions, which are an important culprit for the security issues discussed in this paper, which can be prevented by a stricter type system. Malik et al. [26] advocate for synthesizing type annotations from documentation, while Pradel et al. [28] also advocate for using code context for this goal.

Hoeflich et al. [14] propose synthesizing contracts from type declarations, i.e., runtime checks at the annotation boundary, to enforce gradual types at runtime in JavaScript. Similar to Feldthaus and Møller [12] they find that many type annotations are inconsistent with the types observed at runtime. However, neither of these approaches discuss security-relevant mismatches or assume attackers that can purposely pass values of wrong types.

### JavaScript Security

Traditionally there was a lot of work on JavaScript security in the context of client-side web applications, e.g., XSS [20]. However, in recent years there was an increased interest in analyzing the security of open-source libraries, in isolation, mostly in the context of server-side ecosystems like npm [41]. Xiao et al. [39] discuss hidden property attacks, in which adversaries introduce well-crafted properties in complex objects passed to libraries to achieve various unwanted effects. Similarly, Shcherbakov et al. [35] show that a related problem called prototype pollution is prevalent in JavaScript libraries and that it can often be lifted to remote code execution. Kang et al. [16] show that this vulnerability is also prevalent on the client-side where it can be used as a building block for sophisticated attacks like cross-site scripting [17]. Li et al. [25] propose using object dependence graph, a sophisticated way of modeling a program to detect prototype pollution vulnerabilities. Li et al. [21] extend this approach to detecting other taint-style vulnerabilities. Kang et al. [15] propose an enhancement to speed up abstract interpretation in this domain. Differently, Cassel et al. [6] propose using provenence graph for finding vulnerabilities in server-side JavaScript. Finally, Bhuiyan et al. [3] propose a benchmark of known vulnerabilities with exploits, including many prototype pollution entries. While prototype pollution and hidden property abuse can be prevented by enforcing complex types annotated by developers in the code, no prior work tests the prevalence of these vulnerabilities in the presence of type annotations.

### JavaScript Testing

There is a plethora of prior work using existing unit tests for dynamic analysis, e.g., [19], or for synthesizing tests automatically. Turcotte et al. [38] and Koishybayev and Kapravelos [18] use existing tests to debloat libraries, i.e., to remove unused parts of the code that might contain vulnerabilities. Selakovic et al. [34] proposes a way of generating tests for higher-order functions, which Arteca et al. [2] extends to support nested callbacks. Cassel et al. [5] propose an automatic technique for synthesizing exploits for known vulnerabilities. Finally, Zeng et al. [40] propose a way of leveraging existing type annotations for effective fuzzing. To the best of our knowledge, we are the first to test typed code for purposely-introduced inconsistencies.

## 9 Conclusion

This paper presents TypePatrol, the first adversarial testing approach that targets JavaScript and TypeScript libraries. The framework operates by instrumenting selected code locations within the libraries that includes security-relevant points. After this, we execute the developer-provided test suite, and collect the corresponding runtime behavior. Next, we mutate a subset of unit tests and execute the test suite again to simulate how an adversary might exercise the code and observe the effects i.e., whether any new behavior is triggered. The final step of TypePatrol is to compare the two sets of behaviors and to identify security-relevant type mismatches and analyze the effects.

We evaluate TypePatrol on 30 popular JavaScript and TypeScript libraries and find hundreds of type mismatches during adversarial testing. We find that with increased time budget, TypePatrol can uncover new security-relevant mismatches. At the time of writing, TypePatrol has resulted in ten pull requests in seven libraries. Developers have acknowledged our reports and merged nine of the pull requests demonstrating the practical applicability of TypePatrol.

# Coordinating Agents on a Shared Git Workspace: An Empirical Study of Action-Space Observation for Agentic Software Engineering

**Hasen Özaytürk**

**Feza Buzluca**
Istanbul Technical University, İstanbul, Türkiye

## Abstract

**Background.** Multi-agent approaches to Large Language Model (LLM)-based agentic software engineering, specifically in automated program repair and issue resolution, have converged on architectural patterns that favour isolation: role specialisation, task decomposition in isolated worktrees, or best-of-$N$ with external selection. Collaboration of homogeneous agents on a single task in a shared Git workspace remains understudied, and is actively discouraged in production guidance due to file-level write collisions.

**Aims.** We investigate whether a shared-workspace configuration can be made viable and effective for autonomous bug fixing and patch production through action-space coordination – a paradigm in which agents observe one another's commits, lifecycle transitions, and recent test or error outputs rather than exchanging natural-language messages.

**Method.** We propose PASC (Peer-aware Action-Space Coordination), a layer in which two homogeneous LLM agents share a single Docker container and Git tree. Each agent's effects are auto-committed under its identity, and each next observation is prepended with a structured peer-activity block. The final submission is the team patch derived from the shared history.

**Results.** We evaluated PASC on the full Python subset of SWE-Bench Pro using two independently-developed LLMs, against an isolated single-agent baseline and a "silent" two-agent baseline without the peer-activity feed. PASC delivers a statistically significant lift over the single-agent baseline on both models. Crucially, the silent baseline is statistically equivalent to the single-agent one, confirming that the gain stems from action-space coordination rather than parallelism. PASC also outperforms a deployable federated alternative in which agents share the peer-activity feed but work in isolated worktrees. Relative to the silent baseline, PASC reduces cost per resolved task by ∼20% and destructive concurrent edits by ∼47%. Preliminary observations indicate that beyond two agents, active interference increases several-fold, suggesting that larger populations will require supplementary coordination mechanisms.

**Conclusions.** A shared-workspace configuration of homogeneous agents coordinated through action-space observation improves effectiveness over an isolated single-agent baseline, and does so more economically than a comparable multi-agent baseline without peer awareness.

## 1 Introduction

Issue resolution, bug fixing, and patch production are core software-engineering activities that have traditionally relied on individual developer effort or coordinated team workflows mediated by version control. The recent emergence of LLM-based autonomous agents has introduced a new class of contributor to these workflows, capable of reading issue descriptions, exploring codebases, and producing patches. Agentic software engineering is the discipline that studies how these activities are carried out by such agents. Its systems take several forms. A single agent may be responsible for the entire task, several agents may work on one task together, or the task may be split among agents by subtask or by role. The aim of this study is to test a configuration that has received little attention: two agents of the same kind work on one task in one shared workspace, with no manager assigning subtasks and no selector choosing between their patches, and with each agent kept aware of its peer's actions as they happen. This configuration is evaluated against a single agent, against two agents that share the workspace without that awareness, and against two agents that receive it but work in separate worktrees. All four are evaluated on the full Python subset of SWE-Bench Pro [11], a contamination-resistant benchmark of long-horizon, multi-file issue-resolution tasks.

Single-agent scaffolds such as SWE-agent [38] resolve a substantial fraction of GitHub issues on SWE-Bench [17] and SWE-Bench Verified [25]. Multi-agent extensions for autonomous program repair are a natural lever for further progress, and the research community has explored them extensively. Most published systems fall into one of a few architectural patterns. Role-specialised frameworks assign distinct agents to roles such as project manager, architect, developer, and tester [30, 16, 24, 2]. Task-decomposition systems route subtasks to agents operating in isolated git worktrees [15]. Best-of-$N$ approaches run independent agents in parallel and reconcile their outputs through an external selector or re-ranker [39, 34]. Sequential trajectory replay runs one agent to completion and feeds its trajectory to the next [19]. Production tools converge on worktree-isolated parallelism, placing each agent in its own worktree with a separate task [9, 4, 5]. Production guidance actively discourages the shared workspace on mechanistic grounds: git itself refuses to check out the same branch in two worktrees [5], a rule designed to prevent index and working-tree corruption, and practitioner reports cite shared-file collisions as the principal failure mode of co-located agents [4].

We argue that the standard objections to a shared-workspace configuration are problems of communication rather than architecture. Prior multi-agent systems that target the same task either communicate through natural-language messages [30, 16] or do not communicate during execution at all [39, 15]; both routes pay an architectural price (role heterogeneity, central managers, or external selectors). We instead make agents communicate through their actions, and we place them on one tree rather than in separate worktrees. After each step, each agent's bash-command effects auto-commit to a shared git tree under the agent's identity, and the next observation each agent sees contains a structured digest of what its peer has just done: which files were changed, what tests passed or failed, whether the peer has submitted or appears stuck. The agents do not exchange natural-language messages.

This paper makes the following contributions:

1. We identify a comparatively understudied point in the multi-agent software-engineering design space (Section 2) and build PASC as a coordination layer on top of an existing single-agent framework [32] (Section 3).

2. We evaluate PASC on the full Python subset of SWE-Bench Pro [11] under two independently-developed open-weight LLMs (MiniMax-M2.7 and DeepSeek-V4-Pro), with three independent runs per configuration. On both models the system delivers a statistically detectable improvement over the isolated single-agent baseline, and a ∼20% reduction in cost per resolved instance over the multi-agent baseline without peer awareness (Sections 5.1 and 5.4).
3. We isolate the source of the lift through a controlled comparison against a two-agent shared-workspace baseline that disables the peer-activity render (SILENT). Equivalence testing rules out the parallelism explanation: SILENT is statistically equivalent to SINGLE. The lift is attributable to the peer-activity feed (Section 5.2).
4. We isolate the contribution of workspace topology through a controlled federated comparison in which two agents share the same peer-activity feed but work in isolated worktrees rather than a shared tree. The shared-tree configuration outperforms the deployable federated alternative, and holds up even when that alternative is scored on whichever of its two patches happens to be correct – a non-deployable upper bound that requires perfect external selection (Section 5.3).
5. We provide quantitative diagnostics on shared-workspace behaviour. The peer-activity feed reduces destructive co-edits across both LLMs (Section 5.5), and preliminary observations on $N \in \{2, 3, 5\}$ characterise where the current coordination layer plateaus and what an additional mechanism for larger agent populations would need to address (Section 5.6).

## 2 Related Work

We organise related work along the five families introduced in Section 1, then turn to single-agent baselines on SWE-Bench-style benchmarks, the use of git as a coordination substrate, the literature on inter-agent communication, and coordination findings from pre-LLM collaborative software development.

### 2.1 Multi-Agent LLM Systems for Software Engineering

**Role-specialised systems.** ChatDev [30], MetaGPT [16], AgileCoder [24], and SWE-Search [2] instantiate multi-agent systems in which agents are heterogeneous by construction. The pattern recurs at smaller task scales: Melo et al. [21] apply a sequential four-agent pipeline of role-specialised small language models to method-level test-smell refactoring. AutoGen [36] provides a general orchestration framework for heterogeneous agents. None of these systems addresses the case in which two agents of the same role collaborate on the same task; the collaboration mechanism is always role differentiation.

**Task-decomposition systems with isolated worktrees.** The closest published neighbour to PASC is the CAID paradigm of Geng and Neubig [15]. Both systems use git as the coordination substrate and reach the conclusion that branch-and-merge is the right primitive. The remaining design choices distinguish the two on three axes. First, CAID introduces a central manager that constructs a dependency-aware plan and delegates subtasks; PASC has no central manager. Second, CAID assigns each engineer agent its own isolated git worktree so that concurrent edits cannot interfere; PASC places both agents in a single shared worktree. Third, CAID's parallelism comes from decomposition (each agent works on a different subtask); PASC's agents work on the same task end-to-end. Where CAID asks how to make isolation work better through a centralised planner and test-based integration, PASC asks whether isolation is necessary at all.

**Best-of-$N$ with external selection.** DEI [39] pools heterogeneous SWE-agents (Aider [14], Moatless [27], Agentless [37], OpenHands [35]) and applies a multi-stage rating-and-re-ranking pipeline. Production systems such as Verdent [34] spawn agents that explore distinct approaches in parallel and orchestrate them through a plan-code-verify loop with a verifier agent for selection. These systems do not share workspace state during the run: agents do not see one another's edits, and outputs are reconciled by an external selector.

**Sequential trajectory replay.** SE-Agent [19] addresses the same question as PASC (how should information flow between agents working on the same task?) through a different route: one agent finishes, the next starts from scratch with the prior trajectory as context, with state-of-the-art numbers reported on SWE-Bench Verified. PASC's answer is parallel action-space coordination: agents run concurrently and observe each other's commits and test outputs at every step. SWE-Exp [8] is a related variant that operates across issues rather than within a single one, distilling lessons from prior trajectories into an experience bank.

**Worktree isolation in production tooling.** Developer-facing tools have converged on the same prescription as CAID for the practical setting: place each parallel agent in its own `git worktree`, give it a separate task, and merge sequentially. Cursor 2.0 [9] exposes up to eight parallel agents through worktree or remote-machine isolation; Augment Code's guides [4, 5] frame the shared-workspace configuration as a primary failure mode and recommend decomposition with explicit boundaries and worktree isolation. Git itself enforces the isolation by refusing to check out the same branch in two worktrees. The empirical question of whether this prescription remains necessary when agents are made aware of one another's actions is the question this paper takes up.

## 2.2 Single-Agent Baselines and Benchmarks

The single-agent baseline against which our multi-agent system is compared is MINI-SWE-AGENT [32], a lightweight scaffold descended from SWE-agent [38]. Its developers report that it matches the performance of the original SWE-agent while being substantially simpler, and now recommend it as the default scaffold for research use over SWE-agent itself [33]. Its minimalism is therefore a feature rather than a limitation: it provides a strong single-agent baseline with a small surface area, offering cleaner ground on which the contribution of any extension built atop it can be isolated and attributed.

The original SWE-Bench benchmark [17] has driven a wave of single-agent systems including Agentless [37] (which avoids the agent loop entirely through static structural reasoning), AutoCodeRover [40] and its successor Sonar Foundation Agent [23], Aider [14], and Moatless Tools [27].

## 2.3 Git as a Coordination Substrate

PASC shares CAID's [15] choice of git as a coordination substrate, but reverses the isolation polarity by co-locating agents in a single shared tree and treating the commit log as the coordination signal. The closest non-multi-agent precedent is the use of repository state as feedback in self-refining single-agent systems [31, 20], which exploit version-control state for the agent's own introspection rather than for inter-agent communication.

## 2.4 Inter-Agent Communication

A separate strand of work has investigated how LLM agents should communicate once spawned. Free-form natural-language chat is the default in role-specialised systems [30, 16]; structured envelopes have been proposed as a way to make routing more reliable. PASC's premise is that on long-horizon software-engineering tasks, where most useful information is structural (which file was edited, which test passed or failed), the substrate of communication should be the agent's actions rather than its words.

## 2.5 Coordination in Collaborative Software Development

The challenge of coordinating multiple contributors on a shared codebase predates LLM agents by decades, and findings from that literature shape PASC's design. Dourish and Bellotti [13] distinguished passive awareness – coordination information exploited through the shared workspace itself – from active mechanisms that require explicit communication, arguing that the latter penalise providers and presuppose relevance to recipients. PASC's three-layer peer-activity feed (Section 3) is an instantiation of the passive-awareness principle for LLM agents: commits, lifecycle transitions, and output digests surface through the shared git tree and in-memory boards, with no explicit inter-agent message channel. Brun et al. [7] established that concurrent-edit conflicts in collaborative development are frequent and manifest not only as textual overlaps but also as subsequent build and test failures, and demonstrated that proactive detection mitigates them; PASC's reduction of destructive co-edits (Section 5.5) is the corresponding agent-coordination result.

# 3 PASC: Design and Implementation

PASC is built on MINI-SWE-AGENT [32], whose core loop calls a model, runs the model's bash commands in a sandboxed environment, feeds the outputs back as observations, and terminates when the model emits a designated submission marker. Three protocol-style abstractions define the extension points: `Model` (`query(messages)`), `Environment` (`execute(action)`), and `Agent` (`run(task)`). The single override point inside the loop is `step()`, which constructs one query/observation pair; all extensions in this section are realised through subclasses or wrappers around these three protocols. We describe the system as implemented for two agents; the underlying mechanism is not specific to that choice, and Section 5.6 discusses generalisation to $N > 2$.

## 3.1 Architecture Overview

For a single SWE-Bench Pro instance the orchestrator constructs the following objects:

**Shared environment.** A single Docker container is started that holds the target repository at the benchmark's specified base commit. Its `container_id` is captured and exposed.

**Git operations object.** Encapsulates `docker exec ... git ...` invocations against the detected repository path (typically `/testbed` or `/app` depending on the benchmark image).

**Commit tracker.** Owns a per-agent "last-seen" pointer into the git history and serialises commit operations so that attribution remains clean even when agents step concurrently.

**Peer-activity builder.** Renders, on demand, the structured block that will be injected into an agent's next observation, drawing from the commit tracker and from two thread-safe in-memory boards that hold per-agent lifecycle status and per-agent output digests.

**Shared environment wrapper.** Makes the same container addressable from both agent threads while leaving lifecycle management to the orchestrator.

Two worker threads then run, one per agent. Each thread holds a fresh `Model` instance, points its agent at the same shared environment, and uses the same shared commit tracker and peer-activity builder. A thread terminates when its agent emits the MINI-SWE-AGENT submission marker, hits a failure, or exhausts its step limit; the marker is treated as a terminate hint and the string itself is ignored. After both threads have joined, the orchestrator diffs `HEAD` against `base_commit` and writes the result as `final.patch`. Per-agent "raw" patches are persisted for debugging but are not part of the submission. Figure 1 summarises the resulting structure and the data flow at the step boundary.

The agent class extends MINI-SWE-AGENT's `DefaultAgent` by overriding `step()` to insert two hooks: a *pre-step* hook that prepends the peer-activity block to the most recent observation message, and a *post-step* hook that commits any working-tree changes, updates a stuck-detection counter, and publishes a one-shot output digest. We do not override `query()` or `execute_actions()`; both extensions operate at the step boundary because that is the granularity at which peer-observable events occur.

These design choices place PASC outside the multi-agent families discussed in Section 2 on three axes: agents do not exchange natural-language messages, no central coordinator mediates their outputs, and patch selection is not delegated to an external mechanism. The final submission is uniquely determined by the shared git state at the time both agents stop.

## 3.2 Shared Environment via Composition

A naive subclass of `DockerEnvironment` would not work for this use case: the upstream constructor starts its own container, so two instantiations would launch two containers. We therefore use composition. The orchestrator instantiates one base environment, captures its `container_id`, and wraps it in a `SharedDockerEnvironment` that forwards all methods invoked by the agent loop: `execute` for action execution and `get_template_vars` / `serialize` for prompt and trajectory bookkeeping. The wrapper additionally converts `cleanup()` into a no-op so that container teardown remains the orchestrator's responsibility, ensuring the shared container survives until both agent threads have joined. Concurrent `shared_env.execute()` calls translate to concurrent `docker exec` invocations into the same container; in the shared configuration, however, a workspace-level lock holds bash execution and the post-step commit together as a single critical section (Section 3.3). LLM queries – typically the dominant component of per-step latency – remain fully parallel.

## 3.3 Auto-Commit Pipeline and Attribution

After each step the agent's thought (the assistant text that precedes the bash command) is extracted, normalised to a short single-line summary, and used as the commit subject, prefixed with the agent's identifier and step number. The post-step commit is then issued under the agent's identity, with concurrent commits protected by a workspace-level lock that holds bash execution and the commit together as a single critical section: were only the commit serialised, one agent's uncommitted bash write could be swept into the other's concurrent staging step and leak attribution. If a commit nevertheless fails under transient contention, the pipeline retries with bounded backoff and, on terminal failure, resets the staged index so that the failing agent's working-tree changes are not absorbed into any peer's next commit. Details of the bash pipeline and the git configuration that suppresses background maintenance during the run are documented in the replication package.

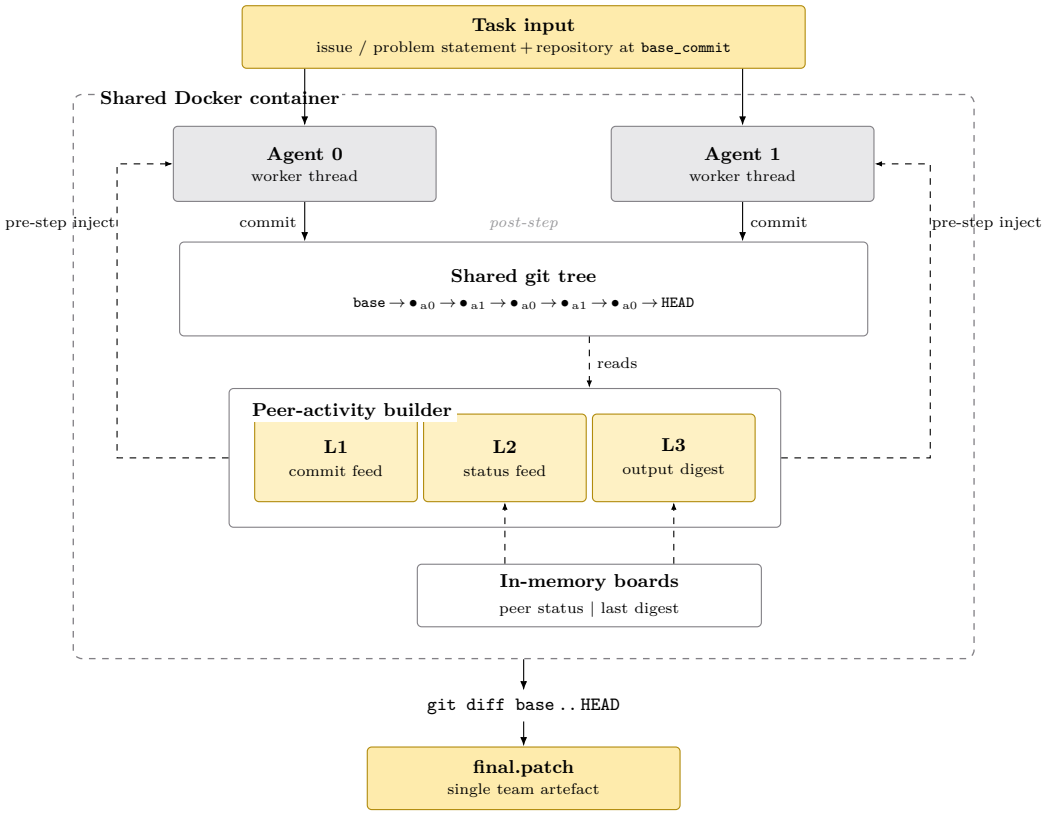

**Figure 1** Architecture of PASC at $N$=2. Solid arrows show post-step commits to the shared git tree. Dashed arrows show pre-step reads from the tree and in-memory boards (L1/L2/L3 sources) and the resulting peer-activity injection into each agent's next observation. No oracle or external selector is involved in producing the final submission.

## 3.4 Three-Layer Peer-Activity Feed

On the next step, before the agent issues its query, the peer-activity builder constructs a single block of text and prepends it to the most recent user message. The block contains up to three layers, each independently computed; layers are omitted when they have nothing to contribute, and an empty block results in no injection at all.

### L1 – Commit feed

Using the per-agent "last-seen" pointer maintained by the commit tracker, the builder enumerates commits authored by the peer in the range (last_seen, HEAD] and renders each as a short SHA, the commit subject, and a per-file `git show -stat` summary. The pointer is then advanced, so each commit is shown to a given viewer at most once. A configurable cap bounds the number of commits surfaced in a single block, ensuring that the peer-activity injection remains a small fraction of the agent's context window. The progressive semantics reflect that each commit is new information once and never again; a monotone pointer suffices.

### L2 – Status feed

Lifecycle events (the peer has submitted, the peer appears stuck through consecutive format errors above a threshold, the peer's worker has failed) are written to a thread-safe status board. The renderer checks whether the current peer status differs from the most recently surfaced status for this viewer agent and, if so, emits a one-shot notice with an actionable hint. This layer addresses a gap of the L1-only design: the submission marker produces no commit of its own and was therefore invisible to the peer. L2 is event-shaped: the "submitted" state is a transition, and only the transition needs surfacing.

### L3 – Output digest

After a step that produced a bash observation, six regular-expression patterns are tried in priority order against the command and its output: a `pytest` summary line, a `unittest` "Ran $N$ tests in $T$ s" line, a Python traceback, a `git apply` or `git am` failure, an invocation of a peer-authored Python script, and a generic non-zero return code. The first match is recorded as a single-line digest in a thread-safe digest board under the producing agent. The peer's next render reads this digest, emits it, and clears it, so the same digest is never replayed on subsequent steps. The peer-authored-script pattern catches the case where one agent runs a reproduction script the other has just committed; without that pattern, an exit-zero "BUG NOT REPRODUCED" output would remain invisible despite being structurally important.

The L3 extractor applies one additional annotation uniformly: when a peer's `pytest` run produces only `PASS`es, an annotator automatically wraps the digest with a reminder that the test set was peer-selected rather than the hidden gold suite. Without this annotation, an all-pass result could be misread by the viewer as evidence that the peer has already produced a working patch, leading the viewer to terminate prematurely on what is, in fact, a peer-selected outcome.

The three layers have distinct cardinality semantics: L1 is progressive (each commit shown once, then never again), L2 is event-shaped (only transitions surface), and L3 is read-and-clear (the most recent volatile signal, replaced rather than accumulated). Figure 2 illustrates how the three layers are triggered on a single SWE-Bench Pro instance. `agent_0` commits an incorrect fix and resumes searching without recognising its architectural error; on the next observation `agent_1` receives this commit through L1, analyses it as the peer's work rather than its own, and arrives at the correct fix. The revert and override commits, together with the passing test digest, return to `agent_0` through L1 + L3, and L2 synchronises submission.

## 3.5 Design Verification on a Pilot Corpus

The three-layer design was settled empirically on a 50-instance pilot corpus drawn from the Python subset of SWE-Bench Pro through balanced sampling across the `ansible`, `openlibrary`, and `qutebrowser` repositories. We inspected agent trajectories to settle qualitative design choices – which regular-expression patterns L3 should recognise, where to bound the L1 commit cap, when L2 should fire – and to verify that each layer's marginal addition was budget-neutral or budget-positive at small scale. No design choice was conditioned on pilot pass counts: at $n$=50, pass-count differences between consecutive layer additions fall within a 1–3 instance range, well below the statistical resolution of any paired test. Per-layer token, commit, and cost diagnostics are reported in the replication package.

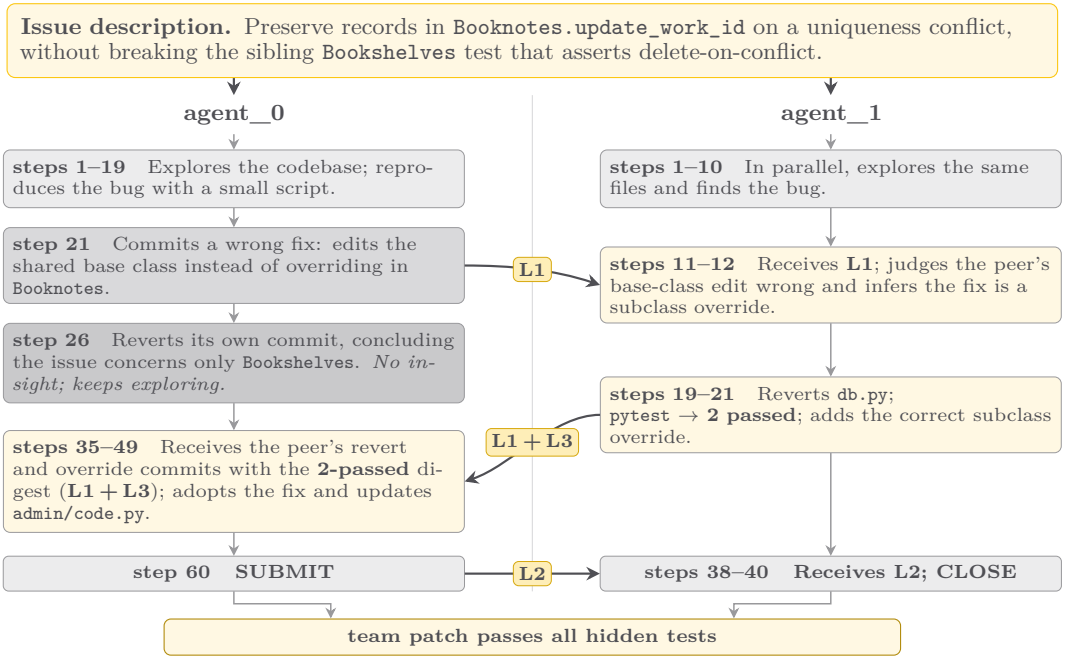

**Figure 2** End-to-end trace of PASC on a single SWE-Bench Pro instance (`internetarchive/openlibrary @ 5069b09`) under DeepSeek-V4-Pro. The two agents work in parallel from the issue description; horizontal arrows mark the inter-agent signals carried by L1 (peer commit), L1 + L3 (commit with test digest), and L2 (submission transition); the joined flow at the bottom is the submitted team patch.

# 4 Experimental Setup

## 4.1 Research Questions

We organise the evaluation around six research questions:

**RQ1 (effectiveness).** Does action-space coordination over a shared workspace improve task resolution over an isolated single-agent baseline, at the same model and decoding regime, and is the effect consistent across independently-developed LLMs?

**RQ2 (mechanism – parallelism).** Is the observed lift attributable to *parallelism* or to the *peer-activity feed*? Specifically, does a two-agent baseline that shares the workspace but disables the peer-activity render (SILENT) match PASC, or is it instead equivalent to the single-agent baseline?

**RQ3 (mechanism – topology).** When two agents share the same peer-activity feed but work in isolated worktrees rather than a shared tree, does the shared-tree configuration of PASC still provide an advantage?

**RQ4 (cost-effectiveness).** How does PASC's cost per resolved instance compare to the single-agent baseline and to a multi-agent baseline without peer awareness?

**RQ5 (failure-mode mitigation).** Does the peer-activity feed mitigate the destructive concurrent-edit thrash that motivates industry guidance against shared workspaces? If so, is the mitigation a routing effect, a cooperation effect, or both?

**RQ6 (preliminary scaling observations).** Does the $N{=}2$ design point generalise to larger agent populations $N \in \{3, 5\}$ under the present coordination layer, or do additional mechanisms become necessary?

## 4.2 Benchmark and Corpora

We evaluate on the Python subset of SWE-Bench Pro [11], comprising 266 instances. SWE-Bench Pro is a contamination-resistant corpus of long-horizon, multi-file coding tasks drawn from 11 publicly released repositories. We deliberately adopt it rather than the earlier SWE-Bench Verified [25], which has been shown to suffer from solution leakage and weak test oracles in roughly one-third of instances [1], and whose results OpenAI has itself ceased reporting, citing contamination and recommending SWE-Bench Pro as the successor [26]. Resolution is determined by a hidden test suite combining fail-to-pass tests (verifying issue resolution) and pass-to-pass tests (verifying no regressions). The Python subset was selected as the evaluation target because the benchmarks that established this literature are Python-only [17, 25], maximising comparability with the baselines against which PASC is positioned.

The full 266-instance corpus serves as the primary evaluation target for RQ1–RQ5. A 76-instance subset is used for the $N \in \{2, 3, 5\}$ scaling observations of RQ6. The 50-instance pilot corpus used for verification of the three-layer feed (Section 3.5) is a subset of the 266-instance evaluation corpus; we discuss the implications in Section 6.

## 4.3 Models and Decoding Regime

To reduce model-specific external-validity threats, we evaluate on two independently-developed open-weight LLMs: MiniMax-M2.7 [22] and DeepSeek-V4-Pro [10]. Both are recent open-weight models, competitive with frontier closed-weight systems on coding tasks at a fraction of the per-token cost. Open weights also keep the evaluation replicable at a later date, whereas proprietary endpoints are subject to undocumented updates and deprecation. All runs use greedy decoding (temperature 0) to reduce decoding-side variance. Greedy decoding alone does not make a run reproducible, and the residual variance can shift measured accuracy [3, 28]; each configuration is therefore repeated three times. Each agent operates under MINI-SWE-AGENT's default per-agent step limit of 250 steps; no token or cost ceiling was imposed on any configuration. The multi-agent configurations apply the same per-agent step limit. All costs are reported under provider list pricing: MiniMax-M2.7 at \$0.30/M input and \$1.20/M output tokens, DeepSeek-V4-Pro at \$0.435/M input (cache miss) and \$0.87/M output tokens. The cost-computation scripts and full pricing details are included in the replication package.

## 4.4 Configurations

Four configurations are evaluated on the full 266-instance corpus:

**single.** A single MINI-SWE-AGENT with no coordination layer; serves as the lower-bound single-agent reference.

**silent.** Two agents on a shared container and shared git tree with auto-commit enabled, but with the peer-activity render *disabled*. Agents observe peer activity only through explicit git inspection commands they choose to issue. This is the mechanism control for RQ2.

**federated.** Two agents working in isolated git worktrees on the same task, with prompts adapted to inform each agent that its peer works in a separate worktree. Final patches are derived per-agent and aggregated post-hoc; we report both individual-agent submissions (deployable) and an oracle UNION that counts an instance as resolved if either agent resolved it (upper bound). This is the topology control for RQ3.

**PASC.** The full system as described in Section 3: shared container, shared git tree, auto-commit, and the three-layer peer-activity feed (L1 + L2 + L3).

### 4.5 Metrics

**Pass count**: the number of instances whose final patch passes the hidden test suite under the SWE-Bench Pro evaluator. **Total cost**: dollar spend across the corpus at list pricing. **Cost per pass**: total cost divided by pass count, the cost-effectiveness metric most directly comparable across configurations of differing token budgets. **Co-edit rate**: the fraction of instances in which both agents issue mutating bash commands targeting overlapping source paths in the repository. Detection is performed on the bash command text via regex against mutating patterns, not on post-hoc git diffs: the metric targets interference attempts, including those git refuses or that exit non-zero, which leave no trace in the committed history. **Any-destructive rate**: a strict subset of co-edit in which the two agents' edits exhibit an overwrite signature. **Sed-reversal rate**: a strict subset of any-destructive, in which an agent's bash command targets a line the peer wrote in a preceding commit. By construction, sed-reversal $\subseteq$ any-destructive $\subseteq$ co-edit.

### 4.6 Statistical Analysis

The unit of analysis is the SWE-Bench Pro instance; outcomes are paired across configurations within model. For RQ1 we report McNemar's test, the appropriate paired test when both conditions are evaluated on the same instances [12], per stratum (model) and a stratified pooled McNemar test across the six strata. We complement these frequentist tests with two model-based analyses, which capture different aspects of the effect: a population-averaged GEE logistic model estimates the marginal odds ratio, while a generalised linear mixed-effects model (GLMM) with random intercepts for instance and run absorbs the clustering induced by repeated evaluation of the same instances and estimates the within-instance conditional odds ratio. Stratum heterogeneity is assessed via the Breslow-Day test [6]; this is the formal precondition for pooling.

For RQ2, equivalence between SILENT and SINGLE is assessed by paired two one-sided tests (TOST) [18] at an equivalence margin of $\pm 5$ percentage points, both per-stratum and pooled. Effect sizes are reported as risk-difference (percentage-point lift) with 95% bootstrap confidence intervals, and as discordant-pair odds ratios (b/c).

## 5 Results

### 5.1 RQ1: Headline Results on the Full Corpus

Table 1 reports outcome counts and statistical contrasts on the full 266-instance Python subset of SWE-Bench Pro for the two LLMs and four configurations.

PASC resolves +5.3 pp more instances than SINGLE on MiniMax (138.3 $\rightarrow$ 152.3) and +4.5 pp on DeepSeek (152.0 $\rightarrow$ 164.0). The primary inference is the pooled stratified McNemar analysis on $n$=1596 paired observations. It is significant for PASC against both SINGLE and SILENT (Table 1). Pooling is licensed by the Breslow-Day homogeneity test, which rejects neither contrast ($p$=0.969 for PASC vs. SINGLE, $p$=0.513 for PASC vs. SILENT). The effect of method on outcome is homogeneous across strata. Bootstrap 95% confidence intervals for the pooled risk differences are $[+2.1, +7.3]$ pp for PASC vs. SINGLE and $[+1.6, +6.3]$ pp for PASC vs. SILENT, both excluding zero.

The model-based analyses agree. A GEE logistic with exchangeable working correlation gives a marginal odds ratio of 1.22 (95% CI $[1.10, 1.36]$, $p = 1.66 \times 10^{-4}$) for PASC vs. SINGLE. A generalised linear mixed-effects model with random intercepts for instance and run gives a conditional odds ratio of $\mathbf{1.75}$ (95% CI $[\mathbf{1.48}, \mathbf{2.07}]$). The marginal OR describes the

**Table 1** Outcome and cost on the full 266-instance Python subset of SWE-Bench Pro under two independently-developed LLMs, averaged across three independent runs per configuration. Costs are reported at provider list pricing. The FEDERATED row evaluates each agent's patch separately and reports the mean of the two pass counts, with the corresponding cost-per-pass; the oracle UNION upper bound and its associated contrasts are reported in Section 5.3.

| LLM | Configuration | Pass / 266 | % | Total $ | $/pass |
|---|---|---|---|---|---|
| DeepSeek-V4-Pro | SINGLE | 152.0 | 57.1% | $9.07 | $0.060 |
| | SILENT | 157.0 | 59.0% | $24.85 | $0.158 |
| | FEDERATED | 156.4 | 58.8% | $21.43 | $0.137 |
| | PASC | 164.0 | 61.7% | $22.47 | $0.137 |
| MiniMax-M2.7 | SINGLE | 138.3 | 52.0% | $12.02 | $0.087 |
| | SILENT | 138.3 | 52.0% | $30.56 | $0.221 |
| | FEDERATED | 140.5 | 52.8% | $20.66 | $0.147 |
| | PASC | 152.3 | 57.3% | $24.36 | $0.160 |

Pooled stratified McNemar ($n$=1596, six strata = two models × three runs): PASC vs. SINGLE $\chi^2$=22.20, $p$=2.45 × $10^{-6}$; PASC vs. SILENT $\chi^2$=15.21, $p$=9.64 × $10^{-5}$; SILENT vs. SINGLE $\chi^2$=0.82, $p$=0.366.

population-averaged effect; the conditional OR describes the within-instance effect controlling for instance difficulty. The divergence reflects the dominant instance-level heterogeneity: the instance random effect has SD 3.79 on the logit scale (95% CI $[3.48, 4.13]$) and accounts for 81% of total logit-scale variance. Run-level variance, by contrast, is negligible (SD 0.27, 95% CI $[0.11, 0.69]$, 0.4% of total variance).

As an additional fairness check, we considered an extended-budget single-agent configuration in which the step limit was doubled to 500 steps. Since a larger budget can only alter a run that the limit actually truncated, we examined the step-bound instances: across all three runs, only one instance reached the 250-step ceiling on MiniMax-M2.7 and two on DeepSeek-V4-Pro. We reran these under the extended budget, and none were resolved. The observed PASC lift is therefore not attributable to single-agent step truncation, and an extended-budget single-agent configuration would not close the gap.

The consistency across MiniMax and DeepSeek (two independently-developed LLMs) is the central external-validity control of this section. It supports a positive answer to RQ1: action-space coordination over a shared workspace improves task resolution over an isolated single-agent baseline, and the effect is detectable on both models.

## 5.2 RQ2: The Lift Is Not from Parallelism

A natural alternative explanation for the RQ1 result is compute scaling: any two-agent configuration might beat one agent simply because two agents explore more. The SILENT baseline is the controlled test of this explanation. It runs two agents in the shared container and on the shared git tree, with auto-commit on, but with the peer-activity render disabled. If parallelism alone drove the lift, SILENT should outperform SINGLE.

It does not. SILENT resolves 157.0 of 266 instances on DeepSeek against 152.0 for SINGLE, and resolves the same number as SINGLE on MiniMax (138.3 of 266); neither difference reaches significance (pooled $\chi^2$=0.82, $p_{\mathrm{McN}} = 0.366$). Paired two one-sided tests for equivalence at a ±5 pp margin confirm the pattern: both strata are statistically equivalent ($p_{\mathrm{TOST}} = 3.12 \times 10^{-4}$ MiniMax; $p_{\mathrm{TOST}} = 0.0173$ DeepSeek), and the pooled analysis across $n = 1596$ paired observations is equivalent with $p_{\mathrm{TOST}} = 4.64 \times 10^{-5}$. A population-averaged

logistic regression gives an odds ratio of 0.96 (95% CI $[0.87, 1.06]$, $p = 0.449$) and a mixed-effects model gives a conditional odds ratio of 0.91 ($[0.78, 1.06]$), neither distinguishable from no effect. Against this null, the pooled McNemar test for PASC versus SILENT is significant at $p = 9.64 \times 10^{-5}$ (Section 5.1). Adding a second agent to the shared workspace, in the absence of the peer-activity render, does not measurably change resolution effectiveness. The lift observed in RQ1 is therefore attributable to the peer-activity feed rather than to the addition of a second agent. Figure 2 provides a qualitative instance of this mechanism: on a SWE-Bench Pro instance where the single-agent baseline and both agents under the SILENT baseline fall into the same architectural error as `agent_0` and submit a wrong fix, the peer-activity feed allows PASC to recover.

## 5.3 RQ3: Shared Workspace Outperforms Federation

Both industry guidance [4, 5] and the closest published multi-agent neighbour, CAID [15], prescribe isolated git worktrees as the safe topology for multi-agent software-engineering agents. RQ3 isolates this single design choice. Holding all other PASC design decisions constant – no central manager, same task end-to-end, identical three-layer peer-activity feed – does the shared-tree topology outperform the isolated-tree alternative?

We evaluated this contrast as a federated configuration: two agents in separate worktrees observing the same peer-activity feed (commits, lifecycle status, output digests) as in the shared setting, with prompts adapted to inform each agent of the federated topology. CAID's other design choices (central manager, task decomposition into different subtasks) are deliberately not adopted, so the comparison isolates the worktree topology decision rather than reproducing CAID. Final patches are derived per-agent; we report both individual-agent submissions (deployable) and an oracle UNION (upper bound).

Under the deployable regime, PASC outperforms each federated agent on both models. On MiniMax, PASC resolves 152.3 of 266 against 140.7 for federated agent_0 and 140.3 for federated agent_1; on DeepSeek, PASC resolves 164.0 against 156.0 for agent_0 and 156.7 for agent_1. Per-stratum stratified McNemar tests (pooled across the three runs within each model, $n$=798 per cell) are significant in all four model-by-agent contrasts: MM vs. agent_0 $\chi^2$=7.80, $p$=$5.22 \times 10^{-3}$; MM vs. agent_1 $\chi^2$=8.42, $p$=$3.72 \times 10^{-3}$; DS vs. agent_0 $\chi^2$=5.54, $p$=0.019; DS vs. agent_1 $\chi^2$=4.65, $p$=0.031. Per-stratum odds ratios cluster tightly between 1.54 and 1.61, and the Breslow-Day test rejects no heterogeneity, licensing pooled inference. The pooled stratified McNemar on $n$=1596 paired observations is $\chi^2$=13.34, $p$=$2.60 \times 10^{-4}$ against agent_0 and $\chi^2$=13.04, $p$=$3.05 \times 10^{-4}$ against agent_1. The two federated agents are themselves statistically indistinguishable within each stratum (all per-run McNemar $p \geq 0.42$), so the contrast does not depend on which federated agent is selected.

Under the oracle regime, FEDERATED reaches 151.7 of 266 on MiniMax and 160.3 on DeepSeek, neither distinguishable from PASC per-stratum (MM $\chi^2$=0.03, $p$=0.865; DS $\chi^2$=1.22, $p$=0.269). The pooled stratified contrast on $n$=1596 is $\chi^2$=0.71, $p$=0.398. The shared-workspace configuration thus matches the federated upper bound on both models even though that bound requires information the deployed system does not have. Within this comparison the outcome tracks the shared-tree topology rather than the mere fact of running two agents on the same task: the shared tree is not surpassed even when the federated alternative is allowed oracle selection, and outperforms it once the alternative is restricted to the selection a deployed system could actually perform. The cost comparison between the two configurations, including selector-mechanism caveats, is reported in Section 5.4.

## 5.4 RQ4: Cost-Effectiveness

Cost figures are reported in Table 1 alongside outcomes.

Two cost facts stand out. First, SINGLE has the lowest cost per pass on both models; this reflects the two- to threefold total spend of the multi-agent configurations and is a genuine trade-off rather than an inefficiency. Second, both PASC and FEDERATED substantially improve cost-per-pass over SILENT: \$0.137 and \$0.137 vs. \$0.158 on DeepSeek-V4-Pro (−13.4%, −13.4%), \$0.160 and \$0.147 vs. \$0.221 on MiniMax-M2.7 (−27.6%, −33.5%). The peer-activity feed is budget-positive regardless of topology: agents waste fewer tokens on redundant exploration when they can see each other's commits and recent outputs.

Between PASC and FEDERATED on a deployable basis, cost-per-pass is identical on DeepSeek-V4-Pro (\$0.137 for both) and slightly higher for PASC on MiniMax-M2.7 (\$0.160 vs. \$0.147, +8.8%). These federated figures already credit the two-agent run with the average resolution rate of its agents; an oracle-selected federated configuration would push the pass count higher (Section 5.3) but is not deployable, since any practical selector – whether an LLM judge, a test-based verifier, an external re-ranker, or another mechanism – adds inference or infrastructure cost not reflected in the table, and offers no guarantee of perfect selection accuracy. PASC's submission is uniquely determined by the shared git state and incurs no such selector overhead. Combined with the outcome contrast of Section 5.3, PASC is effectiveness-dominant against the deployable federated alternative on both models and matches the oracle federated upper bound that requires non-deployable patch selection, at a cost identical on DeepSeek-V4-Pro and modestly higher on MiniMax-M2.7 in exchange for the no-selector deployability property.

## 5.5 RQ5: The Peer-Activity Feed Mitigates Destructive Thrash

Industry guidance against shared-workspace multi-agent configurations rests on a specific failure mode: two agents repeatedly overwrite a contested file, with one agent's edit undoing what the peer has just written [4, 5]. RQ5 asks whether action-space coordination mitigates this empirically, and whether the mitigation is a routing effect (agents stay out of each other's files) or a cooperation effect (agents observe peer edits and do not overwrite them on shared files).

We measure contention at three nested granularities defined in Section 4.5: *co-edit* (broad), *any-destructive* (narrow), and *sed-reversal* (narrowest). Table 2 reports all three on the full $n$=266 corpus under both LLMs.

Routing effect: The peer-activity feed reduces the co-edit rate by 43% on MiniMax (128.3 → 72.7) and 52% on DeepSeek (43.7 → 21.0), both significant under CMH-pooled McNemar (MH-OR 3.67 and 3.43 respectively). Agents that observe which files the peer is working on tend to select different files.

Destructive subset: Within the co-edit subset, destructive-overwrite signatures account for 72% of cases under SILENT on MiniMax (92.7/128.3) and 71% on DeepSeek (31.0/43.7), so co-edit on this corpus typically manifests as actual interference rather than cooperative editing. The feed reduces the any-destructive rate by 45% on MiniMax and 49% on DeepSeek (MH-OR 3.78 and 3.30).

Cooperation effect: Sed-reversal is observed only on MiniMax; DeepSeek produces zero events under either configuration, suggesting that the canonical sed-based thrash signature is partly a model-specific manifestation. Where the pattern is present, the feed nearly eliminates it: 4.0 → 0.3 on MiniMax (12 silent events vs. 1 PASC event total across the three runs), with CMH-pooled MH-OR 12.0 ($p$=$2.28 \times 10^{-3}$). The per-co-edit sed-reversal

**Table 2** Contention diagnostics on the full 266-instance Python subset of SWE-Bench Pro. Counts are 3-run mean flagged instances out of 266. CMH-pooled McNemar across 3 runs: MiniMax co-edit $\chi^2$=96.0, $p<10^{-15}$, MH-OR 3.67; any-destructive $\chi^2$=72.7, $p<10^{-15}$, OR 3.78; sed-reversal $\chi^2$=9.31, $p=2.28\times10^{-3}$, OR 12.0 (12 silent events vs. 1 PASC event total across 3 runs); DeepSeek co-edit $\chi^2$=37.3, $p=1.0\times10^{-9}$, OR 3.43; any-destructive $\chi^2$=24.6, $p=7.0\times10^{-7}$, OR 3.30; sed-reversal undefined (no events in either condition).

| LLM | Signal | Silent | PASC |
|---|---|---|---|
| MiniMax-M2.7 | co-edit | 128.3 | **72.7** |
| | any-destructive | 92.7 | **51.0** |
| | sed-reversal | 4.0 | **0.3** |
| DeepSeek-V4-Pro | co-edit | 43.7 | **21.0** |
| | any-destructive | 31.0 | **15.7** |
| | sed-reversal | 0 | 0 |

rate on MiniMax drops from 3.1% (4.0/128.3) under SILENT to 0.4% (0.3/72.7) under PASC: even when routing fails, the feed prevents agents from targeting peer-written lines. The conditional sample is small, but the direction is consistent with two mitigation effects – routing and cooperation – operating independently.

The peer-activity feed thus reduces contention at all three granularities on both LLMs and largely removes the sed-reversal pattern where it occurs. The mechanism delivering the RQ1 outcome lift also addresses the failure mode that motivates industry guidance against shared workspaces.

## 5.6 RQ6: Preliminary Observations on $N > 2$

We evaluated $N \in \{2, 3, 5\}$ on a 76-instance subset of the SWE-Bench Pro Python corpus under MiniMax-M2.7, repeated across two independent runs. At $n$=76, paired tests detect only effects of roughly ±10 pp, so we report effect directions rather than per-cell significance. Table 3 reports pass rates and contention diagnostics.

Pass rate remains within a ±5 pp band across all three configurations (Cochran's $Q$ non-significant in both runs, $p \geq 0.28$; pairwise McNemar all $p \geq 0.13$). At $n$=76 a sweet-spot or modest degradation of $\sim 5$ pp would be invisible; we therefore read the data as consistent with the coordination layer continuing to operate at higher $N$, while small effects on outcome remain undetectable at this sample size.

The substantive effect of $N$ is on contention. Co-edit rises from 16.8% at $N$=2 to 53.0% at $N$=5, and any-destructive from 10.8% to 46.3% – approximately a three- to four-fold increase in active interference. Two pressure sources explain this trend. First, the probability that two agents touch the same file in the same step grows combinatorially with $N$: for $N$=2 there is a single peer pair, for $N$=3 three, for $N$=5 ten. Second, the peer-activity render must aggregate $N-1$ peers' activity in each layer, so the routing signal each agent receives weakens as $N$ grows even when the per-pair signal strength is constant. Sed-reversal, by contrast, remains rare at all $N$ (0.0%, 2.7%, 3.4%). The cooperation mechanism documented in RQ5 thus continues to suppress targeted-line reversal at higher $N$, even as routing-level interference grows several-fold.

The present coordination layer is calibrated for $N$=2; the routing signal it carries weakens as $N$ grows. At $N > 2$ the system continues to produce successful patches but accumulates routing-level interference several-fold, suggesting that larger agent populations would benefit from an additional coordination mechanism, with a cooperative claim layer the natural candidate (Section 7).

**Table 3** $N \in \{2, 3, 5\}$ comparison on a 76-instance subset under MiniMax-M2.7, averaged across two independent runs. Pass rate differences across $N$ are not statistically detectable (Cochran's $Q$ $p \geq 0.28$ in both runs; pairwise McNemar all $p \geq 0.13$). Contention signatures follow the definitions of Section 4.5; per-run counts are in the replication package.

| Signal | $N$=2 | $N$=3 | $N$=5 |
|---|---|---|---|
| Pass rate (%) | 59.1 | 63.8 | 61.1 |
| Co-edit (%) | 16.8 | 32.2 | 53.0 |
| Any-destructive (%) | 10.8 | 25.6 | 46.3 |
| Sed-reversal (%) | 0.0 | 2.7 | 3.4 |

## 6 Threats to Validity

The evaluation uses greedy decoding (temperature 0) with three independent runs per configuration. The consistency of the lift across MiniMax-M2.7 and DeepSeek-V4-Pro and across all three runs, together with the Breslow-Day rejection of effect heterogeneity and the negligible run-level random-effect variance (ICC 0.4% in the GLMM analysis), supports the robustness of the observed effect.

Generalisation of the empirical claims is bounded by benchmark scope. We chose SWE-Bench Pro precisely for its contamination-resistance properties (Section 4.2); its public Python subset still inherits the structural constraints of long-horizon multi-file Python tasks, and the relative performance of action-space coordination may differ on benchmarks whose tasks are shorter-horizon, single-file, or expressed in languages whose project layout yields a weaker structural signal through the file system. The 76-instance scaling subset of Section 5.6 is a stratified sample from the same pool as the full 266-instance corpus and inherits its scope. For resource reasons, this scaling analysis is restricted to a smaller subset and a single model (MiniMax-M2.7), and its results are intended as scaling observations rather than confirmatory measurements.

Outcome quality is operationalised by SWE-Bench Pro's hidden test suite combining fail-to-pass and pass-to-pass tests, which we adopt as the field-standard proxy for issue resolution; the construct limitations of this proxy carry over from the underlying benchmark. The contention diagnostics of Section 5.5 are constructed from the agents' issued bash commands, with the sed-reversal signal additionally referencing the shared git history to identify peer-written lines; they surface the failure modes that motivate industry guidance against shared workspaces, but are operational measures of interference rather than ground-truth semantic equivalence between peer edits.

The primary inference is the pooled stratified analysis on $n = 1596$, with agreement across McNemar, GEE, and GLMM reducing inferential artifact risk. The SILENT baseline's agents share a git tree and could in principle observe one another through explicit git commands; if this backdoor channel produced coordination, the SILENT $\equiv$ SINGLE equivalence would be harder to obtain, not easier. The $n$=76 scaling subset of Section 5.6 admits detectable effects only above $\pm 10$ pp, and the reported pass-rate invariance across $N \in \{2, 3, 5\}$ should be read with this minimum detectable effect in mind.

The 50-instance pilot corpus used to verify the three-layer feed (Section 3.5) overlaps with the 266-instance evaluation corpus. The pilot involved no algorithmic training and no parameter fitting; its verification targets were operational (regex coverage, injected-block token budget, L2 event shapes) rather than outcome-shaped, and at $n$=50 pass-count differences between consecutive layer additions fall within a 1–3 instance range – below the statistical resolution of any paired test – so no design choice could have been outcome-selected from the pilot.

## 7 Conclusion and Future Work

Homogeneous agents can share a single workspace and a single task without a central manager, an external selector, or a post-hoc merge. What makes this viable is coordination through a structured peer-activity feed over the shared git tree. Under two independently-developed open-weight LLMs, the resulting system resolves more instances than an isolated single-agent baseline, at a lower cost per resolved instance than a two-agent baseline without peer awareness, and with reduced contention on the shared workspace. Without peer awareness, two agents on the shared tree are statistically equivalent to a single agent: the gain comes from the observation, not the second agent. The same feed over isolated worktrees is outperformed under deployable patch selection and attains parity with the shared tree only when granted oracle selection, placing the remainder of the effect in the workspace topology rather than in the feed alone.

For software engineering practice, the implication is that a portion of what an autonomous agent fails to resolve in isolation is recoverable through the addition of a second agent able to observe its work, with the recovery attributable to the observation rather than to the additional agent. Where a single agent proves insufficient on the long-horizon, multi-file tasks that characterise this benchmark, coordination offers a route to extend what a given model resolves, without recourse to a stronger model or a larger step budget. Worktree isolation eliminates concurrent-edit collisions by construction, but substitutes for them the problem of reconciling two patches, whether by selection or by merge. The shared tree instead leaves a single patch, and the peer-activity feed lowers contention across all three signals relative to the SILENT baseline.

Several directions remain open. The present evaluation uses greedy decoding with three independent runs per configuration; while the GLMM analysis suggests that run-level variance contributes little to the method comparison at this scale, a wider sweep – more runs per configuration, alternative inference engines, and non-zero temperatures – would characterise the joint effect of provider-side stochasticity and decoding noise on the coordination lift, particularly on instances near the resolution boundary. The minimal design suffices at $N{=}2$. At $N > 2$ the system continues to produce successful patches but accumulates routing-level interference several-fold (Section 5.6), suggesting that larger agent populations would benefit from an additional coordination mechanism. A natural next step is an L4 cooperative claim layer evaluated as a $\{\text{no-L4}, \text{L4}\} \times \{N{=}3, N{=}5\}$ factorial, isolating its marginal contribution from the agent count. Beyond scaling, evaluating PASC across a wider range of model strengths would test whether the lift remains constant, scales with single-agent strength, or saturates as the single-agent ceiling rises. The coordination mechanism is not specific to MINI-SWE-AGENT; re-evaluating PASC atop richer scaffolds is a natural extension. Finally, the architecture already supports heterogeneity at the system-prompt level: agents can be assigned distinct roles or strategies within the same shared workspace without changes to the coordination layer. A follow-on study pairing heterogeneous models or role-specialised prompts in a single shared tree would extend PASC to combine model diversity [39] with action-space coordination.

## Data Availability Statement

The implementation, per-instance outcome data, analysis scripts, and a `README` for reproducing the headline numbers are available at doi.org/10.5281/zenodo.20276750 and github.com/hasenoz/PASC. The release includes: (i) the implementation of PASC on top of MINI-SWE-AGENT v2.2.6; (ii) the SWE-Bench Pro Python subset configuration files; (iii)

per-instance pass/fail vectors for the four configurations (SINGLE, SILENT, FEDERATED, PASC) on the full 266-instance corpus under both LLMs, and for the $N \in \{2, 3, 5\}$ scaling subset under MiniMax-M2.7, with the 50-instance pilot diagnostics kept separate from the confirmatory data; (iv) the scripts that compute every McNemar, Breslow-Day, GEE, GLMM, and TOST contrast reported in the paper; and (v) the LLM-provider invocation scripts, cost computation, and pricing details. Model weights are not redistributed; reproducing LLM inference requires access to the respective providers' APIs or self-hosted weights.

## Abstract

**Background.** Generating behavioral models like state transition diagrams from natural language requirements presents challenges in requirements analysis and design. Traditional NLP and ML methods struggle to maintain the correct execution flow and structural consistency. Recent advances in LLMs offer new opportunities, though their effectiveness in generating behavioral models, particularly concerning prompting, retrieval, and repair strategies, remains largely unexamined.

**Aims.** This paper evaluates how LLM-based generation strategies (zero-shot, one-shot, few-shot, RAG) affect state transition diagram quality (correctness, completeness, understandability, terminological alignment) and whether iterative repair improves validity.

**Method.** We built a dataset of 80 requirement–diagram pairs from software engineering textbooks. We generated PlantUML code for each requirement using four prompting strategies across four open-source LLMs. To isolate the effect of different knowledge sources, we conducted a RAG analysis study comparing four retrieval corpus configurations (full, examples-only, rules-only, theory-only). We also assessed an iterative repair workflow using automated evaluation. We evaluated syntactic validity via PlantUML validation and structural validity via rule-based analysis, supplementing with human evaluation of quality dimensions. We produced 1,169 PlantUML outputs, of which 120 validated outputs were manually evaluated.

**Results.** Few-shot prompting improved syntactic validity from 28.7% to 93.5% on average over zero-shot. Iterative repair significantly improved structural validity, especially for DeepSeek (from 22.2% to 88.9%), with most repairs succeeding within two iterations. Human evaluation showed understandability was rated higher than correctness, indicating a quality-perception gap.

**Conclusions.** We recommend few-shot prompting with iterative repair for AI-assisted behavioral modeling. Our findings reveal critical trade-offs: retrieval improves syntax but risks hallucination, model architecture matters more than strategy, and automated validation cannot substitute for human correctness assessment. This is the first empirical study systematically evaluating prompting, retrieval, and repair in LLM-based UML state transition diagram generation from natural language.

## 1 Introduction

Requirements engineering bridges stakeholder aspirations and technical software implementation by relying primarily on natural language requirements, which remain widely used due to their flexibility and accessibility for non-technical stakeholders [47]. However, natural language often introduces lexical, syntactic, and semantic ambiguities [43], necessitating rigorous requirements analysis and modeling. Graphical modeling languages like the Unified Modeling Language (UML) [38] provide structured representations of system behavior [32]. UML diagrams are categorized into structural models and behavioral models [1, 45]. Among behavioral models, state transition diagrams are crucial for modeling discrete system states and event-driven transitions. These diagrams are essential in safety-critical applications, such as healthcare, financial processing, embedded systems, and robotics [39], where state logic errors can lead to significant failures. Yet, constructing these diagrams manually is labor-intensive and error-prone, as analysts must infer states, transitions, and guards implicitly embedded in text – a task more challenging than automating structural models [10]. Previous automation attempts, using Natural Language Processing (NLP) or machine learning (ML), failed to achieve the necessary contextual reasoning for global model consistency [61].

Recent advances in large language models (LLMs) enable automation in behavioral software modeling through their ability to process long inputs and capture semantic relationships across requirements [4]. Studies show LLMs effectively support software engineering tasks like code generation and requirements analysis [31, 50, 53, 52, 15, 11, 6, 46, 57]. However, most research has focused on structural UML models, leaving the generation of behavioral models, particularly UML state transition diagrams, underexplored [26, 60].

Behavioral diagrams must preserve global execution semantics [9], including state reachability, transition consistency, branching behavior, and lifecycle correctness [25] across the entire model. Consequently, the challenge lies in not just generating valid diagrams but ensuring they are structurally consistent, behaviorally correct, and comprehensible to practitioners. In practice, generated diagrams often require verification and refinement, making the reliability of AI-assisted modeling contingent on the LLM and the surrounding workflow, which includes prompting strategies, retrieval support, automated validation, and iterative repair. Our study examines how different AI-assisted generation workflows affect the reliability of synthesizing UML state transition diagrams from natural language requirements.

In this paper, we present a dataset and an empirical framework to systematically evaluate LLM-based generation of UML state transition diagrams from natural language requirements. The dataset consists of curated requirement–diagram pairs derived from software engineering textbook sources, including structured requirements and corresponding PlantUML [40] representations. We evaluate multiple open-source LLMs (Meta-Llama-3.1-8B-Instruct [22], DeepSeek-R1-Distill-Qwen-14B [23], Mistral-7B-Instruct [30], and Qwen2.5-7B-Instruct [58]), chosen for their use in recent literature [12, 56, 62], across generation strategies, including structured prompting [55], Retrieval-Augmented Generation (RAG), and an iterative repair workflow for iterative refinement. We introduce diagram-specific metrics such as syntax validity (PlantUML validation), structural validity (rule-based analysis of the diagram detecting orphan states, unreachable states, invalid transitions, etc.), and quality evaluation through human evaluation (correctness, completeness, understandability, and terminological alignment), which enables assessment of the diagrams and workflow. This study investigates the behavior of LLMs in software modeling tasks. While LLMs can generate diagrams from requirements, the impact of different prompting and retrieval strategies on structural

correctness and reliability is unclear. Generating valid state transition diagrams requires identifying states and transitions while ensuring global properties like reachability and consistency. To investigate the effect of generation strategies on structural correctness, we first ask:

**RQ1:** How do LLM-based generation strategies (zero-shot, one-shot, few-shot, RAG) impact the validity (syntactic and structural) of state transition diagrams?

Recent studies suggest that RAG may improve LLM performance by incorporating relevant contextual information; however, its effectiveness in structured diagram generation remains underexplored [54, 18]. To evaluate its impact, we analyze how retrieval augmentation influences syntactic validity and structural validity across different retrieval knowledge-base configurations, including requirement-diagram examples, PlantUML syntax documentation, and theoretical resources on UML state transition diagrams:

**RQ2:** How do different retrieval knowledge base configurations in RAG affect the validity of state transition diagrams?

To explore how repair mechanisms can improve state transition diagrams, we ask,

**RQ3:** How effective are iterative repair workflows in improving the syntactic and structural validity of state transition diagrams?

Beyond structural and syntactic validity, it is important to assess whether generated diagrams accurately represent the intended system behavior and remain understandable to human practitioners. Since the practical usefulness of behavioral models ultimately depends on human interpretation and evaluation, we assess the behavioral quality of generated diagrams through human evaluation across multiple quality dimensions:

**RQ4:** To what extent do UML state transition diagrams generated using different LLM-based strategies satisfy quality dimensions (correctness, completeness, understandability, and terminological alignment)?

The contributions of this work are: (1) a benchmark dataset of 80 requirement–state transition diagram pairs; (2) novel automated metrics for structural validity via rule-based graph analysis; (3) a systematic comparison of prompting, retrieval, and repair strategies for enabling LLMs to function as software modeling assistants; and (4) a human evaluation framework assessing quality dimensions.

## 2 Background and Related Work

### 2.1 Rule-Based and Symbolic NLP Approaches

Early automated software architectural model derivations utilized symbolic NLP techniques like part-of-speech tagging and syntax parsing [59]. ArchE [3] was an early system using predefined architectural reasoning rules for software design. Similarly, frameworks like aToucan [59] applied handcrafted linguistic patterns to extract entities and actions from use case models, mapping them to UML elements. Jahan et al. [28] enhanced rule-based approaches with heuristic mappings for generating sequence diagrams from textual requirements. While effective for structured requirements, these approaches were difficult to generalize across domains. Rule-based systems struggled to capture implicit behavioral dependencies and global execution semantics needed for modeling behaviors in UML state transition diagrams [59, 28, 29]. Consequently, symbolic approaches remained limited to requirement extraction tasks and structural UML models.

## 2.2 Machine Learning for Software Architectural Model Extraction

Later work reframed software model extraction as an ML problem using classification and sequence-labeling techniques [29], which utilized lexical, syntactic, and semantic features to identify software entities and relationships from natural language requirements. However, traditional ML approaches were constrained by the limited availability of large annotated datasets in software engineering [29]. Also, classical ML models often lacked the contextual reasoning capabilities required to preserve behavioral consistency across an entire state transition diagram [29, 37]. Consequently, most prior work focused on extracting structural relationships rather than generating behaviorally consistent UML models.

## 2.3 LLMs in Requirements Engineering and UML Modeling

LLMs have transformed requirements engineering by enabling complex reasoning without extensive manual feature engineering [16, 51]. Studies show LLMs assist in ambiguity detection, requirement refinement, and information extraction from Software Requirements Specifications (SRS) [34]. Frameworks like REQINONE [62] and ReqBrain [24] demonstrate LLMs can convert natural language requirements into structured representations, enhancing clarity and completeness through task-specific tuning. Research also focuses on UML model generation, particularly for structural artifacts like class diagrams [16, 51, 8]. LLMs generally produce higher-quality diagrams when relationships are clearly described [28, 29, 16, 56]. Various approaches aim to enhance AI-assisted software modeling workflows. Cervantes et al. [7] integrate the Attribute-Driven Design (ADD) into LLM interactions for better alignment with expert architectural solutions. Multi-agent systems like NOMAD [19] decompose UML class diagram generation into specialized subtasks for improved modularity. Other studies propose hybrid workflows combining LLM generation with static analysis and verification tools for increased reliability [27]. Despite these advancements, limitations persist. Most studies focus on structural models, leaving behavioral model generation underexplored [16, 51, 8, 12]. Generated diagrams are often evaluated through subjective inspection or syntax correctness, with limited attention to behavioral consistency [51, 37, 27]. Many approaches still rely heavily on manual refinement and expert intervention [51, 34, 7]. Lastly, prior studies lack standardized empirical evaluation frameworks for systematically comparing prompting, retrieval, and repair workflows [29, 16, 51, 12].

## 2.4 Motivation

Existing research shows the potential of LLMs for requirements engineering and structural model generation [16, 51, 62, 24]. However, important gaps remain for behavioral modeling tasks. Prior work focuses on structural UML artifacts like class diagrams [16, 51, 8, 12], whereas behavioral models demand global execution semantics and behavioral consistency across the entire diagram [37, 27]. Moreover, existing approaches rely on manual refinement [51, 34, 7], offer limited automated validation [51, 49, 27], and lack standardized empirical evaluation frameworks for AI-assisted modeling workflows [29, 16, 51, 12]. Additionally, past evaluations treat diagram generation in isolation, rather than as part of a comprehensive software engineering workflow [27, 12], which limits understanding of how workflow components affect the AI-assisted behavioral modeling validity. Motivated by these limitations, this study systematically evaluates prompting strategies, retrieval augmentation, validation-aware repair workflows, and automated and quality evaluation for UML state transition diagram generation from natural language requirements.

# 3 Methodology

We conducted an empirical study to evaluate LLM capability in generating state transition diagrams from natural language requirements. First, we created a ground-truth dataset of requirement-diagram pairs from the literature. Then, we generated diagrams from the requirements using three strategies: prompting, retrieval, and repair. Finally, we evaluated the generated diagrams using automated and human evaluation metrics.

## 3.1 Dataset Preparation

To the best of our knowledge, no existing dataset with requirement-diagram pairs was available as ground truth for state transition diagram generation. Therefore, we constructed a benchmark dataset from 12 software engineering textbooks and UML instructional materials [48, 44, 41, 33, 47, 35, 38, 2, 21, 20, 17, 5]. Textbooks were chosen because they: (A) provide curated examples of system behavior reflecting standard modeling practices; (B) feature clear behavioral logic, essential for reliable ground truth; and (C) are publicly accessible and reproducible, aligning with empirical software engineering standards.

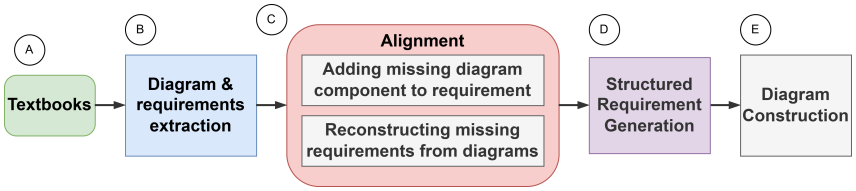

**Figure 1** Behavioral Modeling Dataset Construction Workflow.

For each data point, we extracted the state transition diagram in PNG format and its corresponding natural language requirements in txt format (Figs. 1-A, 1-B). However, many natural language requirements were incomplete or absent, with only diagrams provided in the books. We addressed this inconsistency by updating the requirements to align with the diagrams (Fig. 1-C). In case of absent requirements, we manually reconstructed the requirements from the diagram. In case a diagram introduced states or transitions not present in the requirements, we added the missing requirements. To mitigate bias during manual reconstruction, we enforced two measures: (1) independent dual review – a second researcher independently verified each reconstructed requirement–diagram pair; and (2) consensus resolution – disagreements were resolved through discussion. These steps ensured that reconstructions were driven by diagram evidence rather than subjective assumptions.

After aligning the requirements with the diagrams, we standardized the requirements text of each diagram into a *structured requirements* format (Fig. 1-D). We represented each requirements text as a list of individual requirements so that it is easier and clearer for the LLM to understand when used in prompts. Finally, we generated a corresponding diagram file in PlantUML [40] format (Fig. 1-E). We used PlantUML because its text-based format supports automated syntactic checks, reproducible rendering, and use in software engineering workflows [36]. Each diagram was verified for syntax through PlantUML code compilation and assessed for correctness against the requirements.

Each final data point consists of five artifacts: *raw requirements text* (unstructured natural language), *aligned requirements text* (used when requirements were missing or incomplete), *structured requirements text* (requirements in a standardized list format), *book diagram* (diagram in PNG format from the textbook), and *PlantUML code* (ground truth state transition

diagram in textual UML format). The final dataset contains 80 requirement-diagram pairs. All five artifacts for each case are provided in the companion repository [14]. By addressing data incompleteness, enforcing semantic alignment, and standardizing requirements and diagram representations, our dataset construction process supports reproducible and consistent evaluation of LLM-based state transition diagram generation, following empirical principles of software engineering [42]. We maintained multiple artifact representations to ensure traceability and flexibility for future research.

To map diagrams with varying complexity, we stratified data points by the number of states. Based on the empirical distribution (25th percentile = 6 states, 75th percentile = 14 states), we established three categories: **Simple** ($\leq$ 6 states), **Medium** (7–14 states), and **Complex** ($>$ 14 states). This stratification informed few-shot example selection and facilitated performance analysis. The corpus, spanning diverse domains like ATM/banking, healthcare, and business workflows, includes complex behavioral constructs. Across 80 cases, diagrams frequently exhibit choice nodes, self-transitions, negative/exception guards, temporal triggers, composite states, and entry/do/exit actions.

## 3.2 Diagram Generation Using Different Prompting Strategies

For our empirical exploration of state transition diagram generation, we used four open-source LLMs: Meta-Llama-3.1-8B-Instruct [22], DeepSeek-R1-Distill-Qwen-14B [23], Mistral-7B-Instruct [30], and Qwen2.5-7B-Instruct [58]. These models were chosen for their recent use in software engineering literature [12, 56, 62] and their availability for reproducible research. All generations used a temperature of 0.2, top-p of 0.9, and a maximum of 1,024 output tokens per call, with a 300-second timeout. Models were hosted locally via Ollama. All models used Q4_K_M quantization. From the dataset, we randomly selected 27 data points as the test dataset, using the remaining 53 for prompting and retrieval. For each requirement in the test dataset, we generated PlantUML code using three prompting strategies:

- **Zero-shot**: Only structured requirements text and task instructions were provided.
- **One-shot**: Structured requirements text, task instructions, and one requirement-diagram example (outside the test dataset) were provided.
- **Few-shot**: Structured requirements text, task instructions, and three examples (one from each complexity category: simple, medium, and complex) were provided.

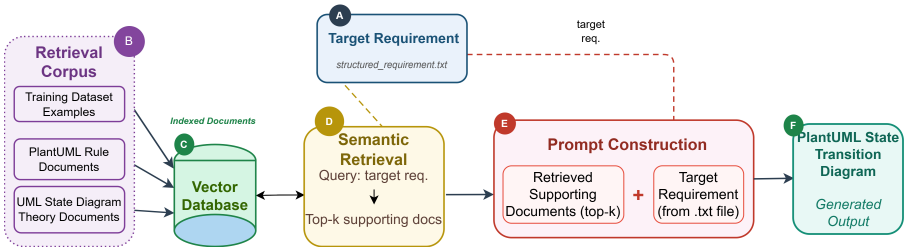

**Figure 2** RAG Construction Workflow: retrieval corpus construction, vector database indexing, semantic retrieval, and prompt augmentation.

## Diagram Generation Using RAG

In addition to different prompting strategies, we explored RAG's capability for state transition diagram generation. Our RAG pipeline, illustrated in Figure 2, enhances prompts with dynamically retrieved contextual information from a retrieval corpus (Fig. 2-B). This

corpus includes: (1) 53 requirement-diagram pairs outside the test dataset, (2) PlantUML documentation, and (3) theoretical resources on UML state transition diagrams. We used ChromaDB with its default all-MiniLM-L6-v2 embedding model and squared L2 distance. Retrieval was source-aware, using up to two rule documents, two theory documents, and three dataset examples. All documents were indexed in a vector database using semantic embeddings (Fig. 2-C). The system performs semantic vector retrieval over these indexed documents (Fig. 2-D), returning the top-ranked supporting documents.

The prompt is constructed using the retrieved supporting documents and the target structured requirements text (Fig. 2-E). Finally, the LLM generates the corresponding PlantUML code for the state transition diagram (Fig. 2-F). The construction details of the retrieval corpus, including document sources and document-level indexing, are documented in the artifact repository [14]. To isolate the contribution of each knowledge source in the retrieval corpus, we conducted an analysis with four RAG configurations: (1) full corpus, (2) examples only, (3) rules only, and (4) theory only. This allowed us to assess how different retrieval knowledge sources affect diagram generation performance.

## 3.3 Diagram Evaluation

Evaluating the quality of generated UML state transition diagrams is inherently multi-faceted. Some aspects can be assessed automatically, such as *syntactic validity*, which checks whether the PlantUML code follows the language grammar, and *structural validity*, which checks whether the diagram follows UML state transition diagram rules. However, other aspects require human judgment, such as whether the diagram correctly captures the intended behavior, is complete with respect to the requirements, is understandable to a human, and uses terminology consistently with the requirements. Therefore, we used a two-stage evaluation process. First, we performed automated evaluation of syntactic and structural validity for every generated diagram. Then, we conducted human evaluation on a subset of diagrams that passed both automated stages. For human evaluation, we used quality dimensions used by other researchers for UML diagram evaluation [56, 36].

### 3.3.1 Automated Evaluation

Automated evaluation consists of two stages: **syntactic validity** and **structural validity**.

Both stages were applied to every generated PlantUML diagram before human assessment. Syntactic validity was assessed using the PlantUML command-line tool with the `plantuml -checkonly` flag. If the code is correct, it completes without errors; if there are violations, the tool reports them. A diagram is syntactically valid only if no errors are reported.

Diagrams that pass this check are evaluated for structural validity using our rule-based graph analyzer. First, the PlantUML code is normalized by removing markdown fences and extracting the @startuml ... @enduml block to retain only the diagram code. This normalized code is parsed into a graph representation, capturing states, transitions, starting points, ending states, and special elements. The analyzer stores each state and records transitions, along with source states, destination states, and transition labels or conditions. It also tracks the initial state, final states, and special elements like choice, fork, join, and history states.

The rule-based graph analyzer checks the graph against the structural rules in Table 1, each implemented as a deterministic check. A diagram passes structural validity only if all rules are satisfied; otherwise, the specific violation types are recorded.

The row (parse_warning) captures syntactically valid PlantUML code with ambiguities or non-standard constructs that hinder reliable graph extraction. The rule-based graph analyzer, detailed in the artifact repository [14], implements rules in Table 1. These rules operationalize

key well-formedness constraints from the UML state-machine specification [38], including requirements for a single initial state, state reachability, and correct pseudostate usage (choice, fork, join). Checks for missing final states and orphan states are also included as practical quality heuristics to catch common LLM omissions and ensure minimal completeness.

**Table 1** Structural validity rules, implementation checks, and violation types.

| Rule | Implementation check | Violation type(s) |
|---|---|---|
| Exactly 1 initial state | initial_targets has length exactly 1. | missing initial state; multiple initial states |
| At least 1 final state | final_states is not empty. | missing final state |
| No duplicate transitions | len(transitions) equals len(set(transitions)). | duplicate transitions |
| No unreachable states | DFS from initial state; all states visited. | unreachable states |
| No orphan states | Every declared state has incoming or outgoing transitions. | orphan states detected |
| Choice node has outgoing transitions | If $\langle\langle choice \rangle\rangle$, at least one outgoing transition exists. | choice node without outgoing transitions |
| Choice node outgoing transitions are guarded | Each outgoing transition from a choice node has a label starting with [. | choice node without guarded outgoing transitions |
| Fork node has $\geq 2$ outgoing branches | If $\langle\langle fork \rangle\rangle$, outgoing_count $\geq 2$. | fork without multiple outgoing branches |
| Join node has $\geq 2$ incoming branches | If $\langle\langle join \rangle\rangle$, incoming_count $\geq 2$. | join without multiple incoming branches |
| History state used with composite state | If $[H]$ or $[H*]$ appears, a composite state must exist. | history state used without composite state |
| Valid graph extraction | Graph extraction completes without parser-level warnings. | parse warning |

### 3.3.2 Human Evaluation

Diagrams that passed both syntactic and structural validation were further assessed through human evaluation. Each selected diagram was independently evaluated by two evaluators with prior academic or industry experience in UML state transition diagrams and software requirements modeling. The evaluators assessed the diagrams using four quality dimensions, following established practices for evaluating generated UML models [56, 36]: **Completeness** (all required states, transitions, events, guards, and initial/final states described in the requirements are present), **Correctness** (diagram's behavior aligns with the intended system behavior in the requirements, without contradictions or invalid flows), **Understandability** (diagram is clear, readable, and free from unnecessary complexity or redundant elements), and **Terminological Alignment** (consistency of state names, transition labels, and behavioral terminology with requirements text is a key indicator for hallucination [36]).

Both evaluators independently rated each criterion using a 5-point Likert scale (1 = very poor, 5 = excellent). Inter-rater agreement was measured using Cohen's Kappa coefficient ($\kappa$). Unlike purely syntactic or structural evaluations, state transition diagram modeling is a subjective modeling task. Multiple valid models can satisfy the same requirements because of differences in abstraction level, state granularity, error handling strategies, or modeling patterns. Therefore, a $\kappa$ value above 0.41, indicating moderate agreement, was

considered acceptable. For correctness, moderate agreement is appropriate as evaluators may legitimately disagree on whether an omission is an error or a deliberate choice. In cases of lower agreement ($\kappa \leq 0.41$) or a Likert scale difference of two or more points, evaluators discussed the diagram to reach a consensus score. The evaluation form and scoring guidelines are provided as "Evaluation Form" in the companion repository [14].

## 3.4 Iterative Repair Workflow

To improve the syntactic and structural validity of generated diagrams, we explored an iterative repair workflow. This workflow was applied using the strongest initial strategy for each LLM, i.e., the strategy that produced the highest number of syntactically and structurally valid diagrams during the initial automated evaluation (see Section 4 for the per-LLM ranking). For each selected strategy, only diagrams from the test dataset that failed automated evaluation entered the iterative repair workflow. The repair process follows the looping mechanism illustrated in Figure 3:

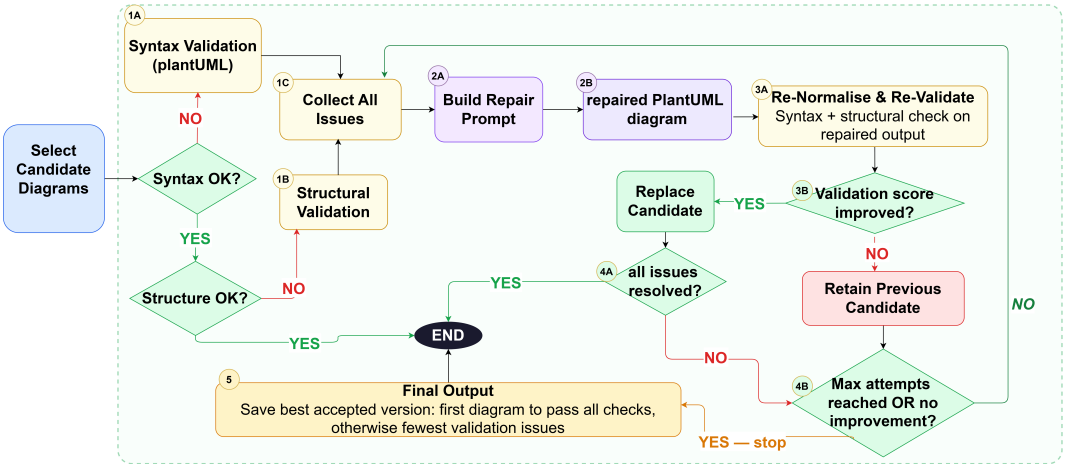

**Figure 3** Validation-aware iterative repair workflow.

**Evaluation and Issue Collection.** The candidate PlantUML diagram is checked using automated evaluation. This includes syntactic validity checking with `plantuml -checkonly` and structural validity checking using the rule-based graph analyzer described in Section 3.3.1. All detected issues, including syntactic error messages and structural violation types from Table 1, are collected into a list.

**LLM Repair.** The same LLM used for generation receives a repair prompt with instructions and identified issues, then generates new PlantUML code.

**Re-evaluation and Acceptance.** The repaired output is normalized and re-evaluated for syntactic and structural validity. If it reduces the recorded validation issues, it replaces the current candidate. Otherwise, the previous version is retained.

**Iteration.** The repair loop is repeated while validity issues remain or repair attempts are still available. The loop stops when the diagram passes all checks or the maximum repair attempt limit is reached.

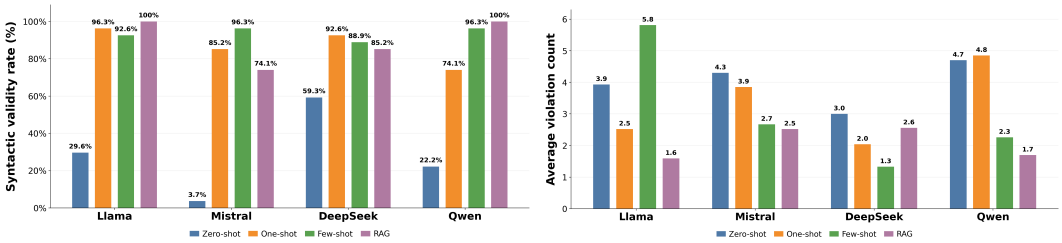
**Final Output.** After the repair loop ends, the best accepted version is saved as the final diagram. This is either the first version that passes all checks or the version with the fewest validity violations.

The repair instruction is deliberately conservative: modify only necessary lines, avoid redesigning the diagram, and refrain from adding unsupported states or transitions. This prevents the LLM from hallucinating large behavioral changes while still allowing targeted corrections. The effectiveness of this workflow is evaluated by comparing the automated and human evaluation scores of the repaired diagrams against their initial counterparts. Results are presented in Section 4. The full repair workflow configuration, including prompt, iteration logging, and acceptance criteria, is available in the artifact repository [14].

# 4 Results & Discussion

## 4.1 RQ1: Impact of Prompting Strategies on Validity

For RQ1, we have evaluated the validity of diagrams generated using zero-shot, one-shot, few-shot, and RAG. Table 2 reports syntactic and structural validity across these strategies.



**Finding 1: PlantUML examples provide essential guidance for syntactic validity.** Zero-shot prompting yields low syntactic validity (lowest–Mistral 3.7%, highest–DeepSeek 59.26 %). Adding an example (one-shot) drastically (58% on average) improves syntactic validity for most models (lowest - Qwen 74.07%, highest - Llama 96.3 %), and few-shot further consolidates this gain by 6.5% on average (lowest - DeepSeek 88.9%, highest - Qwen 96.3%). This shows that LLMs learn the basic syntax of PlantUML (keywords, arrows, brackets) effectively even from a few examples (Table 2, Figure 4a).

**Table 2** Automatic and Human Evaluation Results Across Prompting Strategies and Models (Llama as LM, Mistral as MT, DeepSeek as DS, Qwen as Qwn).

| Evaluation Type | Metric | Zero-shot | | | | One-shot | | | | Few-shot | | | | RAG | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | LM | MT | DS | Qwn | LM | MT | DS | Qwn | LM | MT | DS | Qwn | LM | MT | DS | Qwn |
| Automatic | Syntactic | 29.6% | 3.7% | **59.3%** | 22.2% | **96.3%** | 85.2% | 92.6% | 74.1% | 92.6% | **96.3%** | 88.9% | **96.3%** | **100%** | 74.1% | 85.2% | **100%** |
| | Structural | 0% | 0% | 0% | 0% | **18.5%** | 3.7% | 11.1% | 3.7% | **29.6%** | 7.4% | 22.2% | 11.1% | **22.2%** | 14.8% | 14.8% | 14.8% |
| Human | Complete | – | – | – | – | 4 | **5** | 4 | 3.5 | 3 | 4 | 4 | 4 | 3 | 4.5 | 4.5 | 3 |
| | Correct | – | – | – | – | 4 | **4.5** | 3.5 | 2.5 | 3 | 4 | 4 | 4 | 3 | 4 | **4.5** | 3.5 |
| | Understandability | – | – | – | – | **5** | 4.5 | 3.5 | 2.5 | **5** | 4.5 | **5** | **5** | 4.5 | **5** | **5** | 4.5 |
| | Term. alignment | – | – | – | – | **5** | 3.5 | 4 | 3 | **5** | 4.5 | **5** | **5** | 4.5 | 4 | **5** | 3.5 |

**Finding 2: Structural validity remains low across all prompting strategies.** Even with few-shot or RAG, structural validity never exceeds 29.6% (Llama few-shot). The dominant violation types are missing final states, missing initial states, multiple initial states, and unreachable states (see Table 3). This means the failures are not random; they are systematic omissions of required elements. Consequently, passing syntactic checks gives false confidence; a diagram can be valid PlantUML yet still be structurally invalid.

**Finding 3: Few violation types repeated across many invalid diagrams.** Across all models, the mean number of structural violations per diagram is low. Yet the same violation types (e.g., missing final state) appear repeatedly, suggesting that LLMs nearly understand the rules but consistently miss a few critical elements. Figure 4b shows the average violation counts per model and strategy.

**(a)** Syntactic validity rates. **(b)** Average violation counts.

**Figure 4** Syntactic validity rates across prompting strategies (Figure 4a), and average structural violation counts per diagram (Figure 4b).

**Table 3** Counts of structural violations by model and prompting strategy (Z=zero-shot, O=one-shot, F=few-shot, R=RAG). Models: L=Llama, M=Mistral, D=DeepSeek, Q=Qwen.

| Violation | Llama | | | | Mistral | | | | DeepSeek | | | | Qwen | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Z | O | F | R | Z | O | F | R | Z | O | F | R | Z | O | F | R |
| missing final state | 25 | 10 | 12 | 9 | **27** | 16 | 16 | 11 | **27** | 21 | 16 | 17 | **27** | 18 | 13 | 10 |
| orphan states | **30** | 8 | 6 | 0 | **36** | 22 | 18 | **16** | 16 | 4 | 2 | 14 | **52** | 22 | 6 | 4 |
| unreachable states | 14 | **26** | 20 | 12 | 0 | **28** | 24 | 6 | 0 | 6 | 2 | 6 | 0 | **40** | 34 | 10 |
| invalid choice node | 3 | **105** | 3 | – | 0 | **16** | 2 | 5 | 0 | 0 | 3 | 3 | 0 | 9 | 1 | 1 |
| missing initial state | 8 | 2 | 2 | 0 | **27** | 2 | 3 | 4 | **27** | 13 | 8 | 7 | **27** | 1 | 0 | 0 |
| syntactic error | **19** | 1 | 2 | 0 | **26** | 4 | 1 | 7 | **11** | 2 | 3 | 4 | **21** | 7 | 1 | 0 |
| invalid choice guards | 0 | 9 | 7 | **10** | 0 | **12** | 4 | 7 | 0 | 1 | 3 | **10** | 0 | **27** | 1 | 1 |
| multiple initial states | 6 | 3 | 2 | 6 | 0 | 4 | 3 | **10** | 0 | 5 | 0 | 7 | 0 | 4 | 2 | **13** |
| duplicate transitions | **6** | 1 | 3 | 3 | 0 | 1 | 2 | 2 | 0 | 1 | 2 | 1 | 0 | 3 | 3 | 5 |

**RQ1 Takeaway:** Examples help syntax but not structure. Structural validity stagnates at around 30%, with missing initial/final states as the dominant, recurring errors. As a result, syntax check alone is insufficient for reliability.

## 4.2 RQ2: Retrieval Corpus Analysis – Which Retrieval Source Helps?

To understand how different document sources in the retrieval corpus affect diagram validity, we evaluated RAG using three separate settings: examples only, rules only, and theory only. Table 4 shows structural validity for the RAG configurations; the full-corpus results are shown in Table 2.

**Finding 4: RAG is not uniformly reliable; different sources work best for different models.** For instruction-tuned models (Llama, Qwen), rules-only RAG is most effective (Llama 42.9%, Qwen 50.0%). For Mistral, full RAG (examples + rules + theory) gives the best result (14.8%), while examples-only (4.2%) and rules-only (5.6%) perform poorly. Theory-only RAG is uniformly ineffective (0–5% structural validity). Thus, retrieval corpus design must be model-aware. No single configuration works best for all LLMs.

We identified a failure case demonstrating the unreliability of examples-only RAG. A human evaluator noted that "requirements 3–6 are missing but adding new things." The retrieved example was textually similar but behaviorally different from the target requirement. The generated diagram omitted required states and transitions from the target case and included added ones from the retrieved example, indicating a retrieval-induced hallucination where the model borrowed unsupported behavior from a relevant but different example.

**RQ2 Takeaway:** Reliability of retrieval document source depends on the model. Rules-only helps instruction-tuned models, whereas theory-only performs very poorly. Practitioners must tailor retrieval to the target LLM.

**Table 4** Evaluation Results for RAG Corpus Analysis Settings (Llama as LM, Mistral as MT, DeepSeek as DS, Qwen as Qwn).

| Evaluation Type | Metric | RAG (Only Rules) | | | | RAG (Only Examples) | | | | RAG (Only Theory) | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | LM | MT | DS | Qwn | LM | MT | DS | Qwn | LM | MT | DS | Qwn |
| Automatic | Syntactic | 77.8% | 66.7% | **81.5%** | **81.5%** | **96.3%** | 88.9% | 74.1% | 92.6% | **88.9%** | 25.9% | 63.0% | 81.5% |
| | Structural | 42.9% | 5.6% | 18.2% | **50.0%** | **15.4%** | 4.2% | 10.0% | 12.0% | 4.2% | 0% | 0% | **4.6%** |
| Human | Complete | **5** | 2 | 4.5 | 4 | 3.5 | **5** | **5** | **5** | **5** | – | – | **5** |
| | Correct | 4 | 2 | 4.5 | 4 | 3 | 3 | **5** | 4 | 3 | – | – | **5** |
| | Understandability | **5** | 3 | **5** | **5** | 4.5 | 4 | 4.5 | **5** | **5** | – | – | **5** |
| | Term. alignment | **5** | 4 | **5** | **5** | **5** | **5** | **5** | **5** | **5** | – | – | **5** |

## 4.3 RQ3: Effectiveness of Iterative Repair

To improve invalid diagrams, we explored how iterative repair may increase their structural and syntactic validity. Table 6 presents structural validity outcomes after up to five repair iterations. DeepSeek performed best among all models, achieving 88.89% structural validity after repair, compared to its few-shot baseline of 22.2%. Llama, Qwen, and Mistral also improved, but to a lesser extent (55.6%, 40.7%, and 29.6%, respectively).

**Finding 5: More iterations do not always improve repair.** Most successful repairs occurred within the first two iterations. As shown in Figure 5, DeepSeek made 11 diagrams valid after the first iteration, but only 2 after the fourth iteration. No additional diagram became valid after the fifth iteration. Across all models, the number of newly repaired diagrams drops sharply after the first two iterations. This demonstrates that repair yields limited improvement beyond 2–3 iterations, and excessive repair attempts are not productive.

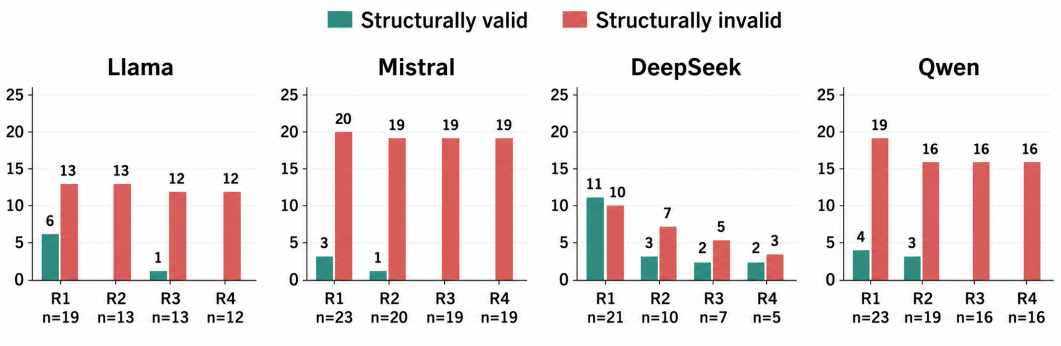


**Figure 5** Repair success per iteration. Most valid diagrams are obtained within the first two iterations; later iterations contribute few or no improvements.

**Finding 6: Repair is effective for diagrams with fewer issues but struggles with many issues.** Diagrams with multiple faults often require more iterations and rarely validate after three attempts. We noted that when violations exceeded two, DeepSeek aggressively attempted fixes, sometimes deleting states and transitions, which removed essential behavioral elements. This indicates that while repairs can manage moderate complexity, overly aggressive corrections may compromise completeness for structural validity.

**Finding 7: Repair success varies by violation type and model.** Table 5 shows that DeepSeek successfully fixes 100% of missing final states, missing initial states, duplicate transitions, orphan states, and invalid choice guards, but fails to address unreachable states (0%). Llama also achieves 100% for missing final states but struggles with other violations, particularly invalid choice guards (0%) and duplicate transitions (0%). Mistral excels at fixing duplicate transitions (100%) but has low success rates for missing final states (27.3%), missing initial states (25.0%), and multiple initial states (20.0%). Qwen is strong on missing final states (90.0%) but performs poorly on multiple initial states (15.4%) and cannot fix invalid choice nodes or guards. These results indicate that some models, like DeepSeek, offer broader repair capabilities, while others are more specialized or limited.

**Table 5** Repair success rates per violation type (percentage of instances fixed).

| Violation Type | DeepSeek | Llama | Mistral | Qwen |
|---|---|---|---|---|
| missing_final_state | 100% (16/16) | 100% (12/12) | 27.3% (3/11) | 90.0% (9/10) |
| missing_initial_state | 100% (8/8) | 50.0% (1/2) | 25.0% (1/4) | – |
| duplicate_transitions | 100% (2/2) | 0% (0/1) | 100% (2/2) | 60.0% (3/5) |
| orphan_states | 100% (1/1) | 66.7% (2/3) | 25.0% (2/8) | 50.0% (1/2) |
| unreachable_states | 0% (0/1) | 60.0% (6/10) | 0% (0/3) | 40.0% (2/5) |
| multiple_initial_states | – | 50.0% (1/2) | 20.0% (2/10) | 15.4% (2/13) |
| invalid_choice_node | – | 40.0% (2/5) | 75.0% (3/4) | 0% (0/1) |
| invalid_choice_guards | 100% (1/1) | 0% (0/1) | 33.3% (1/3) | 0% (0/1) |

**RQ3 Takeaway:** Repair could not improve diagrams with a high number of issues, even after many iterations. This suggests that repair should be used as a targeted tool for small corrections, not as a brute-force method to rewrite entire diagrams. DeepSeek's reasoning capability made it the strongest repair performer. However, even DeepSeek struggled when the initial diagram contained a high number of issues.

**Table 6** Evaluation Results for Iterative Repair.

| Evaluation Type | Metric | Repair | | | |
|---|---|---|---|---|---|
| | | Llama | Mistral | DeepSeek | Qwen |
| Automatic | Syntactic | **96.30%, n=26** | 74.07%, n=20 | 92.59%, n=25 | 92.59%, n=25 |
| | Structural | 55.56%, n=15 | 29.63%, n=8 | **88.89%, n=24** | 40.74%, n=11 |
| Human | Completeness | **4** | **4** | **4** | **4** |
| | Correctness | 4 | **5** | 4 | 4 |
| | Understandability | **5** | **5** | **5** | 3 |
| | Terminological alignment | 4 | **5** | **5** | 4 |

## 4.4 RQ4: Human Evaluation of Quality Dimensions

To evaluate the quality of valid generated diagrams, we collected human evaluation scores for correctness, completeness, understandability, and terminological alignment.

**Finding 8: Even incorrect diagrams can be understandable – a concerning disconnect.** For few-shot prompting, median understandability scores are 5 (excellent) for Llama, DeepSeek, and Qwen, while correctness scores are only 3–4. LLMs produce visually clear, readable diagrams (logical state names, clean layout) that *look* correct on the surface, but often miss

critical behavior. Practitioners may be misled by these aesthetically pleasing but incorrect diagrams. Consider the following real critique from our human evaluation of a microwave oven state diagram:

> "Some confusion regarding transitions... after "CheckExpiry", we should notify the user, but the diagram lacks this. The core user choice requirement is completely ignored ...; instead it makes up "get amount". No transition for when cooking finishes naturally ..."

This example shows that a diagram can be clear but still miss behavioral flows, overlook key requirements, and include incorrect transitions. Such cases highlight a gap between perceived and actual quality in LLM-generated state machines.

**Finding 9: Few-shot prompting yields better behavioral quality than RAG.** Despite RAG achieving higher syntactic validity, human-rated correctness and completeness are consistently higher for few-shot than for RAG. Fixed examples provide more reliable behavioral guidance than retrieved examples, which can introduce irrelevant or misleading content.

**RQ4 Takeaway:** Few-shot prompting is more reliable than retrieval for diagram quality. However, visually understandable diagrams may still be incorrect. This indicates that LLM-based diagram generation requires careful human oversight.

## 4.5 Cross-RQ Findings

**Finding 10: Syntactic validity is necessary but insufficient for behavioral modeling.** A diagram can be perfectly valid PlantUML (e.g., Llama RAG 100% syntax) yet fail all structural rules (only 22% structural validity) (as shown in Table 2). Syntax checks give a false sense of security.

**Finding 11: Structural validity does not guarantee human-perceived correctness.** We observed cases where diagrams passed all structural rules, such as having a single initial state and no unreachable states, but still received low human correctness scores (2–3) because they missed critical transitions. This shows that automated validation alone is not sufficient and must be supported by human oversight.

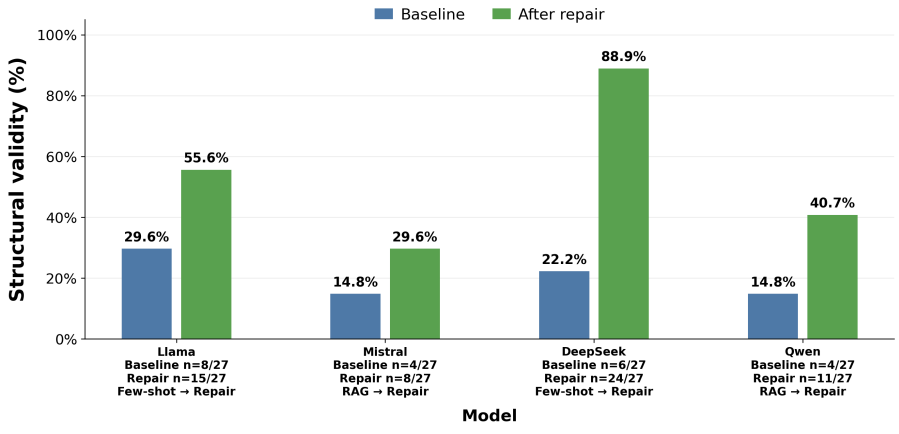

**Figure 6** Baseline structural validity (best strategy) vs. final validity after repair. DeepSeek shows the largest gain (22.2% → 88.9%); all models benefit substantially from iterative repair.

**Finding 12: Repair is the best technique – improves both automated and human evaluation.** DeepSeek achieved the highest repair success rate for structural validity (88.9%), followed by Llama (55.6%), Qwen (40.7%), and Mistral (29.6%) (Figure 6). This success is mainly due to targeted feedback: the LLM receives precise structural violation messages (e.g., missing_final_state) and is instructed to modify only necessary lines. Importantly, diagrams that passed structural validation after repair were also highly rated by human evaluators across all quality dimensions, a trend consistent in both few-shot and RAG-based repair settings. Fixing structural issues consequently improved the behavioral quality of the diagrams. This suggests that automated repair success is a strong indicator of human-perceived quality. Therefore, repair is not only the most effective strategy for structural validity, but also the most trustworthy strategy for practical use.

**Finding 13: Repair effectiveness is model-dependent.** Models that struggle with initial structural validity (Mistral, Qwen) also see lower repair success (29.6%, 40.7%) compared to DeepSeek (88.9%). The repair loop cannot compensate for fundamental limitations in a model's ability to understand state transition diagram semantics.

## 4.6 Practical Recommendations for AI-Assisted Behavioral Modeling

Based on our findings, we provide three recommendations for practitioners using LLMs for state transition diagram generation. **(1) Prioritize few-shot prompting.** Use 3–4 diverse examples (simple, medium, complex) that are structurally correct and domain-aligned. Few-shot prompting improves semantic fidelity and reduces retrieval-induced hallucinations. **(2) Integrate iterative repair.** Most diagrams (70–80%) will have structural violations. Implement an automated repair loop with 2–3 iterations; additional iterations show diminishing returns. This significantly improves structural validity (e.g., DeepSeek from 22.2% to 88.9%). **(3) Incorporate human review for final assessment.** Automated checks alone cannot verify behavioral semantics or completeness. Use automated validation as a filter, followed by domain expert review of a small subset to catch semantic mismatches. Human review is mandatory for safety-critical systems.

In ambiguous industrial settings, adapt the workflow: (1) **Pre-generation clarification:** Prompt the LLM to list open behavioral questions (e.g., missing error handlers) for analyst resolution before generation. (2) **Project-specific retrieval:** Replace textbook examples with the organization's approved state machines and domain glossaries for consistency. (3) **Failure-as-feedback:** If structural repair fails, use the violation log as a structured audit checklist for stakeholders, rather than forcing the LLM to hallucinate missing behavior. This redefines the LLM as a requirements auditor, not an autonomous generator.

## 4.7 Limitations and Future Work

Despite the comprehensive evaluation, several limitations remain. The dataset, while systematically constructed, consists of textbook examples that may not capture industrial complexity (concurrency, timing constraints, hierarchical states). The repair loop was capped at 5 iterations based on pilot experiments showing no improvements beyond this point, but more iterations might benefit certain cases. Human evaluation, while rigorous, involved only two evaluators; larger-scale validation with diverse practitioners would strengthen generalization. Our findings are limited to the four open-source models evaluated (7B–14B parameters) and may not generalize to larger, newer, or commercial models (e.g., GPT-4, Claude) that possess greater reasoning capacity. Additionally, each configuration was executed once due

to the combinatorial scale of our design (27 test cases × 4 models × 4 prompting strategies × 4 RAG ablations + repair evaluations) and the cost of human assessment; LLM generation is inherently non-deterministic, and output variability across runs remains uncharacterized.

Future work should explore: (a) hierarchical state transition diagrams and orthogonal regions, which introduce additional validation complexity; (b) few-shot example selection optimization (currently random, but semantic similarity-based selection may improve performance); (c) using LLMs as judges to automate or augment human evaluation of diagram quality; (d) providing structural rules themselves as part of the RAG context to assess whether explicit rule injection improves structural validity; and (e) analyzing oscillation and regression during repair – specifically, tracking per-iteration errors, fixes, and fix patterns to understand why some models regress and how to design more stable repair prompts; and (f) systematic characterization of output variability across multiple runs to assess whether our findings hold stably and whether certain strategies yield more consistent outputs.

## 5 Threats to Validity

The research identifies several potential threats to the validity of the findings.

**Construct validity:** While PlantUML syntactic and structural validity offer a quantitative measure of diagram correctness, they may not capture a diagram's practical usefulness in development workflows. Human evaluation metrics (correctness, completeness, understandability, terminology alignment) complement automated metrics for a more comprehensive quality assessment.

**Internal validity:** The main internal threat is variability in LLM responses based on prompt construction. A standardized prompt template was utilized for all experiments. The non-deterministic nature of autoregressive generation can produce outliers; we addressed this by running each generation once per configuration and focusing on systematic patterns across 27 test cases per condition.

**External validity:** External validity is limited due to the use of textbook case studies, which may not fully represent the complexities found in actual industrial documents. Textbook examples offer a controlled baseline, but real-world requirements are often messy and incomplete. Future work should evaluate workflows on industrial requirements.

**Human evaluator bias:** Human evaluation introduces subjectivity, especially in assessing behavioral correctness and understandability. To mitigate this, diagrams were independently evaluated by two UML-experienced evaluators using predefined criteria and scoring guidelines. Inter-rater agreement was measured with Cohen's Kappa coefficient ($\kappa = 0.44$–$0.68$ across dimensions), with disagreements resolved through consensus.

**Reliability of reconstructed requirements:** Some requirements were partially reconstructed from textbook diagrams due to missing specifications. Despite manual verification, this reconstruction may introduce implicit assumptions.

**Generality of validation heuristics:** Some structural validation rules are based on practical modeling heuristics rather than strict UML standards. While these heuristics enhance automated diagram quality assessment, alternative interpretations may exist. The full rule set is available in the artifact repository [14] for replication and adaptation.

**LLM training data contamination:** A significant threat is that the evaluated LLMs may have been pre-trained on the same textbooks and UML resources as our dataset. If models "saw" the case study diagrams during training, their performance could be inflated due to memorization. While we cannot rule out contamination, we note: (a) we used structured requirement reformulations differing from original textbook wording; (b) we required

generation in PlantUML syntax, unlikely to appear verbatim in training corpora; and (c) the poor zero-shot performance across all models (0% structural validity) suggests that memorization alone is insufficient, as models still fail without explicit prompting. Future work should validate findings on newly created, non-public requirements.

## 6 Conclusion

This work contributes one of the first validation-aware empirical frameworks for studying AI-assisted behavioral model generation, combining automated structural verification, retrieval-based prompting, iterative repair, and human-centered evaluation. Using a novel dataset of 80 requirement–state transition diagram pairs derived from software engineering textbooks, we evaluated four open-source LLMs across zero-shot, one-shot, few-shot, RAG, and repair workflows. Our key findings are: (1) Few-shot prompting significantly outperforms zero-shot and one-shot for syntactic validity, but structural validity remains low (30%) across all models, with missing final and initial states as common errors. Passing a syntax check alone gives false confidence. (2) RAG's effectiveness is model-dependent. Rules-only RAG works best for instruction-tuned models (Llama, Qwen), while theory-only RAG is uniformly ineffective. RAG can induce hallucination by copying irrelevant content from retrieved examples. (3) Iterative repair dramatically improves structural validity, especially for DeepSeek (from 22.2% to 88.9%), with most repairs succeeding within the first two iterations. Repair is most effective for small, localized errors; diagrams with many violations rarely become valid. Repair success also varies by violation type – DeepSeek fixes missing final states and missing initial states perfectly but cannot handle unreachable states. (4) Human evaluation shows a disconnect: diagrams are rated high for understandability (often 5/5) but low for correctness (3–4/5). Few-shot prompting aligns better with requirements than RAG, and diagrams passing automated validation after repair receive high human ratings, making repair the most reliable strategy. Taken together, these results demonstrate that reliable AI-assisted behavioral modeling is achievable not through larger prompts or more retrieval, but through targeted, validation-aware workflows that combine few-shot examples with iterative repair. Practitioners can adopt our validation rules and repair prompts to integrate LLMs into their modeling processes as collaborative assistants rather than autonomous generators.

# FDRRestTest: Feedback-Driven Logical Testing for REST APIs

**Yutong Huo**
China University of Geosciences, Wuhan, China

**Dongcheng Li**[1]
Cal Poly Humboldt, Arcata, CA, USA

## Abstract

**Background.** REST APIs have become the primary interaction interface for modern software systems, making automated black-box API testing increasingly important. However, existing testing techniques still face three major limitations: over-reliance on dependencies extracted from static specifications, failure to fully utilise failed requests as feedback, and an overemphasis on crash-oriented verification, resulting in insufficient exploration of non-crash-prone logical defects.

**Aims.** We design, implement and evaluate a feedback-driven black-box testing framework that turns runtime feedback from a passive outcome into an active control signal, maximising logical-defect yield within practical budgets.

**Method.** We propose FDRRestTest, which integrates OpenAPI-based static semantic bootstrapping, runtime dependency evolution, a 7-category failure diagnosis and repair loop, a multi-dimensional logical oracle engine and a budget-aware utility scheduler in one closed loop. Under a fixed 600-second time budget, we evaluated FDRRestTest against five state-of-the-art baselines (RESTler, EvoMaster, Morest, ARAT-RL, AutoRestTest) on 12 real-world REST services along five protocols: fixed-time cross-tool comparison, fixed-request cross-tool replication, ablation across three dependency profiles, single-host budget sensitivity, and per-service comparison; significance via two-sided paired Wilcoxon signed-rank tests with Holm-Bonferroni correction, magnitude via standardised paired effect sizes.

**Results.** FDRRestTest improves fault-revealing efficiency (FRE) by up to 6.3% over the strongest baseline, AutoRestTest (0.9878 vs. 0.9294; an upper estimate, as AutoRestTest's FRE is a post-hoc lower bound), while issuing 6.3–11.8× fewer requests than AutoRestTest across the 12 services (8.3× on Features Service). The +12.2% logical-yield advantage holds on every one of the 12 services (+7.0%–+16.5%, geometric mean +12.4%), and the *FRE* gain is consistent across all 12 in per-service means and statistically significant ($p_{\text{adj}} < .005$, $d_z = 3.73$ on logical bug yield, *LBY*). An ablation across six subjects spanning three dependency profiles confirms no single component accounts for the advantage, the oracle contributing most – removing it drops *FRE* below the strongest baseline on all six – while a Pareto-scheduling variant is 4.4% below the weighted utility on the most state-rich host. A manual confirmation study ($N = 120$, stratified over the 236 deduplicated findings of all six tools, 30 per oracle category) confirms 96/120 (80%) as true defects (Cohen's $\kappa = 0.78$), supporting the oracle-finding interpretation of the *LBY* gain.

**Conclusions.** Black-box REST API testing heavily benefits from a tightly coupled closed feedback loop. Within this loop, runtime dependency evolution, failure repair, logical-defect-aware validation, and budget-aware scheduling are each necessary; quantifying their interaction would require multi-component removals, which we leave to future work.

## 1 Introduction

REST APIs serve as the backbone of modern cloud services, microservice platforms, and Internetware systems [10]. Unlike conventional input-output testing it is intrinsically stateful: many operations are meaningful only after prior requests have created or updated the resources they need, so automation must solve dependency inference, sequence orchestration, feedback interpretation, and response validation as well as input generation.

Recent black-box REST API testing has evolved along five paradigms: stateful fuzzing [4], search-based generation [2], dependency-graph-guided exploration [24], learning-based prioritisation [17, 20, 18], and logical-oracle validation [37]; see [11, 38] for surveys.

Three limitations remain. **First**, dependency knowledge is still largely static or only weakly updated at runtime, although many dependencies become visible only after execution (e.g., a returned identifier reusable by another endpoint under a different field name). **Second**, failed requests are treated as penalties or pruning signals, although many carry repairable information: missing dependencies, malformed fields, stale states, inconsistent parameter combinations. **Third**, validation remains crash-centric and misses non-crash logical defects.

We address these by proposing FDRRestTest, a feedback-driven black-box framework for logical-defect-aware REST API exploration. The core idea is to elevate runtime feedback from a passive outcome into an active control signal: FDRRestTest builds a semantic dependency graph from the OpenAPI specification, updates it incrementally during execution, diagnoses and repairs failed requests, validates responses with multi-dimensional oracles, and allocates budget through a utility-based scheduler.

FDRRestTest differs from the closest prior systems [24, 20, 37] along concrete axes rather than generic "integration": Morest updates a model graph from runtime responses but its oracle layer remains crash-oriented; AutoRestTest couples semantic graphs with large language model (LLM)-driven values but treats failures as negative reinforcement; LogiAgent provides scenario-aware logical testing but lacks runtime dependency evolution and budget-aware scheduling (Section 6). FDRRestTest is the only system driving all four–dependency refinement, failure repair, multi-dimensional logical oracles, budget-aware scheduling–from one runtime feedback loop. The ablation is the empirical counterpart of that claim: over six subjects spanning three dependency profiles, removing the oracle drops fault-revealing efficiency below the strongest baseline on all six, the exploration-side removals on three to six (Subsubsection 4.3.2), a pattern that fits mutual reinforcement inside the loop – though single-removal designs establish necessity without quantifying interaction.

The contributions are: (i) a closed-loop black-box framework integrating dynamic dependency evolution, failure repair, logical validation, and budget-aware scheduling; (ii) a runtime-evolving dependency graph beyond static OpenAPI analysis; (iii) a feedback-driven diagnosis-and-repair loop with an explicit 7-category failure taxonomy and prioritised repair actions; (iv) a multi-dimensional oracle framework; and (v) an empirical study across five protocols (fixed-time cross-tool comparison, fixed-request cross-tool replication, ablation, budget sensitivity, per-service analysis) on 12 services, with service-level Wilcoxon tests, Holm-Bonferroni adjustment, standardised paired effect sizes, and a complete artefact for reproducibility.

# 2 Background and Motivation

Existing dependency-aware approaches [4, 24, 17, 20] infer producer-consumer relations from the specification, but such relations are often incomplete or noisy when behaviour depends on runtime state or undocumented rules [25, 1]: *semantic mismatch* (`name` vs. `productName`), *specification incompleteness* (an optional parameter is in practice required), and *runtime-emergent dependencies*. A static-only strategy therefore misses operation chains or wastes budget on dynamically failing sequences. Validation is likewise crash-oriented, yet a 2xx is not semantic correctness: a delete may report success while the resource remains queryable, or a declared constraint may be silently accepted. LogiAgent [37] highlighted this gap, but logical-defect-aware testing remains under-integrated into closed-loop, budget-aware workflows.

**Motivating example.** In a feature-management service, the product-creation endpoint returns a generated identifier that a later configuration endpoint requires, but the specification does not document the relation, so a static model cannot connect the two; the resulting `400` or `404` carries diagnostic clues–wrong identifier variant, stale resource, missing prerequisite–that a "dead-end" strategy discards. Effective testing therefore requires runtime-evolving dependency knowledge, failure-aware diagnosis and repair, and logical-defect-aware validation–objectives O1–O3 of Section 3.

# 3 Method

## 3.1 Overview, Design Objectives, and Architecture

FDRRestTest is designed around four objectives from Section 2: **O1 runtime dependency discovery** – find inter-operation relations beyond what OpenAPI specifies; **O2 feedback reutilisation** – convert failed requests into diagnosis and repair signals rather than penalties; **O3 logical-defect-aware validation** – detect non-crash anomalies such as state inconsistency and cross-endpoint contradictions; **O4 budget-efficient exploration** – maximise fault-revealing utility under fixed budgets rather than request volume. Each maps to one term of the scheduler utility (Subsection 3.7): O1→*Reachability* (Subsection 3.4), O2→*Repairability* (Subsection 3.5), O3→*DefectYield* (Subsection 3.6), O4→*Cost*.

Figure 1 shows the five-layer workflow; runtime responses feed three analyses–dependency evolution, repair, oracle validation–whose outputs update both the graph and the scheduler in a closed loop.

## 3.2 Problem Formulation

Given the operations $\mathcal{O}$ of a specification, a test sequence is an ordered list of executable requests; the goal is to maximise fault-revealing utility under a fixed budget $B$.

**Terminology.** Four terms are used consistently: a *failure* is an observable deviation at the API boundary for one request; a *fault* is the cause inside the implementation, inferred only through failures; an *anomaly* is a raw pre-deduplication oracle signal; a *defect finding* is a deduplicated anomaly, and becomes a *confirmed defect* only after the manual validation of Subsubsection 4.3.3. Outcomes are of three types: **crash failure signals** (typically unexpected 5xx), **logical anomaly signals** (structural, state, consistency, or constraint violations), and **repairable failures**. *Logical Bug Yield* and *Fault-Revealing Efficiency* count oracle-triggering signals in their numerators, so they measure signal density per request rather than confirmed faults.

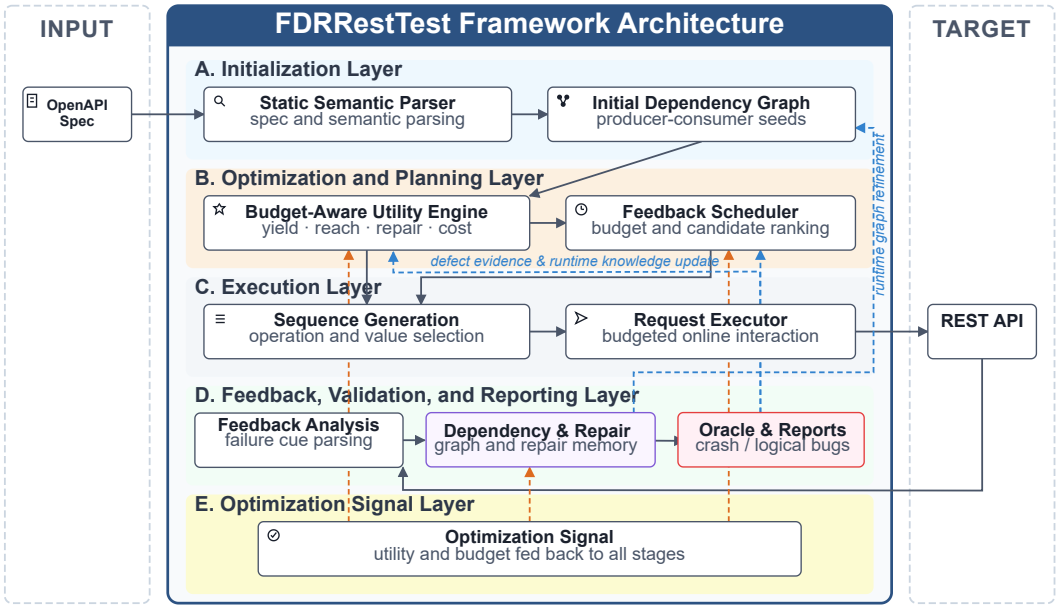

**Figure 1** Overall architecture of FDRRestTest; the five layers A–E are labelled in the figure.

## 3.3 Static Semantic Bootstrapping

FDRRestTest parses the OpenAPI specification (operations, parameters, response schemas and examples, descriptions, field names) into an initial weighted semantic dependency graph $G_0 = (V, E_0, W_0)$: nodes are operations, edges potential producer-consumer relations, and $W_0$ holds confidence weights from lexical similarity (threshold $\tau_{\text{lex}}$), type compatibility, parameter-response matching and schema-level field overlap. The graph is not ground truth but a prior, continuously corrected by runtime evidence.

## 3.4 Dynamic Dependency Evolution

A static graph cannot capture runtime semantics, so FDRRestTest updates it after each execution; at step $t$ it is $G_t = (V, E_t, W_t)$. Reusable response values are matched against other operations' inputs by field-name and description similarity, type and value-shape compatibility, and the success history of similar reuses; a new relation inserts an edge, and an exercised edge is re-weighted by its downstream outcome:

$$W_{t+1}(e) = \begin{cases} \min(1, W_t(e) + \alpha_{\text{r}}), & \text{if reuse succeeds,} \\ \max(w_{\min}, W_t(e) - \beta_{\text{p}}), & \text{if reuse fails.} \end{cases} \tag{1}$$

Here $\alpha_{\text{r}}$, $\beta_{\text{p}}$, and $w_{\min}$ are the reward, penalty, and confidence-floor factors; together with $\tau_{\text{lex}}$, the scheduler weights $\lambda_1 - \lambda_4$, and the repair-memory capacity $|\mathcal{M}|$, all nine hyperparameters are fixed across the 12 subjects after pilot tuning on the held-out *Scout API* (Subsubsection 4.2.4). The graph thus shifts from static speculation toward execution-grounded knowledge.

## 3.5 Failure Diagnosis and Repair Loop

FDRRestTest treats failures as diagnosis opportunities. The 7-category taxonomy: (1) *missing dependency*; (2) *malformed parameter*; (3) *unsatisfied constraint*; (4) *stale state*; (5) *auth issue* (typically 401/403); (6) *unsupported method/route* (typically 405/404); (7) *server-side or undiagnosable failure* (5xx, and any failure for which (1)–(6) lack sufficient evidence).

**Taxonomy derivation.** The taxonomy was not designed a priori: we split the response space by status-code semantics (4xx vs. 5xx), then refined the 4xx side by open-coding failure traces from pilot runs on the held-out *Scout API*, grouping failures that admit the same corrective action and iterating until no pilot failure fell outside the categories. Each category is therefore tied to a distinct repair repertoire rather than to a status code: a `404` may be diagnosed as *missing dependency*, *stale state*, or *unsupported route*, and the three trigger different repairs.

**Diagnosis and ambiguity handling.** Diagnosis is rule-based first-match over a fixed order (1)→(7) on three evidence sources: the status code, response-body keywords (e.g., `"not found"`, `"expired"`, validator-echoed constraint names), and dependency-graph context (whether a producer edge for the failing parameter exists and was recently exercised). Insufficient evidence conservatively assigns category (7), which triggers no repair, trading repair-loop recall for avoiding wasted retries on undiagnosable failures.

**Repair-action selection.** For categories 1–6 we apply a prioritised repair repertoire: (a) value substitution from runtime memory ($\leq$2 retries); (b) prerequisite insertion (1 retry); (c) sequence reordering (1 retry); (d) resource reconstruction (1 retry); (e) constrained mutation within schema bounds; (f) negative-context avoidance (record failing combinations in a negative-context cache $\mathcal{K}$). Actions are attempted in order, filtered by a category-action compatibility map (e.g., *missing dependency* admits (b)–(d), *malformed parameter* (a) and (e)); the first successful retry ends the episode, and the per-action caps bound repair overhead per failure. A first-in-first-out (FIFO) repair memory $\mathcal{M}$ (Subsubsection 4.2.4) stores recent failures, categories and successful corrections for cross-request reuse; the executor records the diagnosed category, attempted actions, and outcome for every failure.

**Taxonomy validation.** Over the 12 subjects (324,868 diagnosed failures), category (7), the fallback that triggers no repair, absorbs 71.2%: the rules send every 5xx and quota rejection there unconditionally, so its share is bounded below by their volume, which this measurement meets exactly (231,214 of 324,868) – no 4xx needed the fallback. The six repairable categories share the remaining 28.8%; their within-subset shares, success rates and per-action tallies are in the replication package. Success rates order as the design predicts: the two categories admitting a deterministic correction lead (*auth issue* 69.6%, *missing dependency* 61.9%), those needing a search over values or states follow (55.4% to 44.3%), and *unsupported method/route* succeeds only 14.8%, as most such failures reflect an operation the service does not expose. The taxonomy is thus validated twice: every category is populated at a non-trivial rate, and the categories separate failures by corrective action, not by status code.

## 3.6 Multi-Dimensional Oracle Engine

A 5xx-only oracle is insufficient for logical testing; FDRRestTest uses five oracles (Table 4 breaks down the four non-crash families; the 7-category repair taxonomy of Subsection 3.5 is a different partition of the same evidence: it characterises *failures* triggering repair, not responses): **Crash** – unexpected 5xx; **Structure** – response-body schema conformance (illustrative: `GET /products/{id}` returning `200` without required `createdAt`); **Constraint** – response consistent with request constraints (illustrative: `"code":"xxxxx"` accepted despite `maxLength: 4`); **State** – lifecycle anomalies, recorded against the write, not the read that exposed it (the one exception is `stale_read_after_write`, recorded against the read, which names the preceding write); **Consistency** – cross-endpoint mismatch (list returns `name="A"` for id 42, detail returns `name="B"`).

Each oracle produces a defect signal with contextual evidence. Signals are deduplicated by ⟨endpoint, oracle type, semantic fingerprint⟩, where the fingerprint is a normalised hash of the response structure skeleton (key names with type tags), the violated constraint identifier (e.g., `type@offset`; the artefact enumerates the identifiers it uses), and the failing oracle predicate; equivalent failures triggered by different values collapse into one entry, while different failure shapes stay apart. Deduplication is applied uniformly to the logs of all five baselines, which we re-evaluate with the shared harness, while FDRRestTest– whose oracle layer is the contribution under study – is reported with its own deduplication (Subsubsection 4.2.3).

## 3.7 Budget-Aware Utility-Based Test Scheduling

The framework prioritises future exploration with a utility function over several objectives:

$$U(s) = \lambda_1 \cdot \text{DefectYield}(s) + \lambda_2 \cdot \text{Reachability}(s) + \lambda_3 \cdot \text{Repairability}(s) - \lambda_4 \cdot \text{Cost}(s), \quad (2)$$

where $\lambda_1, \lambda_2, \lambda_3, \lambda_4$ are tunable non-negative weights fixed across all experimental settings after pilot tuning on a held-out service; values are reported in Subsubsection 4.2.4. **DefectYield** rewards sequences that previously exposed crash or logical signals; **Reachability** favours yet-unreached or under-exercised operations; **Repairability** prioritises paths whose failures appear recoverable, by repair-memory hit rate. **Cost** penalises high-overhead sequences (length above running median), repeated invalid trials (first request matching the negative-context cache), and low-yield repetitions (zero DefectYield over the last $w = 20$ requests); the three sub-terms are equally weighted, normalised to $[0, 1]$ and scaled by $\lambda_4$.

**Why weighted scalarisation rather than Pareto-based scheduling.** The scheduler optimises multiple, potentially conflicting factors through a single weighted utility, i.e., a linear scalarisation, not a Pareto-front search. This is a deliberate trade-off: the decision recurs at every loop iteration on a changing candidate set, and maintaining a non-dominated front at that frequency competes for budget with exploration itself. Because a fixed weight vector selects one point on the trade-off surface, we test the decision empirically: a **Pareto** variant replacing the weighted utility with non-dominated sorting over the four factors (crowding distance breaking ties), every other module unchanged, is a sixth ablation variant on the single ablation host, quantified in Table 3; weight sensitivity is in Section 5.

The five components integrate into a single loop: the scheduler selects the next target from the current graph, repair memory and negative-context cache $(G_t, \mathcal{M}, \mathcal{K})$; a dependency-aware sequence is planned, instantiated, and executed; responses update the graph and store, trigger diagnosis and repair, and are evaluated by the oracles with fingerprint deduplication; the utility and remaining budget are then updated.

FDRRestTest comprises seven cooperating modules (parser, graph manager, scheduler/-planner, executor, repair engine, oracle engine, dedup/reporting); request- and sequence-level traces capture payloads, responses, diagnosed categories, repair attempts and oracle results, and feed the post-hoc dedup pipeline (all in the artefact).

**Implementation basis.** FDRRestTest is built on the open-source AutoRestTest codebase [20], from which it inherits the specification parser, the LLM interface and prompt layer, the multi-agent value-generation machinery, and the execution and reporting infrastructure. The four mechanisms of Subsection 3.4–Subsection 3.7 are new components on top of that basis; the original licence and attribution are preserved in the artefact. This changes how the AutoRestTest comparison should be read, in a direction that strengthens it (Subsubsection 4.2.2).

# 4 Evaluation

## 4.1 Research Questions

The empirical unit here is a controlled comparison, not a tool description: six tools (five baselines plus FDRRestTest) run on 12 heterogeneous REST services under five protocols – the ablation covering six of the 12 services, the budget sweep a single host – with $N$=10 repetitions per cell, service-level paired inference and a manual confirmation study of the findings. The framework of Section 3 is the treatment under study; the questions below concern what can be measured about it and under which conditions those measurements hold.

To systematically evaluate the effectiveness of FDRRestTest, we investigate the following research questions: **RQ1** – does FDRRestTest improve fault-revealing efficiency under fixed testing budgets compared with representative black-box REST API testing baselines? **RQ2** – how much do dynamic dependency evolution, failure repair, the multi-dimensional oracle, and the scheduler each contribute to the overall effectiveness, and does the contribution pattern hold across dependency profiles? **RQ3** – can FDRRestTest detect more non-crash logical defects than crash-oriented baselines, and what is the precision of these findings? **RQ4** – how stable is FDRRestTest under different testing budgets? **RQ5** – how does FDRRestTest perform across different services, and on which service profiles does the repair loop contribute most?

## 4.2 Experimental Methodology

### 4.2.1 Subjects

We evaluate FDRRestTest on 12 REST services spanning open-source systems and public-facing APIs (Table 1; sources and pinned revisions in the table note). The subjects differ substantially in operation scale, dependency structure, parameter constraints, and semantic complexity. Requests issued per service are reported in Table 5; we use requests, not test cases, as the volume unit: the tools group requests into sequences under incomparable definitions, so a sequence count is not a common denominator.

### 4.2.2 Baselines

We compare FDRRestTest against representative black-box REST API testing tools: **RESTler** [4] (stateful grammar-based fuzzing), **EvoMaster** [2] (search-based, black-box mode), **Morest** [24] (dependency-aware testing with execution feedback), **ARAT-RL** [17]

**Table 1** REST services used in the evaluation. N/A denotes services for which lines of code cannot be reported because the service is a public-facing or closed-source API.

| REST Service | LoC | #Ops | REST Service | LoC | #Ops |
|---|---|---|---|---|---|
| Features Service | 1688 | 18 | Market | 7945 | 13 |
| Language Tool | 113170 | 2 | Project Tracking System | 3784 | 67 |
| Rest Countries | 1619 | 22 | YouTube-Mock | 2422 | 1 |
| Genome Nexus | 22143 | 23 | FDIC | N/A | 6 |
| Person Controller | 601 | 12 | Spotify | N/A | 12 |
| User Management | 2805 | 22 | Ohsome API | N/A | 122 |

**Sources.** Seven subjects (Features Service, Language Tool, Rest Countries, Person Controller, User Management, Market, YouTube-Mock) come from the EvoMaster Benchmark (EMB) `https://github.com/EMResearch/EMB` as deployed in the ARAT-RL and AutoRestTest harnesses [17, 20]; Genome Nexus `https://github.com/genome-nexus/genome-nexus` and Project Tracking System `https://github.com/SelimHorri/Project-Tracking-System` from upstream, all cloned on 2026-02-09 at that day's HEAD. The public APIs are FDIC `https://banks.data.fdic.gov`, Spotify `https://api.spotify.com` and Ohsome `https://api.ohsome.org`. For Market and Project Tracking System we use the OpenAPI document shipped with the harnesses, not the upstream one; for Spotify we drive a 12-operation subset of the provider's published Web API, so its *OpR* (Subsubsection 4.2.3) is relative to that subset. Counts are the operations the deployment exposes; User Management's include the six method variants of Spring Boot's default `/error`.

(reinforcement-learning-based testing), and **AutoRestTest** [20] (LLM-enhanced multi-agent testing), covering four of the five paradigms of Section 1; the logical-oracle paradigm is represented by LogiAgent, excluded from the main comparison for the reason below.

**Status of the AutoRestTest comparison.** FDRRestTest is implemented on the AutoRestTest codebase, so the two configurations differ only in the four mechanisms under study; HTTP client, request serialisation, LLM provider and prompting, and reporting are identical. That controlled contrast removes the implementation confounders that ordinarily limit tool-to-tool comparison, and is why AutoRestTest is the primary reference. The other four baselines are independent implementations and retain those confounders; *SEY*, identical across all six tools, is the fairness anchor there (Subsubsection 4.2.3).

LogiAgent [37] is excluded from the main comparison because its LLM-as-agent pipeline cannot be fairly matched under a fixed time budget (per-request cost is dominated by external LLM latency). A matched-token-budget pilot on Features Service ($N$=1) reached $FRE = 1.205$, between AutoRestTest (1.1742) and FDRRestTest (1.2586); having no dispersion it supports no test and we draw no inference from it, and its log is not in the replication package. A full $N$=10 head-to-head is future work.

### 4.2.3 Metrics

We use five black-box efficiency-oriented metrics, chosen because (i) they are computable from externally observable behaviour alone, putting closed- and open-source subjects on equal terms; (ii) the yield metrics are per-request, decoupling effectiveness from raw throughput when request rates differ by an order of magnitude (Table 5); and (iii) they cover operation coverage (*OpR*), input validity (*RVR*), crash detection (*SEY*) and logical-defect detection (*LBY*), with *FRE* as the primary combined endpoint. The five metrics are: **Server Error Yield** $SEY = N_{\text{use}}/N_{\text{req}} \times 100\%$; **Logical Bug Yield** $LBY = N_{\text{lbs}}/N_{\text{req}} \times 100\%$; **Fault-Revealing Efficiency** $FRE = (N_{\text{use}} + N_{\text{lbs}})/N_{\text{req}}$; **Operation Reachability** $OpR =$

$N_{\text{proc}}/N_{\text{ops}} \times 100\%$; and **Request Validity Rate** $RVR = (N_{2\text{xx}} + N_{3\text{xx}})/N_{\text{req}} \times 100\%$, where $N_{\text{use}}$, $N_{\text{lbs}}$, $N_{\text{req}}$, $N_{\text{proc}}$, and $N_{\text{ops}}$ count server-error responses, logical anomaly signals, issued requests, successfully processed operations, and total specified operations. Following prior work we report *SEY* and *LBY* as percentages and *FRE* as a per-request ratio, so $FRE = (SEY + LBY)/100$ holds row-wise wherever the three appear together; fourth-decimal residuals are rounding of the two component percentages.

**Counting basis of the yield metrics.** The numerators of *SEY*, *LBY* and *FRE* count *oracle-triggering signals*: one response may violate several oracles, so *FRE* can exceed 1.0. Neither numerator passes through the cross-request deduplication of Subsection 3.6: both count every triggering response, because a per-request efficiency measure must charge a tool for the budget each signal cost it. *SEY* is consequently dominated by how often a subject answers with a server error, a property of the subject: it separates tools only through how much of the subject's surface they exercise, and equalises once two tools reach the same surface – as FDRRestTest and AutoRestTest do (Subsubsection 4.3.1). It therefore serves as a fairness check between comparable tools, not as a discriminator. Table 4 is the complementary view – signals sharing an ⟨endpoint, oracle type, semantic fingerprint⟩ triple collapse into one entry there – and the two cannot be converted into one another. Recurrence therefore raises both yields by design, while Table 4 carries *how many* distinct defects each tool finds.

**Fairness of *LBY*.** *LBY* is oracle-dependent: because the four non-crash oracles are a contribution of FDRRestTest and not a feature of the baselines, Table 2 applies the shared five-oracle harness post-hoc to every baseline's logs; *SEY*, which depends only on the crash oracle, is the primary cross-tool fairness anchor. The baselines' raw logs and as-published oracle outputs are not in the artefact, which records the harness output; the re-scoring can therefore be re-counted but not re-derived. The lower-bound direction is not a measured comparison: the harness can score only what each log preserves, and the online oracles of Subsection 3.6 read session history and cross-endpoint context that a replayed log does not carry. Table 6 separately shows the harness families to be a superset of Morest's and AutoRestTest's, so the recovered counts do not fall below what those two self-report either.

**No ground-truth defect list.** The 12 subjects carry no curated list of known defects, so no metric here is computed against a ground truth; every defect quantity is an oracle output – raw per-request signals (the yield metrics) or deduplicated findings (Table 4) – whose precision is probed empirically by the manual confirmation study of Subsubsection 4.3.3.

### 4.2.4 Experimental Setup

All tools share one environment (deployments, access configs, authentication, network, budgets); unless stated the budget is 600 s, and RQ4 varies it to rule out single-protocol artefacts. Each cell is repeated $N = 10$; Table 2, Table 3 and Table 5 report means over those repetitions, while Table 4 reports unions over them (Subsubsection 4.2.3); run-to-run dispersion is bounded (over the 24 FDRRestTest/AutoRestTest cells, interquartile range $\text{IQR}_{FRE}$ at Tukey hinges: mean 0.041, max 0.074). Deduplication follows Subsection 3.6; crash failures by ⟨response signature, operation context⟩. Authentication uses pre-provisioned static credentials supplied identically to every tool.

**Hyperparameters.** All nine are fixed across subjects after grid-search pilot tuning (objective *FRE*) on a held-out service, the *Scout API* of the EMB suite (`cs/rest/scout-api`): an open-source multi-step-state create-read-update-delete (CRUD) service disjoint from the 12 subjects. Values: lexical similarity threshold $\tau_{\text{lex}}$=0.70; edge-reuse reward, penalty and confidence floor $\alpha_{\text{r}}$=0.15, $\beta_{\text{p}}$=0.10, $w_{\min}$=0.05; scheduler weights $\lambda_1$–$\lambda_4$ = 0.40/0.30/0.20/0.10 for DefectYield, Reachability, Repairability, Cost (Subsection 3.7); repair-memory capacity $|\mathcal{M}|$=200, FIFO (Subsection 3.5).

**Statistical analysis.** $\alpha$=.05 throughout. All *cross-tool* inferential tests are performed at the *service* level, on the 12 paired per-service means of Table 5, because between-service heterogeneity is the dominant confounder for generalisation claims; every statistic below is recomputable from that table or from the per-service traces in the replication package. We use the two-sided paired Wilcoxon signed-rank test [35] with Holm-Bonferroni adjustment [13] across the family of five cross-tool comparisons; secondary tests (*SEY*, the Pareto variant, the fixed-request caps) are reported unadjusted and are exploratory. We quantify magnitude with the standardised paired difference $d_z$, computed on the 12 service-level paired means, not on individual runs, and with the distribution of per-service margins, following the effect-size guidance of Arcuri and Briand [3]. Magnitude is reported on *LBY* rather than *FRE*, because the common-mode *SEY* term inflates *FRE* equally for every tool and can only dilute an effect size; significance is unaffected, the sign pattern being identical on both, so the tests stay on *FRE*.

Because FDRRestTest's per-service mean *FRE* exceeds every baseline's on all 12 subjects, each pairwise signed-rank statistic attains its extreme value ($W^+$=78), so the exact two-sided $p$ is $2/2^{12} = .0005$ per comparison and $p_{\text{adj}} < .005$ for all five after Holm. The exact $p$ is fixed by the sign pattern alone; for magnitude we report, against AutoRestTest, a paired mean *LBY* difference of 5.83 points (standard deviation SD = 1.57, $d_z = 3.73$) and per-service relative *LBY* margins with median 12.4% and range [7.0%, 16.5%]. A sensitivity analysis for the paired $t$-test ($N$=12, $\alpha$=.05, power = .80) gives a minimum detectable effect of $\approx 0.89\sigma$; the signed-rank test we use has slightly lower asymptotic efficiency, so this is a lower bound on it.

*Scope of effect-size reporting.* Service-level tests are reported for all five cross-tool comparisons; $d_z$ and the per-service margin distribution only for RQ1, against the strongest baseline. Within each host, where the $N$=10 repetitions make run-level comparison meaningful, magnitude is Cliff's $\delta$ [5] on *LBY* between the two tools' independent 10-run distributions. For RQ1, $\delta$ against AutoRestTest ranges over [0.96, 1.00] across the 12 services (mean 1.00) and equals 1.00 on every service against the other four baselines. For RQ2, every removal yields $\delta = 1.00$ on the host of Table 3 and $\delta \geq 0.42$ across all six ablation subjects, the minimum falling on No-Repair, whose effect is the one the ablation itself reports as host-dependent; per-subject values and the within-host Pareto comparison are in the replication package. For RQ4 every budget step yields $\delta = 1.00$ on the reported host, and $\delta \geq 0.54$ on the three further sweep subjects in the package. Run-level observations are never pooled *across* services, where between-service variance would dominate.

## 4.3 Results and Analysis

We present the results in the order of the five research questions: overall effectiveness against all baselines (RQ1), component contribution by ablation (RQ2), non-crash logical defect detection (RQ3), robustness across testing budgets (RQ4), and per-service behaviour with repair impact (RQ5).

**Table 2** Overall comparison under a fixed 600-second budget, averaged across 12 services. "Req./Sig." is $1/FRE$, requests per oracle-triggering signal, not per distinct defect (Subsubsection 4.2.3). Last column: Holm-Bonferroni-adjusted $p_{\text{adj}}$ from the two-sided paired Wilcoxon test on $FRE$; "†" marks $p_{\text{adj}} < .05$; effect sizes in Subsubsection 4.2.4. $LBY$ and $FRE$ for the five baselines are recovered post-hoc with the shared harness and are therefore lower bounds, so their Req./Sig. are correspondingly upper bounds. Only FDRRestTest's $LBY$ comes from its own oracle layer; the AutoRestTest contrast stays controlled on every other axis (parser, LLM interface, value generation, execution, reporting), which is why it is the primary reference.

| Tool | *OpR* (%) | *SEY* | *LBY* | *FRE* | Req./Sig. ↓ | $p_{\text{adj}}$ |
|---|---|---|---|---|---|---|
| RESTler | 42.5 | 24.98 | 4.54 | 0.2952 | 3.39 | $<.005$ † |
| EvoMaster | 67.2 | 35.94 | 8.85 | 0.4479 | 2.23 | $<.005$ † |
| Morest | 75.1 | 40.87 | 11.15 | 0.5202 | 1.92 | $<.005$ † |
| ARAT-RL | 78.7 | 44.81 | 14.55 | 0.5936 | 1.68 | $<.005$ † |
| AutoRestTest | 82.5 | 45.26 | 47.68 | 0.9294 | 1.08 | $<.005$ † |
| FDRRestTest | **93.3** | 45.26 | **53.52** | **0.9878** | **1.01** | – |

### 4.3.1 RQ1: Overall Effectiveness

Table 2 compares FDRRestTest with all baselines under the same fixed 600-second budget, in terms of *OpR*, *SEY*, *LBY*, *FRE*, and requests per oracle-triggering signal, averaged across the 12 services.

FDRRestTest achieves the highest *FRE* (0.9878 vs. 0.9294 for AutoRestTest, +6.3% relative, an upper estimate: AutoRestTest's *LBY*– and hence its *FRE*– is a post-hoc lower bound) and correspondingly the fewest requests per oracle-triggering signal (1.01 vs. 1.08); *SEY* is indistinguishable from AutoRestTest (45.26 vs. 45.26, discussed below) while *LBY* is substantially higher (53.52 vs. 47.68, +12.2%; because AutoRestTest's *LBY* is a post-hoc lower bound, this margin is an upper estimate of the true gap), and *OpR* is the highest at 93.3% (+10.8 percentage points (pp) above AutoRestTest, +14.6 pp above ARAT-RL). Paired Wilcoxon on per-service *FRE* gives $p_{\text{adj}}<.005$ for all five pairwise comparisons, with $d_z = 3.73$ on *LBY* against AutoRestTest (Subsubsection 4.2.4).

*SEY* behaves exactly as the fairness anchor it is meant to be. Over the 12 services the two tools are indistinguishable on it: a paired mean difference of +0.004 points, FDRRestTest ahead on 6 of 12 subjects, two-sided Wilcoxon $p = .57$. That is what a quantity governed by the crash oracle – identical across all six tools – should look like once it is charged per request, and it holds under equal request volume too (+4.1, +2.1 and +0.3 points at the three caps, Subsubsection 4.3.6). *SEY* is therefore a common-mode term: it measures how often a subject answers with a server error, a property of the subject rather than of the search.

The crash dimension separates the tools only after deduplication: the union of crash triples is 44/54/68/47/53/71 over the six tools in the order of Table 2 – identical *SEY*, yet 34% more distinct crashes than AutoRestTest, and Morest isolates 21 more than ARAT-RL despite a lower *SEY*. Hitting server errors and finding different ones are not the same ability. The *FRE* advantage thus rests on *LBY*, which Subsubsection 4.3.2 isolates independently. The one dimension on which FDRRestTest is genuinely worse is wall-clock throughput, apportioned in Subsubsection 4.3.6.

**Table 3** Ablation on **Features Service**, the most state-rich subject, under the 600-second budget, including the Pareto variant of Subsection 3.7. All rows are runs of this ablation campaign, so Full and AutoRestTest differ from the same cell of Table 5 by run-to-run variation. Values are host-specific and not comparable to Table 2, which averages 12 services.

| Variant | *SEY* | *LBY* | *FRE* | *RVR* (%) |
|---|---|---|---|---|
| Full | **50.94** | **75.52** | **1.2647** | 33.85 |
| No-DynDep | 44.63 | 58.42 | 1.0305 | 28.45 |
| No-Repair | 44.35 | 51.26 | 0.9560 | 24.44 |
| No-Oracle | 47.09 | 9.83 | 0.5692 | 31.36 |
| No-Scheduler | 41.71 | 47.94 | 0.8965 | 27.38 |
| Pareto | 48.50 | 72.42 | 1.2092 | 30.94 |
| AutoRestTest | 52.03 | 65.13 | 1.1716 | 29.59 |

### 4.3.2 RQ2: Component Contribution

We ablate **Full** (complete FDRRestTest) against **No-DynDep** (no dynamic dependency evolution), **No-Repair** (no repair loop), **No-Oracle** (crash-only validation), **No-Scheduler** (heuristic scheduling), and **Pareto** (non-dominated sorting in place of the weighted utility, Subsection 3.7), with **AutoRestTest** for reference.

The ablation is run on six subjects spanning three dependency profiles, so that the decomposition is not tied to a single host: *near-stateless* (YouTube-Mock, Language Tool), *medium-scale stateful* (Features Service, User Management), and *large-scale complex* (Ohsome API, Project Tracking System; scale, not write-statefulness, as Ohsome API is read-only and contributes no state findings), $N$=10 per cell. Table 3 reports the per-variant detail on *Features Service*, the most state-rich subject, where component contributions are most visible; the cross-subset picture follows.

On Features Service, Full reaches *FRE*=1.2647, 7.9% above AutoRestTest; removing any single component drops *FRE* below AutoRestTest. No-Oracle leaves a qualitatively distinct footprint: it concentrates almost all loss in *LBY* (75.52→9.83, with *SEY* dropping only 3.9 and *RVR* only 2.5 pp). The other three removals degrade all four metrics in the same ordering (*LBY* hit hardest, *SEY* and *RVR* least) and differ chiefly in magnitude – *FRE* drops by 18.5% (No-DynDep), 24.4% (No-Repair), and 29.1% (No-Scheduler) – with No-Repair also causing the clearest *RVR* drop (−9.4 pp). The residual $LBY = 9.83$ under No-Oracle comes from a minimal schema check retained in the parser-layer runtime store.

Two observations follow. First, the oracle is not substitutable by the exploration-side components: removing it eliminates 87% of *LBY* while *SEY* and *RVR* barely move. Second, no single-component variant reaches AutoRestTest on this host, so the advantage cannot be attributed to any one mechanism alone. The three exploration-side removals share a degradation profile and differ mainly in magnitude, so the ablation ranks their necessity without showing their contributions to be mechanistically distinct. The Pareto variant substitutes a mechanism instead of removing one: non-dominated sorting reaches $FRE = 1.2092$ against 1.2647 (−4.4%; two-sided Mann-Whitney $p < .001$, $N$=10 per variant) while issuing 3.6% fewer requests in the same budget, so the scalarisation is the cheaper of the two at this decision frequency (Subsection 3.7).

The two secondary metrics confirm the mechanism attribution. On *RVR*, No-Repair causes the largest drop (−9.4 pp), consistent with repair recovering otherwise-invalid requests. On *OpR*– per variant in the replication package – removing the scheduler costs the most reachability on each of the four subjects with more than two operations, No-DynDep and

No-Repair less, while No-Oracle leaves it almost intact: the expected separation between exploration- and validation-side components, and independent confirmation that the No-Oracle footprint in *LBY* is not an exploration artefact.

**Consistency across dependency profiles.** Full is highest on all six subjects and the exploration-side losses scale with dependency density. Averaged per subset over the per-subject percentage drops (near-stateless / medium stateful / large complex), No-DynDep costs −2.7% / −15.4% / −22.9% of *FRE* and No-Scheduler −8.7% / −23.6% / −30.7%: both gradients are monotone in dependency density, as the mechanisms predict. Removing the oracle costs −48.5% / −51.5% / −48.1%, essentially profile-independent: the signature of a validation-side component, and the strongest single effect on every subject. No-Repair is the exception: its subset means happen to order (−2.1% / −13.0% / −14.9%), but the within-subset spread reaches 22.8 pp against at most 11.1 pp for any other variant (24.4% on Features Service against 1.6% on User Management, both medium), so we claim no per-subset gradient and report the single-host magnitude instead: repair contributes where inter-operation constraints make intermediate failures frequent, which tracks a service's constraint density, not its profile.

AutoRestTest is closest on the near-stateless subset, where Full leads it by 5.6%, against 6.8% and 6.3% on the other two (these margins are relative to AutoRestTest and are computed on the subset-mean *FRE*, unlike the per-subject means above; the component-removal percentages above are relative to Full). Removing the oracle drops *FRE* below AutoRestTest on all six subjects; the exploration-side removals do so on four (No-DynDep), six (No-Scheduler) and three (No-Repair) respectively. The ablation therefore establishes the oracle layer as indispensable across all six ablation subjects and all three dependency profiles, while the exploration-side components are necessary but not individually sufficient to clear the strongest baseline on every profile.

### 4.3.3 RQ3: Logical Defect Detection

Table 4 reports deduplicated counts for every tool and non-crash category. Because the four non-crash oracles are a contribution of FDRRestTest rather than a feature of the baselines (Table 6), the per-category entries for every tool other than FDRRestTest are produced by applying the shared five-oracle harness post-hoc to its logs; they are therefore lower bounds on what each tool's own reporting would surface. We draw category-level conclusions only from the FDRRestTest–AutoRestTest pair, the two systems that share a code base (Subsubsection 4.2.2) and differ exactly in the mechanisms under study.

Counts increase monotonically across the paradigms, but the per-tool sets are largely disjoint (201 of the 236 union triples come from one tool; the only substantial overlap is the 35 shared by the two systems with a common code base), so the ordering reflects how much of each tool's traffic the shared harness can score, not containment between paradigms. Every column other than FDRRestTest's is a lower bound, so the +41%–+69% steps beneath compare two lower bounds; only the FDRRestTest-vs-AutoRestTest step (+26 findings, +37% on a base of 70) contrasts two systems that share a code base and differ exactly in the mechanisms under study. We read the ordering as a trend across paradigms, not as evidence about any single step. FDRRestTest leads AutoRestTest in all four categories, with the largest gains in constraint findings (+10) and state findings (+7), consistent with the roles of dependency evolution and the constraint oracle.

**Table 4** Logical defect findings across 12 services as *absolute deduplicated counts*: the distinct-defect view, not the per-request signals underlying $LBY$, and not aggregable with them (Subsubsection 4.2.3). FDRRestTest's counts come from its own oracle layer; the other five are recovered post-hoc with the shared harness and are lower bounds. Deduplication applies the ⟨endpoint, oracle type, semantic fingerprint⟩ triple uniformly; counts are the union over the $N$=10 repetitions.

| Finding Category / Tool | RESTler | EvoMaster | Morest | ARAT-RL | AutoRestTest | FDRRestTest |
|---|---|---|---|---|---|---|
| Structural findings | 3 | 5 | 7 | 9 | 16 | 19 |
| State findings | 4 | 6 | 8 | 12 | 19 | 26 |
| Consistency findings | 3 | 5 | 7 | 11 | 17 | 23 |
| Constraint findings | 3 | 6 | 9 | 12 | 18 | 28 |
| Total deduplicated findings | 13 | 22 | 31 | 44 | 70 | **96** |

**Representative defects.** One representative deduplicated defect per non-crash category, each cited by the `predicate` under which the artefact records it: *state*: `idempotent_put_changed_state` on `PUT /api/person` (Person Controller, MC-107), a repeated identical `PUT` leaving a different resource state; *constraint*: `type_coercion_accepted` on `GET /history` (FDIC, MC-062), constraint `type@offset`; *structural*: `response_type_mismatch` on `POST /annotation` (Genome Nexus, MC-087), constraint `type@most_severe_consequence`; *consistency*: `cross_endpoint_divergence` on `GET /elements/area/groupBy/key` (Ohsome API, MC-082). The identifiers are the `sample_id` column of the annotation matrix.

**Manual confirmation study.** This study estimates the precision of the *shared oracle layer* behind every entry of Table 4: native for FDRRestTest, post-hoc for the five baselines. The frame is the union of all six tools' deduplicated findings under the same triple: 236 distinct findings (51/59/56/70 structural/state/consistency/constraint), smaller than the column sums because the sets overlap – FDRRestTest and AutoRestTest, sharing a code base, in 35 triples. We draw 30 per category ($N$ = 120, a 51% sampling fraction), allocated per service in proportion to its share of that category's frame, so read-only subjects contribute nothing to the state stratum. Two annotators labelled each finding independently against source code or documented behaviour, resolving disagreements by discussion. The confirmation rate is 96/120 = 80% (95% Wilson confidence interval, CI, [72.0%, 86.2%]), with inter-annotator agreement Cohen's $\kappa = 0.78$ (95% CI [0.63, 0.93], substantial), computed on the pre-discussion labels. Table 4 therefore reads as an inventory of *oracle findings* of which a substantial majority are genuine defects, for every tool; the interval width still precludes per-category claims. The matrix and guidelines are in the replication package.

### 4.3.4 RQ4: Budget Sensitivity

We vary the time budget on *Features Service*, the most state-rich subject, $N$=10 per cell. Each tier is a separate execution inside this sweep. At 60/180/300/600 s: $SEY$ = 44.80, 48.30, 49.70, 51.44; $LBY$ = 59.62, 66.43, 70.53, 75.32; $FRE$ = 1.0442, 1.1474, 1.2022, 1.2676. At 600 s it reaches $FRE$ = 1.2676, within run-to-run variation of the 1.2586 measured for

**Table 5** Per-service comparison under the 600-second budget; each cell reads *AutoRestTest / FDRRestTest*. Two effects drive FDRRestTest's lower request count – budget-aware scheduling (algorithmic) and per-request diagnosis/repair/oracle overhead (implementation) – apportioned in Section 4.3.6. The higher *OpR* shows the reduced volume still reaches more operations, and Subsubsection 4.3.6 shows the per-request advantage survives equal volume.

| Service | Requests | *OpR* (%) | *SEY* | *LBY* | *FRE* |
|---|---|---|---|---|---|
| Features Service | 52 374 / 6 315 | 100.0 / 100.0 | 52.12 / 51.01 | 65.30 / 74.85 | 1.1742 / 1.2586 |
| Language Tool | 48 513 / 4 102 | 100.0 / 100.0 | 33.57 / 33.87 | 36.27 / 41.62 | 0.6984 / 0.7549 |
| Rest Countries | 54 261 / 6 138 | 90.9 / 100.0 | 46.21 / 45.72 | 51.33 / 56.56 | 0.9754 / 1.0228 |
| Genome Nexus | 28 518 / 4 232 | 82.6 / 95.7 | 45.71 / 43.65 | 48.82 / 54.82 | 0.9453 / 0.9847 |
| Person Controller | 36 414 / 4 831 | 83.3 / 100.0 | 40.09 / 45.21 | 45.20 / 50.67 | 0.8529 / 0.9589 |
| User Management | 32 137 / 4 572 | 81.8 / 95.5 | 47.41 / 47.59 | 52.14 / 57.59 | 0.9955 / 1.0518 |
| Market | 25 668 / 3 681 | 76.9 / 92.3 | 44.46 / 44.56 | 42.30 / 49.28 | 0.8676 / 0.9384 |
| Project Tracking System | 18 504 / 2 914 | 68.7 / 82.1 | 43.41 / 40.87 | 41.91 / 48.49 | 0.8532 / 0.8936 |
| YouTube-Mock | 45 076 / 5 284 | 100.0 / 100.0 | 49.34 / 48.46 | 55.12 / 59.29 | 1.0445 / 1.0776 |
| FDIC | 22 483 / 3 195 | 66.7 / 83.3 | 45.58 / 47.29 | 47.43 / 50.72 | 0.9301 / 0.9801 |
| Spotify | 19 674 / 2 836 | 75.0 / 91.7 | 51.06 / 51.15 | 41.85 / 47.09 | 0.9292 / 0.9823 |
| Ohsome API | 15 435 / 2 457 | 63.9 / 78.7 | 44.14 / 43.77 | 44.53 / 51.23 | 0.8867 / 0.9500 |

the same cell under the main protocol (Table 5). *FRE* increases monotonically across the four budgets – by +21.4% from 60 s to 600 s – with all three adjacent steps giving Cliff's $\delta = 1.00$ on *LBY*. *OpR* rises 72.2/88.9/94.4/100.0% over the same budgets, so the extra time reaches new operations instead of re-walking reached ones. The replication package additionally sweeps Language Tool, Ohsome API and Project Tracking System; there the final 300→600 s step gives $\delta = 0.54$, 0.84 and 0.84, so strict per-step separation is a property of this host rather than a general one.

### 4.3.5 RQ5: Per-Service Behaviour and Repair Impact

Table 5 compares the two tools per service: FDRRestTest wins on *FRE* in all 12, so the gain in Table 2 is not outlier-driven; the largest request-volume reduction is on Language Tool (11.8×). The structural pattern is in *OpR*: gains are large (+9.1–+16.7 pp) on every service not already fully reachable, and do not order by service scale. Relative *FRE* gains do *not* order by state richness: near-stateless Language Tool (+8.1%) is above the 12-service average of +6.3%, YouTube-Mock (+3.2%) below. We therefore support the design hypothesis on reachability, where the mechanism-to-metric link is direct, and claim no monotone relationship between state richness and per-request efficiency. The per-service rows are full configurations and do not isolate the repair loop; that separation comes from Subsubsection 4.3.2: on the state-rich host, removing repair costs 24.4% *FRE* and 9.4 pp *RVR*, the largest validity drop of any single removal. The per-subset decomposition of Subsubsection 4.3.2 finds no ordering with dependency density, so it does not support repair contributing proportionally more on dependency-dense services.

### 4.3.6 RQ5 complement: Robustness to the budget denomination

A fixed-time protocol favours tools differently according to their per-request overhead, so we re-ran the full cross-tool comparison under a *fixed-request* budget: every tool is capped at the same number of issued requests per service and runs to completion, with no time limit. The three caps – 1000, 3000, 6000 requests per service – span the volumes FDRRestTest issues within 600 s (Table 5); 12 services × 6 tools × $N$=10 per cap.

The ranking is unchanged and the margin widens as the cap tightens: at 3000 requests FDRRestTest reaches $FRE = 0.9670$ against 0.8307 (+16.4%), winning on all 12 services (exact two-sided $p = 2/2^{12}$, $d_z = 5.74$); the margin is +24.0% at 1000 and +9.6% at 6000, with the four weaker baselines trailing by +66% or more at every cap on their post-hoc recovered *FRE*, again an upper estimate. The shrinking advantage is expected: the baselines converge towards their own saturation while FDRRestTest is already near its ceiling at 3000 requests.

Two observations matter for interpreting the fixed-time results. First, the *SEY* parity of Subsubsection 4.3.1 survives equalised volume: at 3000 requests FDRRestTest's *SEY* is 35.84 against AutoRestTest's 33.73, converging to 35.67 vs. 35.40 at 6000. Per-request crash detection is thus a property of the shared oracle, not of either search strategy. Second, the closed loop costs wall-clock time: reaching the same request count takes FDRRestTest about 7.3× longer. Under a request-denominated budget FDRRestTest is the more effective tool per request; under a wall-clock budget that advantage must be earned back against a much lower request rate. Neither protocol subsumes the other.

**Apportioning the throughput gap.** Two mechanisms are confounded in the 7.7× request-volume gap: the scheduler *chooses* fewer, better sequences (algorithmic), and diagnosis, repair and oracle evaluation sit inside the request loop (implementation). A same-throughput control separates them – an *async-feedback* variant moving those three stages out of the loop, 12 subjects, $N$=10. Throughput rises 3.00× (4 213 → 12 646 requests per 600 s), leaving 2.56× attributable to the scheduler's restraint; the two shares are comparable, so neither alone explains the gap. The extra volume costs per-request efficiency: *FRE* falls to 0.8385 (−15.1%), entirely through *LBY* (53.52→38.64) while *SEY* barely moves (45.26→45.21), since the added requests are the ones the scheduler had de-prioritised and delayed feedback degrades its choices. Under a quota-bound budget the synchronous configuration is the right operating point; both run sets are in the artefact.

## 4.4 Discussion

The aggregate *FRE* gain over AutoRestTest is +6.3%, an upper estimate (Subsubsection 4.3.1) and a moderate margin whose interpretation rests on three orthogonal properties: *consistency* (12/12 subjects, $d_z = 3.73$ on *LBY*), *budget efficiency* (6.3−11.8× fewer requests), and *statistical reliability* ($p_{\text{adj}} < .005$). Consistency is the strongest of the three: a uniform sign across heterogeneous subjects is harder to produce by chance than a given aggregate margin.

**Practical implications.** The three views of the *LBY* uplift – +12.2% per request, +37% deduplicated count, 26 more distinct findings – translate for a continuous-integration pipeline into a larger share of the API surface within the window (*OpR* 93.3% vs. 82.5%). Each report carries the operation sequence, request, response and predicate, mapping to developer action (*state*→persistence/cache, *constraint*→input validation, *consistency*→cross-endpoint sync, *structural*→schema contract).

# 5 Threats to Validity

**Internal validity / conclusion.** All nine hyperparameters (Subsubsection 4.2.4) are fixed after pilot tuning on a held-out *Scout API* and not re-tuned per subject. Perturbing each by ±20% and re-running all 12 subjects ($N$=5 per configuration): per-service mean *FRE*

varies by at most 7.9% on any subject, the largest absolute shift being 0.082 at $\tau_{\text{lex}}$−20% on Features Service; two of the eighteen perturbations improve *FRE* slightly, so the fixed values are a good operating point, not a sharp optimum. The four scheduler weights $\lambda_1$–$\lambda_4$, the parameters most directly implicated by the scalarisation of Subsection 3.7, stay within that same band. The sweep is one-factor-at-a-time and does not probe parameter interactions, a threat to conclusion validity; the sweep run-level records are in the artefact.

**Construct validity / external validity.** LBY is oracle-dependent, mitigated by the shared harness. Table 4 counts deduplicated oracle findings, not confirmed bugs; the study of Subsubsection 4.3.3 gave 80% true positives (95% Wilson CI [72.0%, 86.2%], $\kappa = 0.78$), so oracle precision is bounded in aggregate but not per category, and the two annotators shared guidelines, which may correlate their errors. The benchmark excludes enterprise-level APIs, and OpenAPI dialect may affect transferability. FDIC, Spotify and Ohsome API enforce quotas and our oracles do not separate a business-logic fault from an infrastructure-level rejection under load, so some error signals may come from throttling; 429 responses are 0.7–0.9% of requests there and differ by at most 0.02 pp between the two tools, so the inflation is common-mode. RQ2 covers six of the 12 subjects and its single-removal design limits it to necessity claims; RQ4 and the Pareto comparison are single-host, so budget-monotonicity is supporting evidence on one state-rich subject.

**Implementation efficiency.** FDRRestTest's request rate is markedly lower than some baselines (Table 5). FRE is per-request, but a lower rate under a fixed time budget might undercount defects requiring many *different* requests. The fixed-request replication of Subsubsection 4.3.6 is the direct test: at the same request count the ranking holds at all three caps and the margin over AutoRestTest widens to +16.4% at 3000, so the advantage is not an artefact of the fixed-time protocol. The residual threat runs the other way: reaching a given request count costs FDRRestTest about 7.3× more wall-clock time, so where the binding constraint is time rather than quota, that overhead limits achievable yield. The same-throughput control of Section 4.3.6 apportions the two shares (3.00× implementation, 2.56× algorithmic) but does not remove the overhead itself. Finally, the exclusion of LogiAgent is a limitation; we treat it as an orthogonal direction requiring special comparison protocols (matched token budgets, per-defect costs).

## 6 Related Work

Building on REST and specification foundations [29, 31, 27, 32], prior black-box REST testing spans stateful fuzzing, search-based, graph-guided, reinforcement-learning, and LLM-assisted paradigms [4, 24, 2, 17, 20, 37, 18], with adjacent tools [15, 26, 33, 23, 36, 7, 12, 6, 1, 25, 19, 16, 8, 30, 14, 9] and surveys [11, 38, 21, 34, 22, 28].

Table 6 makes the differentiation concrete: no row is novel on its own – runtime dependency evolution exists in Morest, a five-family logical oracle in LogiAgent – but no prior system carries all six dimensions, four of which are evaluated here; the ablation of Subsubsection 4.3.2 drops *FRE* below the strongest baseline on every removal.

**Applicability boundaries.** Effectiveness is predicated on a reasonably complete OpenAPI specification and stateful, multi-step interactions; the benefit is narrowest in *OpR*– where the mechanism-to-metric link is most direct – on subjects already reachable without dependency reasoning (YouTube-Mock, Language Tool). Relative *FRE* gains, by contrast, do not order by

**Table 6** Differentiation from the closest prior systems. ✓ present; ∼ partial or auxiliary; × absent.

| Design dimension | Morest | AutoRestTest | LogiAgent | FDRRestTest |
|---|---|---|---|---|
| Runtime dependency-graph evolution | ✓ | ∼ | × | ✓ |
| Failure repair: taxonomy + memory | × | × | × | ✓ |
| Logical oracle, five families | × | × | ✓ | ✓ |
| Non-crash state/consistency oracles | × | × | ✓ | ✓ |
| Budget-aware scheduling | ∼ | ∼ | × | ✓ |
| Fingerprint dedup + statistical test | × | ∼ | ∼ | ✓ |

state richness (Subsubsection 4.3.5). The implementation assumes no dynamic-interaction authentication (e.g., OAuth2.0 grants) and no budget-exhausting rate limit; our FDIC, Spotify and Ohsome API runs were quota-constrained, and OpenAPI 3.1 features remain unexplored.

## 7 Conclusion and Future Work

We presented FDRRestTest, integrating dependency-graph evolution, failure repair, a multi-dimensional logical oracle and budget-aware scheduling in one closed loop; on 12 services against five baselines it delivers a consistent *FRE* improvement (up to +6.3% over the strongest baseline on all 12 subjects, $p_{\text{adj}} < .005$, $d_z = 3.73$ on *LBY*). A stratified manual confirmation study ($N = 120$, 80% confirmed, $\kappa = 0.78$) supports the oracle-finding reading of the headline *LBY* gain, and an ablation over six subjects in three dependency profiles shows the oracle layer costs the most on removal. Future work: a matched-token-budget LogiAgent comparison, multi-component removals to quantify interaction effects, and validation on enterprise-scale APIs.

## Data Availability Statement

The replication package is archived at `https://doi.org/10.5281/zenodo.21964240`: the implementation, the shared-oracle and deduplication harness, the statistical scripts, run-level records for every reported cell with the repair tallies of Subsection 3.5, and – for the 720 fixed-time runs – per-request operation and status-code traces (200 sampled each), per-run histograms, the triggering request and response of every finding, and the $N = 120$ annotation matrix with guidelines and sampling record. Attribution is in `NOTICE`.

## Abstract

**Background.** LLM-as-Judge is increasingly adopted in automated program repair (APR) to assess patch correctness, yet its validity as a measurement instrument remains unaudited: potential benchmark-identifier leakage, evidence-presentation bias, and explanation unreliability have not been systematically examined.

**Aims.** We investigate whether LLM Judge produces unbiased, stable, and well-grounded patch correctness judgments across three validity dimensions: metadata leakage, evidence presentation, and explanation reliability.

**Method.** On a balanced, paired dataset of 326 patches from 163 Defects4J bugs, we evaluate GPT-4o and DeepSeek-V3 across a 12-setting prompt matrix covering benchmark-identifying metadata exposure and evidence presentation variants. We further conduct a manual analysis of 60 GPT-4o explanations using a five-category failure taxonomy and three independent annotators.

**Results.** Under sanitized conditions, GPT-4o achieves an accuracy of 77.3% (MCC = 0.575, FPR = 17.2%), while DeepSeek-V3 achieves 80.4% accuracy (MCC = 0.625, FPR = 22.1%), with no statistically significant difference between the two models. Exposing combined benchmark-identifying metadata yields a suggestive accuracy increase of 4.3 percentage points for GPT-4o and 1.8 percentage points for DeepSeek-V3. Declaring that all tests have passed does not significantly bias either model; in contrast, providing a developer reference patch leads to substantial and statistically significant improvements for both models. Explanation failures are concentrated in misclassified cases, with the false-positive quadrant showing a 93.3% failure rate, primarily driven by hallucinated evidence and missed edge cases.

**Conclusions.** LLM Judge is useful as a triage aid but is insufficient as a standalone correctness oracle. Reliable deployment requires prompt sanitization, explicit false positive rate reporting, clear distinction between reference-assisted and standalone assessment, and treating LLM explanations as investigative hypotheses rather than self-validating justifications.

## 1 Introduction

Automated Program Repair (APR) aims to automatically generate patches that fix software bugs, but assessing the correctness of these patches is a critical challenge for deploying APR tools in real-world scenarios [26, 9, 39, 28]. While existing test suites can verify whether a patch passes all tests, they cannot guarantee that the patch truly fixes the defect rather than merely passing the tests [3]. This phenomenon, known as overfitting, occurs when a patch may pass the tests but does not align with the developer's intent. To address this issue, Automated Patch Correctness Assessment (APCA) techniques have been proposed to tackle the overfitting problem in APR [14].

In recent years, the rapid advancement of large language models (LLMs) has catalyzed a paradigm shift within the APCA landscape, moving from the exploration of learning-based classifiers toward the adoption of LLM-as-Judge (LLM Judge) approaches [36]. LLM4PatchCorrect [40] demonstrated that in-context learning with LLMs outperforms specialised classifiers on Defects4J, achieving over 84.4% accuracy. RePaCA [5] subsequently reported 83.1% accuracy by combining reasoning LLMs with reinforcement learning for static patch assessment. Beyond standalone APCA methods, LLM Judge is increasingly used as a de facto assessment layer in agentic APR pipelines [23], in which a separate model validates each candidate patch before it is accepted. The appeal is clear: LLM Judge requires no task-specific training data, generalises across projects and languages, and produces human-readable explanations that researchers can inspect.

Despite this widespread adoption, the reliability of LLM Judge as a measurement instrument has received virtually no rigorous scrutiny. Existing studies typically treat patch-assessment accuracy as sufficient evidence of trustworthiness. However, accuracy alone cannot rule out three fundamental threats to measurement validity. First, LLMs are trained on large-scale corpora that may contain Defects4J bug reports, patches, and correctness labels. Exposing a bug identifier or project name in the prompt may enable the model to rely on metadata-induced shortcuts, including possible memorization signals, instead of reasoning from the code alone. Such shortcuts can inflate apparent accuracy through benchmark leakage [15]. Second, the order and content of presented evidence can affect LLM judgments in general SE tasks [38]. In APR, a declarative statement that all tests passed, or the inclusion of a developer reference patch, may systematically bias the LLM toward labeling overfitting patches as correct. This bias can increase false positive rates in ways that remain hidden when only aggregate accuracy is reported. Third, even when the predicted label is correct, the accompanying natural-language explanation may include hallucinated code references or unsupported reasoning steps. Such explanations can undermine the validity of human-in-the-loop review processes that rely on them [8]. Wang et al. recently showed that test-based patch assessment in SWE-bench has a 7.8% false-correct rate and 29.6% behavioral divergence from human evaluation [27]. If test-based assessment is unreliable, it remains unclear whether LLM Judge can serve as a trustworthy substitute or instead introduces different forms of unreliability.

In this paper, we seek to clarify these questions by systematically examining the reliability of LLM-as-Judge for patch correctness assessment. Specifically, we formulate four rigorously controlled research questions to evaluate the stability, impartiality, and groundedness of

LLM Judge from the perspective of empirical software engineering measurement. To address these questions, we construct a balanced, paired dataset comprising 326 patches generated by APR tools for Defects4J [10] bugs. We evaluate GPT-4o and DeepSeek-V3 across varied prompting configurations spanning two dimensions: benchmark-identifier leakage and evidence-presentation bias. In addition, we conduct a manual analysis of 60 GPT-4o-generated explanations, applying a five-category failure taxonomy to assess the reliability of the produced rationales. Our study newly raises and answers the following four research questions.

**RQ1: What is the agreement between LLM Judge and human ground-truth labels under sanitized conditions? (3.1)** This establishes the baseline reliability of LLM Judge when no confounding information is present.

**RQ2: Does exposing benchmark-identifying information (bug ID, project name, repair tool name, or developer patch) to LLM Judge systematically shift its judgments? (3.2)** If judgments shift toward ground truth upon receiving identifiers the model may have encountered during pre-training, the effective accuracy may be influenced by metadata-induced shortcuts rather than code reasoning alone.

**RQ3: Does the type and content of evidence included in the prompt systematically bias LLM Judge toward labelling overfitting patches as correct? (3.3)** We distinguish two sub-forms: test-passing bias (inflated FPR when the prompt states that all tests pass) and reference-similarity bias (inflated correct-label rate for patches similar to the developer reference).

**RQ4: Do the natural language explanations produced by LLM Judge provide trustworthy reasoning, or do they contain hallucinated or unsupported claims? (3.4)** This question assesses whether explanations can serve as a valid basis for human-in-the-loop review.

In summary, we make the following contributions:

- We empirically demonstrate that LLM Judge judgments for patch correctness assessment are sensitive to benchmark-identifying information exposed in the prompt, including bug identifiers, project names, repair tool names, and developer patches.
- We show that evidence presentation can systematically distort LLM Judge decisions by separating test-passing bias from reference-similarity bias.
- We introduce an explanation reliability analysis based on 60 manually annotated GPT-4o explanations, three independent annotators, structured adjudication, and a five-category failure taxonomy. The analysis shows that explanation failures concentrate in misclassified cases and differ substantially across confusion-matrix quadrants.
- We provide concrete protocol recommendations for APR researchers who use LLM Judge as a patch evaluation instrument.

# 2 Study Design

## 2.1 Dataset Construction

Our study dataset builds upon the dataset introduced by Lin et al. [16], which comprises 1,179 patches spanning 356 Defects4J bugs produced by 23 APR tools and human developers, with ground-truth correctness labels established through rigorous manual inspection. Using this raw source directly would introduce two confounds that are particularly harmful for a reliability study: (1) Class imbalance (533 correct vs. 646 overfitting patches, with substantial per-bug skew) would make precision, recall, and F1 difficult to interpret without controlling

for prior probability. (2) Within-bug correlation would inflate agreement statistics: multiple patches from the same bug share identical buggy code, test suites, and contextual information, so LLM judgments on them are not independent observations.

To eliminate both confounds, we randomly retain only bugs that contain at least one correct and at least one overfitting patch. When multiple candidate patches exist within a given class, we prefer patches from APR tools over developer patches, as the former carry an independent developer-written reference patch that is used in RQ3. The resulting main dataset comprises 326 patches drawn from 163 Defects4J bugs (Chart: 18, Closure: 55, Lang: 29, Math: 53, Time: 8), with a 1:1 correct-to-overfitting ratio. Of the 163 correct patches, 54 originate from APR tools and are accompanied by an independent developer reference patch, while the remaining 109 are developer patches. The 1:1 balance ensures that accuracy, precision, recall, F1, and MCC are directly interpretable without class-prior adjustment, and the paired structure enables within-bug McNemar's tests to control for bug context.

## 2.2 Prompt Design

**Sanitized Baseline Prompt (`S0`/`E0`.).** All experiments share a common sanitized base prompt that contains only information directly derivable from the patch itself: the buggy function source code and the unified-diff patch. The LLM is instructed to output a strict JSON object with three fields: label $\in$ {correct, overfitting, uncertain}, confidence $\in$ [1, 5], and a 2–4 sentence explanation. The `uncertain` label allows the model to abstain when the provided evidence is insufficient to classify a patch as either `correct` or `overfitting`; it is not a ground-truth class in our dataset.

**Leakage Settings for RQ2.** The inputs of APCA tools may combine patch code with auxiliary artifacts, which may directly or indirectly expose benchmark-identifying information [40]. To measure benchmark-identifying information leakage, we define six main prompt variants that progressively expose meta-information about the patch origin, plus two counterfactual controls, as shown in Table 1. Each variant appends one or more information blocks to `S0`. `S5` is treated as an upper-bound reference because the developer patch constitutes a near-complete answer. The `S4R` control randomly reassigns the complete bug-ID/project/tool metadata triple to a different patch using a fixed seed, while `S4F` replaces the real bug ID with a non-existent benchmark-style identifier and keeps the real project and tool names. These controls test whether any `S4` shift depends on the correct metadata linkage or merely on the presence of benchmark-looking text.

**Table 1** Leakage prompt settings (RQ2). Each variant appends the listed information to the sanitized baseline `S0`.

| Setting | Additional Information | Purpose |
|---|---|---|
| `S0` | (none – sanitized baseline) | Baseline |
| `S1` | Bug identifier (e.g., `Math-1`) | Bug-ID leakage |
| `S2` | Project name (e.g., Apache Commons Math) | Project leakage |
| `S3` | Repair tool name (e.g., `TBar`) | Tool leakage |
| `S4` | Bug ID + project + tool | Full ID leakage |
| `S4R` | Shuffled bug ID + project + tool | Counterfactual metadata control |
| `S4F` | Fake bug ID + real project + tool | Fake-ID format control |
| `S5` | Developer/reference patch diff | Reference leakage |

**Evidence Settings for RQ3.** To measure evidence-presentation bias, we define five prompt variants that vary the type of evidence provided alongside the patch, as shown in Table 2. `E2` is the critical test-passing bias probe: it exposes only the fact that all tests passed, without any test code, so the LLM cannot reason about test semantics. `E4` provides the developer patch, enabling a reference-similarity bias analysis separate from the leakage experiment.

**Table 2** Evidence prompt settings (RQ3). Each variant appends the listed evidence to the sanitized baseline `E0`.

| Setting | Additional Evidence | Bias Probe |
|---|---|---|
| `E0` | (none – patch only) | Baseline |
| `E1` | Failing test source code | Test-semantic reasoning |
| `E2` | Declaration that all tests passed | Test-passing bias |
| `E3` | Passed/failed test list (execution summary) | Execution evidence |
| `E4` | Developer/reference patch diff | Reference-similarity bias |

## 2.3 LLM Configuration

In the main experiments for RQ1–RQ3, we evaluate two judge models, GPT-4o [7] and DeepSeek-V3 [2], both configured with a temperature of 0 to reduce sampling variability [21]. GPT-4o represents a widely used closed-source model, whereas DeepSeek-V3 represents a widely used open-source model. Both models receive identical prompts and are evaluated on the same 326-patch dataset across the complete prompt matrix (`S0`–`S5`, `S4R`/`S4F`, and `E0`–`E4`); because `E0` is identical to `S0`, this yields 12 executed settings per model.

## 2.4 Explanation Failure Taxonomy

For RQ4, we define a five-category failure taxonomy, summarized in Table 3. Three annotators (three authors of this paper) independently apply this taxonomy to a stratified sample of 60 explanations drawn from the `S0` results, with 15 explanations sampled from each confusion-matrix quadrant (TP, TN, FP, and FN). For each explanation, annotators record whether any failure is present, assign zero or more taxonomy-defined failure types, and rate the severity on an ordinal scale (none, minor, major, critical).

## 2.5 Experimental Metrics

In RQ1, we report Accuracy, macro-F1 [22], Matthews Correlation Coefficient (MCC) [18], Cohen's Kappa [1] (against human labels), False Positive Rate (FPR: proportion of overfitting patches mislabelled as correct), and uncertain rate (proportion of patches labelled `uncertain`). Because the dataset contains only `correct` and `overfitting` ground-truth labels, `uncertain` predictions are counted as errors for accuracy, macro-F1, MCC, and Cohen's Kappa. Note that FPR is the primary safety-critical metric in this setting: each false positive accepts an overfitting patch as correct, thereby inflating reported repair effectiveness.

To analyze the impact of benchmark-identifying information leakage and evidence presentation bias on LLM Judge judgments, we introduce Label Flip Rate, Flip Direction, Odds Ratio (OR), $\Delta$Acc and $\Delta$FPR metrics in RQ2 and RQ3. Here, Label Flip Rate denotes the proportion of patches whose predicted labels change relative to the baseline setting (`S0` or `E0`); Flip Direction indicates the number of flips toward the ground-truth label (Better) or

**Table 3** Explanation failure taxonomy.

| Failure Type | Definition |
|---|---|
| Hallucinated Evidence | Explanation references variables, methods, logic, or behavioral claims absent from or unsupported by the provided code. |
| Test Overtrust | Explanation uses "tests pass" as the primary or sole justification for correctness (circular argument). |
| Behavioral Misunderstanding | Explanation mischaracterises what the patch actually does semantically. |
| Missed Edge Cases | Explanation fails to identify boundary-input behavior where the patch diverges from the correct fix. |
| Contradictory Explanation | Explanation is internally inconsistent, or contradicts the final label. |

away from it (Worse) relative to the baseline; Odds Ratio is the ratio of toward-ground-truth flips to away-from-ground-truth flips; and $\Delta$Acc and $\Delta$FPR represent the changes in accuracy and FPR relative to the baseline setting, respectively.

We further apply McNemar's test [19] (paired nominal, two-sided) to each baseline–variant label pair, comparing `S0` with each $\texttt{S}_i$ for RQ2 and `E0` with each $\texttt{E}_i$ for RQ3. We report Holm-corrected $p$-values ($p_{\text{Holm}}$) to assess whether the observed label shifts relative to the baseline are statistically significant. For RQ3, we additionally compute a Test-passing Bias Index $= (\text{FPR}_{E2} - \text{FPR}_{E0})/\text{FPR}_{E0}$, and for `E4` we stratify patches by token-level similarity to the developer patch and examine whether flip rate correlates with similarity quartile. In RQ4, we assess inter-annotator agreement using Fleiss' Kappa [4] for the binary failure label, Krippendorff's Alpha [12] for nominal failure types and ordinal severity ratings.

# 3 Results

## 3.1 RQ1: Baseline Agreement

We begin by examining how closely the two LLM judges (i.e., GPT-4o and DeepSeek-V3) align with human ground-truth labels when all benchmark-identifying information has been removed from the prompt. Table 4 reports the agreement metrics for GPT-4o and DeepSeek-V3 under the sanitized `S0` setting on the 326-patch balanced dataset. As shown in Table 4, DeepSeek-V3 obtains slightly higher accuracy, Macro-F1, MCC, and Cohen's Kappa than GPT-4o; however, this advantage comes at the cost of a higher false-positive rate, indicating that DeepSeek-V3 is more prone to accepting overfitting patches as correct.

To better understand where these aggregate differences originate, Table 5 presents the full confusion matrices. GPT-4o correctly identifies 125 of 163 correct patches (recall = 76.7%) and 127 of 163 overfitting patches (recall = 77.9%), yielding a relatively symmetric error profile. DeepSeek-V3, by contrast, exhibits an asymmetric pattern: it achieves higher recall on correct patches (140/163 = 85.9%) but lower recall on overfitting patches (122/163 = 74.8%). This asymmetry is directly reflected in its elevated FPR (22.1% vs. 17.2%): DeepSeek-V3 is more inclined to label patches as correct, which recovers more true positives at the expense of also admitting more overfitting patches.

**Table 4** RQ1 baseline agreement metrics (`S0`).

| Metric | GPT-4o | DeepSeek-V3 |
|---|---|---|
| Accuracy | 77.3% | 80.4% |
| Macro-F1 | 0.796 | 0.817 |
| MCC | 0.575 | 0.625 |
| Cohen's Kappa | 0.571 | 0.620 |
| FPR (overfitting→correct) | 17.2% | 22.1% |
| Uncertain rate | 5.8% | 3.4% |

**Table 5** RQ1 confusion matrices (`S0`). Rows are ground truth; columns are LLM predictions.

| Model | | Corr. | Overfit. | Unc. | Total |
|---|---|---|---|---|---|
| GPT-4o | Correct | 125 | 27 | 11 | 163 |
| | Overfitting | 28 | 127 | 8 | 163 |
| DeepSeek-V3 | Correct | 140 | 17 | 6 | 163 |
| | Overfitting | 36 | 122 | 5 | 163 |

The `uncertain` label is used sparingly by both models, though GPT-4o invokes it more frequently than DeepSeek-V3 (5.8%, 19 patches vs. 3.4%, 11 patches). Despite these distributional differences, a paired cross-model McNemar comparison on the same 326 patches reveals no statistically significant difference in overall accuracy ($p = 0.164$). DeepSeek-V3 is correct where GPT-4o is wrong on 26 patches, whereas GPT-4o is correct where DeepSeek-V3 is wrong on 16 patches (OR = 1.63); the two models produce different labels on 48 patches in total. In other words, the two models exhibit comparable baseline reliability, albeit through markedly different error profiles.

**Table 6** Confidence-stratified RQ1 results under `S0`. FP/OF denotes false-positive acceptances over all overfitting patches in the confidence band.

| Model | Conf. | N | Acc. | FP/OF | FPR |
|---|---|---|---|---|---|
| GPT-4o | 1–3 | 19 | 0.0% | 0/8 | 0.0% |
| | 4–5 | 307 | 82.1% | 28/155 | 18.1% |
| DeepSeek-V3 | 1–3 | 16 | 31.3% | 0/10 | 0.0% |
| | 4–5 | 310 | 82.9% | 36/153 | 23.5% |

As shown in Table 6, confidence provides only a limited triage signal: lower-confidence predictions should be prioritized for human review, but false-positive acceptances from both models still occur among high-confidence predictions. Therefore, confidence cannot validate a `correct` judgment or exempt high-confidence accepted patches from verification.

### Answer to RQ1

LLM Judge provides a useful but incomplete signal under sanitized conditions. GPT-4o achieves 77.3% accuracy (MCC = 0.575) with FPR = 17.2%, while DeepSeek-V3 achieves 80.4% accuracy (MCC = 0.625) with FPR = 22.1%; the difference in overall accuracy is not statistically significant ($p = 0.164$). The two models fail in different ways: GPT-4o is more conservative, whereas DeepSeek-V3 accepts more correct patches but also more overfitting patches. Thus, neither model is reliable enough to serve as an unsupervised patch-correctness oracle, although both can provide a triage-level assessment signal.

## 3.2 RQ2: Benchmark-Identifying Information Leakage

In RQ2, we investigate whether exposing benchmark-identifying metadata alters model judgments beyond what is already inferable from the sanitized patch context alone. Table 7 summarizes the effect of progressively reintroducing such metadata into the prompt. Specifically, each row reports the change in accuracy, the change in FPR, the number of label flips relative to `S0`, and the Holm-corrected McNemar $p$-value. **GPT-4o.** For GPT-4o, the

**Table 7** RQ2 leakage results. "Better" / "Worse" count patches that flip to / from the ground-truth label vs. `S0`. "OR" is the odds ratio of flipping toward vs. away from ground truth. $p_{\text{Holm}}$ applies Holm correction within each model's test family.

| Model | Setting | ΔAcc | ΔFPR | Better | Worse | OR | $p_{\text{Holm}}$ |
|---|---|---|---|---|---|---|---|
| GPT-4o | `S1` +bug ID | +2.1 | +1.8 | 14 | 7 | 2.00 | 0.946 |
| | `S2` +project | +0.6 | +2.5 | 10 | 8 | 1.25 | 1.000 |
| | `S3` +tool | +2.1 | −5.5 | 18 | 11 | 1.64 | 0.946 |
| | `S4` +all IDs | +4.3 | −5.5 | 20 | 6 | 3.33 | 0.056 |
| | `S4R` +shuffled IDs | −1.5 | −4.9 | 16 | 21 | 0.76 | 1.000 |
| | `S4F` +fake ID | +2.1 | −4.9 | 16 | 9 | 1.78 | 0.946 |
| | `S5` +dev patch | +10.4 | −11.0 | 40 | 6 | 6.67 | **<0.001** |
| DeepSeek-V3 | `S1` +bug ID | +1.2 | −0.6 | 12 | 8 | 1.50 | 1.000 |
| | `S2` +project | −0.6 | +2.5 | 5 | 7 | 0.71 | 1.000 |
| | `S3` +tool | +2.1 | −5.5 | 15 | 8 | 1.88 | 1.000 |
| | `S4` +all IDs | +1.8 | −0.6 | 11 | 5 | 2.20 | 1.000 |
| | `S4R` +shuffled IDs | +0.3 | −2.5 | 12 | 11 | 1.09 | 1.000 |
| | `S4F` +fake ID | +2.1 | −4.9 | 14 | 7 | 2.00 | 1.000 |
| | `S5` +dev patch | +7.1 | −9.8 | 32 | 9 | 3.56 | **0.003** |

individual identifiers in `S1`–`S3` produce only small, non-significant changes, indicating that no single metadata field yields a measurable shift. Combining the identifiers in `S4` instead produces a positive shift that is marginal after Holm correction; we therefore interpret it as suggestive rather than conclusive evidence of metadata sensitivity. The shuffled-metadata and fake-ID controls do not reproduce the full `S4` pattern, so this signal is not explained solely by benchmark-looking text and does not constitute direct evidence of memorisation. By contrast, `S5` produces the largest, statistically significant improvement, showing that developer-reference access substantially amplifies agreement.

**DeepSeek-V3.** DeepSeek-V3 shows a similar directional tendency under `S3` and `S5`, but its metadata-only effects are more attenuated. Neither the individual identifiers nor their combination in `S4`, including the counterfactual controls, is significant after Holm correction. This provides little evidence of identifier-driven sensitivity for this model on our dataset. In contrast, `S5` again produces a large, significant improvement, confirming that the developer-reference effect is robust across both models.

**Cluster-aware robustness.** Because each bug contributes one correct and one overfitting patch, we additionally resampled bug-level pairs with replacement and computed 95% bootstrap confidence intervals for the core comparisons. For GPT-4o, the `S4` accuracy shift remains positive, while `S4R` and `S4F` cross zero. For DeepSeek-V3, all three metadata-only intervals cross zero . By contrast, the developer-reference conditions are stable across clusters for both models. These intervals support a conservative reading: `S4` is a suggestive GPT-4o metadata shift, whereas `S5` is a robust reference-patch effect.

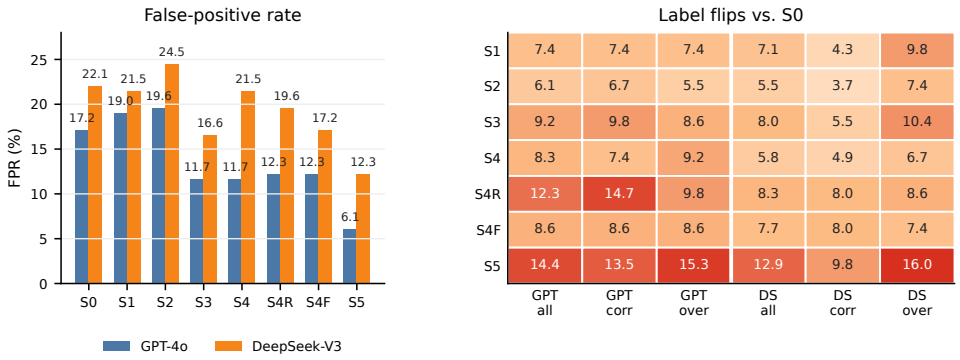

**Figure 1** RQ2 metadata-leakage effects for GPT-4o and DeepSeek-V3. The left panel reports false-positive rates; the right panel reports label-flip rates relative to `S0`.

Fig. 1 visualises these patterns from two complementary perspectives. As shown in the left panel of Fig. 1, DeepSeek-V3 consistently maintains a higher FPR than GPT-4o across all metadata exposure conditions, even when accuracy is comparable. The right panel shows that the label-flip rate is highest for `S5` (developer patch) for both models, with a pronounced skew toward flipping overfitting patches to correct, which is consistent with a strong reference-similarity effect.

### Answer to RQ2

Benchmark-identifying metadata can shift LLM Judge outcomes, but the effect is uneven across metadata types and models. Individual bug IDs, project names, and tool names do not produce significant shifts; however, their combination in `S4` yields a suggestive GPT-4o improvement, which becomes marginal after Holm correction ($p_{\text{Holm}} = 0.056$) and does not appear for DeepSeek-V3. The shuffled-metadata and fake-ID controls do not reproduce the full `S4` pattern, suggesting a cautious metadata-induced-shift interpretation rather than a strong causal claim. By contrast, exposing the developer patch in `S5` produces large and significant gains for both models ($p \leq 0.003$). Therefore, including benchmark-identifying information, especially developer patches, can overestimate LLM Judge reliability by up to 10 pp.

## 3.3 RQ3: Evidence-Presentation Bias

In RQ3, we investigate whether different forms of supporting evidence systematically alter LLM Judge behaviour when benchmark-identifying metadata remains sanitized. Table 8 summarizes the effect of each evidence variant relative to `E0`. Both models are evaluated under all four evidence conditions.

Test code (E1). As shown in Table 8, failing test source code produces model-dependent behaviour: the two models move in different accuracy directions, while both show higher FPR. Although neither within-model change is significant after Holm correction, the cross-model paired comparison is significant, indicating that the models interpret raw test code in qualitatively different ways.

Test-passing bias (E2). Contrary to our initial hypothesis, declaring that all tests passed does not significantly alter either model's judgments. The corresponding test-passing bias is small and directionally inconsistent, indicating that a test-passing declaration alone is not strong evidence of correctness for either model.

**Table 8** RQ3 evidence bias results. $p_{\text{Holm}}$ applies Holm correction within each model's test family.

| Model | Setting | ΔAcc | ΔFPR | Better | Worse | OR | $p_{\text{Holm}}$ |
|---|---|---|---|---|---|---|---|
| GPT-4o | E1 +test code | −2.8 | +4.9 | 13 | 22 | 0.59 | 0.526 |
| | E2 +tests pass | +1.2 | +1.2 | 10 | 6 | 1.67 | 0.909 |
| | E3 +exec info | +0.6 | +6.1 | 17 | 15 | 1.13 | 0.909 |
| | E4 +dev patch | +9.5 | −11.0 | 40 | 9 | 4.44 | **<0.001** |
| DeepSeek-V3 | E1 +test code | +0.9 | +3.1 | 9 | 6 | 1.50 | 1.000 |
| | E2 +tests pass | +0.9 | −0.6 | 9 | 6 | 1.50 | 1.000 |
| | E3 +exec info | +0.6 | +3.1 | 11 | 9 | 1.22 | 1.000 |
| | E4 +dev patch | +7.1 | −8.0 | 31 | 8 | 3.88 | **0.001** |

Execution information (E3). Including passed/failed test lists produces a directionally similar but statistically weaker pattern: FPR increases for both models, but neither increase remains significant after correction.

Reference patch (E4). Consistent with the S5 findings in RQ2, providing the developer patch produces the largest and statistically significant effect among all evidence variants: accuracy improves and FPR decreases for both models. This pattern indicates that the developer patch serves as a strong reference anchor rather than ordinary contextual evidence.

The cluster-aware robustness analysis gives the same practical interpretation for the two core RQ3 probes. For E2, accuracy intervals cross zero for both models, confirming that a test-passing declaration alone is not a robust source of accuracy shift. For E4, the developer-reference effect remains stable under bug-level resampling.

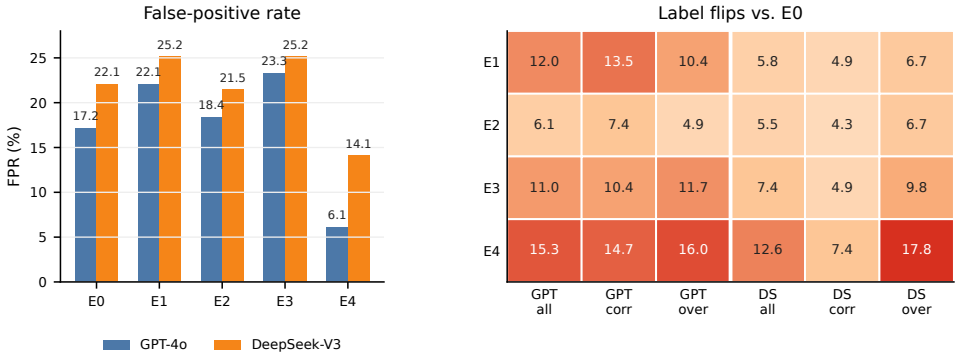

**Figure 2** RQ3 evidence-presentation effects for GPT-4o and DeepSeek-V3. The left panel reports false-positive rates; the right panel reports label-flip rates relative to E0.

To test whether the reference effect is simply driven by lexical similarity, we stratified the patches with an available developer reference into token-similarity quartiles. Flip rates under both E4 and S5 vary non-monotonically across these quartiles. Thus, the developer patch clearly improves judgments, but the mechanism is not reducible to a simple token-level similarity effect. Fig. 2 reinforces this contrast visually. As shown in the left panel of Fig. 2, the FPR increases for both models under E1 and E3, while remaining relatively stable under E2. The right panel of Fig. 2 shows that the label-flip rate is highest for E4 (developer patch) for both models, with a pronounced skew toward flipping overfitting patches to correct, which is consistent with a strong reference-similarity effect.

### Answer to RQ3

We find little evidence that a bare test-passing statement is sufficient to bias LLM Judge decisions. Declaring that all tests passed (`E2`) does not significantly shift either model (GPT-4o $p = 0.909$; DeepSeek-V3 $p = 1.000$), and the Test-passing Bias Index is small and directionally inconsistent (+7.1% for GPT-4o and −2.8% for DeepSeek-V3). Raw test code and execution traces have more model-dependent effects and tend to increase FPR, but most within-model changes are not significant. The only consistently strong evidence effect comes from the developer reference patch (`E4`), which significantly improves accuracy for both models ($p \leq 0.001$). This effect is best interpreted as a near-oracle comparison signal rather than ordinary evidence-presentation bias, and its benefit is not reducible to token-level lexical similarity.

## 3.4 RQ4: Exploratory Explanation Reliability

To assess explanation reliability, we conducted an exploratory manual analysis of 60 LLM explanations sampled from the `S0` results (15 per confusion-matrix quadrant) using the five-category failure taxonomy defined in Table 3. Three annotators independently labelled each explanation, and disagreements were resolved through a structured adjudication process. Because the sample is limited to GPT-4o under `S0` and the annotation task exhibits low-to-fair agreement, we treat RQ4 as an exploratory audit of explanation risks rather than as a definitive estimate of explanation failure prevalence across models and prompts.

**Table 9** RQ4 inter-annotator agreement (3 annotators, 60 samples).

| Metric | Value |
|---|---|
| Fleiss' Kappa (`has_failure`) | 0.237 |
| Krippendorff's $\alpha$ (`has_failure`) | 0.241 |
| Krippendorff's $\alpha$ (severity) | 0.279 |
| Exact 3-way severity agreement | 28/60 (46.7%) |
| Full unanimous annotation | 26/60 (43.3%) |
| Adjudication required | 34/60 (56.7%) |

Inter-Annotator Agreement. We first examine inter-annotator agreement (IAA) to assess the inherent subjectivity of the annotation task, with the results reported in Table 9. As shown in Table 9, agreement on the binary failure judgment is low to fair, with Fleiss' Kappa of 0.237 and Krippendorff's Alpha of 0.241. Agreement on severity is similarly modest, with Krippendorff's Alpha of 0.279. Full three-way unanimity is reached for only 26 of the 60 samples (43.3%), while the remaining 34 samples (56.7%) require adjudication. These results indicate that judging whether an LLM explanation is well grounded is an inherently subjective and challenging task, even for trained annotators. They also highlight a practical concern for human-in-the-loop review: the same explanation may be judged as hallucinated or acceptable depending on how strictly evidential support is interpreted. To resolve disagreements, we use a structured adjudication process. We first compute a majority-vote consensus and then ask the three annotators to jointly review all 34 disagreement cases. Final updates are accepted only when at least two annotators endorse the same revision. This process yields five accepted adjudication updates, while nine minority concerns remain at the preliminary consensus level.

Consensus Results. After adjudication, 20 of the 60 explanations (33.3%) were found to contain at least one failure. As shown in Table 10, the contrast across quadrants is pronounced but should be interpreted with caution. In this stratified sample, explanations

**Table 10** RQ4 explanation failure rate by quadrant.

| Quadrant | Failures | Total | Rate |
|---|---|---|---|
| TP (correct, pred correct) | 0 | 15 | 0.0% |
| TN (overfitting, pred overfitting) | 0 | 15 | 0.0% |
| FP (overfitting, pred correct) | 14 | 15 | 93.3% |
| FN (correct, pred overfitting) | 6 | 15 | 40.0% |
| **Overall** | **20** | **60** | **33.3%** |

**Table 11** RQ4 failure type prevalence and distribution by quadrant.

| Failure Type | Count | Rate | TP | TN | FP | FN |
|---|---|---|---|---|---|---|
| Hallucinated Evidence | 14 | 23.3% | 0 | 0 | 9 | 5 |
| Behavioral Misunderstanding | 7 | 11.7% | 0 | 0 | 5 | 2 |
| Missed Edge Cases | 10 | 16.7% | 0 | 0 | 10 | 0 |
| Test Overtrust | 0 | 0.0% | 0 | 0 | 0 | 0 |
| Contradictory Explanation | 0 | 0.0% | 0 | 0 | 0 | 0 |

associated with correctly classified patches (TP and TN) contain no failures identified by consensus, whereas failures are concentrated among explanations for misclassified patches: 93.3% in the FP quadrant and 40.0% in the FN quadrant. The Fisher exact test indicates that the failure rate in the FP quadrant is significantly higher than that in the TP quadrant ($p < 0.001$), and that the failure rate in the FN quadrant is also significantly higher than that in the TN quadrant ($p = 0.035$). This result does not imply that all explanations with correct labels are reliable; rather, it indicates only that our consensus process did not identify formal failures among the 30 sampled TP/TN explanations.

**Table 12** RQ4 severity distribution.

| Severity | Count | Rate |
|---|---|---|
| None | 40 | 66.7% |
| Minor | 3 | 5.0% |
| Major | 16 | 26.7% |
| Critical | 1 | 1.7% |

Table 11 presents the prevalence of each failure type. As shown in Table 11, Hallucinated Evidence is the most prevalent category (23.3%), followed by Missed Edge Cases (16.7%) and Behavioral Misunderstanding (11.7%). Notably, Test Overtrust and Contradictory Explanation were not observed in the sample. Within the FP quadrant, Missed Edge Cases is nearly universal (10/14 failed explanations), suggesting a tendency of the model to defend overfitting patches by overlooking inputs on which the evaluated patch and the correct fix diverge. In the FN quadrant, by contrast, Hallucinated Evidence dominates (5/6 failed explanations), indicating that the model fabricates code-level criticisms to justify rejecting actually-correct patches. Finally, Table 12 reports the severity distribution. Among the 20 failed explanations, 16 are rated as *major* and 1 as *critical*, indicating that the vast majority of explanation failures are not minor annotation disagreements but substantive reasoning errors that could mislead practitioners.

**Answer to RQ4**

LLM explanations are reliable mainly when the underlying label is already correct. In our exploratory GPT-4o/`S0` sample, 33.3% of explanations contain at least one consensus failure, but the failures are concentrated in misclassified cases: 93.3% of FP explanations and 40.0% of FN explanations contain failures, whereas no consensus failures appear in the sampled TP/TN explanations. Hallucinated Evidence is the most common failure type (23.3%), followed by Missed Edge Cases (16.7%), and most failures have major severity. The low inter-annotator agreement ($\kappa = 0.237$) further suggests that explanation reliability is difficult to judge, making unverified LLM rationales a risky basis for human-in-the-loop patch review.

# 4 Discussion

## 4.1 LLM Judge as a Triage Aid, Not a Replacement

The RQ1 results demonstrate that both GPT-4o and DeepSeek-V3 achieve moderate agreement with human ground-truth labels under sanitized conditions (77.3% and 80.4% accuracy, MCC = 0.575 and 0.625, respectively), and that neither model significantly outperforms the other ($p = 0.164$). Although this level of performance is useful for triaging large volumes of candidate patches – reducing manual inspection effort by filtering out likely-overfitting patches – it is insufficient for unsupervised deployment as a sole correctness oracle. False positive rates of 17.2% (GPT-4o) and 22.1% (DeepSeek-V3) indicate that between one in five and one in six overfitting patches would be accepted as correct, potentially propagating inflated repair accuracy claims throughout the research literature. The cross-model comparison reveals broadly similar reliability across the full prompt matrix: after Holm correction, the only setting exhibiting a statistically significant patch-level accuracy difference is `E1` ($p_{\text{Holm}} = 0.046$). Accordingly, the primary concern is not which model achieves marginally higher accuracy, but the fact that both models continue to accept a substantial proportion of overfitting patches. We therefore recommend that LLM Judge be positioned as a triage aid: a first-pass filter that ranks candidates for human review, rather than a replacement for ground-truth verification.

## 4.2 The Metadata Leakage Threat

RQ2 reveals that combining benchmark-identifying information (bug ID, project name, and tool name in `S4`) produces a suggestive accuracy improvement for GPT-4o (+4.3 pp, OR = 3.33) but not for DeepSeek-V3 (+1.8 pp, OR = 2.20). This model-dependent asymmetry is notable: although both models receive identical metadata, only GPT-4o exhibits a cluster-robust metadata-induced shift, and even that shift remains marginal after the expanded Holm correction ($p_{\text{Holm}} = 0.056$). The individual metadata settings for DeepSeek-V3 are likewise non-significant, suggesting that benchmark-identifying shortcuts exert a weaker influence on this model within our dataset. One plausible explanation is that the training data of GPT-4o contains more Defects4J-related content (e.g., from papers, repositories, and tutorials) than the corpus of DeepSeek-V3, thereby enabling stronger shortcut recognition; however, this result should be interpreted as a possible memorisation signal rather than direct causal evidence. The two counterfactual controls reduce, but do not eliminate, this ambiguity: shuffled metadata removes the GPT-4o improvement, while a fabricated bug ID does not reproduce the full `S4` shift. Regardless of the underlying mechanism, the implication for experimental design is clear: studies that include file paths containing project names, bug identifiers in variable names, or tool attribution in comments may inadvertently enable

certain LLMs to short-circuit code reasoning – even when the effect is model-dependent. We therefore recommend that all benchmark-identifying metadata be stripped from prompts when evaluating LLM Judge reliability, in accordance with the `S0` sanitization protocol, and that future leakage claims include counterfactual metadata controls.

## 4.3 Test-Passing Evidence: Limited Bias

Contrary to our initial hypothesis, the explicit declaration that all tests passed (`E2`) does not significantly bias LLM judgments for either model (GPT-4o: $p = 0.909$; DeepSeek-V3: $p = 1.000$). This cross-model consistency suggests that both LLMs, at temperature 0, do not naïvely equate test passage with patch correctness – a more sophisticated reasoning pattern than anticipated. However, providing raw test code (`E1`) or execution traces (`E3`) trends toward an increased false positive rate for both models. The most pronounced model-dependent difference emerges under the raw test code condition: DeepSeek-V3 significantly outperforms GPT-4o in patch-level correctness under `E1` after cross-model Holm correction ($p_{\text{Holm}} = 0.046$), although its false positive rate remains elevated. This finding warrants caution: supplementary test evidence may introduce model-specific noise rather than uniformly improving reasoning quality.

## 4.4 The Developer Patch: Oracle or Leakage?

Both `S5` (RQ2) and `E4` (RQ3) demonstrate that providing the developer reference patch substantially improves LLM accuracy for both models: GPT-4o gains +10.4 pp and +9.5 pp, and DeepSeek-V3 gains +7.1 pp across both settings ($p \leq 0.003$). This improvement is expected and legitimate when the developer patch is genuinely available, as similarity comparison constitutes a valid reasoning strategy. However, the magnitude of the improvement raises a critical concern: when a study reports LLM Judge accuracy with developer patches included in the prompt, the reported figure reflects pattern-matching against a known answer rather than the independent code-reasoning ability of the LLM. Notably, both models converge to nearly identical accuracy under `S5`/`E4` (∼87%), despite differing by 3 pp under `S0` – indicating that the reference patch effectively eliminates model-specific differences. Studies should therefore clearly distinguish between reference-assisted assessment, which is legitimate but requires a developer patch, and standalone assessment, which represents the common use case in which no reference is available.

## 4.5 Explanation Reliability: An Exploratory Risk Signal

RQ4 yields an exploratory risk signal: explanation quality is strongly contingent on label correctness. When the LLM classifies a patch correctly (TP and TN), the corresponding explanations contain no consensus-identified failures across the 30 sampled TP/TN cases. By contrast, when the classification is incorrect, explanation failures are substantially more frequent – a failure rate of 93.3% for false positives and 40.0% for false negatives.

This asymmetry creates a particularly dangerous feedback loop. A practitioner reviewing a false positive explanation encounters a plausible, well-structured argument that an overfitting patch is correct. Such an explanation may reference specific code elements, discuss behavioral semantics, and present a seemingly coherent conclusion; yet within the false positive sample, 93.3% of such explanations contain hallucinated evidence, missed edge cases, or behavioral misunderstandings. The practitioner possesses no reliable signal to distinguish a trustworthy explanation from a hallucinated one without independently verifying the underlying code

reasoning – an effort that defeats the efficiency rationale for employing an LLM judge. The low inter-annotator agreement ($\kappa = 0.237$) on explanation failures further reinforces this concern: even trained annotators struggle to reliably identify whether an LLM explanation is well-grounded or subtly fabricated. If domain experts disagree on whether an explanation contains hallucinated reasoning, practitioners with less domain expertise are unlikely to detect such failures during review.

## 4.6 Practical Recommendations

Based on the findings of this study, we offer the following recommendations for APR researchers employing LLM Judge:

### 4.6.1 APCA-specific recommendations

**Sanitize prompts.** Removing or masking benchmark-identifying metadata (bug IDs, project names, tool names, and file paths) should be viewed as a prudent precaution to reduce the risk of metadata-induced shortcuts, rather than as a universally validated requirement. When investigating leakage, include shuffled-metadata or fabricated-ID controls so that benchmark-formatting effects are not conflated with genuine metadata linkage.

**Distinguish reference-assisted assessment from standalone assessment.** When a developer patch is used as evidence, this should be clearly stated, and the results should not be generalized to settings in which no reference patch is available.

### 4.6.2 General principles for LLM-as-Judge evaluation

**Report task-specific safety metrics alongside accuracy.** Evaluation should expose the decision error with the greatest task-level cost and report the full error profile. In APCA, this safety-critical metric is the false-positive rate, together with the full confusion matrix.

**Do not treat explanations as self-validating.** LLM explanations are least reliable precisely when they matter most – on misclassified patches. Explanations should be treated as starting points for further investigation rather than as self-contained justifications.

**Deploy LLM Judge as a triage filter.** LLM Judge should be used to rank and filter candidates for human review, not as a replacement for manual correctness assessment.

# 5 Threats to Validity

**Internal validity.** The main internal threat is prompt sensitivity: different prompt wordings or output formats may induce different LLM judgments. We reduce this threat by using one prompt template across all settings, varying only the information content inserted into that template, and set the temperature to 0 to reduce sampling variability. For RQ4, the low inter-annotator agreement ($\kappa = 0.237$) indicates that explanation-failure labels partly depend on the adjudication protocol. We mitigate this risk through independent annotation, majority-vote consensus, and a conservative adjudication rule in which label changes are accepted only when at least two of three annotators agree on the change direction.

**External validity.** Our dataset is drawn exclusively from Defects4J, a Java benchmark covering five Apache projects. Results may not generalise to other programming languages or APR benchmarks. Defects4J is a widely adopted benchmark in the APR community, encompassing multiple real-world Java projects, and thus offers a degree of representativeness. The present study focuses primarily on Java, the dominant language in this domain; future work will explore broader language support, including Rust and Python. Furthermore, GPT-4o represents a widely used proprietary model and DeepSeek-V3 represents an open-source model with competitive performance. We deliberately selected this pair to contrast proprietary and open-source LLMs, rather than to claim that two models cover the full LLM landscape. Models with different architectures, training data, reasoning capabilities, or release dates may exhibit different reliability profiles. Accordingly, the observed model-dependent effects should not be generalised to all LLMs. Future work will repeat the protocol on additional proprietary and open-source models as releases evolve.

# 6 Related Work

## 6.1 Automated Patch Correctness Assessment

The APCA technique is designed to address the overfitting problem in test-based APR, wherein a generated patch may pass all available tests yet still fail to achieve the intended repair. Existing APCA techniques can be broadly organized into dynamic and static methods, depending on whether correctness evidence is obtained from program execution or code and change representations [37, 20].

Dynamic APCA methods assess patches by observing their behavioral effects under existing, generated, or augmented tests [31, 29, 30]. For instance, Opad [31] employs mutation testing to augment test cases for patch validation, DiffTGen [29] generates tests to expose test-suite-overfitted patches, PATCH-SIM [30] compares behavioral similarity between generated and developer patches, Ye et al. [35] scale such checks to large APR corpora, and xTestCluster [17] groups generated patches by their test-observed behavior. Dynamic methods provide executable evidence and can reveal concrete counterexamples, but their effectiveness remains constrained by test generation quality, oracle availability, and the observability of the fault-relevant behavior.

Static APCA methods infer patch correctness from code, change, and contextual features without requiring additional executions [34, 24, 16, 25, 11, 14]. For example, ODS [34] uses a classifier over statically extracted code features, Tian et al. [24] learn representations for code changes, Cache [16] develops context-aware code-change embeddings, Quatrain [25] explores correlations between bug descriptions and patch descriptions, Kang et al. [11] leverage language models for patch prioritization, Shibboleth [6] analyses production/test code impact. Reliability-oriented studies further show that APCA labels and checking procedures can be unstable, that current APCA methods still leave substantial error rates, and that existing checking approaches vary widely in assumptions and coverage [13, 26, 32]. Overall, static methods reduce dependence on generated tests and scale well to large patch corpora, but they also introduce risks from dataset bias, feature leakage, and limited cross-project generalization.

More recently, LLMs have been introduced into APCA, recasting patch assessment as a natural-language and code-understanding task [36, 40, 5, 33]. For example, APPT [36] fine-tunes pre-trained models for patch correctness prediction, LLM4PatchCorrect [40] retrieves similar patches and uses them as context to assist LLM predictions of patch correctness, Yang et al. [33] apply parameter-efficient fine-tuning with attributed patch semantic graphs to inject structured patch semantics into LLMs, RePaCA [5] employs reinforcement learning fine-

tuned LLMs to generate chain-of-thought reasoning for patch correctness assessment. These methods often report stronger predictive performance than earlier feature-based classifiers, but most studies optimize accuracy rather than validating whether LLM judgments are stable, unbiased, and grounded measurement outcomes. Our work therefore differs from prior APCA research by auditing LLM-as-Judge itself: we examine how metadata leakage, evidence availability, model choice, and explanation quality affect the reliability of LLM-based patch correctness assessment.

## 6.2 LLMs as Judges in Software Engineering

The use of LLMs as evaluation instruments has expanded rapidly beyond APR into code generation, code review, and software testing. CodeJudgeBench [8] evaluated LLM-as-Judge for code generation and testing tasks, finding systematic biases in LLM evaluations. Liang et al. [15] reported memorisation-related benchmark-recognition signals in SWE-bench, where LLMs may recognise benchmark instances from pre-training data rather than reasoning from first principles. Bias-in-the-Loop [38] audited LLM-as-Judge for software engineering tasks and found evidence of position bias, verbosity bias, and self-enhancement bias. Our work contributes to this growing body of evidence by providing a controlled, multi-dimensional reliability audit specific to the APCA task, with particular attention to benchmark-identifying information leakage and explanation quality.

# 7 Conclusion

This paper presents an empirical reliability study of LLM-as-Judge for automated patch correctness assessment. Across a balanced Defects4J dataset, GPT-4o and DeepSeek-V3 achieve moderate accuracy but still produce substantial false-positive rates, indicating that LLM Judge is useful for triage but insufficient as a standalone correctness oracle. Benchmark-identifying metadata can induce model-dependent accuracy shifts, which reinforces the need for prompt sanitization and counterfactual metadata controls. Test-passing declarations do not significantly bias judgments in our setting, whereas raw test code and execution traces may increase false positives. Providing the developer reference patch substantially improves accuracy, but this result should be interpreted as reference-assisted assessment rather than standalone evaluation. Finally, our exploratory explanation audit shows that one-third of sampled explanations contain failures, concentrated among misclassified patches, with hallucinated evidence and missed edge cases as the dominant failure types.

Future work should extend this reliability audit to additional LLMs, programming languages, and APR benchmarks, and investigate whether prompt engineering or fine-tuning can reduce explanation failures without introducing new biases.

## Abstract

**Background.** Large Language Models (LLMs) are increasingly being applied to Software Engineering (SE) tasks, achieving high accuracy across problems such as clone detection, vulnerability prediction, and code summarization. However, their high computational demands and energy consumption raise sustainability concerns and hinder their use on consumer hardware and resource-constrained platforms. A common way to report the computational cost of an LLM in the literature and industry is to use the number of Floating Point Operations (FLOPs) required to perform a pass over the network.

**Aims.** This paper investigates the implications of energy-aware knowledge distillation for SE, aiming to improve model efficiency while maintaining performance and to determine whether FLOPs is a reliable energy-aware metric.

**Method.** We conduct a controlled experiment using MORPH, a Many-Objective Optimization-based distillation methodology, to empirically examine whether FLOPs accurately reflect energy consumption in Clone Detection and Vulnerability Prediction tasks. We extend this methodology to include energy-surrogate models that directly estimate CPU and GPU energy consumption during optimization, and we apply MORPH to generative tasks using CodeT5+ for code summarization.

**Results.** Our results show that FLOPs is not always a reliable indicator of energy consumption, and better results can be achieved by using energy-surrogate models. Distilled student models can reduce inference energy consumption by up to 90% and memory usage by 86%, with only modest accuracy trade-offs.

**Conclusions.** Energy-aware knowledge distillation when guided by direct energy surrogates rather than FLOPs can improve the energy consumption, sustainability, and deployability of LLMs for SE applications, enabling efficient models on consumer hardware.

## 1 Introduction

Large language models (LLMs) have recently emerged as a highly useful tool for tasks that require language understanding and generation. Among them, LLMs are capable of supporting an extensive number of Software Engineering (SE) tasks [12], including both classification (e.g., clone detection [20], vulnerability prediction [48]) and generation tasks (e.g., code summarization [1] or code completion [15, 23]). Their capabilities come from massive scales: billions of parameters trained on terabytes of open-source code from platforms such as GitHub [25]. This scale poses significant computational challenges, including the need for large datacenters with dedicated hardware for parallel computation, such as GPUs [44]. Powering these datacenters requires massive amounts of energy: the International Energy Agency projects that datacenters' energy consumption will double over the next 5 years [17], further straining existing electrical infrastructure and increasing greenhouse gas emissions and environmental costs [34].

Optimizing LLM energy consumption requires addressing where and how operational costs accumulate. Because inference dominates lifetime energy usage for high-volume models [10], relying on large, general-purpose models over long sequences incurs substantial computational and energetic overhead [27]. To mitigate this, model compression reduces the compute and memory footprint per query, directly lowering operational energy demands. For SE workflows, such compressed models provide a dual benefit: they minimize runtime power consumption and enable lightweight, local deployment directly inside IDEs, avoiding energy-intensive calls to remote cloud servers [29, 40].

A promising technique that can generate smaller, more efficient models addressing these three aspects is knowledge distillation (KD) [16], where a smaller model (*student*) learns the implicit knowledge of a larger model (*teacher*) for a downstream task. By learning to mimic the teacher's output probability distribution, the student model maintains similar accuracy while using considerably fewer resources. In the context of SE tasks, Panichella [29] proposes MORPH, a method that compresses BERT models to smaller sizes using evolutionary algorithms and predictive models (or surrogates) to improve accuracy and metamorphic robustness. This method achieves state-of-the-art performance on clone detection and vulnerability prediction tasks, surpassing prior work on this topic [35].

While these results are promising, two aspects limit their generalizability. First, MORPH relies on Floating Point Operations (FLOPs) as a proxy for energy consumption. The approach aims to minimize the FLOPs used by a model to reduce energy requirements. FLOPs measure the number of floating-point operations required for a training or inference pass and can be derived directly from a model's architecture and hyperparameters. Their simplicity and hardware-agnostic nature make FLOPs attractive, and they have therefore been widely used in the Machine Learning literature as a stand-in for energy consumption in LLM research [18, 24, 22].

However, the validity of FLOPs as a proxy for energy consumption remains debated in the literature, where their correlation to energy usage is heavily dependent on the context. Most FLOPs estimates – such as those from common profiling tools[1] – capture only the theoretical count of mathematical operations (e.g., matrix multiplications, additions) while ignoring runtime factors that strongly influence energy usage, including memory access patterns, data movement overheads, and hardware-level optimizations on GPUs or TPUs [10, 2, 9]. As a result, FLOPs may not reliably reflect actual energy consumption.

[1] `https://docs.pytorch.org/docs/stable/profiler`

Second, the evaluation for MORPH is limited to BERT-like models compressed from up to 500 MB to 3 MB. Such size reductions do not necessarily yield proportional energy savings, as energy is subject to diminishing returns due to baseline power consumption or memory bandwidth saturation. Furthermore, BERT is now relatively dated, while newer architectures such as CodeT5 [43] and Starcoder 2 [25] have since emerged, raising questions about generalizability. Moreover, the experiments focus only on two binary classification tasks. More complex tasks involving generation not only require students to capture deeper semantic knowledge but also involve multiple forward passes during autoregressive decoding. This substantially increases inference costs and makes energy estimation more challenging.

To address these limitations, we first revisit the efficiency assumptions behind MORPH and then extend the method to optimize for measured energy directly and to handle generation tasks. Concretely, we ask the following research questions:

**RQ$_1$**: *Are FLOPs a good proxy of energy consumption in the context of model distillation using Many Objective Optimization?*

To answer this question, we replicate the experiments from the original paper and measure energy during the training and inference phases for different student models with varying FLOPs, using an energy profiler to capture CPU and GPU energy. Statistical testing shows that FLOPs do not correlate well with energy measurements from the profiler, and that other factors, such as specific hyperparameters, may provide stronger correlations with energy.

Based on these results, we modify MORPH to improve its energy estimation. Instead of relying on FLOPs, we introduce measured energy (from the profiler) as a new optimization objective and build a surrogate model to predict energy consumption from hyperparameter combinations. This naturally motivates our next question:

**RQ$_2$**: *How energy efficient are MORPH models when using actual energy as an objective?*

This lets MORPH search for configurations that are efficient with respect to observed hardware behavior rather than architectural estimates alone.

Finally, we examine whether Many-Objective Optimized Distillation can be effective beyond classification, in more complex generative tasks that may require deeper semantic knowledge. To investigate this, we extend the MORPH methodology with a new distillation pipeline and investigate:

**RQ$_3$**: *How effective is MORPH at reducing LLMs costs for generation tasks, and what is the accuracy tradeoff?*

We evaluate the modified method with CodeT5+ [43], distilling models for code summarization with energy as an additional optimization objective. We compare the resulting students with the teacher model in terms of accuracy (ROUGE-L), size, and energy consumption.

In summary, this paper makes the following contributions:

- Empirical study of FLOPs vs. energy. We replicate MORPH's experiments and show that FLOPs correlate inconsistently with actual energy consumption in SE tasks.
- Energy-aware extension of MORPH. We introduce measured energy as an optimization objective, with surrogate models to estimate energy from hyperparameters.
- Application of the extended method to CodeT5+ for code summarization, achieving up to 90% lower energy and 86% smaller memory footprint, with modest accuracy trade-offs.

## 2 Background

Knowledge distillation [16] is a technique for compressing large pretrained models into smaller, more efficient models, ideally with minimal impact on accuracy. The smaller model serves as the student, and the larger model acts as the teacher. Instead of learning directly from

the dataset, the student model learns to predict responses similar to the teacher's. To do this, the training dataset is fed into the teacher and the student, and the student's loss is computed to minimize the distance between the student's and teacher's output probability distribution. Distillation can be done with generic pretraining tasks, to compress general-purpose models [8], or as task-specific distillation, where the student learns from a teacher finetuned to perform a specific task, and can be used for the same task without any additional finetuning.

Knowledge distillation brings multiple advantages. The dataset size required for distilling a student model is smaller, as is the number of epochs needed to reach convergence, which lowers training costs. However, it requires an already pretrained, high-performing teacher. Additionally, for task-specific distillation, depending on the task's complexity, some pretrained weights are required for the student model. For example, in binary classification tasks, the student model's weights can be randomly initialized, whereas more complex tasks, such as generation, may require pretraining or copying weights from the teacher.

On top of this, finding the optimal hyperparameter set for the student model can be challenging. The possible combination of hyperparameters, such as the number of layers or attention heads, makes the search space extremely large. To tackle this, several approaches model this search as an optimization problem with one or more objectives, and the different hyperparameters as variables. The state-of-the-art implementation MORPH [29] employs a Many-Objective optimization approach to compress models for two binary classification SE tasks: Clone Detection and Vulnerability Prediction. It defines 4 objectives for the student model: maximum accuracy, minimum memory footprint, minimum FLOPs, and maximum robustness. For robustness, the paper uses metamorphic testing, which involves creating new data samples by applying transformations to the input data that preserve the code's functionality and semantics, such as replacing English words with synonyms or expanding acronyms. Robustness is measured using prediction flips: given a code sample modified by metamorphic transformations, prediction flips determine whether the model maintains the original prediction.

To solve the Many-objective optimization problem, MORPH employs AGE-MOEA [28], an evolutionary algorithm that evolves an initial population of solutions and converges towards the Pareto front. In Many-objective optimization, the Pareto front is the set of solutions that achieve optimal trade-offs among the objectives. These are solutions in which improving one objective would negatively impact the others. To explore the population space without distilling and evaluating every possible student, MORPH employs surrogate models to improve accuracy and reduce prediction flips. By uniformly sampling the configuration space and training a set of student models, it builds two surrogate models to predict the accuracy and prediction flips of a given configuration, without training that configuration

## 3 Related Work

**Many-Objective Knowledge Distillation for LLMs.** Multi- and Many-Objective optimization for Knowledge Distillation is a relatively recent technique that explores the configuration space of student models to optimize for two or more objectives, including maximizing accuracy and minimizing computational cost and size. The first proponent was Shi et al. [36] with COMPRESSOR, which used a single-objective genetic algorithm to distill binary classification models, minimizing a combination of Giga FLOPs and model size. Later, they introduced AVATAR [35], which uses a multi-objective genetic algorithm with 3 objectives: minimize FLOPs and model size, and maximize accuracy.

MORPH [29] builds on top of this previous work, introducing robustness as an additional objective, which is done using metamorphic testing, as explained in Section 2. With its additions – metamorphic testing, surrogate models, and Many-Objective optimization – MORPH achieves state-of-the-art performance compared to AVATAR, but leaves some questions unanswered. First, it uses FLOPs as an optimization objective for energy and sustainability, as does the previous work. However, the relationship between FLOPs and energy consumption is not straightforward and depends on factors such as the target hardware and the potential optimizations it enables. In this work, we aim to determine whether FLOPs is an adequate objective to minimize when reducing the energy consumption of a distilled model.

Another topic these approaches do not address is their validity for generation tasks. Previous work only performs distillation for binary classification tasks, namely, Clone Detection and Vulnerability Prediction. These tasks are much simpler than generation tasks and require less complex models, allowing for more aggressive compression during distillation. In this paper, we will apply this technique to a generation task, Code Summarization, and investigate whether the advantages it offers can be applied to generation tasks.

**FLOPs as proxy for energy consumption.** The validity of floating-point operations (FLOPs) as a proxy for an AI model's energy consumption is an ongoing debate in the field. FLOPs were first proposed as an energy proxy in the early stages of Green AI [34, 21] because they can be easily calculated solely from architectural details. Desislavov et al. [10] perform a study on inference energy consumption for a set of AI models for Computer Vision and Natural Language Processing tasks. Here, the authors propose using FLOPs as a proxy for energy consumption, relating the FLOPs used by a model during inference to hardware FLOPs and combining them with GPU hardware specifications, specifically TFLOP/s and power. However, this study fails to address the gap between logical and hardware FLOPs, as it does not account for potential hardware optimizations enabled by GPUs or TPUs.

Asperti et al. [2] investigated the validity of FLOPs as a proxy metric for energy consumption of Convolutional Neural Networks (CNN). They show that FLOPs do not correlate well with energy consumption and propose a metric, $\alpha$-FLOPS, that accounts for hardware and model architecture to estimate energy more accurately. However, this work focuses solely on CNNs and does not consider other architectures, such as transformers, widely used by LLMs. A similar study by del Rey et al. [9] on multiple Deep Neural Network architectures shows that FLOPs might be a better estimator of GPU usage than energy consumption.

A gap remains regarding whether the correlation between FLOPs and energy consumption observed in previous studies is still applicable to LLMs. Despite this, many LLM-related papers still use it to reflect energy costs of models, as seen in Section 3 with MORPH, but also many others [18, 24, 22]. This paper aims to shed light on this topic and investigate whether FLOPs are a viable proxy for energy consumption in certain LLM tasks.

## 4 Methodology

This section introduces the changes applied to the original MORPH methodology to investigate our research questions. For $\mathbf{RQ}_1$, we maintain the original approach, and empirically measure energy usage of the distilled models in the Pareto front. For $\mathbf{RQ}_2$, we extend this approach by adding energy as an additional objective in the function. For $\mathbf{RQ}_3$, we take this one step further and use our modified approach for a more complex generation task.

## 4.1 Adding Energy as Optimization Objective

For research question $\mathbf{RQ}_2$, we closely maintain the original methodology steps. The only change we introduce is to redefine the efficiency function, using energy rather than FLOPs to measure a model's energy efficiency.

To do this, we adapt the surrogate model methodology proposed in the original paper for predicting accuracy and the number of prediction flips. We sample a representative subset of the hyperparameter subset using Latin Hypercube Sampling (LHS), which provides a uniformly distributed set of configurations across the sampling space. For each hyperparameter set, we assess median CPU and GPU energy consumption across multiple runs, following the protocol described in Subsection 5.4, along with accuracy and prediction flips. Then, we use the energy measurements to train two additional regression models to predict GPU and CPU energy consumption for a given set of hyperparameters.

During the optimization phase, instead of computing and minimizing FLOPs for the sampled population, we predict CPU and GPU energy consumption and use the sum as our new minimization objective. If the surrogate models are sufficiently accurate, this serves as an alternative proxy metric for energy.

## 4.2 Morph for Generation

To investigate $\mathbf{RQ}_3$, we adapt Morph's objective function to work for a generation task. Concretely, we will test Morph and CodeT5+ performance for the Code Summarization task. To evaluate the efficacy of a student model for this task, we want the student model to produce summaries as close as possible to those in the dataset, while minimizing energy usage and model size. Therefore, we redefine the problem and objective function as follows:

*Definition: Given a LLM teacher model, find a hyperparameter configuration* $C = [c_1, \ldots, c_m]$ *for the student model* $S$ *that optimizes the following objectives:*

$$\begin{cases} min\ O_1 = & size(S) \\ min\ O_2 = & efficiency(S) \\ max\ O_3 = & effectiveness(S, V) \end{cases}$$

where $V$ is the validation set. The main changes to the original formulation lie in the lack of a robustness metric and the measurement of efficiency and effectiveness. To measure effectiveness, we require metrics that measure similarity between generated texts and ground truth. Ideally, we would compare the summaries' semantic similarity using human judgment or an LLM serving as a judge. However, since the methodology requires training and testing a relatively high number of models, this would significantly increase the time and resources needed. Therefore, we select an ngram-based metric. To partially mitigate the lack of human judgment, we select ROUGE-L as our accuracy metric. ROUGE-L has been shown to align better with human judgment [11] than other state-of-the-art metrics, such as BLEU, METEOR, or CodeBLEU, for code-related tasks.

To assess robustness, the original paper used the number of prediction flips as a metric, since it dealt with binary classification tasks. In the case of summarization, robustness is much more difficult to assess, since there is not a single correct summary for a piece of code. Furthermore, introducing metamorphic code changes, such as synonymizing parameter names, can yield the same changes in the summary, maintaining semantic similarity while using different words. This could also potentially be addressed with human or LLM judgment, but such techniques do not fit the size of these methodologies.

Finally, to measure efficiency, we will use energy measurements of the inference process in Joules, rather than FLOPs, following the process defined in the previous section. Using the same inference dataset, we measure the energy required for each student to complete it.

To create the surrogate models, we follow the technique described in Section 4.1 for the first two research questions and GraphCodeBERT. We sample the hyperparameter space using LHS, distill the models, and measure their ROUGE-L scores on the validation set and their inference energy consumption.

**Weight subcloning.** Because clone detection and vulnerability prediction are binary classification tasks, the student model weights were randomly initialized, as the number of epochs required for convergence is relatively small. However, for summarization, the implicit knowledge the student model needs to learn is larger, and convergence takes longer with random initialization. Additionally, in our preliminary studies, we observed that randomly initialized students converge to generic responses independently of the input. To solve this, we clone part of the teacher model's weights into the student model before starting the distillation process.

To copy the most important weights, we apply a weight subcloning technique [33]. This technique runs inference on the teacher model over a small subset of the validation set (around 80,000 tokens) and captures the input and output magnitudes of different neurons and attention heads. Based on these inputs and outputs, it ranks neurons and layers by importance, and copies the most important weights into the student model, respecting the new architecture. According to the study, student models initialized this way achieve 4x faster training times.

**Teacher Logit extraction and Distillation Loss.** In the original MORPH for binary classification tasks, inference is run on the teacher over the training set, and the two logits per sample (positive probability, negative probability) are saved. These logits are later used during offline distillation, where only the student model needs to be instantiated in memory.

Compared to binary classification, generative tasks can be viewed as classification over the vocabulary size at each output position, making it infeasible to store logits. In our preliminary experiments, the logits for only 64 training samples already required about 1 GB of disk space. Since it is unfeasible to store all the logits, we perform online distillation. We instantiate the teacher and student models on the same GPU and, for each batch, first perform inference on the teacher to obtain the logits, then perform the training step on the student. While this helps avoid storage problems with logits, it increases computational demand, since we need two models instantiated and running inference simultaneously.

To compute the loss between the student output, teacher output, and ground truth, we used the average of the Kullback-Leibler Divergence (KLD) and cross-entropy loss. KLD is a loss function to compute the difference between two probability distributions. In this case, it takes the student and teacher logits and compares the probability distributions for each output token across the entire vocabulary. This loss is the standard used across Knowledge Distillation tasks [47, 3] and it has been shown to work well with LLMs [45].

To ensure the student models remain aligned with the ground truth, we include the cross-entropy loss between the student predictions and the ground-truth probability distribution.

# 5 Evaluation

The goal of this study is twofold: (1) to validate the use of MORPH for optimizing LLMs with respect to energy consumption, and (2) to assess its applicability to generation tasks.

- $\mathbf{RQ}_1$: *Are FLOPs a good proxy of energy consumption in the context of model distillation using Many Objective Optimization?*
- $\mathbf{RQ}_2$: *How energy efficient are MORPH models when using actual energy as an objective?*
- $\mathbf{RQ}_3$: *How effective is MORPH at reducing LLMs costs for generation tasks, and what is the accuracy tradeoff?*

The objective of $\mathbf{RQ}_1$ is to empirically assess the validity of FLOPs as a proxy for energy consumption by examining their correlation in models generated by MORPH, thereby identifying potential weaknesses in the existing distillation approaches for code-specific LLMs [29, 35]. $\mathbf{RQ}_2$ evaluates our proposed modifications to MORPH, which incorporate energy directly into the optimization. The goal is to determine whether these models are more energy-efficient than those distilled using the standard approach.

Finally, the objective of $\mathbf{RQ}_3$ is to verify the applicability of our modified MORPH method to generation tasks for software engineering. The original MORPH approach is only tested for binary classification tasks. Text generation is a much more complex task, and achieving results similar to those presented in the original paper might not be possible. With this question, we aim to verify whether we can train LLM models suitable for generation tasks that preserve accuracy while being significantly smaller and more energy-efficient.

## 5.1 Downstream tasks

For $\mathbf{RQ}_1$, to keep alignment with the MORPH experiments [29], we evaluate energy consumption of MORPH models on the same software engineering tasks and datasets: Clone Detection and Vulnerability Prediction. With this, we can replicate previous results exactly and draw valid comparisons. For the clone detection task, the dataset used is BigCloneBench [39], a collection of Java code clones obtained by mining 25,000 Java projects from SourceForge and Google Code. For vulnerability prediction, the dataset used is Devign [49], which contains C code from two open-source libraries, FFmpeg and Qemu. As explained in previous research, this selection avoids data leakage problems [29].

As a generation task, we chose Code Summarization. We chose this task because it is quick to evaluate (does not require running test cases, as in code generation) and provides an objective score quickly via ROUGE-L. However, it is still a relevant task that is used for automated commit messages or pull requests. We use two separate datasets to avoid data leakage problems. For finetuning the teacher, we use the Python split of the CodeXGLUE code summarization dataset [26]. This dataset is extracted from CodeSearchNet and comes from publicly available, open-source GitHub repositories.

However, CodeT5+, the model used for summarization, has been pretrained on CodeSearchNet data, so we cannot use the validation and test splits of CodeXGLUE for evaluation of the model due to data leakage. To solve this problem, we will extract validation data from The Heap [19]. This is a contamination-free dataset extracted from GitHub projects with non-permissive licenses and has been de-duplicated against the most popular training datasets. Using a Python AST parser, we extract functions with docstrings and use them as our evaluation dataset.

## 5.2 Large Language Models

We employ two pretrained models for these experiments, GraphCodeBERT [14], and CodeT5+ [43]. GraphCodeBERT is a bimodal model pretrained on natural-language and programming-language data, based on BERT and CodeBERT [13], and extends the latter's capabilities by incorporating information from the code snippet's data flow graph. In the original MORPH study [29], both CodeBERT and GraphCodeBERT are tested. However, for $\mathbf{RQ}_1$, based on the architecture similarity and the study's results, we replicate the results only for GraphCodeBERT, since the conclusions from this should be applicable to both models.

For the generation tasks, we use CodeT5+ [43]. This model is based on the Google T5 model and has been pretrained on multiple code-related tasks, including code summarization, using the CodeSearchNet and BigCode datasets. We chose this model because it is more recent than GraphCodeBERT and offers better capabilities. This family also provides small versions, from which we choose the model with 220M parameters. This choice is motivated by our hardware constraints and the need to perform online distillation with 2 models loaded simultaneously. Our experiments also require multiple distillations to create surrogate models and multiple energy measurement runs. Using a smaller model reduces the execution times of the experimental pipeline.

## 5.3 Empirical Methodology

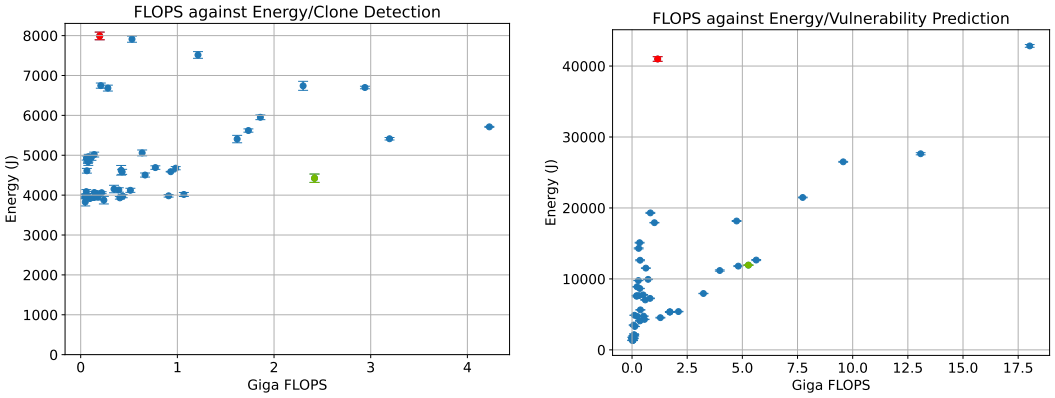
To answer $\mathbf{RQ}_1$, we sample models with varying FLOPs, measure their energy consumption, and analyze the correlation between the two. To obtain these models, we generate a Pareto front of optimal solutions using the original MORPH approach. In many-objective optimization, the Pareto front consists of solutions for which no objective can be improved without sacrificing at least one other objective. Therefore, sampling the Pareto front will yield a diverse set of models with varying FLOP requirements. After measuring the energy consumption of these models, we use statistical methods, such as ANOVA, to identify correlations among energy, FLOPs, and other hyperparameters.

To answer $\mathbf{RQ}_2$, we compare the models generated by the original MORPH methodology with a modified method that substitutes the FLOPs objective with actual energy consumption predictions, using the surrogate model to predict energy consumption in inference, similar to the surrogate method used for prediction flips. We compare both methodologies using the metrics from the original paper (*size*, *accuracy*, *robustness*, and *FLOPs*) as well as *inference energy consumption* to determine whether models actually consume less energy during inference. We run the original MORPH and the modified version, generating new Pareto fronts and models for both cases. Given the random nature of the MOP optimization algorithm, we distill 20 models and report the median results for the previous metrics, along with the interquartile range. To compare with the original MORPH results, we use the same model selection criteria, choosing the model with size closest to 3MB. We analyze the results using the Wilcoxon signed-rank test [5] to determine whether there is a statistically significant difference in energy consumption between standard and modified MORPH, and the Vargha-Delaney $\hat{A}_{12}$ statistic [42] to determine the effect size.

Finally, to answer $\mathbf{RQ}_3$, we distill a CodeT5+ model using MORPH and the energy objective, and compare the student model with the teacher model. We compare based on three metrics: accuracy (using ROUGE-L), size, and energy efficiency. We also manually inspect some test samples to evaluate the models' performance based on human judgment.

## 5.4 Energy Measurement Setup

For our experiments, we measure only energy usage during the inference step. We exclude tokenization and decoding since they depend on the tokenizer, which is not affected by the distillation. Measuring the energy consumption of an AI model is difficult because software cannot run in a vacuum; it depends on its environment: operating system, dependencies, memory, and hardware. Additionally, the hardware can be affected by external constraints, such as room temperature. Consequently, obtaining a precise measurement with a single execution is not guaranteed.



We follow existing guidelines to mitigate external factors [6]. The first is to make execution times long enough to reduce variance in energy measurements. Accordingly, we assess inference energy of the distilled models using an automated script that: (1) loads the model and test dataset, and (2) runs inference on the dataset multiple times. The multiple inferences are run so the energy costs of loading the model do not overshadow the inference costs. Another mitigation is to repeat measurements for each model in a randomized order, with short pauses in between, to reduce variation caused by unexpected system activity. Following the guidelines, we perform 20 executions [6] and report the median energy consumption across runs. Between measurements, we reset the GPU context to ensure no cached results affect the measurements.

The experiments are run on a server equipped with an AMD Ryzen 9 7900X processor, 64 GB of RAM, and an NVIDIA GeForce RTX 4090 GPU. The server runs Ubuntu 22.04.3, with Linux kernel version 6.2.0, and Docker 24.0.5. To measure CPU and GPU energy consumption, we use EnergiBridge [32], a software profiling tool compatible with AMD CPUs and Nvidia GPUs, among others, that uses RAPL and NVML under the hood.

## 5.5 Parameter settings

For the components of the methodology that remain unchanged from the original implementation, we maintain the parameter configuration from the original paper [29]. This includes the parameters for population creation and mutation, optimization algorithm, and hyperparameter space for GraphCodeBERT. We also replicate the configuration of the original paper for the new energy surrogate models, using Gradient Boosting Regression, and grid search to optimize GBR hyperparameters accross the following predefined parameter space: (1) number of decision trees $\in \{50, 100, 150\}$; (2) learning rate $\in \{0.05, 0.10, 0.15, 0.20, 0.25\}$; (3) maximum depth of each decision $3 \in \{2, 3, 4, 5\}$; (4) the minimum number of samples in internal node $\in \{2, 3, 4\}$; (5) minimum number of samples in leaf nodes $\in \{1, 2, 3\}$.

For Code Summarization distillation in CodeT5+ we use the following configuration space: (1) number of hidden layers $\in [1, 12]$; (2) hidden activation $\in \{gelu, relu, silu, gelu\text{-}new\}$; (3) number of decoder layers $\in [1, 12]$; (4) hidden size $\in [16, 768]$; (5) number of attention heads $\in [1, 12]$; (6) projection size $\in [1, 64]$; (7) intermediate size $\in [16, 3072]$; (8) relative attention buckets $\in [4, 32]$; (9) relative attention max distance $\in [32, 128]$; (10) dropout rate $\in \{0.1, 0.2, 0.3\}$; (11) feed forward projection $\in \{relu, gated\text{-}relu\}$; (12) learning rate $\in \{0.001, 0.0001, 0.00005\}$; (13) batch size $\in \{8, 16\}$. This configuration's maximum values are equivalent in size to the teacher model (CodeT5+ 220M). This way, student models will be no larger than the teacher model. We chose this because, a priori, we do not know the level of compression that can be achieved for this task and model, and it may be that the maximum accuracy lies in the teacher's model size.

**(a)** Clone Detection.

**(b)** Vulnerability Prediction.

**Figure 1** Inference energy usage against FLOPs.

Additionally, compared to the original paper, we removed hyperparameters for the tokenizer, since modifying it would require retraining the teacher model, since the number of logits equals the vocabulary size for each token.

Finally, for inference during evaluation, we use beam-search multinomial sampling with 5 beams.

# 6 Results

## 6.1 RQ1: Correlation of FLOPs and Energy Consumption

We ran MORPH with its default configuration and extracted details of the Pareto front for the Clone Detection and Vulnerability Prediction tasks. For each Pareto front, we ran energy tests on inference, using the same test set for every model and testing each model multiple times in a randomized order, as explained in Section 5.4. Figure 1 shows a scatterplot of total inference energy consumption vs FLOPs for the Pareto Front of the Clone Detection (Figure 1a) and Vulnerability Prediction (Figure 1b) tasks.

For the Clone Detection task, the figure shows no clear correlation between FLOPs and Energy. Most models with fewer Giga FLOPs accumulate around the 4,000 J mark, but there are many models that do not show a straight relationship between FLOPs and energy. For example, the most expensive model uses around 8,001 J while their computational cost is 0.20 Giga FLOPs (highlighted in red), while a model with 2.4 Giga FLOPs uses 4,423 J, around 44 % less energy (highlighted in green).

For the Vulnerability Prediction task (Figure 1b), the results reveal a different behavior and show a much clearer correlation between FLOPs and energy consumption, with a higher number of FLOPs translating into higher inference energy. However, despite a clearer correlation, there is again no straightforward relationship between FLOPs and energy consumption. Similarly to Clone Detection, some models use significantly less energy than others with higher FLOP counts. For example, a model with 1.16 GFLOPs is using 41,122 J (highlighted in red), while a model with 5.27 GFLOPs is using 11,945 J, or 70% less energy (highlighted in green). Relying solely on this correlation may obscure outlier models that are far more energy efficient or, conversely, favor models that are substantially less efficient.

**Table 1** ANOVA test results against inference energy for Clone Detection (CD) and Vulnerability Prediction (VP). Grey denotes significance. For CD, all models in the Pareto front have Num Hidden Layers = 1.

| Hyperparameter | CD | VP |
|---|---|---|
| Tokenizer | 0.06 | 0.82 |
| Vocabulary Size | 0.03 | 0.04 |
| Num Hidden Layers | – | 8.26e-11 |
| Hidden Size | 2.95e-5 | 1.89e-4 |
| Hidden Activation | 0.01 | 2.23e-4 |
| Number of Attention Heads | 3.69e-14 | 6.54e-09 |
| Max Sequence Length | 6.97e-08 | 1.71e-05 |
| Position Embedding Type | 3.71e-3 | 0.11 |
| Learning Rate | 0.53 | 0.906290 |
| FLOPS | 0.16 | 6.48e-07 |

Additionally, during our experiments, we tracked and made surrogate models for both CPU and GPU energy. However, we observed that CPU power usage is mostly constant, and total energy only depends on inference time. This means that the bulk of the processing was happening on the GPU. Higher CPU energy comes only from measuring the same power usage over a longer period. Therefore, for these results, we report total energy consumption (CPU + GPU), since the CPU's energy consumption is relevant but does not show a clear trend on its own.

Table 1 reports the results of the ANOVA test for inference energy against the different hyperparameters of the model, with p-values $< 0.05$ indicating a statistical correlation between inference energy and the hyperparameter. For Clone Detection, the ANOVA test results confirm that there is no statistical correlation between FLOPs and energy, with a $p$-value=0.17. Additionally, the results reveal that other hyperparameters, such as Hidden Size, Number of Attention Heads, and Max Sequence Length, show a high correlation with energy ($p$-value $\ll 0.05$). However, despite these hyperparameters being part of the FLOPs computation, their correlation with energy does not transfer to the FLOPs metric. From the Figure, it is clear that higher FLOPs do not always translate to higher energy consumption.

For the Vulnerability Prediction task, the ANOVA results confirm the correlation observed in the figure, with a $p$-value of $6.48e-07$ for the FLOPs metric against energy consumption. The test also confirms the correlations with the other hyperparameters already observed in Clone Detection.

The results for both tasks suggest that FLOPs can be a somewhat accurate proxy for energy consumption, but other factors that affect energy consumption are not reflected in this metric. In the original MORPH methodology, the same FLOPs computation algorithm taken from Clark et al. [4] is used for both classification tasks. This suggests that FLOPs is not a task-agnostic proxy for energy consumption and fails to capture certain behaviors in the Clone Detection task that strongly influence energy consumption.

**Answer to RQ$_1$.** For Clone Detection, FLOPs fail as an energy proxy ($p = 0.17$), while for Vulnerability Prediction FLOPs are statistically associated with energy ($p = 6.48 \times 10^{-7}$). This task-dependent contrast shows that FLOPs are not a reliable task-agnostic proxy, and the observed spread of models with similar FLOPs but different energy confirms that FLOPs are not directly proportional to energy consumption.

## 6.2 RQ2: Substituting FLOPS with surrogate energy prediction

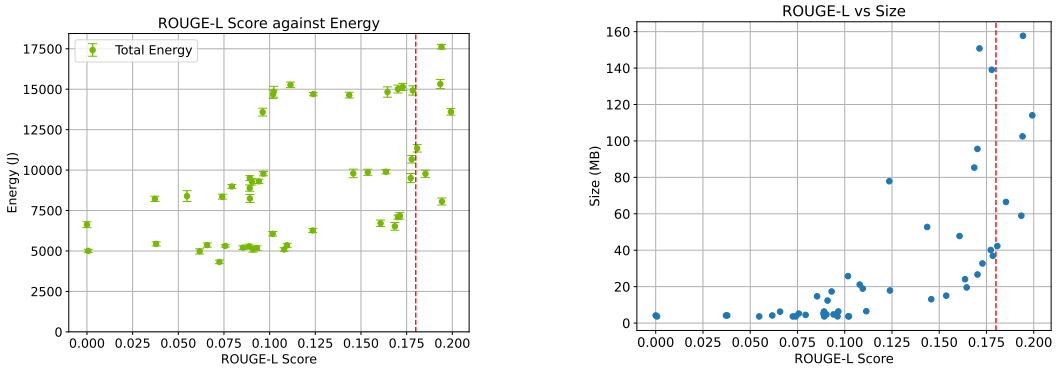
**Table 2** Results of Morph using FLOPs and surrogate energy as optimization objectives. The best result for each metric is highlighted in grey.

| Task | Objective Metric | Accuracy (%) | | Size (in MB) | | # Pred. Flips | | Giga FLOPs | | Energy (J) | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Median | Diff. | Median | Diff. | Median | Diff. | Median | Diff. | Median | Diff. |
| Clone Detection | FLOPS | 95.26 (2.42) | | 3.00 (0.01) | | 43.00 (14.25) | | 0.79 (0.36) | | 5355.83 (1391) | |
| | Energy | 95.95 (0.97) | +6.09% | 3.01 (0.06) | +0.01 | 37.00 (27.00) | -57% | 0.98 (0.24) | +21% | 3604.50 (824) | -39% |
| Vulnerability Prediction | FLOPS | 55.60 (4.77) | | 2.98 (0.11) | | 143.00 (257.00) | | 0.68 (0.47) | | 10505.50 (6762.75) | |
| | Energy | 56.20 (4.50) | -0.27% | 2.99 (0.13) | +0.01 | 218.00 (260.00) | -33% | 0.98 (0.20) | +36% | 14219.00 (8568.75) | +30% |

We apply Morph to produce 20 student models optimized for FLOPs and energy, respectively. Due to the method's stochastic nature, each model yields different trade-offs. Table 2 reports median and interquartile range for accuracy, model size, prediction flips, GFLOPs, and energy. As per Section 5.3, we select the model with size closest to 3MB.

For accuracy and prediction flips, neither optimization strategy significantly outperforms the other. Energy optimization yields slightly higher accuracy, but the difference is not statistically significant ($p$-value>0.3) for both Clone Detection and Vulnerability Prediction. Conversely, FLOPs optimization shows fewer prediction flips, but again the difference is not significant ($p$-value>0.5).

An opposite but similar effect occurs with robustness: the original FLOPs optimization outperforms energy optimization in of prediction flips (e.g., better model robustness). However, this difference is again not statistically significant ($p$-value>0.5) for both tasks.



Finally, when looking at sustainability and energy use, improvement results are mixed, depending on the task. For Clone Detection (where FLOPs did not show a statistical correlation with energy), the results show that the energy-optimized approach produces models with higher GigaFLOPs (21%) than the FLOPs-optimized approach. This difference is statistically significant ($p$-value $< 0.01$) with a medium effect size ($\hat{A}_{12} = 0.68$). Nevertheless, we observe that this increase in FLOPs does not translate to higher energy consumption, and the energy optimization approach outperforms the original approach with a difference of 39% in median inference energy. This is a statistically significant difference ($p$-value $< 0.01$) with a large effect size ($\hat{A}_{12} = 0.925$).

For Vulnerability Prediction – where FLOPs correlated with energy – the energy-based approach yields models with 36% more GFLOPs and about 30% more energy, though the differences are not statistically significant ($p$-value>0.2).

These results suggest that the energy optimization approach can be useful when FLOPs are unreliable or lack a statistical correlation with energy consumption, as is the case for Clone Detection. For Vulnerability Prediction, the energy approach neither improves nor shows a statistically significant degradation.

**Answer to RQ$_2$.** Using surrogate energy instead of FLOPs reduces median inference energy in Clone Detection by 39% (from 5355.83 J to 3604.50 J), and this gain is statistically significant ($p < 0.01$, $\hat{A}_{12} = 0.925$). In Vulnerability Prediction, where FLOPs already correlate with energy, the energy-based optimization changes median energy by +30% and GFLOPs by +36%, but these differences are not statistically significant ($p > 0.2$), and accuracy remains non-significantly different as well ($p > 0.3$).

## 6.3 RQ3: Application to generation tasks

**(a)** Energy. **(b)** Size.

**Figure 2** ROUGE-L of the Pareto front compared to inference energy and model size.

Figure 2 shows the ROUGE-L scores of different generative code summarization models on the Pareto front, along with the other two optimization objectives: energy (Figure 2a) and size (Figure 2b). The red line indicates a threshold for the ROUGE-L score of 0.18. By manually inspecting individual amples and generating summaries, and observing that summaries with approximately 0.15 still fit well to the source code, despite the summary being worded differently and being much shorter. To be conservative with our choice, we selected 0.18 as an acceptable lower bound for our use case. We observe that, for Code Summarization, the Pareto front shows more constraints and much higher trade-offs between the objectives. One of the main observations we can make is that, unlike classification tasks, the 3MB selection rule from the previous study [29] cannot be applied, since models below 10MB achieve ROUGE-L scores below 0.1, which has a significant impact on performance.

**Table 3** ROUGE-L, Size and Inference Energy for the teacher model and the most accurate student model. The best result for each metric is highlighted in grey.

| Model | ROUGE-L | Size (MB) | Energy (J) |
|---|---|---|---|
| Teacher | 0.229 | 830 | 82 396 |
| Most Accurate | 0.199 (-13%) | 114 (-86%) | 13 600 (-83%) |
| Most Efficient | 0.194 (-15%) | 157 (-81%) | 8 059 (-90%) |

Table 3 shows the objectives for the teacher model, which obtains an ROUGE-L score of 0.231. Compared with the most accurate student model, the score is 0.199 (a 13% decrease). Therefore, even in the best case, we observe a slight decrease in accuracy. However, by manually inspecting the output of different models, we see that summaries are mostly coherent. Student models struggle more with code that uses specialized nomenclature, such as specific libraries or services. Despite a small decrease in accuracy, this student model achieves an 83% reduction in energy usage while processing the same number of inference samples and a 86% reduction in memory footprint.

Other student models can also achieve a similar level of accuracy to the most accurate student while achieving higher energy savings. To illustrate this, Table 3 also showcases the results for the most efficient model obtained under the constraint that the ROUGE-L score exceeds 0.18. We defined this threshold based on the performance we observed during

manual inspection, since models with this score still perform well with simpler pieces of code. Then, we selected the most efficient model by dividing the ROUGE-L score by the total inference energy, obtaining an Accuracy per unit of Energy metric. We selected the model with the highest value in this metric to prioritize both accuracy and efficiency: choose a model that provides greater accuracy with less energy usage. This kind of selection criterion can be useful for systems with high energy constraints [7, 30]. For this model, we observe an even higher energy reduction, up to 90% compared to the teacher model and 40% less than the most accurate student, albeit with a slightly higher memory footprint.

**Answer to $\mathbf{RQ}_3$.** For code summarization, many-objective distillation reduces inference energy from 82,396 J to 8,059 J (most efficient student), a 90% reduction, and reduces model size from 830 MB to 114 MB for the most accurate student, an 86% reduction. The performance trade-off is moderate: ROUGE-L drops from 0.229 to 0.199 (−13%) for the most accurate student and to 0.194 (−15%) for the most efficient student.

# 7 Discussion

## 7.1 FLOPs as a proxy for energy

Our experiments for $\mathbf{RQ}_1$ show that FLOPs are not a consistent proxy for energy consumption: there is no correlation between FLOPs and inference energy for the Clone Detection task, but a positive correlation for the Vulnerability Prediction task. Furthermore, even for the Vulnerability Prediction task, where statistical correlation is present, we still cannot detect a direct relationship between FLOPs and energy consumption. In this task, we observe some models with similar FLOPs that use vastly different amounts of energy, and models with similar energy that differ widely in FLOPs. By using FLOPs alone to select an energy-efficient model, an AI engineer would miss models that stand out from the correlation and show a reduced energy consumption despite the elevated number of FLOPs.

These results suggest that FLOPs, as a metric, do not capture all the complexities and components involved in a model's total energy consumption. The approach used to compute FLOPs for a model [4] treats FLOPs as mathematical operations rather than machine instructions, treating operations such as multiplications and additions as equally costly. A similar thing happens with profilers from libraries, including PyTorch, which use formulas to estimate mathematical operations and, in some cases, ignore operations such as additions.

This computation also uses only a subset of the model's hyperparameters (Hidden Size, Number of Layers, Sequence Length, Vocabulary Size, Intermediate Size, and Number of Heads). Other factors, such as additional model hyperparameters, dataset characteristics, or inference steps, may influence energy consumption across the whole task. For example, from the ANOVA test, we observe that the Hidden Activation function also has a statistical correlation with energy. Each possible activation function has a different implementation, which can affect FLOPs and energy in different ways. These aspects make FLOPs an unreliable proxy, since the computation understates some aspects and fails to account for others that can affect energy consumption.

The FLOPs computation is also blind to software or hardware optimizations introduced by the libraries or the GPU during execution time. Underlying libraries provided by the operating system and hardware drivers, along with their versions, can affect the energy consumption of any program [31]. An example of this is the omission of operations due to sparsity, where GPUs introduce optimizations to avoid multiplying by 0. Something similar can happen with respect to sequence padding. In this methodology, FLOPs are computed

using a maximum sequence length. However, not all inputs to the model use all this sequence length, with shorter inputs requiring fewer FLOPs. Additionally, when processing a batch through an LLM model with a defined batch size, all inputs get padded to the length of the longest input. The largest sequence sets the length for the entire batch. Other sequences are padded with padding tokens, which are ignored during computation using an attention mask. The FLOPs costs for these padding tokens cannot be assumed to be the same as for normal tokens, since the GPU can introduce optimizations to avoid computations with these tokens. Therefore, the FLOPs count provided by this methodology is an upper bound rather than an exact count of computations per input.

These optimizations might explain the lack of correlation in the Clone Detection task. To perform this task, the maximum sequence length is used when tokenizing each code block. To compare two blocks of code, they are concatenated, giving an effective maximum length of twice the input to the tokenizer. While this is considered for FLOP computation, it also means the average padding length doubles, resulting in the Clone Detection task having more "empty" FLOPs.

In conclusion, FLOPs metrics, as used in this approach and in most of the literature, serve as an upper bound that does not account for all characteristics of the model and task. For simpler tasks or datasets, such as Clone Detection, the actual computation can fall far short of this upper bound, making FLOPs a poor proxy for energy consumption. In comparison, more complex tasks, such as Vulnerability Prediction, are closer to the upper bound on FLOPs and exhibit higher correlation.

A more accurate proxy for energy consumption than FLOPs is inference time, which shows a strong correlation with energy consumption, according to previous studies [2]. Compared to energy, this is a much more accessible metric, since it does not require the use of profilers or energy measurement guidelines [6]. However, to compare with FLOPs, the model still needs to be run. Running and measuring energy for a model can be extremely time-consuming, especially in many-objective optimization problems, where multiple configurations must be evaluated. Using inference time is a reasonable tradeoff, since it still requires running the model, but does not require additional setup for energy measurements. Additionally, inference time provides no insights into the model's energy impact.

From the results for $\mathbf{RQ}_2$, we learn that, in cases where FLOPs and energy present a correlation (Vulnerability Prediction), using surrogate models instead of FLOPs does not have a statistically significant effect on the final result, for better or worse. However, when FLOPs cannot accurately reflect energy consumption, the surrogate models bridge this gap and produce more efficient models without impact on accuracy. These results show that energy surrogate models are preferable to FLOPs, as they can account for more factors that affect sustainability and perform well regardless of whether a correlation is present.

To build the energy models, we need to measure the inference energy consumption of all the sampled models in the surrogate step of MORPH. This adds an additional step to the sampling, training, and evaluating pipeline from the original methodology. Energy measurements are a costly step, especially in larger student models that tackle more complex tasks, as in the case of CodeT5+ and Code Summarization. Therefore, it is preferable to use FLOPs when we are certain of the correlation, such as in the Vulnerability Prediction task, since these additional costs do not yield any benefits.

In any case, the trade-offs between FLOPs and energy only apply during the optimization phase of this methodology. Once MORPH provides the Pareto front of the optimal models, we observe that, statistical correlations aside, there is no direct relationship between FLOPs and

energy. This is an important consideration when selecting a final student model that meets our constraints. If we wish to select a model with the lowest possible energy consumption, selecting the one with the lowest FLOPs is not guaranteed to yield the lowest energy consumption. FLOPs might be useful for solving the optimization problem, as they are easy to compute (and may correlate with energy). Nevertheless, we propose that developers prioritize actual energy measurements over FLOPs when selecting a final student model, particularly for heavily constrained systems. This recommendation stems from our findings, which indicate that FLOPs are not a reliable proxy for energy consumption in this context, and that related literature should be cautious in its use.

## 7.2 Many-Objective Optimization for Generation Tasks

Our experiments for $\mathbf{RQ}_3$ show that Many-Objective distillation can be used for generative SE tasks like Code Summarization, albeit with some caveats. This technique produces student models with a significant reduction in size (up to 86% of the teacher model) and energy consumption during inference (up to 90%). However, none of the student models match the teacher model's accuracy, resulting in a slight decrease in ROUGE-L score. This drop is similar to results from the literature on other distillation approaches for summarization [37, 38].

Our study also shows how sensitive state-of-the-art models are when applied to datasets other than their original evaluation dataset. To mitigate contamination, we are using The Heap [19] as our evaluation dataset. This dataset follows more strict deduplication techniques than other publicly available datasets to avoid contamination. This affects final ROUGE-L scores for both teachers and students, with both obtaining scores slightly lower than those of other state-of-the-art summarization models. For example, our fine-tuned teacher model has an average ROUGE-L of 0.22 in The Heap. Comparatively, when evaluating the teacher model on CodeXGLUE as in the original CodeT5+ paper [43], we obtain an average ROUGE-L of 0.33, closer to the original results. This indicates that the model is not generalizing well for a different evaluation dataset. This calls for more research on how these models should be evaluated and highlights the need for metrics that better reflect the actual correctness of generative model outputs for software engineering problems, as well as for improved generalization beyond predefined benchmarks.

In our experiments, the student model's savings come at the cost of a drop in performance. While the observed drop is moderate, it will depend on the use case whether it is acceptable. For example, local models running on a laptop and used for commit message generation can have a strict energy cap, and the accuracy drop is acceptable for such low-critical tasks. On the other hand, a model intended to summarize pull request contributions requires an accurate summary to guide the reviewer who will eventually accept or reject the PR. What is an acceptable drop in accuracy and energy savings will depend on the specific use case, and is hard to define in a research setting.

The Many-objective approach also provides greater flexibility in the student architecture, thanks to weight subcloning. Other approaches in the literature need a student model that has been pretrained and has some general knowledge first [37, 38], or distill into pretrained checkpoints of smaller models. In this case, the available configurations are only those that are pretrained and open source. In comparison, our approach copies the most important weights from the teacher model using weight subcloning. This distillation technique can provide a wider range of hyperparameters while avoiding the expense of pretraining.

## 8 Threats to Validity

Our approach has some limitations regarding its validity. First is the distillation loss used for the Code Summarization task. In this paper, we used a standard distillation loss function based on the KL-divergence and the cross-entropy function. Model distillation is a rapidly developing subfield of AI. Newer methods are being proposed and bring improved and more complex losses [46], or different distillation paradigms [41]. However, the loss we applied for this paper is widely adopted in state-of-the-art solutions. Moreover, the focus of this paper is the application of Many-Objective Problem optimization towards exploration of the configuration space. We decided to use a standard, well-founded distillation loss and reduce the influence of other variables. Combining newer methods with Many-Objective solvers might yield improved distillation results.

Additionally, for the generation task, we used the ROUGE-L score as the model's objective, which measures n-gram overlap. This metric is widely adopted in state-of-the-art evaluation, but it comes with its own limitations. ROUGE-L overlooks semantic similarity: there can be different valid summaries paraphrased in different ways. Evaluating semantic similarity would require human judgment or that of a reliable LLM, which incurs significant time and financial costs due to the need for an additional LLM or human participants and does not guarantee the validity of the judgment, especially in the case of LLM-as-a-judge. Given the amount of sampling necessary for the method applied in this paper, this kind of metric would be too costly and not entirely objective for the purpose of Many-Objective optimization. We selected ROUGE-L because, despite its shortcomings, it is widely used in the literature and aligns more closely with human judgment, according to the latest studies [11].

## 9 Conclusion

This study investigates the validity of FLOPs as an energy proxy for many-objective LLM knowledge distillation. Our findings reveal that the correlation between FLOPs and inference energy of the student model is often unreliable. For Clone Detection, FLOPs do not present a statistical correlation with energy, while Vulnerability Prediction does. Besides this correlation, FLOPs does not show a direct relationship with energy. Selecting the model with lower FLOPs does not always imply selecting the model with lower energy usage.

To address this, we proposed using surrogate energy models to estimate energy consumption for a given hyperparameter set before training. This approach converges to models that are 39% more energy-efficient for Clone Detection tasks, bridging the gap in the correlation between FLOPs and energy efficiency.

We also applied this approach to Code Summarization in CodeT5+, testing its potential for generation tasks. The results showed significant compression levels for students (up to 86% smaller) and reduced energy usage (up to 90%), with a modest impact on accuracy.

Future work will expand the generalizability of these findings by applying them to tasks such as code generation. We also intend to analyze the pitfalls of FLOPs and define metrics that correlate better with energy while requiring less effort than direct energy measurement.

## Data Availability Statement

A replication package is available in Zenodo[2]. This package contains the scripts to distill surrogate and final models, as well as a script to measure the energy consumption of the models. It also contains the data collected from our hardware setup, as well as the analysis scripts used to generate the plots and tables in this paper.

Rinn AI Research Ireland Centre on AI and Data Science, Dublin, Ireland

**Silvana Togneri MacMahon**
School of Computing, Dublin City University, Ireland

## Abstract

**Background.** Users can express the same request in many ways when interacting with LLM agents, particularly non-native English speakers whose writing reflects linguistic patterns transferred from their first language (L1). Existing benchmarks for evaluating API usage in LLM-based software systems typically rely on standardized English and overlook linguistic diversity. At the same time, collecting such data from users with diverse linguistic backgrounds is costly and difficult to scale.

**Aims.** This study proposes L1-AUG, an L1-aware utterance generation method, and investigates three research questions: whether LLMs can generate API-calling utterances reproducing linguistic patterns of non-native English speakers; whether L1-aware utterance generation leads to higher linguistic diversity; and whether API-calling utterances that simulate non-native English linguistic patterns are more challenging for LLM agents to solve.

**Results.** L1-AUG can generate utterances reflecting linguistic patterns extracted from essays written by non-native English speakers; L1-AUG generates benchmarks with higher linguistic diversity; and LLM agents achieve lower performance on the benchmark created using L1-AUG.

**Conclusions.** Conditioning benchmark generation on linguistic patterns extracted from non-native English essays produces benchmarks that better reflect users with diverse linguistic backgrounds. Our results indicate that LLM agents struggle more with such inputs, suggesting that training on linguistically diverse datasets may be necessary to improve robustness in API-calling tasks.

## 1 Introduction

Large Language Model (LLM) agents have been widely adopted in conversational AI, serving as assistants that fulfill user utterances by connecting LLMs to external tools via APIs, reasoning over intermediate steps, and maintaining conversational memory [32]. APIs expand the scope of standalone LLMs by giving them access to up-to-date information (e.g., exchange rates, weather forecasts), control over physical environments (e.g., robot control), or the

ability to orchestrate cross-platform digital workflows [29]. As these systems increasingly interact with software services, ensuring LLM agent robustness becomes a major challenge. Nevertheless, LLM agents' effectiveness depends on their ability to interpret different user intents and map them to structured API calls [19].

Given the richness of language, users can express the same request in many different ways, including variations in vocabulary, phrasing, sentence structure, and writing style [24, 20]. These variations are influenced by users' linguistic backgrounds, as speakers may transfer linguistic conventions from their first language (L1) to their second language (L2) writing, a phenomenon known as L1 transfer [15, 1]. For instance, Mandarin speakers writing in English may omit articles and auxiliary verbs, since neither feature is grammaticalized in Mandarin. However, recent studies have shown that LLMs are not robust to lexical and syntactic variations [16] and perform worse when processing text generated by non-native English writers [18, 23]. This limitation is particularly concerning given the scale of L2 English use: English is the second language of over one billion speakers, compared to approximately 400 million native speakers [25]. Besides, widely used API-calling benchmarks, such as BFCL [19] and ToolBench [21], do not explicitly evaluate the effect of L1-aware linguistic diversity on API use. Ensuring robustness to diverse utterances is essential for reliable LLM agents and for quality assurance in software systems that integrate them, as untested linguistic diversity can cause service failures and degrade user experience.

Crowdsourcing is an effective method for obtaining diverse utterances, where humans are recruited via online platforms to curate benchmarks [22]. Including people from different backgrounds, countries, cultures, and domain knowledge enables the collection of diverse linguistic data that reflects real-world language variations [34]. Furthermore, each person carries distinct linguistic patterns, defined as systematic and recurring features of language use that collectively represent a "signature" of a person's writing style, such as lexical and syntactic preferences, punctuation habits, and preferred sentence lengths [14, 17]. However, crowdsourcing has limitations, including cheating, coordination overhead, long collection times, and high labor costs, which make scaling benchmark construction difficult [33].

LLMs have been used to address crowdsourcing's scalability limitations, enabling automatic generation of API-calling benchmarks. However, traditional LLM-based benchmark generation often lacks the linguistic diversity associated with text provided by real users and tends to produce common English utterances. Recent approaches [5, 7] attempt to increase diversity by conditioning LLMs on personas, defined as user profiles combining sociodemographic attributes (e.g., native language, age, gender) and psychosocial attributes (e.g., occupation, hobbies, interests) [28]. Although existing persona-based approaches improve diversity, they rely primarily on abstract attribute labels (e.g., "native language: Mandarin", "occupation: engineer") rather than actual linguistic behavior. We hypothesize that representing personas with only abstract attribute labels limits LLMs' ability to capture linguistic patterns associated with L1 transfer in non-native English writing, because such representations are not grounded in text generated by real users.

In this study, we propose the L1-Aware Utterance Generation Method (L1-AUG), a data-driven approach for generating API-calling utterances that reflect linguistic patterns extracted from essays written by non-native English speakers. Unlike existing approaches that rely only on sociodemographic and psychosocial attributes, L1-AUG conditions utterance generation on sociodemographic attributes and linguistic patterns extracted from real non-native English writing. L1-AUG first uses a Chain-of-Thought (CoT) [30] prompting strategy to extract recurring linguistic patterns, such as common vocabulary choices and grammatical mistakes, from essays written by people from 20 countries from the ICNALE corpus [13]. Then, L1-AUG uses the extracted linguistic patterns to steer utterance and API-call generation.

The proposed approach enables the creation of datasets and benchmarks that support (1) evaluating the robustness of LLM agents to diverse utterances and (2) fine-tuning LLMs to improve their robustness to diverse utterances. We evaluate the performance of an LLM agent in fulfilling the generated utterances, allowing us to assess whether these utterances pose greater challenges for agents. We investigate the following research questions (RQs):

- **RQ1: Can LLMs reproduce linguistic patterns extracted from essays written by non-native English speakers when generating API-oriented utterances?** LLMs tend to generate text aligned with native English conventions, reflecting the distribution of their training data [9]. In this RQ, we investigate (1) whether utterances generated by L1-AUG reproduce linguistic patterns extracted from essays written by non-native English speakers, and (2) whether conditioning generation on personas associated with different countries results in distinct linguistic patterns. If successful, this would support using LLMs to generate diverse benchmarks that reflect non-native English writing while providing a scalable alternative to human data collection. We generate utterances and API calls for 10 APIs across different domains using 5 LLMs.
- **RQ2: Do utterances generated by L1-AUG provide higher linguistic diversity compared to other generation methods?** In this RQ, we investigate whether L1-AUG leads to higher linguistic diversity compared to two API-calling benchmark generation methods: (1) ToolAlpaca [27] (ALP), an approach that promotes diversity without persona conditioning; and (2) Persona ToolAlpaca (P-ALP), a persona-based approach conditioned on sociodemographic and psychosocial attributes obtained from PersonaHub [5]. We hypothesize that grounding utterance generation in real linguistic behavior extracted from learner essays leads to more linguistically diverse utterances.
- **RQ3: Are utterances generated by L1-AUG more challenging for a general-purpose LLM agent to fulfill compared to utterances from other benchmarks?** In this RQ, we evaluate whether a general-purpose LLM agent can fulfill utterances generated by the ALP, P-ALP, and L1-AUG methods. Our goal is to investigate whether utterances generated by L1-AUG are more challenging for an LLM agent to fulfill compared with utterances generated using other generation methods. To ensure the generalizability of our findings, we evaluate three LLM backbones: Ministral-3-8B, Llama-3.1-8B, and Qwen3.5-9B.

Our results show: (1) L1-AUG can generate utterances that reproduce linguistic patterns extracted from essays written by non-native English speakers from different countries; (2) L1-AUG generates benchmarks with higher linguistic diversity compared to P-ALP and ALP; and (3) L1-AUG generates utterances that are more challenging for LLM agents to fulfill than those generated by P-ALP and ALP.

The remainder of this paper is organized as follows: Section 2 reviews related work. Section 3 presents the proposed L1-AUG pipeline. Section 4 describes the experimental setup, results, and analysis for each RQ. Finally, Section 5 concludes the paper and outlines directions for future research.

## 2 Related Work

Patil et al. [19] introduced BFCL, a function-calling benchmark for evaluating LLM agents' ability to invoke APIs and generated using crowdsourcing and LLMs. Qin et al. [21] generated ToolBench, an LLM-generated API-calling dataset covering utterances that require invoking a single API or coordinating between multiple APIs. While these datasets are widely used to evaluate LLMs' API-calling capabilities, they rely on conventional English and do not explicitly account for linguistic diversity.

Other works introduced mechanisms to improve diversity. Tang et al. [27] generated utterances using guidelines to encourage the use of different syntactic patterns and avoid verb repetition. Santos et al. [24] used the *logit bias* parameter of LLMs to encourage lexical diversity by penalizing frequently used tokens when paraphrasing utterances. Berro et al. [2] showed that GPT-3.5 can generate syntactically diverse paraphrases by simulating crowdsourcing workflows used for collecting utterances in task-oriented dialogue systems. While these approaches improve lexical or syntactic diversity, they do not incorporate personas during utterance generation, limiting the generation of utterances that reflect rich user contexts, such as occupation, hobbies, cultural background, or writing style.

Other works generated API-oriented utterances by simulating personas with different characteristics. Huang et al. [12] represented personas with different emotional states (e.g., happiness, anger, or sadness); Xu et al. [31] used mood, gender, English dialect, and age to simulate personas; and Cheng et al. [7] incorporated demographics (e.g., gender, age, weight, profession), personal interests (e.g., enjoying exercise), preferences (e.g., user prefers to buy at Amazon), and environmental context (e.g., city, date, time, weather). While these methods generate utterances that reflect richer contexts and improve linguistic diversity, they rely on abstract attribute labels to represent personas and do not incorporate examples of text generated by real users. Consequently, they do not explicitly capture how users from different linguistic backgrounds write when interacting with conversational systems.

Gao et al. [8] showed that LLMs can generate English dialogues with linguistic patterns influenced by a speaker's L1 when conditioned on real examples. However, their work focuses on multi-turn spoken dialogue generation between native and non-native English speakers beyond the API-calling domain. Also, they focus on spoken language, including hesitation markers such as "um" or "uh". In contrast, our work focuses on the API-calling domain and generates single-turn utterances grounded in written language.

Prior work on generating API-calling benchmarks has focused on improving lexical and syntactic diversity or on conditioning generation on personas represented by abstract attribute labels, such as age, gender, and occupation. However, these approaches are not grounded in text written by real people and do not capture how non-native English speakers write. Consequently, the resulting benchmarks do not evaluate how such linguistic variation may affect LLM agent performance. To address this gap, we propose a pipeline that conditions LLM generation on linguistic patterns extracted from essays written by English learners from 20 different countries. Although these patterns are extracted from argumentative essays rather than conversational interactions, they provide a data-driven alternative to abstract persona attributes for conditioning utterance generation.

## 3 Generation of API-oriented utterances and API calls

In this section, we first describe the preprocessing of the ICNALE corpus [13], which we use as seed data for generating personas. We selected ICNALE because it provides sociodemographic attributes (e.g., age, gender, occupation, and country) and also essays written by real users. Next, we describe our proposed L1-AUG method.

### 3.1 ICNALE Corpus Processing and Analysis

The ICNALE [13] includes a corpus of English essays written by English learners from 28 countries. Each writer produced two essays on the following topics: (1) "part-time jobs for college students" and (2) "non-smoking at restaurants." The dataset includes metadata such as gender, age, academic major/occupation, and proficiency level. Essays are available as .txt files with filenames encoding writer metadata, including country, topic, unique ID, and proficiency.

We pre-processed ICNALE and produced a CSV file with the following data for each writer: country, L1, gender, age, major/occupation, proficiency level, and essays. We excluded writers from the United States, Great Britain, and Australia to focus on non-native English speakers. We also excluded countries with fewer than 40 essays to ensure enough seed essays for utterance generation. The final dataset includes 20 countries with the following sample sizes: Bangladesh (101 people), Brunei (50), Cambodia (52), China (400), Hong Kong (100), India (191), Indonesia (200), Japan (400), South Korea (300), Laos (40), Malaysia (107), Myanmar (132), Nepal (50), Pakistan (200), Philippines (200), Singapore (200), Taiwan (200), Thailand (400), United Arab Emirates (100), and Vietnam (438).

We analyzed the preprocessed ICNALE corpus to determine whether essays written by English learners from different countries show distinct linguistic patterns. We treat speakers from different countries as representing distinct linguistic backgrounds, even when they share the same native language. This design choice reflects the fact that linguistic diversity in non-native English writing may also be influenced by educational, cultural, and sociolinguistic factors of a given country beyond the speaker's L1.

We represent essays written by the same person as a feature vector composed of lexical and syntactic features commonly used in the literature [11, 25]. More precisely, we used the following features: (1) average words per sentence; (2) average characters per word; (3) root type-token ratio; (4) function word ratio, computed as the normalized frequency of function-word tokens based on the ONIX stop word lexicon (English)[1]; and (5) 17 part-of-speech (POS) tag ratios: adjectives, ad positions, adverbs, auxiliary verbs, coordinating conjunctions, determiner, interjections, nouns, numerals, particles, pronouns, proper nouns, punctuation, subordinating conjunctions, symbols, verbs, and other.

Feature vectors were normalized using $z$-score normalization to ensure comparability across features with different numerical scales. We then computed pairwise cosine distances between all normalized vectors. Formally, for two essays $i$ and $j$, with normalized vectors $\mathbf{z}_i$ and $\mathbf{z}_j$, the cosine distance is denoted by $d_{ij}$, where lower values indicate higher linguistic pattern similarity between essays. Now, let $\ell_i$ denote the country label associated with essay $i$. We define the set of within-country pairs as $D_{\text{within}} = \{(i,j) \mid i < j,\ \ell_i = \ell_j\}$ and the set of between-country pairs as $D_{\text{between}} = \{(i,j) \mid i < j,\ \ell_i \neq \ell_j\}$. The mean within-country distance is then defined as:

$$\bar{d}_{\text{within}} = \frac{1}{|D_{\text{within}}|} \sum_{(i,j)\in D_{\text{within}}} d_{ij}, \tag{1}$$

and the mean between-country distance is defined as

$$\bar{d}_{\text{between}} = \frac{1}{|D_{\text{between}}|} \sum_{(i,j)\in D_{\text{between}}} d_{ij}. \tag{2}$$

We test the hypothesis that essays from the same country show higher linguistic pattern similarities than those from different countries (i.e., $\bar{d}_{\text{within}} < \bar{d}_{\text{between}}$). Our results confirm this, with $\bar{d}_{\text{within}} = 0.861$ and $\bar{d}_{\text{between}} = 1.009$. To assess statistical significance, we ran a permutation test (1,000 iterations) in which we randomly shuffled country labels across essays while keeping pairwise distances fixed. Using the observed separation $\Delta_{\text{obs}} = \bar{d}_{\text{between}} - \bar{d}_{\text{within}} = 0.148$, we obtained $p < 0.01$, confirming statistical significance.

Figure 1 presents the average cosine distances for each country pair. Results show lower average cosine distance values along the diagonal, indicating that essays written by speakers from the same country are more similar to each other than those written by speakers from

[1] `https://eecs.csuohio.edu/~sschung/DSA460/StopwordList1.pdf`

different countries. Some South Asian countries (India, Nepal, and Bangladesh) show similar distances, consistent with their geographic proximity and shared exposure to British English. Japan shows higher distances overall, suggesting more distinctive L1 transfer patterns. Surprisingly, Thailand, the United Arab Emirates, and Laos also show low distances among themselves. These findings show that English learners from different countries show distinct linguistic patterns, motivating the design of L1-AUG.

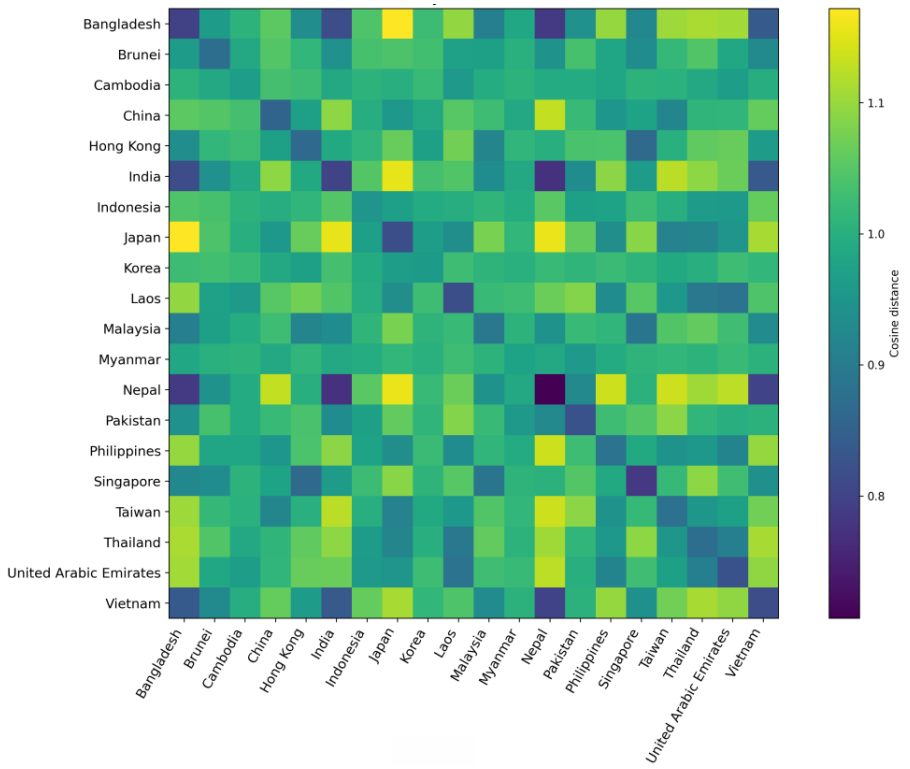

**Figure 1** Average cosine distance between essays of different countries.

## 3.2 L1-Aware Utterance Generation Method

In this section, we present L1-AUG, our proposed method for generating utterances and API calls conditioned on linguistic patterns extracted from essays written by non-native English speakers. We first define a persona using sociodemographic and linguistic attributes derived from ICNALE [13]. Next, we use a CoT prompting method to analyze linguistic patterns in the provided essays and generate utterances conditioned on the extracted patterns and persona attributes. We adopt a CoT prompting strategy because it allows the model to explicitly identify recurring linguistic patterns in the essays before generating utterances. This intermediate reasoning step encourages generation conditioned on the extracted patterns rather than defaulting to grammatically standard English. We provide implementation details of L1-AUG in the remainder of this section.

### 3.2.1 Persona Definition

We define a persona $P$ using the following template: *"You are a [age]-year-old [gender] from [country] who speaks [language] with an English proficiency level of [level]. Your job involves working in [major]. These are examples of essays showing how you write: [reference_essays]".*

The placeholders are filled using data from ICNALE [13], although alternative data sources can also be used. This representation enables an LLM to condition its generation on the demographic and linguistic contexts associated with people from different countries.

### 3.2.2 Linguistic Patterns Extraction

Given a set of essays $E = \{e_1, e_2\}$ written by a persona $P$, an LLM is prompted to analyze and extract linguistic patterns of $E$ before generating utterances and API calls. Specifically, we instruct LLMs to identify and output the following linguistic patterns from essays: (1) vocabulary choices that are uncommon in native English; (2) recurring syntactic structures; (3) spelling and grammatical errors; (4) false cognates; and (5) literal translations arising from L1-to-L2 transfer. These patterns were selected based on prior work in second language acquisition that maps and annotates texts written by non-native English speakers in terms of orthographic, lexical, morphological, grammatical, and L1 interference [1]. This step produces a set of descriptive linguistic patterns $L$ associated with a persona's writing style.

### 3.2.3 Utterance and API Call Generation

We designed instructions to guide the LLM in generating utterances that reflect the persona's background, resemble real interactions with LLM agents, and reproduce linguistic patterns extracted from essays written by non-native English speakers.

We provide an LLM with a persona template and API documentation. Then, we instruct the LLM to generate utterances that reflect both the persona's linguistic patterns and background while promoting diversity. Specifically, the LLM is instructed to role-play the provided persona, generate $n$ utterances related to the provided API that reflect the extracted linguistic patterns (as explained in Section 3.2.2), incorporate parameter values (e.g., locations, currencies, and food items) based on the persona's nationality, use the persona's professional occupation as context when appropriate, and change lexical and syntactic choices across utterances while remaining consistent with the persona's linguistic patterns.

During an iterative prompt-development phase, we observed that some utterances reproduced conclusion markers commonly associated with argumentative essays, such as "In conclusion", "To sum up", and "As I mentioned". We also observed API terminology that users do not commonly use when making requests. Therefore, we also instructed the LLM to generate utterances that resemble natural interactions with conversational agents, not incorporate essay-specific conclusion markers, to avoid technical API terminology (e.g., including "page number" or "API key" data), and use natural expressions such as "next Monday" rather than fixed formats like "2024-06-18".

Finally, we prompted the LLM to generate the API calls needed to obtain the information required to answer each user utterance. To ensure API calls are valid, we included guidelines requiring arguments to follow the formats specified in the API documentation (e.g., ISO dates, standardized codes, and enumerated values) and forbidding the model from generating parameter values that cannot be inferred from utterances.

## 4 Experiments

Figure 2 provides an overview of our experimental design, which consists of three phases. First, we use L1-AUG with multiple LLMs to generate utterances and API calls that simulate linguistic patterns extracted from essays written by non-native English speakers across 20 countries. RQ1 evaluates whether the generated utterances indeed reproduce linguistic

patterns of the provided essays written by people from different countries. Second, we use the best-performing LLM in RQ1 to generate API-calling benchmarks using three methods: a no-persona baseline (ALP), a persona-based baseline (P-ALP), and the proposed L1-AUG method. RQ2 compares the linguistic diversity across these three benchmarks. Third, we evaluate a general-purpose LLM agent using 20% random samples of each benchmark. RQ3 compares the agent's performance when deployed using three different LLMs, evaluating whether the benchmark generated by L1-AUG is more challenging than other benchmarks.

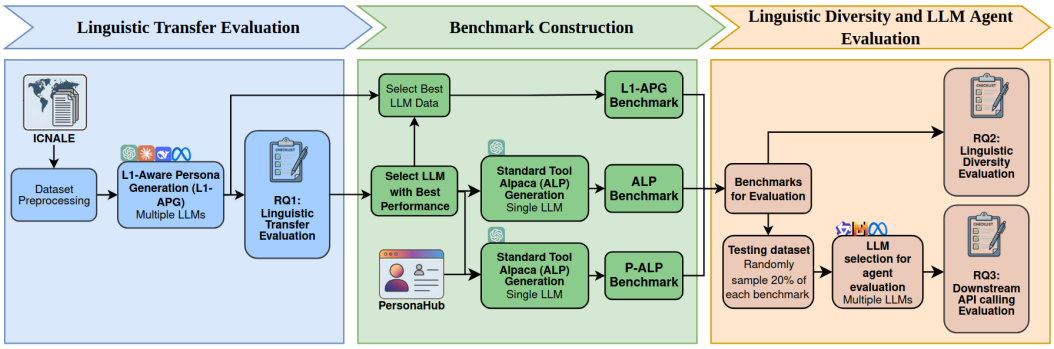

**Figure 2** Overview of experiment design.

## 4.1 RQ1: L1 Transfer Evaluation

In Section 3, we showed that essays written by non-native English learners from different countries show distinct linguistic patterns. In this section, we investigate whether L1-AUG can reproduce these linguistic patterns when generating API-oriented utterances.

### 4.1.1 Experimental Setup

We generate benchmarks using the L1-AUG method across 5 LLMs, 10 APIs, and 600 personas. In this subsection, we describe the data generation and evaluation processes.

**LLMs.** We generate utterances and API calls using five LLMs: GPT-5.4, Claude-4-Sonnet, DeepSeek-V4-Pro, GPT-4o-mini, and Llama-4-Maverick. We selected these models to cover both closed- and open-source LLMs with different inference costs and parameter scales. We use the OpenAI API[2] for generating data with GPT-5.4 and GPT-4o-mini, and the DeepInfra API[3] for Claude-4-Sonnet, DeepSeek-V4-Pro, and Llama-4-Maverick. We use a temperature of 1.0 for all models.

**APIs.** We generate utterances and API calls for 10 APIs across different services: paper search (ArXiv), currency conversion, exercise retrieval, movie search, food nutrition lookup, tourist place search, restaurant search, stock price retrieval, current weather, and weather forecast. We selected APIs from different domains and with different numbers of input parameters to evaluate agents across tasks of different complexity while keeping the benchmark manageable for comparing generation methods and LLMs. While these APIs rely on existing

[2] https://openai.com/api/
[3] https://deepinfra.com/

third-party services, we manually created documentation and developed Python wrapper functions for each API to handle request formatting, error checking, and data parsing. This interface allows an LLM agent to invoke APIs using function calls.

**Data Generation.** For each API, we randomly sample 3 personas from each of the 20 countries listed in Section 3.1, yielding 60 personas per API. Then, for each persona, we request 5 utterances and corresponding API calls. We use each persona only once per API generation process. We keep the persona set fixed across all LLMs to ensure fair comparisons. This process generates 300 utterances per API (60 personas $\times$ 5 utterances = 300 utterances), scaling to 3,000 utterances for each evaluated LLM across all 10 APIs. It also yields 150 utterances for each country (3 personas $\times$ 5 utterances $\times$ 10 APIs = 150 utterances). This distribution balances the dataset across countries while supporting meaningful analysis of non-native linguistic patterns.

**Evaluation Metrics.** We follow the same evaluation procedure described in Section 3. However, instead of computing feature vectors from the reference essays, we concatenate the five utterances generated for each persona and compute the same feature vectors using the lexical and syntactic features described in Section 3. Feature vectors are normalized using $z$-score normalization and compared using cosine distance. We report the same metrics defined in Section 3: $\bar{d}_{\text{within}}$, $\bar{d}_{\text{between}}$, $\Delta = \bar{d}_{\text{between}} - \bar{d}_{\text{within}}$, and a $p$-value from a permutation test (10,000 iterations) in which country labels are shuffled while keeping pairwise distances fixed. If $\bar{d}_{\text{within}} < \bar{d}_{\text{between}}$, utterances generated based on essays written by people from the same country are more similar to each other compared with utterances generated from essays written by people from different countries. This provides evidence that L1-AUG reproduces country-associated linguistic patterns extracted from the source essays.

We also conducted an exploratory qualitative analysis by sampling a subset of 500 generated utterances (100 per model). An annotator then manually evaluated these utterances to verify whether they simulate linguistic patterns consistent with the source reference essays. The annotator observed patterns in the essays, such as common misspellings and grammatical mistakes, typical sentence length, repeated words throughout the text, and unnatural phrasing, and evaluated whether these patterns were reproduced in the generated utterances. This analysis is a qualitative check, providing insight into whether the generated utterances show these linguistic patterns. We report the **Pattern Preservation Rate (PPR)**, defined as the proportion of utterances that preserve the linguistic patterns observed in the reference essays.

### 4.1.2 Results

We found **that L1-AUG generates utterances whose linguistic patterns are more similar to each other when conditioned on essays written by English learners from the same country than from those of different countries. Furthermore, qualitative analysis shows that GPT-5.4 had the best performance in reproducing linguistic patterns extracted from the reference essays, achieving the highest $\Delta$ (0.1165) and PPR (0.72).** Table 1 presents the results.

Results show different performance across models. GPT-5.4 and DeepSeek-V4-Pro achieved the two highest $\Delta$ values (0.1165 and 0.0893, respectively), indicating stronger country-level separation in generated utterances. Llama-4-Maverick and Claude-4-Sonnet produced moderate separation ($\Delta = 0.0658$ and 0.0570), while GPT-4o-mini achieved the lowest $\Delta$ (0.0144). Nevertheless, all models yielded $p < 0.001$, confirming that the observed

**Table 1** Cross-country linguistic pattern transfer evaluation across different LLMs.

| LLM | $d_{\text{within}} \downarrow$ | $d_{\text{between}} \uparrow$ | $\Delta \uparrow$ | $p$-value $\downarrow$ | PPR $\uparrow$ |
|---|---|---|---|---|---|
| GPT-5.4 | 0.8901 | 1.0060 | 0.1165 | $p < 0.001$ | 0.72 |
| DeepSeek-V4-Pro | 0.9153 | 1.0045 | 0.0893 | $p < 0.001$ | 0.26 |
| Llama-4-Maverick | 0.9373 | 1.0031 | 0.0658 | $p < 0.001$ | 0.12 |
| Claude-4-Sonnet | 0.9460 | 1.0030 | 0.0570 | $p < 0.001$ | 0.51 |
| GPT-4o-mini | 0.9871 | 1.0015 | 0.0144 | $p < 0.001$ | 0.04 |

separation is statistically significant. In the qualitative analysis, GPT-5.4 achieved the highest PPR (0.72), while GPT-4o-mini achieved the lowest (0.04), consistent with the quantitative results. Claude-4-Sonnet achieved a relatively low $\Delta$ (0.0570) but a moderate PPR (0.51), suggesting that this model successfully generated utterances reproducing linguistic patterns extracted from the reference essays, but with lower country-level separation compared with the other models. DeepSeek-V4-Pro showed the opposite pattern, achieving a higher $\Delta$ (0.0893) but a lower PPR (0.26).

Table 2 shows examples of generated utterances. Example 1 includes many patterns that are present in the original essays, such as run-on sentences connected by commas, frequent use of the word "because", plural and tense errors, and unusual phrasing (e.g., "split my concentration"). Example 2 includes over-intensification ("more than enough important"), unusual phrasing ("put a finger on"), and a preposition error ("fit for my routine") that mirror patterns from the original essays. Example 3 shows preposition mistakes ("from Kyoto" instead of "in Kyoto"), a missing verb ("I interested") and a plural error ("temple" instead of "temples"). Although all examples include linguistic patterns from the original essays, Examples 1 and 2 more closely reflect the structural and lexical patterns specific to the persona. In contrast, Example 3 contains isolated grammatical mistakes that are less distinctive of the original writing style.

**Table 2** Examples of generated utterances per model using L1-AUG.

| # | Model | Utterance |
|---|---|---|
| 1 | GPT-5.4 | Some of my friend in Jakarta talking about Pengabdi Setan, so I need that movie search, maybe only 5 result is enough because too many movies sometimes make me confused and split my concentration. |
| 2 | Claude-4-Sonnet | From my point of view, having strong core muscles is more than enough important for maintaining good posture during long working hours. I need to put a finger on some good abdominal exercises that fit for my routine using resistance bands. |
| 3 | GPT-4o-mini | Can you show tourist places from Kyoto? I interested in temple and some historical places there. |

Finally, Figure 3 shows the average pairwise cosine distances between countries for utterances generated by GPT-5.4. The diagonal values are lower, indicating that utterances conditioned on linguistic patterns extracted from essays written by people from the same country are more similar to each other than to those from different countries. Furthermore, some interesting patterns emerge. Brunei, the Philippines, and Singapore show lower pairwise distances, likely reflecting shared patterns of Southeast Asian English resulting from their

shared history of English as an official language. Similarly, Nepal, Pakistan, and Bangladesh form a closer cluster, consistent with shared South Asian English features rooted in Indo-Aryan linguistic patterns. Japan and Korea also show low pairwise distances.

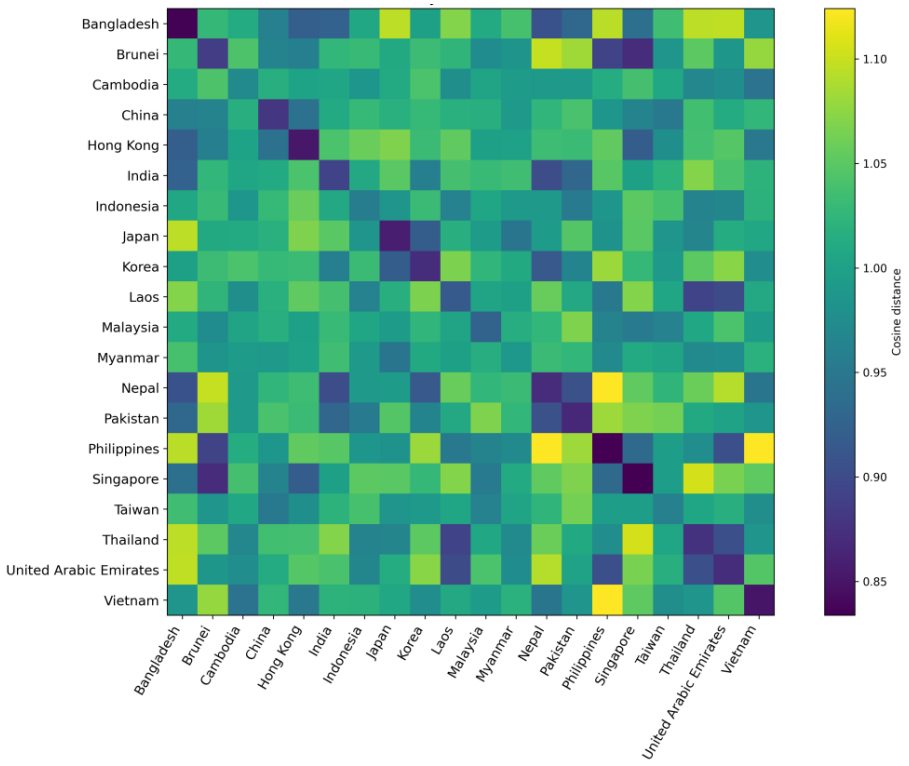

**Figure 3** Average cosine distance between utterances generated by GPT-5.4 across personas from different countries.

## 4.2 RQ2: Linguistic Diversity Evaluation

In this section, we compare the linguistic diversity of benchmarks generated by three generation methods: (1) ToolAlpaca [27] (ALP), an approach that promotes diversity without persona conditioning; (2) Persona ToolAlpaca (P-ALP), a persona-based approach conditioned on sociodemographic and psychosocial attributes obtained from PersonaHub [5]; and (3) L1-AUG. Benchmarks with higher linguistic diversity reflect a broader range of ways in which users may express utterances, making them better suited for evaluating models.

### 4.2.1 Experimental Setup

We selected GPT-5.4 for benchmark generation because it achieved the highest performance in reproducing linguistic patterns extracted from essays written by non-native English speakers, as shown in Section 4.1.2. We generated utterances for the 10 APIs described in Section 4.1.1.

**Generation Methods.** To ensure a fair comparison across generation methods, we generated 300 utterances per API. For ALP and P-ALP, we achieve this by executing 60 programmatic calls to GPT-5.4 per API, with each prompt requesting a batch of 5 utterances (60 calls $\times$ 5 utterances $=$ 300 utterances). The three evaluated generation methods are described as follows:

- **ALP**: This method uses the prompt proposed by ToolAlpaca [27], which instructs the LLM to generate utterances for a given API while promoting lexical and syntactic diversity. It does not include any persona conditioning.
- **P-ALP**: This method extends the ToolAlpaca [27] prompt by conditioning generation on persona descriptions sampled from PersonaHub [5]. Personas include attributes such as occupation, expertise, beliefs, and demographic characteristics (e.g., *a political analyst specialized in El Salvador's political landscape*). For each generation iteration, we randomly sample one persona and instruct the LLM to incorporate the persona profile when generating utterances. Personas are not repeated across generations.
- **L1-AUG**: We use the benchmark generated by GPT-5.4 described in Section 4.1.1.

**Evaluation Metrics.** We use multiple established metrics based on prior work [10, 6, 36]. **Unique-*n*** [10] is the ratio of unique $n$-grams to total $n$-grams. We report Unique-$n$ across unigrams, bigrams, and trigrams, allowing for evaluation of the proportion of new words and their combination across generation methods. **Syntax Similarity Mean (SSM)** [6] computes the average tree edit distance (TED) between constituency parse trees, computed over all pairwise utterance combinations per API using the top three parse tree levels. **Total Number of Words (TNW)** reflects the length of generated utterances. **Self-BLEU (SB)** [36] measures $n$-gram overlap within all utterances generated for the same API, where lower values indicate higher diversity. **Pairwise Semantic Similarity (PSS)** [10] computes one minus the average pairwise cosine similarity between utterance embeddings for the same API, as defined in Equation 3. The rationale is that utterances associated with the same API method should preserve the same intent while varying in writing style across personas with distinct backgrounds. Thus, lower pairwise cosine similarity indicates greater semantic diversity and results in higher PSS values. We selected these metrics because they provide complementary measures of lexical, syntactic, and semantic diversity.

$$\text{PSS} = 1 - \frac{2}{n(n-1)} \sum_{1 \le i < j \le n} \cos(\mathbf{e}_i, \mathbf{e}_j) \tag{3}$$

where $n$ is the number of utterances for a given API and $\cos(\mathbf{e}_i, \mathbf{e}_j)$ is the cosine similarity between embeddings $\mathbf{e}_i$ and $\mathbf{e}_j$ of utterances $\mathbf{u}_i$ and $\mathbf{u}_j$, respectively. Embeddings are computed using `Qwen/Qwen3-Embedding-4B` [35], which was chosen given its high performance at the Massive Text Embedding Benchmark (MTEB) at the time of the experiments. We compute all metrics for each API and average them across APIs to obtain a single score.

### 4.2.2 Results

We found that **L1-AUG produced benchmarks with higher syntactic and semantic diversity, and a higher ratio of unique trigrams, while P-ALP achieved higher ratios of unique unigrams and bigrams. ALP showed the lowest diversity across all metrics.** These results support the hypothesis that conditioning utterance generation on L1 transfer patterns extracted from essays promotes linguistic diversity beyond what persona-augmented generation alone achieves. Table 3 presents the results.

P-ALP achieved the highest Unique-1 and Unique-2 scores (0.1761 and 0.4899, respectively), suggesting that using personas from PersonaHub [5] increases the diversity of unigrams and bigrams. We believe this is driven by the specificity of persona definitions, which prompt the model to use more context-specific vocabulary. For instance, a persona defined as "*A farmer who relies on disease-resistant crops for a successful harvest*" led to an utterance

**Table 3** Diversity evaluation of generated utterances for GPT-5.4.

| Pipeline | TNW ↑ | UNIQ1 ↑ | UNIQ2 ↑ | UNIQ3 ↑ | SSM ↑ | SB ↓ | PSS ↑ |
|---|---|---|---|---|---|---|---|
| ALP | 4919.7 | 0.0504 | 0.1719 | 0.2924 | 5.5304 | 0.8497 | 0.3454 |
| P-ALP | 8169.6 | **0.1761** | **0.4899** | 0.6778 | 7.1950 | 0.4820 | 0.4337 |
| L1-AUG | **12879.0** | 0.0990 | 0.4785 | **0.7805** | **10.5188** | **0.3780** | **0.4611** |

containing "*disease-resistant tomato*", representing an unusual wording that contributes to higher unigram diversity. Nevertheless, L1-AUG led on Unique-3 (0.7805), indicating that while P-ALP diversifies at the word level, L1-AUG produces more diverse trigram combinations. The baseline ALP scored the lowest across all Unique-$n$ metrics.

L1-AUG achieved the highest SSM score (10.51), indicating higher diversity in sentence structure. P-ALP also improved over ALP (7.195 vs. 5.5304), suggesting that persona conditioning alone contributes to syntactic diversity. The large gap between ALP and L1-AUG highlights the impact of conditioning generation based on linguistic patterns extracted from real essays written by English learners from different countries.

L1-AUG led with the highest PSS (0.4611) and the lowest Self-BLEU (0.3780), indicating that its utterances include more diverse meanings with less $n$-gram overlap. ALP showed the highest Self-BLEU score (0.8497), suggesting that without persona or L1 conditioning, the model tends to generate semantically redundant utterances. P-ALP falls between the two methods, confirming that persona conditioning enhances semantic diversity but does not reach the level of diversity achieved by L1-AUG.

It is worth noting that L1-AUG produces longer utterances on average (TNW = 12879) compared to P-ALP and ALP. Increased utterance length expands the collection of $n$-gram combinations, which may contribute to higher Unique-3 scores. At the same time, longer utterances can increase word repetition and reduce the proportion of unique unigrams and bigrams, which may explain why P-ALP achieves higher Unique-1 and Unique-2 scores, and L1-AUG achieves the highest Unique-3 score. Although L1-AUG generates longer utterances, it achieves lower SB scores than ALP and P-ALP. Since longer utterances increase opportunities for $n$-gram overlap, this suggests that the diversity introduced by L1-AUG is not only a consequence of verbosity, but also reflects higher diversity across generated utterances. The increased utterance length is also consistent with findings from second-language research, which report that non-native speakers often use longer utterances and more explicit expressions when they lack shorter native-like phrases [3, 4]. These observations support the idea that L1-AUG achieves greater linguistic diversity than ALP and P-ALP.

## 4.3 RQ3: Evaluating the API-Use Capabilities of LLM Agents

In this section, we compare the performance of an LLM agent in fulfilling utterances generated by L1-AUG, P-ALP, and ALP. As shown in Sections 4.1 and 4.2, L1-AUG generates utterances that reproduce linguistic patterns extracted from essays written by non-native English speakers and achieves higher linguistic diversity. This experiment investigates whether these characteristics make the resulting utterances more challenging for LLM agents to fulfill.

### 4.3.1 Experimental Setup

We implement an LLM agent architecture and evaluate its deployment using three LLMs serving as the underlying reasoning engines. By testing with multiple LLMs, we ensure that our evaluation reflects the difficulty of the generated benchmarks rather than the limitations of any single LLM. The remainder of this section describes the agent implementation, LLMs, the testing dataset, and evaluation metrics.

**LLM Agent Architecture.** The agent is designed to process user utterances that require external APIs. The LLM agent operates as a general-purpose assistant with access to the ten APIs detailed in Section 4.1.1. The agent operates in an iterative loop. At each step, the agent can execute one or more API calls to gather the necessary information to answer the user's utterance or return a final answer. API responses are appended to the agent's conversation history, allowing it to reason over intermediate results and dynamically plan its next actions. We set a maximum execution of five iterations to prevent the agent from looping indefinitely while allowing recovery from intermediate errors.

**LLM Selection and Deployment.** We evaluated three LLMs as the agents' reasoning models: Ministral-3-8B, Llama-3.1-8B, and Qwen-3.5-9B. We chose these LLMs because they support native tool-calling and are open-source, allowing local deployment. To ensure a fair comparison and accommodate local computational constraints, we restricted our selection to models with fewer than 10 billion parameters. We deployed all models locally on a machine with a single NVIDIA GeForce RTX 4090 GPU (24 GB VRAM) and an Intel Core i9 CPU (24 cores, up to 5.8 GHz).

**Testing Dataset.** We randomly sampled 20% of the data from each benchmark generated by ALP, P-ALP, and L1-AUG to build the test set. This selection yields 600 utterances and their corresponding ground-truth API calls per benchmark. This sampling strategy provides broad coverage while keeping evaluation costs manageable. Because our agent executes generated API calls against real API backends during evaluation, running experiments on the full benchmark would require at least 27,000 API calls (3,000 utterances $\times$ 3 benchmarks $\times$ 3 LLMs), making evaluation computationally expensive and time-consuming. To ensure balanced representation, we apply stratified sampling [26] across API for all benchmarks. For L1-AUG, we also stratify by country to ensure equal representation across linguistic backgrounds. This configuration results in 60 test instances per API for each benchmark.

**Evaluation Metrics.** We evaluate the LLM agent's API-calling capabilities by verifying whether its generated API calls execute successfully and match the ground-truth API calls. Accurate API calls ensure that the agent retrieves the correct data required to fulfill the user's utterance. We measure performance using the following metrics: (1) **Execution Success Rate (ESR)**: Measures the proportion of total API calls generated by the agent that execute successfully across all testing instances. We consider an individual API call successful if it returns an HTTP 200 status code upon execution. (2) **API Selection Precision (ASP)**: Measures the proportion of predicted API methods that correctly match the ground-truth API endpoint for a given utterance. By disregarding parameter values, ASP isolates the agent's capability to identify the correct API independent of argument extraction. (3) **Semantic Exact Match (SEM)**: Measures whether an LLM agent generates an API call that semantically matches the ground-truth API call required to answer a user's utterance. For each evaluated utterance, SEM is assigned a value of 1 if at least one API call generated

by the agent matches the ground-truth API call, and 0 otherwise. Because the agent is permitted up to five iterations to correct formatting errors, invalid parameters or invalid API calls, this metric checks whether the agent successfully converges on the correct API call at any point during its multi-turn reasoning loop. A valid match requires: (1) the same API endpoint; and (2) semantically equivalent parameter values. To compare parameter values, we compute cosine similarity between their embeddings and consider them equivalent when the similarity exceeds 0.95. We selected this threshold empirically by manually inspecting examples with semantic equivalence. We use semantic similarity because several APIs accept free-form textual parameters rather than exact string matches. For example, in a paper search API, queries such as *"large language models for API use"* and *"LLMs for API calling"* correspond to equivalent search intents and should be considered valid matches. We again use `Qwen/Qwen3-Embedding-4B` [35] to compute parameter embeddings.

### 4.3.2 Results

We found that **agents achieved lower performance when fulfilling utterances produced by L1-AUG than those generated by P-ALP and ALP, suggesting that utterances simulating linguistic patterns extracted from essays written by English learners are more challenging for LLM agents to fulfill. Furthermore, Qwen-3.5-9B achieved the highest performance.** Table 4 presents the full results.

**Table 4** Downstream API calling performance of LLM agents deployed using three LLMs and three benchmarks.

| LLM Agent | Method | ESR ↑ | ASP ↑ | SEM ↑ |
|---|---|---|---|---|
| Qwen-3.5-9B | ALP | 0.9482 | 0.9983 | 0.8483 |
| | P-ALP | 0.9064 | 0.9908 | 0.8067 |
| | L1-AUG | 0.8870 | 0.9980 | 0.6533 |
| Ministral-3-8B | ALP | 0.9092 | 0.9910 | 0.7100 |
| | P-ALP | 0.9033 | 0.9886 | 0.6817 |
| | L1-AUG | 0.8488 | 0.9850 | 0.6583 |
| Llama-3.1-8B | ALP | 0.7032 | 0.9792 | 0.5650 |
| | P-ALP | 0.6886 | 0.9598 | 0.5167 |
| | L1-AUG | 0.6707 | 0.9704 | 0.4783 |

L1-AUG yielded the lowest ESR and SEM scores for all LLMs. The performance drop from ALP to L1-AUG is most evident on SEM, with drops of 0.1950 for Qwen-3.5-9B, 0.0867 for Llama-3.1-8B, and 0.0517 for Ministral-3-8B, suggesting that utterances incorporating linguistic patterns extracted from essays written by non-native English speakers indeed impact the agent's ability to extract and map parameters correctly. ASP remained high and stable across all benchmarks and LLMs, ranging from 0.9598 to 0.9983, indicating that API selection is robust to diversity. P-ALP performed between ALP and L1-AUG on most metrics, confirming that persona-based conditioning introduces greater difficulty compared to the baseline, but does not reach the level of challenge posed by L1-AUG.

Qwen-3.5-9B achieved the strongest overall performance, obtaining the highest ESR across all benchmarks and the highest SEM on ALP and P-ALP. Ministral-3-8B ranked second and achieved the highest SEM for L1-AUG, demonstrating competitive performance under the most challenging benchmark. Llama-3.1-8B showed the weakest performance, particularly

on SEM, suggesting higher sensitivity to linguistic diversity in user utterances. Nevertheless, most models showed the same performance ordering across pipelines: ALP achieved the highest scores, followed by P-ALP and L1-AUG. This consistent ordering indicates that the difficulty introduced by L1-aware generation persists across different LLMs.

Table 5 shows utterances from different benchmarks and whether each LLM agent successfully answered them. Example 1 shows a grammatically correct utterance generated by ALP. Ministral-3-8B incorrectly interpreted the temporal clause ("*before the cricket match starts*") as a mandatory constraint and requested additional information about the cricket match rather than invoking an API. Llama-3.1-8B and Qwen-3.5-9B produced valid API calls and answered the utterance correctly. This highlights how agents may over-interpret information, leading to unnecessary clarification steps. Example 2 illustrates an utterance generated by P-ALP that incorporates additional context given a persona. Llama-3.1-8B issues an invalid API call and responds using its internal knowledge rather than relying on API execution. Ministral-3-8B generates a partially correct response, returning only four exercises instead of six. Qwen-3.5-9B successfully generates both the correct API call and the corresponding final response. Example 3 shows a non-native construction *"movie like legal thriller, for instance A Few Good Men"* that conflates a genre description with a movie title. All three models initially treat "legal thriller" as the movie title, resulting in a failed API call. Llama-3.1-8B repeats the same failing API call three times. Ministral-8B includes the correct movie name on its third attempt and provides the correct answer to the user. Qwen-3.5-9B includes the correct title in its second call but then issues additional API calls for unrelated movies, ultimately failing to provide a final answer.

**Table 5** Examples of utterances per pipeline and whether each model successfully resolved the API call. ✔ indicates a correct and complete response, ✔ indicates a partially correct response, and ✗ indicates a failed or incorrect response. Models are Qwen-3.5-9B (Qwen), Ministral-3-8B (Ministral), and Llama-3.1-8B (Llama).

| Method | Utterance | QWEN | MINISTRAL | LLAMA |
|---|---|---|---|---|
| ALP | Give me the current weather in Sydney before the cricket match starts. | ✔ | ✗ | ✔ |
| P-ALP | Could you find me 6 body-weight exercises for abs? I want a routine that captures raw effort and breath, not another lecture disguised as fitness advice. | ✔ | ✔ | ✗ |
| L1-AUG | For this weekend,as I am a law student from Myanmar and after reading many case materials,my mind is very tired.So, I need some movie like legal thriller,for instance A Few Good Men, and if there are in 1992, it will be more or less suitable for me. | ✗ | ✔ | ✗ |

An interesting observation emerged during evaluation. Some semantically valid API calls returned runtime errors, revealing inconsistencies in the API provider. For example, all agents correctly generated the following API call in response to a request involving Brunei dollars: `"name": "converter_currency", "arguments": "amount": 500, "from_currency": "USD", "to_currency": "BND"`. However, this API call returned an execution error because `BND` was not accepted as the value for the `to_currency` parameter, despite being listed as a supported currency in the official API documentation. This suggests that benchmarks generated using L1-AUG can expose edge cases in API providers that standard benchmarks would not cover by incorporating country-specific parameter values tied to the user's nationality. Thus, L1-AUG can serve as a tool for diversity-aware API testing.

## 4.4 Threats to Validity

In this section, we discuss the main threats to the validity of our findings and the measures taken to mitigate their impact.

**Construct Validity.** Our quantitative evaluation in RQ1 relies on lexical and syntactic features that capture broad characteristics of writing rather than directly measuring L1 transfer, such as article omission, false cognates, or literal translations. Thus, the quantitative results show that L1-AUG generates utterances with linguistic patterns that differ across countries, but they do not establish that these differences reflect authentic L1 transfer. To address this limitation, we manually analyzed patterns in the generated utterances and compared them with L1 transfer features observed in the reference essays. However, a single annotator conducted this analysis, limiting the reliability of the qualitative assessment.

Furthermore, we extracted the linguistic patterns used to generate utterances from argumentative essays. Consequently, some generated utterances may reflect characteristics of argumentative writing rather than natural interactions with LLM agents. Lastly, L1-AUG generates longer utterances than the baseline methods, which may influence some diversity metrics by providing more opportunities to produce unique words and n-grams. To account for this, we also report TNW to interpret diversity in the context of utterance length.

**Internal Validity.** Downstream LLM agent evaluation relies on live and third-party APIs. As a result, provider-side failures unrelated to agent performance can affect the ESR metric (e.g., a semantically correct call failing due to a server error). Although all agents were evaluated under the same API conditions, these failures may affect individual evaluations differently depending on the API calls and parameter values each agent generates. Therefore, provider-side failures may introduce noise into comparisons between agents.

**External Validity.** We focused on generating utterances based on essays from English learners from 20 countries in the ICNALE corpus, 10 APIs, 5 LLMs, and a specific agent configuration. Thus, we cannot generalize the findings to all countries, API domains, LLMs, or agent architectures. Future work should evaluate L1-AUG across these dimensions.

# 5 Conclusion

In this paper, we introduced L1-AUG, a novel LLM-based pipeline for generating API-calling benchmarks conditioned on linguistic patterns extracted from essays written by non-native English speakers. We also presented an empirical study evaluating LLM agents' ability to fulfill such utterances. Our results show that L1-AUG generates utterances with higher linguistic diversity than alternative generation methods and that these utterances are more challenging for LLM agents to fulfill, exposing weaknesses that other API-calling benchmarks fail to reveal. These findings suggest that incorporating linguistic patterns extracted from real corpora can improve benchmark construction by exposing failure cases that conventional benchmark generation methods overlook. Consequently, L1-AUG can support the robustness evaluation of LLM agents under more linguistically diverse inputs and provide training data for fine-tuning models to better handle variation in non-native English writing. Beyond benchmark generation, L1-AUG can also support diversity-aware API testing by automatically generating diverse API-oriented test cases with diverse parameter values.

This study has limitations that suggest avenues for future research. First, our qualitative evaluation relies on a single human annotator to verify the incorporation of linguistic patterns. Incorporating multiple annotators with L2/L1 transfer expertise in future work would strengthen the reliability of the findings. Second, L1-AUG relies on essay-based corpora

to extract L1 patterns from speakers in 20 Asian countries. Future work should explore additional types of corpora and a broader set of countries to improve linguistic coverage. Third, our benchmark covers ten APIs, and extending it to a large-scale API ecosystem would strengthen the generalisability of our findings. Fourth, we evaluate only off-the-shelf LLMs, and it remains an open question whether models fine-tuned on L1-AUG data would better handle linguistically diverse utterances. Fifth, L1-AUG targets utterances involving a single API call. Future work should extend this to multi-API and multi-turn settings, which more closely reflect the complexity of real-world interactions.

## Data Availability Statement

To support reproducibility and transparency, we provide all artifacts associated with this study in an online repository available at: `https://github.com/vitorgaboardi/l1-apg`.

## Ethical Considerations

To account for the tendency of LLMs to generate grammatically standard English, our approach includes instructions requiring LLMs to reproduce errors and unusual phrasing only when these are identified in the analyzed essays. Our goal is not to reproduce or reinforce stereotypes associated with linguistic communities, but rather to create diverse benchmarks for evaluating the robustness of LLM agents in understanding utterances from different linguistic backgrounds. The generated utterances should not be interpreted as representative of how all non-native English speakers from a particular country write, nor should L1-AUG be used to generate cultural or linguistic stereotypes.

## Abstract

**Background.** Continuous Integration (CI) aims to shorten release cycles by automating tests on every change. When the same test method keeps failing across consecutive revisions, new defects get buried among existing failures, dulling developer vigilance and weakening CI's benefit of rapid bug localization.

**Aims.** We define `Test Alert Snooze` as the state in which the same test method fails across two or more consecutive revisions, and provide its first empirical characterization: its prevalence, persistence in revisions and elapsed time, the commits developers make during `Test Alert Snooze`, and what they change to resolve it.

**Method.** We analyzed 27 open-source Python and Java projects on GitHub Actions with high test execution frequencies. From build histories and logs over a 90-day window (December 21, 2025 to March 20, 2026), we identified test methods that failed across two or more consecutive revisions, and classified both the commits made during `Test Alert Snooze` and those that resolved it.

**Results.** `Test Alert Snooze` accounts for 42.9% of observed test failures, with a median persistence of 2 consecutive revisions and about one day; extreme cases reached 11 commits and 16 days. During `Test Alert Snooze`, `fix` commits made up only 8.2% of developer activity, while `docs`, `test`, `refactor`, and `feat` collectively dominated. Resolutions were mostly single-category modifications to *Test* or *Product* files, and among resolving commits `test` was the most frequent (32.4%), well above `fix` (11.8%).

**Conclusions.** Test-failure persistence is not a single phenomenon but differs across the build, job, and test-method levels. At the test-method level, resolving a failure often takes the form of test-code maintenance rather than bug fixing, so predicting, detecting, and repairing `Test Alert Snooze` calls for techniques targeting test code alongside product code. This first characterization lays the groundwork for such techniques and for CI features that visualize test-method-level failure persistence.

## 1 Introduction

Continuous Integration (CI) has become a widely adopted practice in software projects that follow modern development methodologies such as Agile and DevOps. In a CI environment, an automated build and test pipeline is triggered on a dedicated server every time a developer commits a change to the shared repository. By keeping the codebase in a constantly release-ready state, CI is expected to shorten the release cycle, that is, the time required to deliver new features to end users, and to provide rapid feedback on integration defects [8].

For CI to deliver these benefits, developers are expected to follow a fundamental discipline [8]: before pushing a commit to the shared repository, they should run the relevant tests in their local environment and submit the change only if those tests pass. This discipline is critical because a newly introduced defect can easily be masked by pre-existing test failures. Once the CI build is already broken, any regression caused by a later commit produces the same failing status as the original problem, and developers cannot distinguish a new defect from the old one without additional investigation. Consequently, the bug-introducing commit may go undetected for an extended period of time, weakening one of the most important benefits of CI, namely the prompt identification of faulty changes.

Although this discipline is repeatedly highlighted in both practitioner guides and academic studies [12, 27], prior empirical work has reported that test failures are surprisingly frequent in real-world repositories [3]. Our preliminary observation is consistent with this finding. As illustrated in Figure 1, several open-source projects exhibit long streaks of consecutive failing builds, during which the CI system reports test failures across many commits and, in some cases, across several days or weeks.

When test failures become routine, developers tend to treat the failing CI status as background noise rather than as an actionable alert. We refer to this state, in which the same test method fails across two or more consecutive revisions without timely remediation, as `Test Alert Snooze`. Under this condition, the CI pipeline continues to execute, yet its diagnostic value is severely degraded: failing builds no longer signal fresh problems, the responsibility for resolving the failure is diffused across the team, and the effort required to restore a green build grows together with the number of accumulated defects. While the broader topic of software test failures has attracted substantial attention in recent software engineering research [3, 22, 18], very few studies have focused specifically on consecutive failures and the developer behaviors that surround them.

This paper characterizes the phenomenon of `Test Alert Snooze` through an empirical analysis of open-source repositories. To structure this investigation, we formulate five research questions that address (i) how prevalent `Test Alert Snooze` is among CI test failures, (ii) how many consecutive revisions `Test Alert Snooze` persists for, (iii) how long `Test Alert Snooze` persists in elapsed time, (iv) what kinds of commits developers make during `Test Alert Snooze`, and (v) what they change to resolve `Test Alert Snooze`.

This paper makes the following contributions:

- **Definition.** We define `Test Alert Snooze` as the state in which the same test method fails across two or more consecutive revisions on CI, formalizing it as a behavioral proxy for test-method-level failure persistence that is distinct from the build-level and job-level persistence examined in prior work.

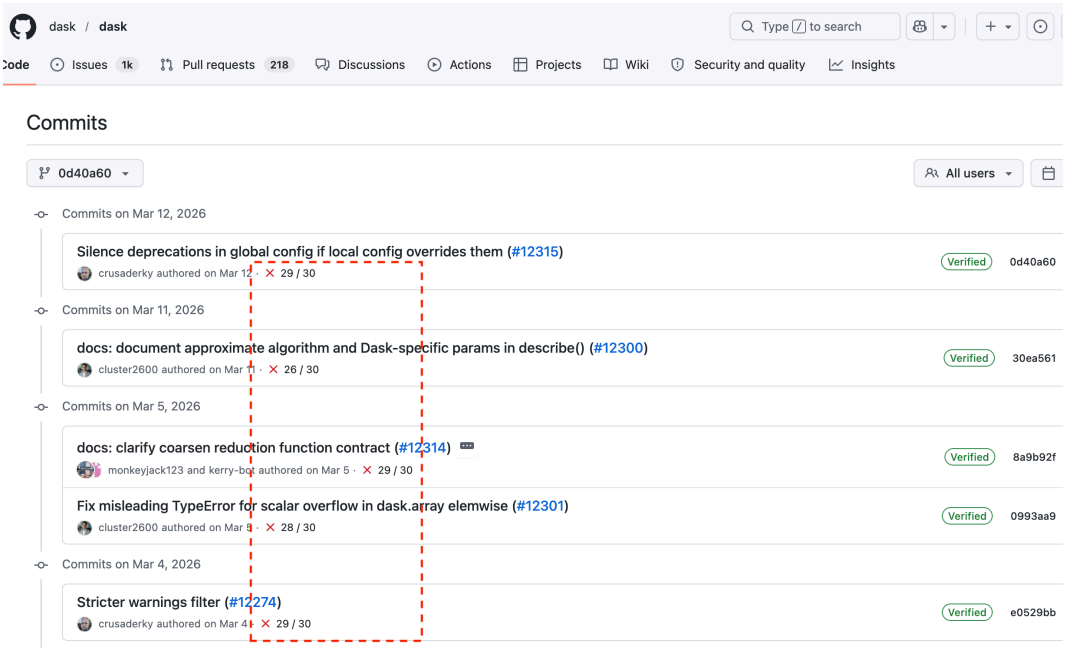

**Figure 1** Examples of consecutive test failures in a project (URL: `https://github.com/dask/dask/commits/0d40a604284e021d098682b71c55d0387a414925` ).

- **Identification methodology.** We propose a procedure for identifying `Test Alert Snooze` occurrences from CI logs that handles three sources of noise: inconclusive revisions such as skipped or cancelled tests, workflow and job configuration drift across commits, and renamed test methods detected via RefactoringMiner.
- **Empirical characterization.** Our analysis of 27 open-source Python and Java projects on GitHub Actions over a 90-day window reveals that `Test Alert Snooze` accounts for 42.9% of observed test failures, with a median persistence of 2 consecutive revisions and approximately one day, and that resolving commits are dominated by `test` (32.4%) rather than `fix` (11.8%), indicating that test-code maintenance plays a central role in resolution.
- **Replication package.** We publicly release our dataset, which includes test failure logs, RefactoringMiner detection results, per-revision test details, and the scripts used for each research question, to support replication and follow-up studies.

**Paper Structure.** The remainder of this paper is organized as follows. Section 2 reviews related work on CI practices and software test failures. Section 3 describes our dataset and analysis methodology. Section 4 presents the results for each research question. Section 5 discusses the implications of our findings. Section 6 discusses threats to validity. Section 7 concludes the paper and outlines directions for future work.

## 2 Background

This section provides a motivating example of consecutive test failures observed in an open-source project, and reviews prior empirical work on CI failures and test failures.

## 2.1 Motivating Example

Figure 1 shows a sequence of commits in the dask project, a widely used Python library for parallel computing. GitHub reports the outcome of CI jobs for each commit through a status indicator adjacent to it. When the count falls short of the total, at least one of the configured jobs failed for that revision. As Figure 1 illustrates, several consecutive commits in this project carry such failure marks, indicating that the CI signal stayed in a non-passing state across multiple revisions.

The persistence of failures at the build and job level has been documented in prior empirical work. Jin and Servant [13] reported that, of all failed builds, a median of 52% were preceded by another failed build, a state they term *Subsequent Build Failure*. Gallaba *et al.* [10] further showed that at least 44% of failing builds are cases in which only a subset of the jobs within the build actually failed while the others passed. At the granularity of individual tests, however, the persistence of failures across revisions has not been empirically investigated. We refer to such a state, in which the same test method continues to fail across consecutive revisions, as a "*Test Alert Snooze*", which we formalize in Section 3.1.

A failure notification from automated tests on CI is one of the primary channels through which developers learn of a defect in their code changes. Upon receiving such a notification, developers first identify which tests have failed before opening an investigation. What happens, then, when a test that has already been investigated continues to fail across consecutive revisions? In broader cybersecurity and operational domains, this condition is known to induce *alert fatigue*: a phenomenon in which repeated exposure to high volumes of identical or false-positive alerts gradually desensitizes the recipient, to the point that even critical threats may be overlooked [21]. The same pattern has been documented in software engineering: developers exposed to repeated failures from flaky tests have been shown to give up on identifying the root cause and instead settle for re-running the tests [19, 9, 11].

The consequences extend beyond developer awareness. As a foundational discipline of CI, broken builds, including those caused by test failures, must be fixed immediately [8]. Yet when the same test continues to fail across consecutive revisions, a newly introduced defect surfacing in a similar setting can be dismissed as "the usual failure", leaving the bug unfixed. Therefore, independent of general process factors such as time pressure and prioritization, this study analyzes the occurrence patterns, resolution times, and fix strategies of Test Alert Snooze. We believe that understanding this phenomenon will help developers identify candidate locations that require fixing, thereby contributing to preventing bugs from being overlooked and left unaddressed.

## 2.2 Related Work

CI failures are an everyday phenomenon in modern software development, and they have been studied extensively in prior empirical work. Kerzazi *et al.* [15] reported a build failure rate of 17.9% in an industrial CI environment, with each build failure requiring an average of 57 minutes to repair. In open-source contexts, Beller *et al.* [3] similarly showed that 10–20% of CI builds on Travis CI contain test failures, confirming that CI failures are routine rather than exceptional events.

Among the sources of these CI failures, automated test failures have consistently been identified as the dominant origin. Rausch *et al.* [20] analyzed Java open-source CI workflows and found that test failures account for over 80% of build failures in some projects. Vassallo *et al.* [24] contrasted open-source and industrial CI failure profiles and observed that unit test failures alone account for 28% of open-source build failures. More recently, Zheng *et*

*al.* [28] analyzed GitHub Actions workflow failures and reported that test failures constitute 32% of all workflow failures, the single largest category. These findings motivate a focus on test failures as the primary CI failure category.

The underlying causes of test failures have also been studied, with flaky tests in particular receiving the most concentrated research attention. Luo *et al.* [18] conducted a foundational analysis identifying asynchronous waits, concurrency, and test order dependency as the dominant root causes of flaky tests. Subsequent studies have documented how developers experience this phenomenon. Eck *et al.* [9] combined a classification analysis of 200 flaky test instances fixed by 21 professional developers with an online survey of 121 developers (median industry experience of 5 years). They found that 79% of respondents regard flaky tests as a moderate-to-severe problem, and that only 25% of time-dependency flaky tests were repaired rather than disabled.

# 3 Study Design

This section defines `Test Alert Snooze` as a behavioral proxy for consecutive test-method failures, details the procedure for identifying its occurrences from CI logs, and describes the dataset used in our analysis.

## 3.1 Definition of Test Alert Snooze

Figure 2 illustrates five test methods (Test A–E) observed across four consecutive revisions $r_i$, $r_{i+1}$, $r_{i+2}$, and $r_{i+3}$. Test A fails at both $r_i$ and $r_{i+1}$; this constitutes a `Test Alert Snooze` because the same test method fails across two consecutive revisions. Test B, which fails only at $r_{i+1}$ and passes at $r_{i+2}$, does not qualify because the failure does not persist.

A revision is counted toward consecutiveness only when its test result is conclusively determined, *i.e.,* when the test either passes or fails. Revisions whose test results are not conclusively determined, which we refer to as *inconclusive revisions*, are excluded from the count. An inconclusive revision falls into one of three cases: *Test Skipped* (the CI system skips a test without executing it), *Test Cancelled* (execution is interrupted before completion), or *No Test* (no test result is available at all). Thus, if a test method fails at revision $r_i$ and fails again at the next conclusive revision, the state qualifies as a `Test Alert Snooze` regardless of any inconclusive revisions between them.

When a failure persists across two or more consecutive conclusive revisions, we treat the entire span as a single `Test Alert Snooze` rather than as multiple occurrences. We define its resolution as the moment when the failing result transitions to a passing one.

## 3.2 Test Alert Snooze Identification

We identify `Test Alert Snooze` occurrences from CI logs using the following procedure.

**1. Identify the workflow, job, and step that run the tests.** For each project, we target the workflows defined as YAML files (`.yml`) under the `.github/workflows` directory on the default branch, and consider only those that execute tests. We exclude workflows used for purposes other than testing, such as code review or dependency management [6], as well as workflows that do not explicitly list individual test methods upon failure.

Using the GitHub API, we retrieve the workflow execution history of the past 90 days ending at the initial latest commit, which corresponds to the maximum log retention period of GitHub Actions [7]. We then refer to the latest revision with a successful workflow execution and manually identify the workflow, job, and step names associated with testing.

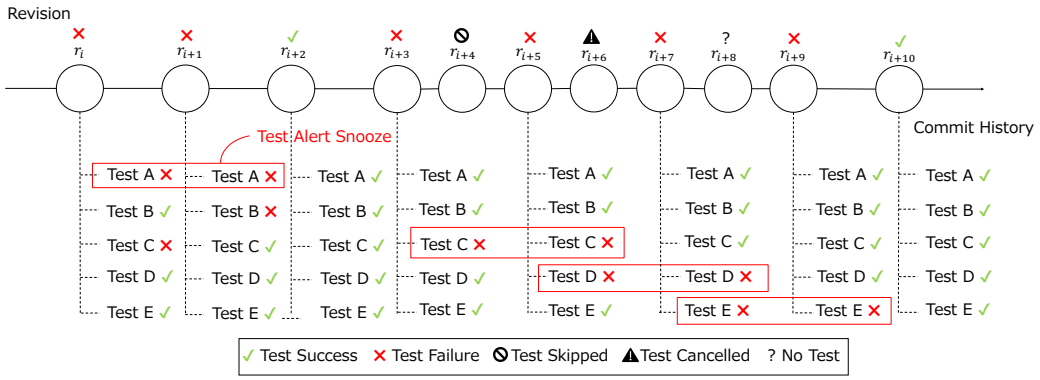

**Figure 2** Definition of `Test Alert Snooze`.

When multiple jobs run tests within the workflow, we focus on the job with the highest test execution frequency in each project. When multiple jobs share the maximum count, we prioritize those meeting three criteria: a Linux OS, `allow_failure: false`, and the most recent execution environment. If the selection is still ambiguous, unit tests are prioritized over other types. For package tests, full-featured environments are selected, while the most fundamental modules are chosen for module-level tests. Any further ties are resolved by selecting the job with the higher number of test cases. If multiple test steps exist within the selected job, we apply the same criteria but prioritize steps other than doctests and smoke tests, including the latter only if no other test types are available.

If all executions within the 90-day window failed, we identify the most recent successful revision for each individual job to assess the testing process. If every job also failed, we evaluate the latest available revision to determine whether tests were being executed.

**2. Retrieve and parse job logs.** To preserve build logs beyond GitHub's 90-day retention limit, we built a system that programmatically collects and stores logs in a local environment, and runs a monthly automated retrieval process.

Because the GitHub Actions API does not provide a way to retrieve logs at the step level, we target jobs in which the test step identified in Step 1 failed, and retrieve the entire job log. We then parse the portion of the retrieved log that corresponds to the test step.

Figure 3 shows an example of such a log. We extract lines that begin with the fixed marker "FAILED" followed by a fully qualified test method name (*e.g.,* the red lines in Figure 3) and treat the listed test methods as failing in that revision. All other lines are ignored.

**3. Identify `Test Alert Snooze` occurrences.** In this step, we use the information obtained above to scan the commit history and identify the spans of `Test Alert Snooze` occurrences. As a preliminary step, we assign one of three states to each (revision, test method) pair:

- **Pass**: none of the above applies.
- **Fail**: the corresponding test step failed and the test method was extracted under a "FAILED" marker during the parsing in Step 2.
- **Inconclusive**: the test result is not conclusively determined. This covers the three cases defined in Section 3.1: *Test Skipped*, where the GitHub API reports the step status as `skipped`; *Test Cancelled*, where the step status is `cancelled` (*i.e.,* execution was

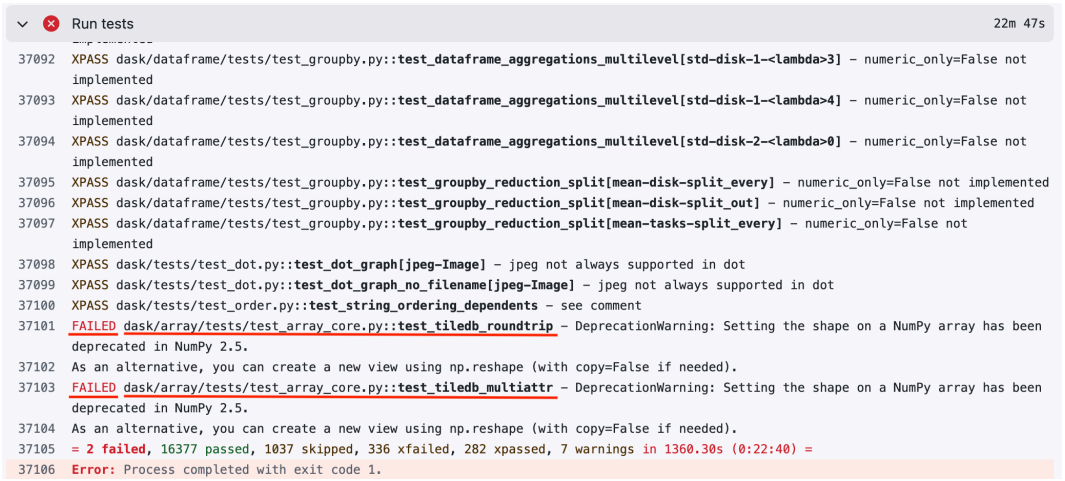

**Figure 3** For example of build logs for failed tests (URL: `https://github.com/dask/dask/actions/runs/23369249959/job/67989498814` ).

interrupted before completion); and *No Test*, where the target test step itself does not exist in this revision, which can occur when the workflow or job configuration changes across commits and the step identified in Step 1 is temporarily absent.

We then reconstruct the parent–child relationships of all commits within the period specified in Step 1 on the default branch. Starting from a parent revision and proceeding through its successive children, we examine the state sequence of each test method. When merge commits occur, the most recent child commit is prioritized.

During this scan, each run of consecutive `Fail` states is recorded as one `Test Alert Snooze` occurrence. `Inconclusive` states are treated as state-preserving: they do not affect the consecutiveness, and the next conclusive revision determines whether the run continues.

To prevent renamed test methods from being incorrectly merged into a single `Test Alert Snooze`, we use RefactoringMiner [2] to detect Rename refactorings (at the package, file, class, and method levels) between adjacent revisions.[1] If a Rename is detected within a candidate `Test Alert Snooze` span, the span is split at that point, because the renamed test method is no longer considered the same test. Rename refactorings detected within Inconclusive intervals are aggregated and reflected in the final determination. Test method identity is verified by the triple of file path, class name, and method name.

## 3.3 Dataset

In this study, we selected 27 projects by filtering the 20 Java and Python projects from Bouzenia and Pradel [4] and 14 projects from Cheng *et al.* [5] to include only those with revisions created on the default branch between December 21, 2025, and March 20, 2026, that underwent at least one test execution. The specific details of these 27 projects are presented in Table 1, and they serve as the basis for investigating our Research Questions.

Furthermore, due to the constraints of using RefactoringMiner [2], this study is limited to projects where the primary programming language is either Java or Python.

[1] `https://github.com/tsantalis/RefactoringMiner`

**Table 1** Studied projects (As of May 9, 2026), Build data (90-day period from December 21, 2025, to March 20, 2026).

| Project | Main Language | Commits | Stars | Contributors | Total Build | Build Top Jobs |
|---|---|---|---|---|---|---|
| Activiti | Java | 11,434 | 10,524 | 228 | 35 | 35 |

| ultralytics | Python | 3,940 | 56,926 | 354 | 3,366 | 341 |

## 4 Research Questions

To characterize `Test Alert Snooze` empirically, we formulate five research questions that examine its prevalence, persistence, and the developer activity surrounding it. RQ1 quantifies how prevalent `Test Alert Snooze` is among CI test failures. RQ2 and RQ3 measure how long a `Test Alert Snooze` persists, in terms of consecutive failing revisions and elapsed time respectively. RQ4 examines what kinds of commits developers make while a `Test Alert Snooze` is ongoing, and RQ5 analyzes what they change to resolve it.

### RQ1: How Prevalent Is Test Alert Snooze?

**Motivation.** Beller *et al.* [3] reported that approximately 10–20% of CI builds on Travis CI contain test failures, indicating that test failures are a routine phenomenon in CI practice. However, the proportion of these failures that persist across consecutive revisions, *i.e.,* those that qualify as `Test Alert Snooze`, has not been quantified. If `Test Alert Snooze` is rare, most failures are resolved promptly and CI functions as intended. If it is common, persistent failures represent a non-trivial challenge that warrants systematic investigation. Therefore, in RQ1, we quantify the prevalence of `Test Alert Snooze` across projects. Specifically, by quantifying the proportion of test failures that transition into `Test Alert Snooze`, we highlight the severity of these failures and the delays in addressing them.

**Approach.** For each project, we use the job selected in Section 3.1 and quantify the prevalence of `Test Alert Snooze` along two dimensions. First, we report the fraction of projects with at least one `Test Alert Snooze` during the observation window. Second,

**Table 2** `Test Alert Snooze` prevalence per project (only projects with ≥ 1 failure).

| Project | # All Test Failures | # Isolated Test Failures | # Test Alert Snooze (Occurrences) | # Test Failures during Test Alert Snooze |
|---|---|---|---|---|
| aeon | 17 | 1 | 5 | 16(94.1%) |
| dask | 34 | 5 | 5 | 29(85.3%) |
| flink | 143 | 83 | 24 | 60(42.0%) |
| rocketmq | 11 | 7 | 2 | 4(36.4%) |
| ansible-lint | 1 | 1 | 0 | 0( 0.0%) |
| guava | 1 | 1 | 0 | 0( 0.0%) |
| molecule | 5 | 5 | 0 | 0( 0.0%) |
| pandas | 35 | 35 | 0 | 0( 0.0%) |
| scikit-learn | 2 | 2 | 0 | 0( 0.0%) |
| ultralytics | 5 | 5 | 0 | 0( 0.0%) |
| Total | 254 | 145 | 36 | 109(42.9%) |

*All Test Failures = Isolated Test Failures + Test Failures during Test Alert Snooze

treating each isolated failure and each `Test Alert Snooze` occurrence (regardless of length) as one failure event, we compute the fraction of failure events that were `Test Alert Snooze`, per project and overall.

**Results.** Table 2 summarizes the prevalence of `Test Alert Snooze` across the 27 projects analyzed. 10 projects (approximately 37.0%) had at least one test failure during the observation window, and `Test Alert Snooze` was observed in 4 of these 10 projects (40.0%). This indicates that `Test Alert Snooze` was observed in 4 out of all 27 projects (approximately 15.0%). Overall, `Test Alert Snooze` accounted for 42.9% of all test failures across the studied projects. Furthermore, every one of the 4 projects in which `Test Alert Snooze` was observed exhibited a per-project `Test Alert Snooze` share exceeding 36%.

**Answer to RQ1**

Test Alert Snooze occurred in 4 out of all 27 projects (approximately 15.0%), and and accounted for 42.9% of all observed failure events.

## RQ2: How Many Revisions Does Test Alert Snooze Continue?

**Motivation.** Jin and Servant [13] reported that 52% of build failures occur in builds where the previous build also failed, and Gallaba *et al.* [10] showed that 83% of builds following a branch-point failure also fail immediately. These findings suggest that consecutive build failures are common and that immediate resolution is often difficult. However, build-level analysis cannot capture how many consecutive revisions the same test method continues to fail once a `Test Alert Snooze` begins. If `Test Alert Snooze` persists for many revisions, developers are repeatedly exposed to the same failing test method. Tariq *et al.* [21] showed that such repeated exposure causes operators to dismiss even genuine alerts, and Levén *et al.* [17] demonstrated that exposure to such degraded states lowers developers' coding standards, increasing the risk of introducing further defects. RQ2 measures the number of consecutive revisions for which each `Test Alert Snooze` persists, clarifying how many times developers end up observing the same failing test method.

**Approach.** For each `Test Alert Snooze` occurrence, we count the number of consecutive failing revisions of the same test method. As described in Section 3.1, inconclusive revisions (*e.g.,* Test Skipped or Test Cancelled) preserve consecutiveness but are not counted toward the run length. We report the distribution (median and maximum) over all occurrences. As a secondary observation, we also count, for each `Test Alert Snooze`-experienced method, how many `Test Alert Snooze` occurrences it had, and report whether any method experienced `Test Alert Snooze` more than once (recurrence) on a per-project basis.

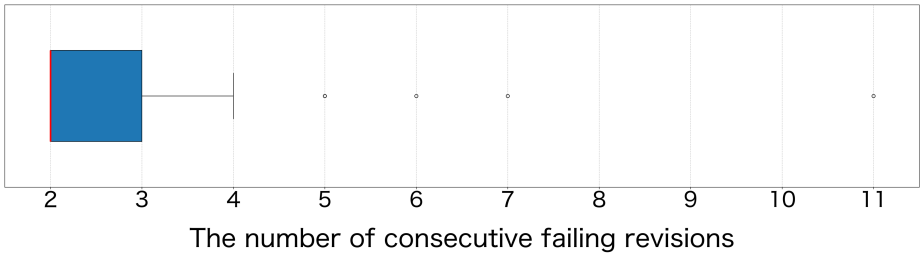

**Figure 4** Distribution of consecutive failing revisions per Test Alert Snooze occurrence.

**Results.** Figure 4 shows the distribution of consecutive failing revisions per `Test Alert Snooze` occurrence. The number of consecutive failing revisions per `Test Alert Snooze` occurrence had a median of 2 and a maximum of 11. Notably, 61.1% of occurrences ended at 2 consecutive revisions, indicating that most cases are resolved quickly. However, the long upper tail (with outliers at 5, 6, 7, and 11 revisions) shows that some `Test Alert Snooze` occurrences persist for multiple revisions before the failing test is fixed, a behavior inconsistent with the principle of immediate fix in CI [8].

As a secondary observation, we examined whether the same test method experiences `Test Alert Snooze` more than once during the observation period. In 3 of the 4 projects with `Test Alert Snooze` (aeon, dask, and rocketmq), every `Test Alert Snooze`-experienced method hit a `Test Alert Snooze` only once. flink was the exception: all 3 of its `Test Alert Snooze`-experienced methods recurred, giving a 100% recurrence rate and showing substantial inter-project variability.

**Answer to RQ2**

`Test Alert Snooze` occurrences last for a median of 2 consecutive revisions, with 61.1% falling at this length, while the maximum reaches 11 consecutive revisions.

## RQ3: How Long Does It Take to Resolve Test Alert Snooze?

**Motivation.** While RQ2 measures the persistence of `Test Alert Snooze` in terms of revision count, revision count alone does not capture how long a failure remains visible to developers in real time. Gallaba *et al.* [10] reported that build breakages persist for seven days on average, indicating that elapsed time is an independent dimension of failure persistence. A `Test Alert Snooze` spanning five revisions may take only a few hours in one case and several weeks in another, with substantially different implications for developers. The longer a `Test Alert Snooze` persists in elapsed time, the greater the risk of developer desensitization and missed defects. RQ3 measures the elapsed time of each `Test Alert Snooze` to clarify its temporal impact on developers.

**Approach.** For each `Test Alert Snooze` occurrence, we compute the elapsed time as the difference between the commit timestamp of the first failing revision and that of the revision at resolution (*i.e.,* when the test returned to passing), as defined in Section 3.1. We report the distribution (median and maximum) over the 34 occurrences resolved within the observation window (the remaining 2 are right-censored).

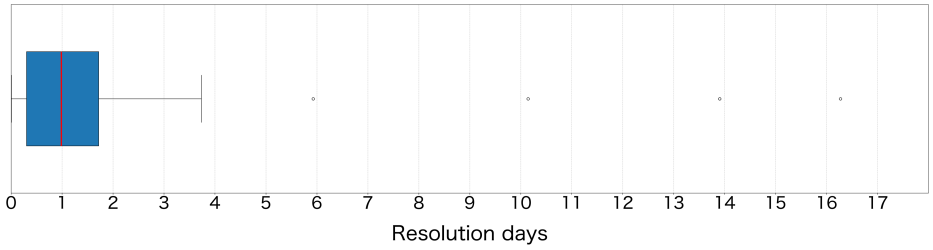

**Figure 5** Distribution of resolution days per `Test Alert Snooze` occurrence.

**Results.** Figure 5 shows the distribution of resolution days per `Test Alert Snooze` occurrence. The elapsed time per `Test Alert Snooze` occurrence had a median of 23h 38min and a maximum of 16 days. 52.9% of occurrences were resolved within one day, indicating that most cases are addressed quickly. On the other hand, cases persisting for up to 16 days were also observed. Such prolonged exposure increases the risk of developer desensitization and missed defects.

Placed alongside the consecutive failing revisions observed in RQ2 (median of 2, maximum of 11), the typical persistence of a `Test Alert Snooze` occurrence is on the scale of "two revisions and about one day". Although this comparison is limited to medians, the fact that the median revision count is as low as 2 while the median elapsed time spans approximately one day suggests that revision count and elapsed time may not always align.

**Answer to RQ3**

`Test Alert Snooze` occurrences are resolved in a median of approximately 24 hours (23h 38min), with the maximum reaching 16 days. While the median revision count of 2 and the median elapsed time of about one day both indicate that typical persistence is short, the two dimensions do not always coincide at the level of individual occurrences.

## RQ4: What Commits Do Developers Make During Test Alert Snooze?

**Motivation.** When a CI test failure first occurs, Parry *et al.* [19] and Vassallo *et al.* [23] characterized typical developer responses such as rerunning the build, inspecting logs, and attempting local reproduction. At industrial scale, Aïdasso *et al.* [1] further showed that silent failures, in which build jobs are marked as successful despite failing to complete their tasks, are routinely dismissed by reruns rather than by code fixes, producing an illusion of success. Although `Test Alert Snooze` differs from silent failures in that its failure is explicit, both share the property of repeated failures that developers may dismiss without addressing the root cause. However, how developers respond when a test failure persists across many revisions has not been studied. They may apply the same rerun-driven dismissal that Aïdasso *et al.* observed, ignore the failure under alert fatigue, or be unaware that the same test continues to fail. RQ4 investigates what kinds of commits developers make during a `Test Alert Snooze`.

**Table 3** CCS categories (%) during `Test Alert Snooze` ($n = 73$).

| Category | Description | Ratio |
|---|---|---|
| `feat` | Addition of new features | 19.2% |
| `build` | Changes related to the build system | 4.1% |
| `style` | Code style changes | 0.0% |
| `chore` | Miscellaneous tasks or other changes | 6.8% |
| `perf` | Performance improvements | 4.1% |
| `ci` | Changes related to CI | 6.8% |
| `test` | Addition or improvement of tests | 15.1% |
| `refactor` | Code refactoring | 11.0% |
| `docs` | Documentation-only changes | **24.7%** |
| `fix` | Bug fixes | 8.2% |

**Approach.** For each `Test Alert Snooze` occurrence, we examine the commits made between the second failing revision and the last failing revision. We exclude the first failing revision because developers may not yet recognize the failure as a recurring issue at that point; the second failing revision onward marks when the `Test Alert Snooze` pattern becomes observable. We classify each commit using the fine-tuned large language model released by Zeng *et al.* [25], which is designed specifically for assigning CCS (Conventional Commits Specification) types to commit content. CCS is a widely adopted convention that categorizes commits by their intent into ten types such as `feat`, `fix`, `docs`, `refactor`, and `test`. We report the distribution of CCS categories across all classified commits.

**Results.** We analyzed 73 commits drawn from snooze periods across all studied projects. Table 3 (column "RQ4: During") summarizes the distribution of CCS categories during `Test Alert Snooze`. The most frequent category was `docs` (24.7%), followed by `test` (15.1%), `refactor` (11.0%), and `feat` (19.2%). Notably, commits explicitly aimed at fixing the failure (`fix`) accounted for only 8.2% of the total.

This pattern differs from the typical CCS distribution reported by Zeng *et al.* [25], in which `fix` is the most frequent category across 88,704 conventional commits from 116 open-source projects. The relatively low proportion of `fix` during `Test Alert Snooze` periods suggests that fix-driven engagement was not the dominant activity.

Furthermore, the distribution reveals two notable patterns. First, categories with no apparent connection to the failing test – `docs` (24.7%), `feat` (19.2%), and `chore` (6.8%) – together account for 50.7%, suggesting that developers continue routine development activities while the `Test Alert Snooze` persists. Second, categories that could potentially relate to the failing test – `test` (15.1%) and `refactor` (11.0%) – together account for 26.1%.

**Answer to RQ4**

During `Test Alert Snooze`, explicit `fix` commits accounted for only 8.2% of developer activity, while `docs` (24.7%), `test` (15.1%), `refactor` (11.0%), and `feat` (19.2%) were more frequent. Commits whose connection to the failing test is not immediately apparent collectively dominated, suggesting that fix-driven engagement was not the primary activity while the failure persisted.

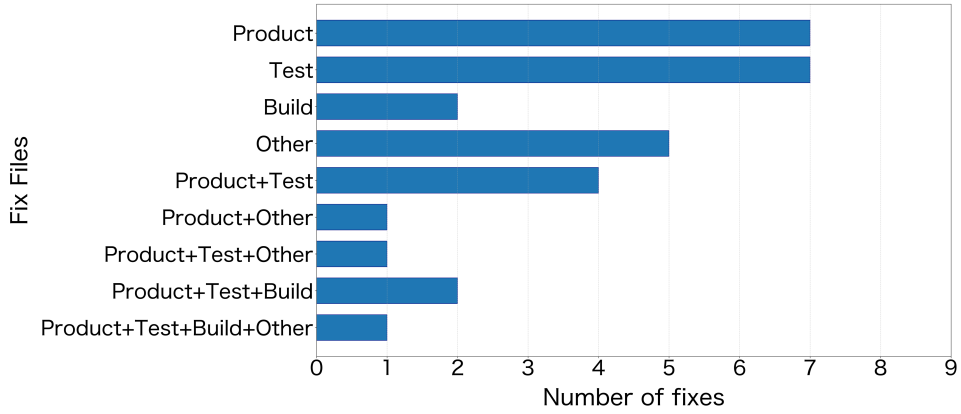

**Figure 6** Ratio of Fix Locations for `Test Alert Snooze` by all projects.

## RQ5: What Do Developers Change to Resolve Test Alert Snooze?

**Motivation.** Vassallo *et al.* [23] showed that resolving CI test failures is challenging, often requiring local reproduction and deep understanding of the changes involved. The structural scope of such fixes has been studied for general bugs by Zhong and Su [29], who found that real-world fixes frequently span multiple files, and for test failures by Vahabzadeh *et al.* [22], who showed that the buggy artifact is sometimes the test code itself rather than the code under test. However, whether fixes for `Test Alert Snooze` are confined to a single artifact or span multiple file categories has not been investigated. RQ5 examines what developers change when resolving `Test Alert Snooze`, by analyzing both the categories of files modified and the intent of the resolving commits.

**Approach.** RQ5 is computed over the 34 resolved occurrences. For each `Test Alert Snooze` occurrence, we analyze the resolution from two perspectives: the categories of modified files and the classification of resolving commits.

For the first perspective, we extract the files modified between the second failing revision and the final commit (*i.e.,* where the test returned to a passing state) using `git diff`, and classify each modified file into one of four categories: *Test* (`.py`, `.java`, `.scala`, or `.ts` files whose path or name contains "test"), *Product* (the remaining `.py`, `.java`, `.scala`, or `.ts` files), *Build* (build-related files such as `pyproject.toml`, `pom.xml`, `build.gradle`, `.yml`, and `.lock`), and *Other* (*e.g.,* README). We report the frequency of each combination of modified file categories across all occurrences. For the second perspective, we classify the resolving commit using the same LLM as in RQ4 [25], and report the distribution of CCS categories.

**Results.** Figure 6 shows the classification of modified files in the `Test Alert Snooze`-resolved revisions across the 4 projects in which `Test Alert Snooze` occurred. Overall, single-category modifications were predominant, accounting for 70.0% of `Test Alert Snooze` resolutions, with Product and Test being the most frequent and equally represented categories.

As for the resolving commit classification, Table 4 (column "RQ5: Resolving") summarizes the distribution of CCS categories assigned to the 34 resolving commits. The most frequent category was `test` (32.4%), followed by `docs` (8.8%) and `refactor` (8.8%). Notably, `test` alone accounts for nearly one third of resolving commits, while explicit `fix` commits accounted

**Table 4** CCS categories (%) during `Test Alert Snooze` ($n = 73$) and resolving ($n = 34$).

| Category | Description | RQ4: During | RQ5: Resolving | Diff |
|---|---|---|---|---|
| `feat` | Addition of new features | 19.2% | 8.8% | -10.4 |
| `build` | Changes related to the build system | 4.1% | 5.9% | +1.8 |
| `style` | Code style changes | 0.0% | 5.9% | +5.9 |
| `chore` | Miscellaneous tasks or other changes | 6.8% | 2.9% | -3.9 |
| `perf` | Performance improvements | 4.1% | 5.9% | +1.8 |
| `ci` | Changes related to CI | 6.8% | 8.8% | +2.0 |
| `test` | Addition or improvement of tests | 15.1% | **32.4%** | **+17.3** |
| `refactor` | Code refactoring | 11.0% | 8.8% | -2.2 |
| `docs` | Documentation-only changes | **24.7%** | 8.8% | -15.9 |
| `fix` | Bug fixes | 8.2% | 11.8% | +3.6 |

for only 11.8%. Compared to the activities during `Test Alert Snooze` (Table 4, column "RQ4: During"), `test` replaces `docs` as the most frequent category, rising from 15.1% to 32.4% (a difference of +17.3), while `docs` drops from 24.7% to 8.8%.

**Answer to RQ5**

`Test Alert Snooze` resolutions are dominated by single-category modifications, most frequently to *Product* or *Test* files. Among resolving commits, the most frequent CCS category was `test` (32.4%) rather than `fix` (11.8%), indicating that resolving `Test Alert Snooze` often involves modifications to the test code itself rather than to product code alone.

# 5 Implications

In this section, we discuss the implications of our findings for researchers, practitioners, and CI tool providers.

## 5.1 Implications for Researchers

The implications for researchers concern perspectives for positioning `Test Alert Snooze` as a new research target and directions for future research.

**Researchers should measure the persistence of `Test Alert Snooze` at the test-method level rather than inferring it from build- or job-level results.** Jin and Servant [13] reported a 52% consecutive failure rate at the build level, and Gallaba *et al.* [10] showed that 83% of builds following a branch-point failure also fail immediately. At the test-method level, we observed `Test Alert Snooze` at a rate of 42.9% (RQ1). These figures are not directly comparable: they are defined over different granularities and different events, and our measurement covers only a small number of tests across 4 projects. What they do indicate is that the relationship between persistence at the build or job level and persistence at the level of individual test methods has not yet been established. Researchers should therefore measure persistence at the build, job, and test-method levels separately to determine at which level alert fatigue actually arises, and validate our test-method-level results on a substantially larger set of projects and tests.

**Researchers should develop new prediction and repair approaches that target test code.** The results of RQ5 showed that 32.4% of resolving commits fell into the `test` category, while explicit `fix` commits accounted for only 11.8%. This suggests that the resolution of `Test Alert Snooze` is not a simple bug-fixing task but rather involves modifications to the test code itself. Existing Just-in-time defect prediction techniques [14], which predict whether a commit introduces a defect at the time of the commit, predominantly target product code. Consequently, applying these techniques directly to `Test Alert Snooze` is insufficient. Researchers should develop new prediction models and automated repair techniques that jointly target both test code and product code.

**Researchers should clarify the boundary between `Test Alert Snooze` and flaky tests.** In this study, we defined `Test Alert Snooze` solely based on temporal persistence (Section 3.1); however, it remains unclear what fraction of the observed `Test Alert Snooze` occurrences stems from genuine defects versus flaky tests (tests whose outcomes are non-deterministic). Researchers should leverage rerun-based flaky test detection techniques (*e.g.,* [16]) together with our persistence-based definition to separate "`Test Alert Snooze` caused by genuine defects" from "`Test Alert Snooze` caused by flaky tests" and to compare how each affects practitioners' cognitive load.

**Researchers should establish techniques for distinguishing individual defects within a `Test Alert Snooze`.** Even when the same test method fails consecutively during a `Test Alert Snooze`, there is no guarantee that the underlying defect remains the same. If a newly introduced defect produces the same failure status (*e.g.,* `AssertionError`) as the existing failing test, practitioners may have difficulty distinguishing between them, potentially delaying the detection of the new defect. The results of RQ5 in this study showed that a non-trivial fraction of `Test Alert Snooze` resolutions involved modifications spanning multiple file categories, which also suggests that multiple distinct defects may have coexisted during the Snooze period. Prior work such as BuildSheriff [26] has proposed techniques for clustering test failures within a single build according to their root causes; however, what is needed in the context of `Test Alert Snooze` is a technique that identifies individual defects along the temporal axis within a sequence of consecutive failures spanning multiple builds. Researchers should investigate techniques that use failure logs, stack traces, and error messages to distinguish individual defects within consecutive failures.

## 5.2 Implications for Practitioners

The implications for practitioners concern suggestions for how to respond when encountering a `Test Alert Snooze`.

**Practitioners should recognize that resolving a `Test Alert Snooze` does not always conclude with modifications confined to a single artifact category.** The results of RQ5 showed that while single-category modifications were the most common pattern, a non-trivial fraction of `Test Alert Snooze` resolutions involved modifications spanning multiple categories among *Product*, *Test*, *Build*, and *Other*. Practitioners should remain open to the possibility that resolving a failing test may require modifications outside the immediately suspected artifact (*e.g.,* outside the test code itself), particularly when an initial fix does not restore the build to a passing state.

**Practitioners should treat the test itself as a primary candidate for modification, not only the product code under test.** RQ5 showed that, among single-category resolutions, *Test* and *Product* files were modified with equal frequency, and that the most common CCS category among resolving commits was `test` (32.4%), well above `fix` (11.8%). This indicates that a persistently failing test is often resolved by updating the test itself (*e.g.,* to reflect intentional changes in product behavior, to relax brittle assertions, or to remove ordering dependencies) rather than by debugging the product code. Practitioners should therefore include the failing test in their early investigation rather than defaulting to product-code debugging, which may shorten the resolution time and reduce the team's exposure to the failing alert.

## 5.3 Implications for CI Tool Providers

The implications for CI tool providers concern functionalities that CI platforms could provide to address `Test Alert Snooze`.

**CI tool providers should offer visualization of consecutive failures at the test method level.** Most current CI platforms, including GitHub Actions, visualize pass/fail status at the build level but do not provide standard functionality for tracking how many times an individual test method has failed consecutively. As suggested by the results of RQ1, persistence at the test method level is a different indicator from persistence at the build level (42.9% vs. 52%, though the two metrics are defined at different granularities) and carries information that build-level visualization alone cannot capture. By presenting this information on the dashboard, CI tool providers can enable practitioners to intervene before alert fatigue sets in.

**CI tool providers should offer mechanisms that present individual defects within consecutive failures as distinguishable signals to practitioners.** When the same test fails consecutively during a `Test Alert Snooze`, a newly introduced defect may become buried under the existing failing test as it carries the same status, creating the risk that practitioners will overlook its detection. This significantly undermines the *rapid bug localization* capability that CI is intended to provide. As discussed in the Implications for Researchers, techniques for distinguishing individual defects within consecutive failures remain an open research challenge; building on such future advances, CI tool providers should consider design choices that provide notifications and visualizations that distinguish newly introduced defects from existing failing tests. Such mechanisms would help practitioners maintain attention to new defects even during a `Test Alert Snooze`.

# 6 Threats to Validity

## 6.1 Internal Validity

We retrieved 90 days of build logs from GitHub Actions, which corresponds to the upper limit of its log retention period. `Test Alert Snooze` occurrences that are truncated at either end of our observation window, or that persist beyond 90 days, cannot be observed; therefore, the maximum values reported in this study (11 commits and 16 days) should be interpreted as conservative estimates. Nevertheless, 61.1% of the observed `Test Alert Snooze` occurrences were resolved within 2 commits, suggesting that cases persisting for as long as 90 days are likely to be exceptionally rare.

For each project, we analyzed only the job with the highest test execution frequency. Furthermore, the identification of the workflow, job, and step that run the tests was performed through manual inspection, which may introduce selection bias. Other jobs within the same project (running on different operating systems, language versions, or test layers) may also exhibit `Test Alert Snooze` occurrences that we do not detect. Consequently, the `Test Alert Snooze` rates reported in this study should be interpreted as lower bounds on the project-wide rates.

## 6.2 Construct Validity

We defined `Test Alert Snooze` based solely on the temporal persistence of test failures, regardless of their underlying causes. This persistence-only definition is a behavioral proxy rather than a direct measurement of developer attention or alert fatigue. Therefore, continuous test failures do not necessarily indicate that developers ignore `Test Alert Snooze`. Rather, the observed instances of `Test Alert Snooze` may arise from several distinct underlying mechanisms. Examples include flaky tests [18], whose failures are non-deterministic and unrelated to actual defects; active investigation of difficult bugs that legitimately requires multiple commits to resolve; and long-running build pipelines that produce repeated failures during normal execution. Moreover, the determination of resolution, defined as a transition from failing to passing, is similarly susceptible to flakiness-driven transient successes. In addition, because our analysis is grounded in commit history and CCS classification, developer activities that do not result in a commit (*e.g.,* local debugging) fall outside the scope of our observation.

Although these multiple factors may be intertwined – representing a limitation of our approach – the observable phenomenon that the same test fails repeatedly across consecutive revisions remains consistent with alert fatigue reported in other domains [21]. Therefore, treating these cases collectively as `Test Alert Snooze` provides a useful behavioral proxy for studying this class of failures, even when the underlying cognitive mechanism cannot be directly measured.

## 6.3 External Validity

We analyzed CI logs from 27 projects; however, test failures were observed in only 10 projects, and `Test Alert Snooze` occurrences in only 4 projects. As a result, the findings from RQ2 through RQ5 rest on a small project base. In particular, the 100% recurrence rate reported for one project is based on only 3 test methods and is therefore susceptible to outliers. Furthermore, the projects analyzed were drawn from prior studies [4, 5], and most of them are large and active open-source projects. Smaller projects or those with weaker testing discipline may exhibit different patterns. In this study, we focused on a selected set of projects with high test execution frequency and conducted a careful analysis; however, a more accurate assessment of `Test Alert Snooze` requires replication over a longer observation period and a larger set of projects.

This study is constrained to projects written in Java or Python that use GitHub Actions as their CI platform. Projects in other languages (*e.g.,* JavaScript, Go, C/C++) or those using other CI tools (*e.g.,* Jenkins, GitLab CI, CircleCI) may exhibit different `Test Alert Snooze` patterns due to differences in testing conventions, retry policies, and job structures. Investigations covering additional languages, CI platforms, and industrial settings are left as future work.

## 7 Conclusion

This paper introduced `Test Alert Snooze`, a state in which the same test method fails across two or more consecutive revisions on CI. While prior empirical work has examined the temporal persistence of CI failures at the build or job level [13, 10], persistence at the granularity of individual test methods has remained empirically uncharacterized. We formalized `Test Alert Snooze` as a behavioral proxy that captures this finer-grained persistence and provided its first empirical characterization.

Through an analysis of 27 GitHub Actions projects written in Python or Java over a 90-day period, we found that `Test Alert Snooze` accounts for 42.9% of observed test failures, with a median persistence of 2 consecutive revisions and approximately one day. While most occurrences are resolved promptly, extreme cases persisted for up to 11 commits and 16 days. Examination of developer activity during `Test Alert Snooze` revealed that explicit `fix` commits accounted for only 8.2%, with the majority being commits whose connection to the failing test is not immediately apparent. Furthermore, resolving commits were dominated by `test` (32.4%) rather than `fix` (11.8%), suggesting that the resolution of `Test Alert Snooze` frequently involves modifications to test code itself rather than to product code alone.

## Data Availability Statement

To support reproducibility, we provide an anonymous replication package at `https://github.com/ayane-shi/TestAlertSnooze-Replication`. The repository contains data for the subject projects, covering revisions created during the 90-day period from Dec 21, 2025, to Mar 20, 2026. The dataset includes test failure logs, RefactoringMiner detection results, test details for each revision, and the scripts used for each research question.

## Abstract

**Background.** Large language models (LLMs) can generate executable code, but their reliability across programming languages remains difficult to characterize.

**Aims.** We investigate multilingual code capability under problem alignment, focusing on functional reliability, cross-language consistency, translation behavior, problem and sampling effects, and execution quality.

**Method.** We present McIBench, covering 1,489 programming problems and eight languages, of which 1,466 have execution-validated coverage in all eight languages. We evaluate representative LLMs through multilingual generation and analyze source-code-conditioned translation on 100 randomly selected all-language-covered problems.

**Results.** Performance varies substantially across models and target languages, while source-code-conditioned translation also exhibits marked variation across source-target settings. Problem difficulty and candidate budget materially affect correctness, strong aggregate performance does not necessarily imply cross-language consistency, and accepted programs differ in runtime and memory efficiency.

**Conclusions.** Aggregate pass@$k$ alone is insufficient for characterizing multilingual code capability, motivating evaluation that considers language consistency, problem sensitivity, sampling behavior, translation settings, and post-correctness execution quality.

**2012 ACM Subject Classification** Software and its engineering → General programming languages; Computing methodologies → Artificial intelligence

## 1 Introduction

Large language models (LLMs) have shown strong capabilities in generating executable programs from natural-language descriptions [8, 2]. However, their reliability across programming languages remains difficult to characterize [6]. Many existing evaluations either focus on a single language or aggregate results over heterogeneous problem sets [4, 1, 5, 12]. Such results provide useful overall indicators, but they make it difficult to determine whether a model solves the same problems consistently across languages, how its performance varies with problem characteristics and candidate budget, and whether functionally correct programs exhibit comparable execution quality.

A key challenge is *problem comparability*. When different languages are evaluated on different problem sets, observed performance gaps may reflect task composition rather than target-language effects. We therefore adopt a problem-aligned design in which the same underlying programming problems are evaluated across target languages under a unified execution-based protocol. This design enables multilingual behavior to be compared under matched problem semantics and supports analyses beyond aggregate pass@$k$, including language consistency, failure behavior, sampling effects, and post-correctness execution quality.

To support this study, we construct McIBench, a problem-aligned evaluation infrastructure containing 1,489 algorithmic programming problems across eight languages: Python3, Java, C, C++, Rust, JavaScript, C#, and Golang. Among them, 1,466 problems have execution-validated program coverage in all eight languages. McIBench integrates problem descriptions, difficulty labels, algorithmic tags, language-specific templates, generated outputs, executable submissions, and execution records, allowing model behavior to be analyzed consistently across problems and languages.

Figure 1 summarizes the evaluation setting. Our primary study focuses on multilingual code generation, where the same problem description is used to generate solutions in each target language. We additionally randomly select 100 all-language-covered problems for a complementary analysis of source-code-conditioned translation across 56 ordered source-target settings. This analysis examines how translation performance varies across source-target combinations, language roles, and reversed translation directions. All generated and translated programs are evaluated through execution, with correctness, failure status, runtime, and memory recorded when available.

We evaluate representative advanced LLMs together with a Qwen3 scaling series. Our analyses examine overall reliability and failure modes, consistency across target languages, sensitivity to problem difficulty and algorithmic characteristics, the benefit of additional candidates, source-code-conditioned translation behavior, and runtime-memory efficiency of accepted programs. The results show substantial variation across models and languages, and

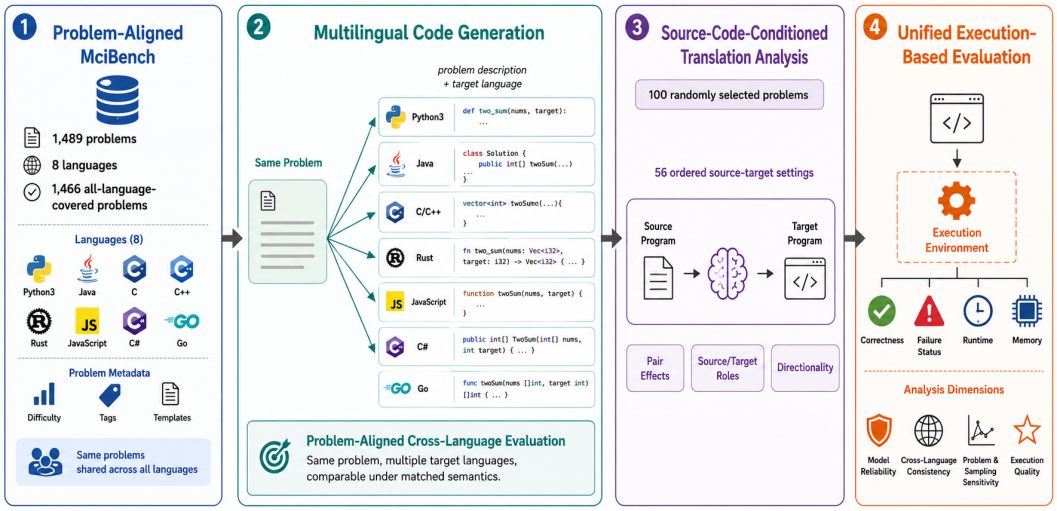

**Figure 1** Problem-aligned multilingual evaluation for code generation and code translation.

demonstrate that strong aggregate pass@$k$ does not necessarily imply consistent multilingual behavior. Problem difficulty and candidate budget also materially affect correctness, while accepted programs can differ in execution efficiency even when they are functionally correct.

This paper makes three contributions:

- We construct MciBench, a problem-aligned multilingual code evaluation infrastructure containing 1,489 programming problems across eight languages, including 1,466 problems with execution-validated coverage in all eight languages.
- We provide a unified execution-based pipeline that integrates multilingual code generation, source-code-conditioned translation, failure categorization, candidate sampling, and runtime/memory collection.
- We conduct a large-scale empirical study of multilingual code capability across models, target languages, translation settings, problem characteristics, candidate budgets, and post-correctness execution quality.

# 2 Related Work

## 2.1 General Code Generation Evaluation

LLMs have demonstrated strong capabilities in generating executable code from natural-language requirements [21, 19]. Benchmarks such as HumanEval [4] and MBPP [1] evaluate functional correctness through execution on controlled programming tasks. While these benchmarks have established widely used evaluation protocols, they primarily focus on individual programming languages and provide limited support for studying whether the same model behaves consistently on the same problems across multiple languages.

## 2.2 Multilingual and Cross-Language Code Evaluation

Recent benchmarks extend code evaluation to multilingual settings. HumanEval-based resources, including HumanEval-X [29], HumanEvalPack [16], MultiPL-E [3], HumanEval-XL [17], and mHumanEval [18], provide code-generation tasks in multiple programming languages. Other benchmarks, such as XLCoST [30], XCODEEVAL [10], and PseudoEval [26],

**Table 1** Comparison with representative code generation and code translation benchmarks.

| Benchmark | Year | Scale | #Lang. | Aligned Coverage | Code Gen. | Code Trans. |
|---|---|---|---|---|---|---|
| MBPP [1] | 2021 | 974 tasks | 1 | – | ✓ | – |
| HumanEval [4] | 2021 | 164 problems | 1 | – | ✓ | – |
| XLCoST [30] | 2022 | 901 problems | 7 | Partial | ✓ | ✓ |
| HumanEval-X [29] | 2023 | 164 problems | 5 | 164 aligned | ✓ | – |
| HumanEvalPack [16] | 2023 | 164 problems | 6 | 164 aligned | ✓ | – |
| MultiPL-E [3] | 2023 | 1,138 problems | 18 | Partial | ✓ | – |
| G-TransEval [9] | 2023 | 400 pairs | 5 | – | – | ✓ |
| HumanEval-XL [17] | 2024 | 80 problems | 12 | 80 aligned | ✓ | – |
| XCODEEVAL [10] | 2024 | 7.5K problems | 11 | Partial | ✓ | ✓ |
| mHumanEval [18] | 2025 | 164 problems | 25 | 164 aligned | ✓ | – |
| PseudoEval [26] | 2025 | 357 problems | 3 | 333 aligned | ✓ | – |
| **MciBench** | **2026** | **1,489 problems** | **8** | **1,466 all-language-covered** | ✓ | ✓ |

*) "Aligned Coverage" indicates whether the same programming problem has corresponding multilingual solutions or execution-validated program coverage across languages. "Partial" means that multilingual solutions are available only for some problems, languages, or language pairs.

further support multilingual generation, cross-language tasks, or aligned evaluation settings. As summarized in Table 1, these resources vary considerably in scale, language coverage, problem alignment, and supported evaluation tasks.

Problem alignment is particularly important for cross-language comparison because performance differences measured on different problem sets may reflect task composition rather than programming-language effects. MciBench therefore evaluates the same underlying problems across target languages, enabling direct comparison under matched problem semantics. It additionally supports source-code-conditioned translation on problems with multilingual program coverage, allowing generation and translation to be studied under a common execution-based framework. Prior translation benchmarks such as G-TransEval [9] provide complementary support for evaluating cross-language program transformation.

## 2.3 Execution-Based and Quality-Aware Evaluation

Execution-based evaluation is central to code generation and translation because textual similarity is a weak proxy for functional correctness [4, 1, 11]. Metrics such as pass@$k$ measure whether generated programs satisfy executable tests rather than whether they resemble reference implementations [4]. In multilingual settings, execution also exposes language-specific failures related to compilation, type systems, libraries, runtime behavior, and submission interfaces. LLMs have also been explored for software-quality analysis beyond code generation, including large-scale inspection of static bug warnings [22, 20]. Beyond execution-based testing, recent LLM-assisted formal-methods research has explored translating natural-language requirements into LTL specifications and synthesizing program specifications through static analysis and neuro-symbolic reasoning [13, 14, 23, 24].

Functional correctness, however, does not fully characterize generated code. Accepted programs may still differ in runtime and memory consumption, motivating post-correctness evaluation of execution quality. Compared with existing benchmarks, MciBench combines problem-aligned multilingual generation with execution records that support failure analysis, candidate-sampling analysis, source-code-conditioned translation analysis, and runtime-memory evaluation of accepted programs.

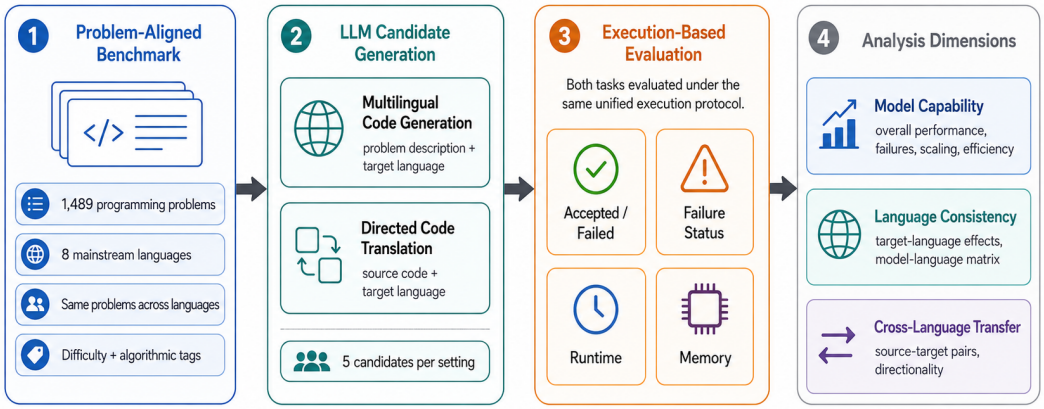

**Figure 2** Overview of the MciBench evaluation workflow and analysis dimensions.

# 3 Study Design

## 3.1 Overview

Figure 2 summarizes the MciBench evaluation workflow. Starting from a problem-aligned benchmark, we evaluate LLMs on two programming tasks: multilingual code generation and source-code-conditioned translation. For both tasks, each model generates multiple candidates, which are converted into executable submissions and evaluated under the same execution-based protocol. The resulting records capture functional correctness, failure status, runtime, and memory, supporting analyses from model-, language-, problem-, and execution-quality perspectives.

Our primary evaluation focuses on multilingual code generation, where the same programming problems are evaluated across eight target languages under matched problem semantics. We further conduct a complementary source-code-conditioned translation analysis on a randomly selected set of all-language-covered problems. Using the same 100 problems across all 56 ordered source-target settings enables controlled analysis of source-target variation, language roles, and translation directionality.

## 3.2 Benchmark Construction

MciBench organizes executable programming problems, multilingual program coverage, language-specific templates, model outputs, and execution records under a unified evaluation framework. For each problem, we store its platform identifier, description, difficulty label, algorithmic tags, and language-specific submission templates.

Starting from 2,029 collected problem records, we retain 1,489 algorithmic programming problems covering Python3, Java, C, C++, Rust, JavaScript, C#, and Golang. The retained set contains 481 Easy, 723 Medium, and 285 Hard problems. Problems are retained if they support executable submission in the selected languages and can be evaluated through a stable submission-and-check protocol.

For multilingual code generation, all 1,489 problems are evaluated across the eight target languages using the same problem identities and execution protocol. Because generated candidates are checked directly through execution, generation does not require an existing reference implementation in every target language.

To support code translation, MciBench further maintains multilingual program implementations across languages. As shown in Table 2, the initially collected reference solutions are highly uneven across languages, and only 331 problems have reference implementations in

**Table 2** Coverage of initially collected reference solutions in MciBench before execution-validated solution enhancement.

| Per-language solution coverage | | | Per-problem solution alignment | |
|---|---|---|---|---|
| **Language** | **#Problems** | **Coverage** | **#Collected Lang.** | **#Problems** |
| C++ | 1,448 | 97.2% | 1 | 10 |
| Python3 | 1,353 | 90.9% | 2 | 168 |
| Java | 1,338 | 89.9% | 3 | 98 |
| JavaScript | 1,163 | 78.1% | 4 | 81 |
| C | 1,120 | 75.2% | 5 | 212 |
| C# | 1,014 | 68.1% | 6 | 420 |
| Golang | 568 | 38.1% | 7 | 169 |
| Rust | 371 | 24.9% | 8 | 331 |

**Table 3** Overview of MciBench.

| Item | Description |
|---|---|
| Problems | 1,489 algorithmic programming problems |
| Difficulty | 481 Easy, 723 Medium, 285 Hard |
| Languages | Python3, Java, C, C++, Rust, JavaScript, C#, Golang |
| Code generation | 1,489 problems × 8 target languages |
| Initial all-reference coverage | 331 problems with solutions in all eight languages |
| All-language coverage | 1,466 execution-validated problems |
| Translation analysis | 100 randomly selected problems × 56 ordered source-target settings |
| Candidates | 5 candidates per setting |
| Evaluation protocol | Execution-based submission and checking |
| Evaluation outputs | Correctness, failure status, runtime, memory |
| Metadata | Difficulty levels and algorithmic tags |

all eight languages. We therefore expand multilingual coverage through execution-validated solution enhancement, retaining additional problem-language implementations only after they pass the execution-based checker. This process results in 1,466 problems with validated program coverage in all eight languages. For the translation analysis in this study, we randomly select 100 problems from this all-language-covered set.

With eight languages, each selected problem supports 56 ordered source-target translation settings. For the translation analyses reported in this paper, the same 100 problems are evaluated across all 56 ordered source-target settings, enabling controlled comparison of translation behavior across language combinations. Table 3 summarizes the benchmark scale and evaluation settings.

## 3.3 Evaluation Tasks

**Task 1: Multilingual Code Generation.** Given a problem description and a target language, the model generates candidate solutions in the requested language. The same problem identities are evaluated across all eight target languages, enabling direct comparison of multilingual behavior under matched problem semantics.

**Task 2: Source-Code-Conditioned Translation.** Given an execution-validated source-language implementation and a target language, the model generates a semantically equivalent program in the target language. The eight languages define 56 ordered source-target settings. In this study, we analyze these translation results across models, source-target combinations, source/target language roles, and reversed translation directions.

**Table 4** Evaluated models.

| Model | Role | Generation | Translation |
|---|---|---|---|
| qwen3-coder-480b-a35b-instruct | Cross-model comparison | ✓ | ✓ |
| gpt-4o | Cross-model comparison | ✓ | ✓ |
| glm-4 | Cross-model comparison | ✓ | ✓ |

| qwen3-8b | Scaling analysis | ✓ | – |
| qwen3-4b | Scaling analysis | ✓ | – |
| qwen3-1.7b | Scaling analysis | ✓ | – |

*) For qwen3-coder-480b-a35b-instruct, the model has 480B total parameters, with 35B parameters activated during inference.

### 3.4 Research Questions

We organize the empirical study around five research questions.

**RQ1: How reliable are LLMs in problem-aligned multilingual code generation?** We examine overall functional correctness, model scaling, and failure profiles in the full generation setting.

**RQ2: How consistently do LLMs solve the same problems across programming languages?** We analyze target-language performance and model-language variation under aligned problem semantics.

**RQ3: How does source-code-conditioned translation vary across models and language settings?** We analyze overall translation performance, source-target pair effects, source/target language roles, and differences between reversed translation directions on the 100-problem translation set.

**RQ4: How sensitive is multilingual code-generation reliability to problem characteristics and candidate budget?** We study performance across difficulty levels and algorithmic topics, together with the benefit of generating multiple candidates.

**RQ5: Does functional correctness imply comparable execution quality?** We compare runtime and memory characteristics among accepted generated programs to examine post-correctness execution quality.

## 4 Experimental Setup

### 4.1 Evaluated Models

Table 4 summarizes the evaluated models. Five representative advanced LLMs are evaluated on both multilingual generation and source-code-conditioned translation. We additionally evaluate a Qwen3 scaling series on multilingual generation to examine how model scale affects cross-language coding performance.

### 4.2 Candidate Generation

Each model generates five candidates per evaluation setting, enabling empirical pass@$k$ evaluation and analysis of candidate-budget effects. For multilingual generation, the prompt contains the problem description and requested target language. For translation, the prompt contains an execution-validated source implementation and the requested target language. The complete prompt templates, decoding parameters, and model invocation configurations are included in the accompanying artifact.

Model outputs are post-processed into executable submissions using the corresponding target-language templates. If fenced code blocks are present, we select the first block matching the target language; otherwise, we use the first complete code block or cleaned raw output. Post-processing only extracts code and fills submission templates; it does not repair program logic or manually correct generated outputs. Outputs that cannot be converted into executable submissions are treated as failed candidates.

Following prior execution-based code evaluation [4], empirical pass@$k$ is the proportion of evaluation instances for which at least one of the first $k$ generated candidates passes the execution-based tests. Unless otherwise stated, we report pass@1 and pass@5.

## 4.3 Execution and Result Collection

Each generated or translated program is submitted through the target-language execution interface under a common submission-and-check protocol. A candidate is accepted only if it passes all available target-language tests. For failed candidates, we record the returned status, including wrong answer, compile error, runtime error, time limit exceeded, memory limit exceeded, and output limit exceeded. For accepted candidates, runtime and memory are recorded when available.

The same execution protocol is applied across models, tasks, and target languages. The resulting records include raw model outputs, extracted submissions, execution status, failure type, runtime, and memory measurements.

## 4.4 Statistical Analysis

The evaluation unit depends on the task. For multilingual generation, an instance is a problem-target-language pair. For translation, an instance is a problem-source-target triple. We report aggregate pass rates over the corresponding instances and use 95% Wilson confidence intervals for the main pass@5 results [25].

For comparisons across models and target languages, we use the same underlying problem instances whenever possible to reduce confounding from problem composition. For the translation analyses in RQ3, the same 100 problems are evaluated across all 56 ordered source-target settings. Pair-level, role-level, and direction-level results are therefore computed over matched problem identities, reducing variation caused by different problem compositions.

Runtime and memory analyses are conducted only on accepted generated programs. Because raw measurements are not directly comparable across problems or target languages, we normalize them within each problem-language group, comparing accepted programs only with other accepted programs solving the same problem in the same target language. Confidence intervals for the normalized efficiency results are estimated by bootstrap resampling. These measurements are interpreted as relative, platform-reported post-correctness indicators rather than machine-independent performance measures.

# 5 RQ1: Reliability of Multilingual Code Generation

RQ1 examines the functional reliability of LLMs in problem-aligned multilingual code generation. We first compare overall correctness across models and then examine how unsuccessful candidates fail. Target-language effects, candidate-budget effects, problem characteristics, and execution efficiency are analyzed in subsequent RQs.

**Table 5** Overall results for multilingual code generation. Each model generates 59,560 candidates.

| Model | Accepted | Cand. Acc. | Pass@1 | Pass@5 | Pass@5 95% CI |
|---|---|---|---|---|---|
| qwen3-coder-480b-a35b-instruct | 53,022 | 89.0% | 89.1% | 92.1% | [91.6, 92.6] |
| gpt-4o | 46,050 | 77.3% | 77.2% | 88.6% | [88.0, 89.2] |
| qwen3-32b | 44,608 | 74.9% | 74.7% | 87.6% | [87.0, 88.2] |
| glm-4 | 40,073 | 67.3% | 67.4% | 82.6% | [81.9, 83.3] |
| deepseek-v3.2 | 27,855 | 46.8% | 46.4% | 77.8% | [77.0, 78.5] |
| claude-3-5-haiku-20241022 | 38,855 | 65.2% | 65.1% | 77.2% | [76.4, 77.9] |
| qwen3-14b | 31,790 | 53.4% | 53.1% | 64.6% | [63.7, 65.5] |
| qwen3-8b | 29,942 | 50.3% | 50.2% | 52.1% | [51.2, 53.0] |
| qwen3-4b | 24,645 | 41.4% | 41.4% | 43.2% | [42.3, 44.1] |
| qwen3-1.7b | 13,686 | 23.0% | 22.9% | 24.1% | [23.3, 24.9] |

## 5.1 Overall Model Performance

Each model is evaluated on 1,489 problems and eight target languages, with five candidates generated for each problem-language pair. This yields 11,912 evaluation instances and 59,560 generated candidates per model. We report candidate-level acceptance rate together with empirical pass@1 and pass@5. The 95% confidence intervals in Table 5 are Wilson intervals computed over the instance-level pass@5 outcomes.

Table 5 shows substantial differences in multilingual generation reliability. qwen3-coder-480b-a35b-instruct achieves the highest pass@5 at 92.1%, followed by gpt-4o at 88.6% and qwen3-32b at 87.6%. At the other end of the spectrum, qwen3-1.7b reaches only 24.1%. Within the Qwen3 scaling series, pass@5 increases consistently with model size, from 24.1% for qwen3-1.7b to 87.6% for qwen3-32b, indicating a strong association between model scale and multilingual code-generation reliability.

Candidate-level acceptance and pass@5 capture different aspects of performance. For example, deepseek-v3.2 accepts 46.8% of individual candidates, while its instance-level pass@5 reaches 77.8%. This difference illustrates that candidate-level success rates and best-of-$k$ reliability should not be interpreted interchangeably. We analyze the effect of candidate budget in detail in RQ4.

## 5.2 Failure Mode Analysis

Pass@$k$ measures whether a model eventually produces an accepted program, but does not explain why unsuccessful candidates fail. We therefore categorize rejected candidates according to the execution status returned by the evaluation platform: wrong answer, compile error, runtime error, time limit exceeded, memory limit exceeded, and output limit exceeded.

Figure 3 reveals heterogeneous failure profiles across models. Wrong answers account for a substantial fraction of failures, particularly for several smaller Qwen3 models, and may arise from incorrect algorithms, missed corner cases, or misunderstood problem constraints. Compile and runtime errors instead reflect failures in realizing an executable target-language implementation, such as syntax, typing, library, or interface mismatches. Resource-limit failures indicate another class of problems related to computational or implementation efficiency. Thus, similar aggregate pass rates can arise from qualitatively different failure patterns.

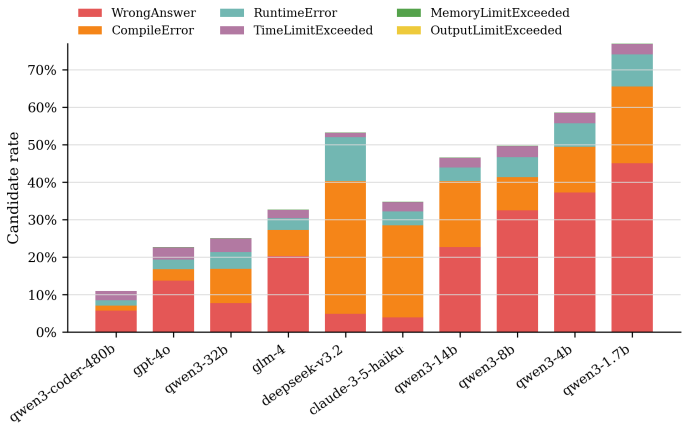

**Figure 3** Failure type distribution in multilingual code generation.

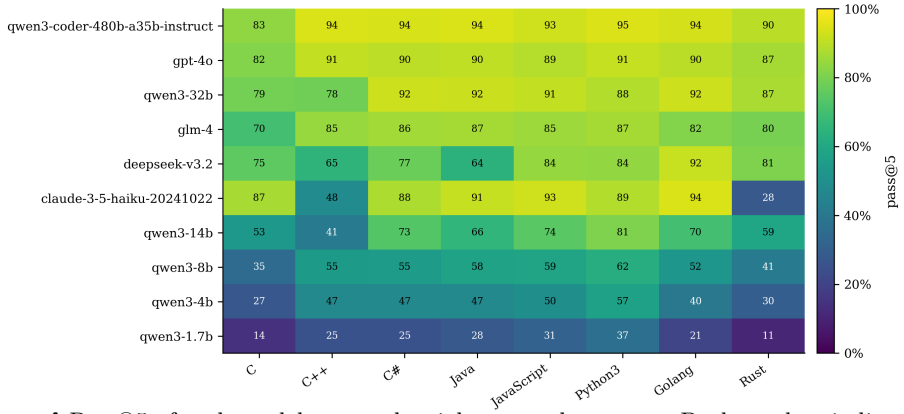

**Figure 4** Pass@5 of each model across the eight target languages. Darker colors indicate higher pass@5.

**Finding 1 (RQ1).** LLMs exhibit substantial differences in problem-aligned multilingual code-generation reliability. Within the Qwen3 scaling series, larger models consistently achieve higher pass@5. Failure analysis further shows that unsuccessful generations arise from distinct semantic, implementation, and resource-related errors, demonstrating that aggregate correctness alone does not fully characterize model reliability.

## 6 RQ2: Multilingual Consistency across Programming Languages

RQ2 examines whether LLMs behave consistently across programming languages when solving the same underlying problems. Because all 1,489 problems are evaluated in the same eight target languages, observed differences can be analyzed under aligned problem semantics rather than heterogeneous task composition. We first examine target-language performance and then compare the cross-language consistency of individual models.

### 6.1 Target-Language Performance

Figure 4 presents the model-language pass@5 matrix. Performance varies substantially across target languages, and the magnitude of these differences is strongly model-dependent. Some models remain relatively stable across languages, whereas others exhibit pronounced weaknesses on particular targets.

**Table 6** Average generation performance by target language.

| Language | Tasks | Pass@1 | Pass@5 | 95% CI | Gain |
|---|---|---|---|---|---|
| Python3 | 14,890 | 66.3% | 77.0% | [76.3, 77.7] | 10.7% |
| JavaScript | 14,890 | 66.4% | 74.9% | [74.2, 75.6] | 8.5% |
| C# | 14,890 | 62.6% | 72.8% | [72.1, 73.5] | 10.1% |
| Golang | 14,890 | 63.9% | 72.6% | [71.9, 73.3] | 8.7% |
| Java | 14,890 | 62.4% | 71.7% | [71.0, 72.4] | 9.3% |
| C++ | 14,890 | 50.1% | 63.0% | [62.2, 63.8] | 12.9% |
| C | 14,890 | 50.4% | 60.7% | [59.9, 61.5] | 10.3% |
| Rust | 14,890 | 48.0% | 59.2% | [58.4, 60.0] | 11.2% |

**Table 7** Cross-language consistency in multilingual code generation.

| Model | Mean Pass@5 | Weakest Lang. | Strongest Lang. | Range | Std. |
|---|---|---|---|---|---|
| qwen3-coder-480b-a35b-instruct | 92.1% | C (83.4%) | Python3 (94.6%) | 11.2% | 3.6% |
| gpt-4o | 88.6% | C (81.6%) | Python3 (91.3%) | 9.7% | 3.0% |
| qwen3-32b | 87.6% | C++ (78.4%) | C# (92.2%) | 13.8% | 5.3% |
| glm-4 | 82.6% | C (70.2%) | Python3 (86.7%) | 16.5% | 5.2% |
| deepseek-v3.2 | 77.8% | Java (64.2%) | Golang (91.6%) | 27.4% | 8.8% |
| claude-3-5-haiku-20241022 | 77.2% | Rust (27.8%) | Golang (94.3%) | 66.5% | 23.3% |
| qwen3-14b | 64.6% | C++ (40.7%) | Python3 (80.6%) | 39.9% | 12.2% |
| qwen3-8b | 52.1% | C (35.1%) | Python3 (62.4%) | 27.3% | 8.7% |
| qwen3-4b | 43.2% | C (27.3%) | Python3 (57.3%) | 30.0% | 9.5% |
| qwen3-1.7b | 24.1% | Rust (10.6%) | Python3 (36.7%) | 26.1% | 8.0% |

Table 6 summarizes generation performance averaged over the evaluated models. Python3 achieves the highest average pass@5 at 77.0%, followed by JavaScript, C#, Golang, and Java, while C++, C, and Rust obtain lower scores. Rust has the lowest average pass@5 at 59.2%, producing a 17.8-point gap from Python3. Because the same problem set is evaluated in every language, this difference cannot be explained simply by variation in problem composition.

The observed target-language differences likely reflect several interacting factors, including language syntax and type constraints, library and interface conventions, evaluation templates, and the models' familiarity with different programming ecosystems. For example, lower performance on C, C++, and Rust may be associated with stricter compilation requirements or more explicit implementation constraints. However, these results should not be interpreted as intrinsic rankings of programming-language difficulty.

The benefit of additional candidates also differs across target languages. For example, C++ exhibits a larger pass@1-to-pass@5 gain than JavaScript or Golang. We defer a systematic analysis of candidate-budget effects to RQ4.

## 6.2 Model-Level Cross-Language Consistency

Language-level averages do not reveal whether an individual model performs reliably across all target languages. A model may achieve a high overall pass@5 while still exhibiting a substantial weakness in one or more languages. We therefore characterize each model using its mean pass@5, strongest and weakest target languages, range, and standard deviation across the eight languages.

Table 7 reveals that high average performance does not necessarily imply strong cross-language consistency. GPT-4o has a relatively narrow 9.7-point range across languages, while qwen3-coder-480b-a35b-instruct spans 11.2 points. By contrast, claude-3-5-haiku-20241022 exhibits a 66.5-point range, largely due to its substantially lower Rust performance relative to Golang and JavaScript. Deepseek-v3.2 also shows marked cross-language variation, performing strongly on Golang but considerably worse on Java.

**Table 8** Overall results for directed code translation.

| Model | Candidates | Accepted | Accepted Rate | Pass@1 | Pass@5 | 95% CI |
|---|---|---|---|---|---|---|
| qwen3-coder-480b-a35b-instruct | 28,000 | 24,433 | 87.3% | 87.5% | 90.5% | [89.7, 91.2] |
| gpt-4o | 28,000 | 17,295 | 61.8% | 61.8% | 85.8% | [84.9, 86.7] |
| glm-4 | 28,000 | 15,141 | 54.1% | 54.3% | 73.8% | [72.6, 74.9] |
| deepseek-v3.2 | 28,000 | 12,215 | 43.6% | 43.8% | 60.5% | [59.2, 61.8] |
| claude-3-5-haiku-20241022 | 28,000 | 10,477 | 37.4% | 37.4% | 59.0% | [57.7, 60.3] |

These differences demonstrate that model ranking and multilingual consistency capture distinct properties. Two models with similar average pass@5 can differ substantially in their weakest target language and cross-language variance. For practical model selection, the intended programming language may therefore matter as much as aggregate multilingual performance.

**Finding 2 (RQ2).** Problem-aligned evaluation reveals substantial and model-dependent variation across target languages. Python3 achieves the highest average pass@5 and Rust the lowest, with a 17.8-point difference under the same problem set. Moreover, strong average performance does not necessarily imply cross-language consistency: some models remain stable across languages, whereas others exhibit pronounced language-specific weaknesses.

# 7 RQ3: Directed Cross-Language Transfer

RQ3 examines source-code-conditioned translation as a complementary multilingual programming setting. Unlike direct generation, translation must preserve the behavior of an existing implementation while producing executable code in another language. We analyze the 56 ordered source-target settings from overall, pair-level, role-level, and direction-level perspectives. Unless otherwise stated, the pair-, role-, and direction-level translation analyses report pass@5 averaged over the five models evaluated on the translation task.

## 7.1 Translation Subset

For translation, we randomly select 100 problems from the all-language-covered set described in Section 3. Each problem has an execution-validated implementation in all eight languages, allowing every language to serve as a source and every other language as a target. The same 100 problems are used across all 56 source-target settings, and correctness is determined through target-language execution.

## 7.2 Overall Translation Performance

Each model is evaluated on 100 problems and 56 ordered source-target settings, with five candidates per instance, yielding 5,600 translation instances and 28,000 candidates per model. As in generation, we report candidate-level acceptance together with instance-level pass@1 and pass@5.

Table 8 shows substantial differences across models. qwen3-coder-480b-a35b-instruct achieves the highest pass@5 at 90.5%, followed by gpt-4o at 85.8%, while glm-4, deepseek-v3.2, and claude-3-5-haiku-20241022 reach 73.8%, 60.5%, and 59.0%, respectively. The broad ordering resembles the generation results in RQ1, suggesting that general code-generation capability remains relevant when source code is provided. However, aggregate scores do not reveal how translation performance varies across language settings.

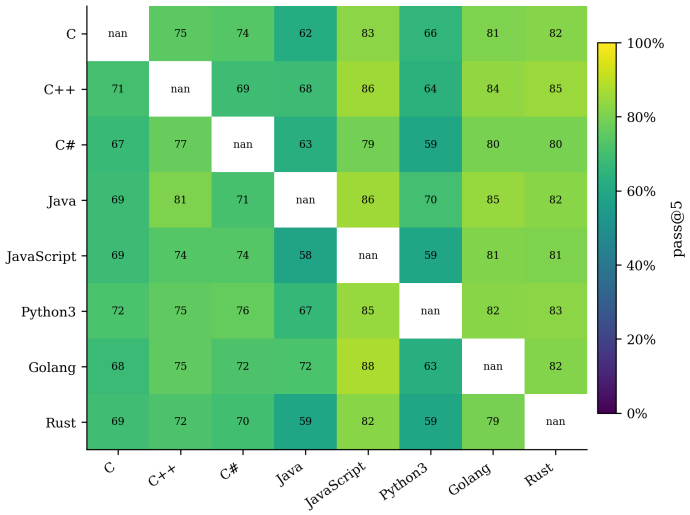

**Figure 5** Directed source-target pass@5 matrix for code translation.

**Table 9** Average pass@5 when each language is used as source or target in directed translation.

| Language | As Source | As Target | Target–Source (pp) |
|---|---|---|---|
| Python3 | 77.1% | 62.7% | -14.4 |
| Java | 77.6% | 64.1% | -13.5 |
| C | 74.5% | 69.2% | -5.3 |
| C++ | 75.2% | 75.5% | 0.3 |
| C# | 72.1% | 72.2% | 0.1 |
| Golang | 74.2% | 81.7% | 7.5 |
| Rust | 70.0% | 82.0% | 12.0 |
| JavaScript | 70.7% | 84.0% | 13.3 |

## 7.3 Source-Target Pair Effects

We next aggregate pass@5 by ordered source-target pair to examine variation hidden by model-level averages.

Figure 5 shows substantial variation across source-target combinations. The same target language can obtain markedly different pass@5 depending on the source language, indicating that translation performance depends on their combination rather than on the target alone. Such variation may reflect differences in source comprehension, target realization, type adaptation, library mapping, and interface reconstruction.

## 7.4 Source and Target Language Roles

We further summarize each language by its average pass@5 when used as a source and when used as a target.

Table 9 reveals clear role differences. Python3 and Java achieve higher averages as source languages than as targets, whereas JavaScript, Rust, and Golang perform better in the target role. C++ and C# are comparatively balanced. These results suggest that a single language-level translation score can obscure differences between source interpretation and target-language realization.

**Table 10** Largest directional gaps in code translation.

| Direction | Pass@5 | Reverse Pass@5 | Gap (pp) |
|---|---|---|---|
| Java→JavaScript | 85.8% | 58.4% | 27.4 |
| JavaScript→Python3 | 58.6% | 84.6% | 26.0 |
| Python3→Rust | 82.6% | 58.6% | 24.0 |
| Java→Rust | 82.4% | 58.8% | 23.6 |
| Golang→Python3 | 63.0% | 82.4% | 19.4 |

**Table 11** Generation performance by problem difficulty.

| Difficulty | Tasks | Pass@1 | Pass@5 | Pass@5 95% CI | Gain |
|---|---|---|---|---|---|
| Easy | 38,480 | 73.4% | 81.8% | [81.4, 82.2] | 8.4% |
| Medium | 57,840 | 57.7% | 68.2% | [67.8, 68.6] | 10.5% |
| Hard | 22,800 | 36.8% | 49.3% | [48.7, 49.9] | 12.5% |

## 7.5 Directionality

Finally, we compare each source-target setting with its reverse direction. If translation behavior were symmetric, the two directions of a language pair would have similar pass@5; the results show otherwise.

Table 10 reports the largest differences between reversed language pairs. For example, Java→JavaScript reaches 85.8% pass@5, compared with 58.4% for JavaScript→Java, while Python3→Rust reaches 82.6% compared with 58.6% in the reverse direction. Several reversed pairs differ by more than 20 percentage points, showing that pair-level averages can conceal substantial variation.

Together, the pair-, role-, and direction-level results show that source-code-conditioned translation is highly heterogeneous across language settings. These aggregate observations do not establish the causes of individual gaps, but they identify settings where source interpretation and target realization warrant more detailed analysis.

**Finding 3 (RQ3).** Source-code-conditioned translation varies substantially across models and language settings. Translation success depends on the source-target combination, languages exhibit different source and target roles, and several reversed pairs differ by more than 20 pass@5 points. Thus, aggregate translation scores alone provide an incomplete view of cross-language transfer.

# 8 RQ4: Effects of Problem Attributes and Candidate Sampling

RQ4 examines how sensitive multilingual code-generation reliability is to problem characteristics and candidate budget. We analyze performance across difficulty levels and algorithmic topics, and then quantify how additional candidates change measured success.

## 8.1 Impact of Problem Difficulty

We first group generation results by the platform-provided difficulty labels: Easy, Medium, and Hard. Table 11 reports pass@1, pass@5, 95% confidence intervals, and the gain from five candidates.

Difficulty is strongly associated with generation success. Pass@5 decreases from 81.8% on Easy problems to 68.2% on Medium and 49.3% on Hard problems, while pass@1 drops from 73.4% to 36.8%. The gain from pass@1 to pass@5 also increases with difficulty, from

**Table 12** High-performing algorithmic tags in multilingual code generation.

| Tag | Tasks | Pass@1 | Pass@5 | Gain |
|---|---|---|---|---|
| Counting Sort | 640 | 73.6% | 82.5% | 8.9% |
| Simulation | 7,280 | 64.9% | 75.1% | 10.2% |
| Randomized | 720 | 65.7% | 72.8% | 7.1% |
| Counting | 8,400 | 62.8% | 72.4% | 9.6% |
| Reservoir Sampling | 160 | 63.7% | 71.9% | 8.1% |
| Two Pointers | 10,080 | 62.1% | 71.6% | 9.6% |
| String | 38,080 | 59.1% | 69.3% | 10.3% |
| Sorting | 19,600 | 58.7% | 69.2% | 10.5% |
| Math | 24,320 | 59.4% | 69.1% | 9.8% |
| Array | 72,080 | 58.7% | 69.0% | 10.3% |

8.4 percentage points on Easy problems to 12.5 points on Hard problems. Thus, additional candidates provide greater benefit on harder problems, but do not close the substantial Easy–Hard performance gap.

## 8.2 Impact of Algorithmic Tags

Difficulty labels provide only a coarse characterization of problem complexity. We therefore further group generation results by algorithmic tags. Because a problem may have multiple tags, the same problem-language instance can contribute to multiple groups. Table 12 reports the highest-performing tags by pass@5.

Higher-performing categories include Counting Sort, Simulation, Counting, Two Pointers, String, Sorting, Math, and Array. Many of these tags correspond to frequently occurring algorithmic patterns, which is consistent with models performing better on familiar implementation structures. However, tags overlap and are correlated with factors such as difficulty, problem length, and data-structure requirements. The observed differences should therefore be interpreted as descriptive topic-level variation rather than independent causal effects.

## 8.3 Benefit of Multiple Candidates

We next examine how the candidate budget affects measured reliability. Pass@1 reflects first-attempt success, whereas pass@5 captures whether an accepted solution appears within five attempts.

Table 13 and Figure 6 show that the benefit of additional candidates varies substantially across models. qwen3-coder-480b-a35b-instruct begins with high pass@1 and gains only 3.0 percentage points by pass@5. In contrast, deepseek-v3.2 improves by 31.3 points, indicating that later attempts frequently recover instances missed by the first candidate. Several smaller Qwen3 models gain little from additional sampling, showing that a larger candidate budget does not benefit all models equally.

The translation results exhibit the same general phenomenon. For example, gpt-4o improves from 61.8% pass@1 to 85.8% pass@5, while claude-3-5-haiku-20241022 and glm-4 gain 21.7 and 19.5 percentage points, respectively. These results reinforce that single-candidate evaluation can substantially underestimate models whose successful programs appear in later attempts.

## 8.4 Relative Magnitude of Empirical Effects

Finally, we place the observed sources of variation in context using descriptive range-based gaps. These quantities summarize different analyses and should not be interpreted as causal effect sizes or directly comparable estimates of importance.

**Table 13** Pass@5 gains over pass@1 from generating five candidates.

| Task | Model | Pass@1 | Pass@5 | Gain |
|---|---|---|---|---|
| Generation | qwen3-coder-480b-a35b-instruct | 89.1% | 92.1% | 3.0% |
| Generation | gpt-4o | 77.2% | 88.6% | 11.4% |
| Generation | qwen3-32b | 74.7% | 87.6% | 12.8% |
| Generation | glm-4 | 67.4% | 82.6% | 15.2% |
| Generation | deepseek-v3.2 | 46.4% | 77.8% | 31.3% |
| Generation | claude-3-5-haiku-20241022 | 65.1% | 77.2% | 12.1% |
| Generation | qwen3-14b | 53.1% | 64.6% | 11.5% |
| Generation | qwen3-8b | 50.2% | 52.1% | 1.8% |
| Generation | qwen3-4b | 41.4% | 43.2% | 1.8% |
| Generation | qwen3-1.7b | 22.9% | 24.1% | 1.2% |
| Translation | qwen3-coder-480b-a35b-instruct | 87.5% | 90.5% | 3.0% |
| Translation | gpt-4o | 61.8% | 85.8% | 24.0% |
| Translation | glm-4 | 54.3% | 73.8% | 19.5% |
| Translation | deepseek-v3.2 | 43.8% | 60.5% | 16.7% |
| Translation | claude-3-5-haiku-20241022 | 37.4% | 59.0% | 21.7% |

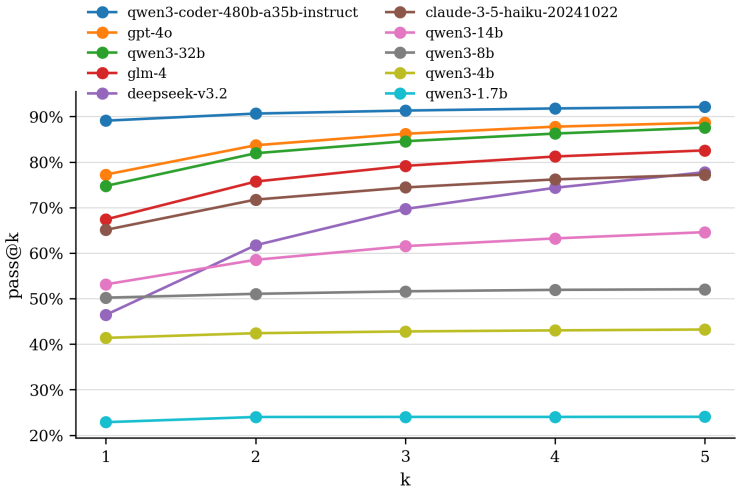

**Figure 6** Generation pass@k curves by model.

Table 14 shows that model capability produces the largest observed generation gap, with 68.0 pass@5 points between the strongest and weakest models. Problem difficulty produces a 32.5-point Easy–Hard gap, while the spread in generation sampling gains reaches 30.1 points. For context, the largest translation directional gap observed in RQ3 is 27.4 points, and the generation target-language range is 17.8 points. These results illustrate that measured performance depends not only on model choice, but also on the problem set, target language, and candidate budget.

**Finding 4 (RQ4).** Multilingual code-generation reliability is highly sensitive to both problem characteristics and candidate budget. Harder problems substantially reduce pass@1 and pass@5, algorithmic tags reveal topic-level variation, and the benefit of additional candidates differs markedly across models and difficulty levels. Therefore, aggregate pass@$k$ should be interpreted together with problem- and sampling-aware analyses.

**Table 14** Magnitude of major empirical effects observed in MciBench.

| Factor | Comparison | Observed Gap (pp) |
|---|---|---|
| Model capability in generation | best vs. weakest model pass@5 | 68.0 |
| Problem difficulty in generation | Easy vs. Hard pass@5 | 32.5 |
| Candidate sampling in generation | largest vs. smallest pass@5 gain | 30.1 |
| Model capability in translation | best vs. weakest model pass@5 | 31.5 |
| Translation directionality | largest A→B vs. B→A gap | 27.4 |
| Target language in generation | easiest vs. hardest language pass@5 | 17.8 |

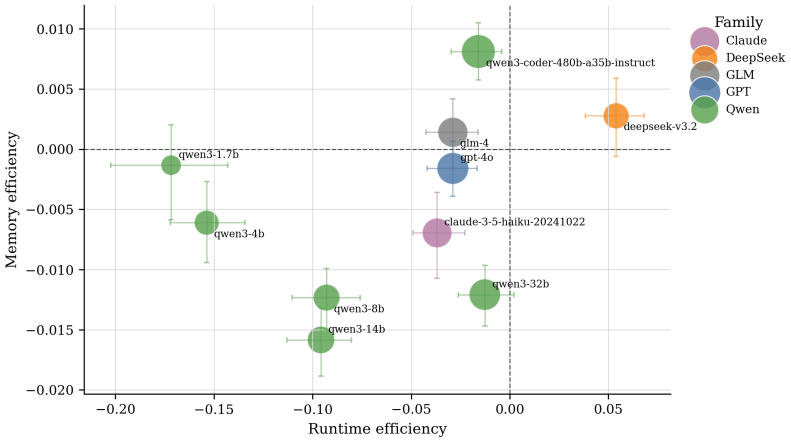

**Figure 7** Runtime-memory efficiency of accepted generated programs.

## 9 RQ5: Runtime-Memory Efficiency of Accepted Code

RQ5 examines whether functionally correct programs generated by different LLMs exhibit comparable execution quality. Because pass@$k$ treats all accepted programs as equally successful, we conduct an accepted-only analysis of runtime and memory efficiency.

### 9.1 Efficiency Measurement

We analyze accepted generated programs only. For each problem-language pair and model, if multiple candidates are accepted, we retain the first accepted candidate, corresponding to a practical first-success strategy. Because raw runtime and memory measurements are not directly comparable across problems or target languages, we normalize them within each problem-language group. Specifically, for a measurement $x$ (runtime or memory), we compute its relative efficiency as $e(x) = \frac{\bar{x}-x}{\bar{x}}$, where $\bar{x}$ is the mean measurement of accepted programs within the same problem-language group. Each accepted program is therefore compared only with other accepted programs solving the same problem in the same language. Higher runtime-efficiency and memory-efficiency scores indicate faster execution and lower memory consumption, respectively. For each model, we aggregate these normalized scores by averaging over its accepted problem-language instances.

### 9.2 Runtime-Memory Efficiency across Models

Figure 7 summarizes post-correctness execution quality across models. Each point represents a model; the x- and y-axes denote normalized runtime and memory efficiency, respectively, point size represents candidate acceptance rate, and error bars show bootstrap confidence intervals. Larger values indicate better relative efficiency.

Correctness and execution efficiency do not necessarily align. qwen3-coder-480b-a35b-instruct achieves the highest candidate acceptance rate and competitive memory efficiency, but does not dominate runtime efficiency. Conversely, deepseek-v3.2 has substantially lower correctness than the strongest models, yet its accepted programs achieve the highest relative runtime efficiency in this analysis. Differences in memory efficiency are smaller, but accepted programs are nevertheless not resource-equivalent.

These results show that pass@5 captures whether a model can produce a correct program, but not the execution quality of that program. A model with high correctness may generate relatively expensive accepted solutions, while a lower-performing model may produce efficient programs on the subset of problems it solves. Since the analysis is conditioned on successful outputs and relies on platform-reported measurements, these results should be interpreted as relative post-correctness efficiency rather than unconditional model efficiency.

**Finding 5 (RQ5).** Functional correctness does not imply comparable execution quality. Accepted programs exhibit meaningful runtime-memory differences across models, and models with higher pass@$k$ do not necessarily dominate post-correctness efficiency. Runtime and memory therefore provide complementary information beyond correctness, while remaining accepted-only and platform-dependent measures.

## 10 Discussion

Our results show that multilingual LLM code capability cannot be adequately characterized by a single aggregate pass@$k$ score. Even under problem-level alignment, performance varies across target languages, translation settings, problem characteristics, candidate budgets, and post-correctness execution quality. These observations lead to several implications for multilingual code evaluation. First, evaluation should be *language-aware*, because models with similar average performance may exhibit substantially different strengths and weaknesses across target languages. Second, task formulation should be considered explicitly: direct generation and source-code-conditioned translation impose different requirements, and translation performance can further vary across source-target settings. Third, evaluation should be *problem-aware*, since difficulty levels and algorithmic topics reveal non-uniform behavior across problems. Fourth, it should be *sampling-aware*, because pass@1 and pass@5 capture different aspects of reliability, and the benefit of additional candidates varies considerably across models. Finally, it should be *quality-aware*, as functionally correct programs can still differ in runtime and memory efficiency. Model selection for multilingual programming should therefore consider the intended language, translation setting, problem characteristics, candidate budget, and execution-quality requirements in addition to aggregate correctness.

**Threats to Validity.** Several threats affect the interpretation of our results. First, McIBench focuses on online algorithmic programming problems in eight mainstream languages, so the findings may not generalize to repository-level development, domain-specific languages, or production maintenance tasks. Second, the evaluated problems are publicly available and may have appeared in model training data; our results should therefore be interpreted as benchmark performance under a problem-aligned execution protocol rather than evidence of generalization to unseen tasks. Third, prompt design, decoding settings, post-processing rules, language templates, and submission interfaces may affect measured performance, although we apply a common protocol across models and languages and release the corresponding artifacts for inspection. Fourth, the translation analysis uses 100 randomly selected problems

from the all-language-covered set, and the execution-validated source implementations may differ in provenance, style, idioms, and complexity; these factors can influence translation performance and limit the generality of source-target comparisons. Finally, execution-based correctness depends on the available tests and does not establish full semantic equivalence. Recent work combining LLMs with formal verification and proof synthesis suggests complementary mechanisms for stronger semantic validation [15, 28, 7, 27]. Runtime and memory are analyzed only for accepted programs and are platform-dependent. Accordingly, the efficiency results should be interpreted as relative post-correctness indicators rather than unconditional or machine-independent measures of model quality.

## 11 Conclusion

This paper presented a large-scale empirical study of problem-aligned multilingual code generation and source-code-conditioned translation by LLMs. Across 1,489 programming problems and eight languages, our generation results reveal substantial variation across models, target languages, problem characteristics, candidate budgets, and execution quality; a complementary analysis on 100 problems further shows substantial variation across source-target translation settings. These findings demonstrate that aggregate pass@$k$ alone provides an incomplete view of multilingual code capability. Reliable evaluation should therefore consider cross-language consistency, translation settings, problem and sampling effects, and post-correctness execution quality.

## Abstract

**Background.** Developers increasingly coordinate dependent review workflows by submitting sequences of related changes rather than monolithic ones. In Gerrit, these dependencies form *relation chains*: structured review units that link changes together. As chains become more common, they shape review activities through synchronization overhead, CI amplification, and merge-ordering constraints.

**Aim.** We investigate how developers adopt relation chains and how these dependency structures influence review dynamics and outcomes.

**Method.** We analyze 29,580 relation chains from 15 repositories across three Gerrit ecosystems (OpenStack, Wikimedia, ONAP), comprising 401,256 changes, using Mann–Kendall trend tests, Mann–Whitney with Cliff's $\delta$ for chain-vs-solo comparison, and Spearman correlations for base–descendant dependency.

**Results.** Chain prevalence ranges from 5% to 49% across projects, increasing in 14 of 15. Chain changes take a median of 2.6× longer to merge than size-matched solo changes, with the gap widening for very large changes. Review effort propagates through dependency-linked review workflows: base-change review activity co-varies with descendant review activity ($\rho = 0.43$–$0.61$ in 14–15/15 projects), and 33.5% of chain members undergo structural evolution during review.

**Conclusions.** Relation chains operate as durable, ecosystem-shaped coordination units with internal structure that change-centric analyses cannot capture. Future review analytics, reviewer-assignment systems, and AI-assisted review tools should reason over chains rather than isolated changes.

## 1 Introduction

Modern Code Review (MCR) is used to detect defects, discuss design decisions, transfer knowledge, and enforce coding conventions [6, 34, 29, 24, 26]. Large engineering tasks such as refactorings, migrations, and multi-component features are increasingly decomposed into sequences of dependent changes submitted as *stacked changes*. In Gerrit, these structures are represented as *relation chains*, a higher-level coordination abstraction in modern code-review workflows; similar abstractions exist in Phabricator, Graphite, GitHub, and `ghstack` [32, 20, 19, 30].

Following the Gerrit documentation [18], we use the term *relation chain* to denote a dependency-linked review structure in which multiple changes evolve simultaneously and the state of one review directly influences the validation, synchronization, and mergeability of dependent reviews. In this paper, relation chains refer specifically to Gerrit parent-SHA dependency structures reconstructed from patchset-level parent relationships; while similar workflows exist in GitHub stacked pull requests, Phabricator, and `ghstack`, our operationalization and findings are specific to Gerrit-based review ecosystems. Relation chains let reviewers reason about large engineering efforts as coordinated structures rather than isolated changes. Figure 1 shows an OpenStack Neutron example: a `pylint` migration[1] decomposed into descendants addressing different warning categories. The same dependency that enables this coordination can also become a source of friction: updates to one chain member can cascade across descendants through forced rebasing, repeated CI validation, and delayed merge propagation. On ONAP `oom` change 100114[2], a reviewer warned the author that "*as parent is abandoned, we cannot merge... please rebase on master*," surfacing parent abandonment, merge blocking, and forced rebasing as everyday chain-coordination costs. Understanding how such dependency structures influence review processes matters for review analytics, prioritization, and tooling [39].

(a) Gerrit's *Relation Chain* panel

(b) Relation chain dependency graph.

**Figure 1** A branching relation chain in OpenStack Neutron (change #883464[1]). (a) Gerrit's flat *Relation Chain* panel. (b) The same chain reconstructed from patchset-level parent SHAs: blue is the base, green is a descendant. All five members merged.

Despite their growing adoption, prior research has overlooked relation chains as first-class review artifacts. Existing work captures only fragments: studies of cross-component dependencies [3] model pairwise relationships between repositories rather than the chain that links a sequence of changes within a single review; `Depends-On`/`Needed-By` annotation analyses [2] require the dependency to be declared in the commit message, missing chains

[1] `https://review.opendev.org/c/openstack/neutron/+/883464`
[2] `https://gerrit.onap.org/r/c/oom/+/100114`

created implicitly through parent-SHA links; and patch-linkage research [23, 44, 43] traces references between review discussions but not the structural dependency graph that determines merge order. Properties that emerge only when a change is read together with its in-review parents and children (friction propagation from base to descendant, mid-review restructuring of the dependency graph, position-dependent review effort) fall outside what existing methods can observe. These workflow effects remain largely invisible when reviews are analyzed as isolated artifacts. The literature has no empirical characterisation of relation chains as the unit through which developers coordinate dependent review work at scale.

To address this gap, we present an empirical characterisation of relation chains as first-class review artifacts. We analyze 401,256 reviewed changes and 29,580 chains across three Gerrit ecosystems (OpenStack, Wikimedia, ONAP), selected to span different development cultures, CI-gating regimes, and community sizes. The study combines three lenses: temporal-trend analysis of chain adoption, stratified comparison of chain members against size-matched solo changes, and dependency-aware correlation analysis between base changes and their descendants. Together they let us characterise chains both as a structural feature of the review graph and as a coordination mechanism whose dynamics shape review outcomes that change-level studies cannot observe. Because our analyses are observational, we interpret the reported effects as associations rather than causal consequences of chain membership.

Our results converge on a single characterisation: relation chains are durable, ecosystem-shaped, internally-structured coordination units whose review dynamics differ from those of isolated changes. Each of the four findings below contributes evidence along one of these dimensions. First, chains are *prevalent and growing*: prevalence ranges from 5% to 49% and increases in 10 of 15 projects, so dependent-change workflows are not a niche pattern. Second, chains carry *review costs not visible at the change level*: members take a median of 2.6× longer to merge than size-matched solo changes, with overhead concentrating in very large changes (Cliff's $\delta = 0.49$), and CI activity is amplified five- to twenty-fold under strict gating. Third, chains have *internal structure that shapes review outcomes*: middle-of-chain members absorb the highest review effort, and base-change review activity co-varies with descendant activity ($\rho = 0.43$–$0.61$ in 14–15 of 15 projects), a regularity we call the *foundation effect*. Fourth, chains are *not static*: 33.5% of members undergo a structural change in their parent SHA before merging, and chains can persist across multi-year intermittent timespans, with the longest merge gap reaching 2.85 years on a chain in OpenStack `Neutron`. These results call into question the default assumption underlying current review tooling, which processes each change independently [40, 31, 25], and motivate chain-aware review analytics, reviewer-assignment systems that prioritise members whose merge unblocks the largest downstream subgraph, and AI-assisted review agents that condition on chain position and base-change review state.

## 2 Background: Modern Code Review, Gerrit, and Relation Chains

Modern Code Review (MCR) is a tool-supported form of peer review used in industrial and open-source development [6, 34, 26], supporting defect detection, design discussion, knowledge transfer, and coding-convention enforcement [29, 24, 8]. Smaller, focused changes are easier to review and more likely to be accepted [45, 33]; larger engineering tasks therefore motivate developers to split work across related changes.

Gerrit is a web-based code review platform used by projects such as OpenStack, Android, Chromium, Wikimedia, and ONAP [17, 39]. Each review request is a *change* identified by a `Change-Id` and refined through successive *patchsets*. When a developer uploads a change whose parent commit corresponds to another change still under review, Gerrit links them as a parent–child dependency; a sequence of such linked changes forms a *relation chain* [18].

Relation chains let developers continue dependent work without waiting for earlier changes to merge. The same workflow appears in Phabricator [32], Graphite [20], Meta's `ghstack` [30], and GitHub's native stacked PRs [19]; earlier work on Linux kernel patch series [35] shows dependent review workflows predate modern platforms. Figure 2 illustrates a typical workflow. Throughout this paper, *base*, *middle*, and *top* denote the first, intermediate, and last members of a chain, and *solo* denotes a change with no in-review parent or child.

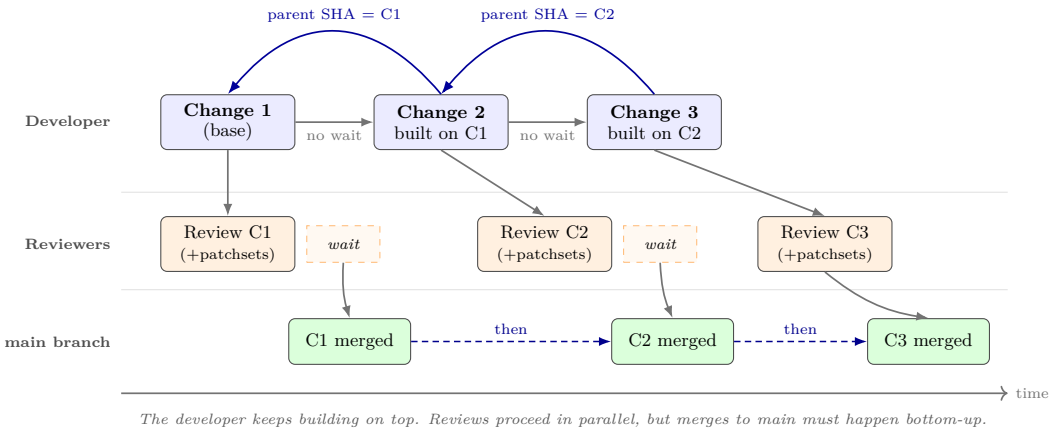

**Figure 2** Working with a relation chain in Gerrit. The developer builds C2 on C1 and C3 on C2 without waiting. Reviews proceed in parallel; merges into the main branch are bottom-up.

## 3 Related Work

We position our study with respect to three lines of work: (i) empirical studies of modern code review that examine review outcomes at the change level, (ii) reviewer recommendation and review automation systems that consume change-level features, and (iii) change decomposition and dependent-review research that touches on multi-change workflows. For each, we summarise what the line has shown and clarify how our chain-level focus differs.

### 3.1 Empirical Studies in Modern Code Review

Empirical work has examined MCR at the change level, characterizing factors that shape review latency and outcomes [8, 24, 47, 48] and the role of reviewer expectations and practice [6, 34, 26]. McIntosh et al. [29] showed that low review coverage and participation correlate with post-release defects; follow-up work examined review participation across Android, Qt, and OpenStack [39] and code ownership in MCR [38]. Change size is a recurring predictor [45, 33], and CI plays a parallel role: prior studies analyzed its effect on review duration [9], the cost of repeated builds in OpenStack [27], and bot activity in review [46].

**Key difference from our work.** Prior empirical MCR studies treat each review as an independent unit. We shift the focus to chain-level coordination (review effort, conversation, and dependency-graph evolution when a change belongs to a relation chain) and identify intra-chain structural factors such as chain position, base-change activity, and structural evolution that change-level analyses cannot observe.

## 3.2 Reviewer Recommendation and Review Automation

Two adjacent lines of work aim to reduce review effort through tooling. *Reviewer recommendation* systems suggest reviewers based on file-location history [40] or expertise and workload [31], while pull-request decision factors have been studied on GitHub [48]. *LLM-based review automation* extends this with pre-trained models that generate or refine review comments [25, 41, 21]. Related work has built predictive models on change-level features for merged-vs-abandoned classification [11], completion-time prediction [12], and effort-aware prioritization [10].

**Key difference from our work.** Existing tools operate on individual changes and do not consume chain-level signals such as chain position, base-change review state, or evolving dependency graphs. Our study shows the importance of accounting for this dependency context when reasoning about review outcomes, providing a concrete extension point for chain-aware tooling.

## 3.3 Change Decomposition and Dependent Reviews

The benefits of smaller review units create a tension: focused changes improve reviewability, but real engineering tasks are often too large for a single review. Prior work has studied *change decomposition*: Barnett et al. [7] proposed automated decomposition for tangled changesets at Microsoft, and Di Biase et al. [15] showed decomposed changes reduce false-positive review comments and improve review quality. Related work on dependencies: Arabat and Sayagh [3] found inter-component dependencies persist in microservice systems; Arabat et al. [2] examined explicit `Depends-On`/`Needed-By` annotations in OpenStack; *patch linkages* [23, 44, 43] trace references between review discussions; and *change coupling* [16, 49] mines version histories for co-evolving files.

**Key difference from our work.** Decomposition research treats decomposition as a property of individual changes; dependency research models dependencies as pairwise or textual. Relation chains are the mechanism by which developers implement decomposition in practice, introducing structural dynamics (base-change effects on descendants, merge-ordering constraints, dependency-graph evolution) that change-level studies cannot observe.

# 4 Study Design

Figure 3 shows an illustration of our study.

## 4.1 Research Questions

We organize our study around three research questions that progressively examine relation chains as code-review artifacts: how developers adopt them across projects and over time, how chain membership relates to review outcomes compared to isolated changes, and which intra-chain structural factors shape those outcomes.

**RQ1.** *[Chain Usage]* What characterizes the usage of relation chains across projects and ecosystems?

**RQ2.** *[Chain vs. Solo Outcomes]* How do relation chains reshape review coordination, validation workload, and review latency compared to isolated changes?

**RQ3.** *[Intra-chain Structural Factors]* What structural factors within a chain shape its review outcomes?

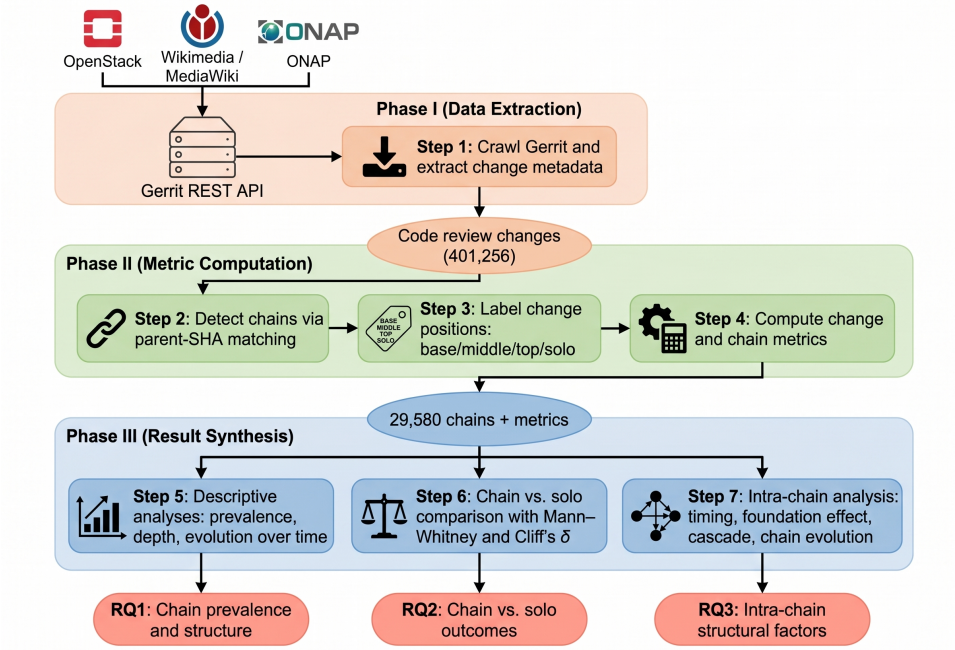

**Figure 3** Study methodology overview.

RQ1 establishes how often, how deeply, and over what time horizon developers use chains. The basic shape of chain usage (prevalence, depth, temporal stability) determines whether chain-level analysis is broadly relevant or confined to a narrow slice within a few projects. RQ2 examines whether reviews that belong to a relation chain differ systematically from isolated reviews in terms of review duration, rebasing activity, discussion, and CI workload. We compare chain and solo changes within the same size categories and inspect whether similar patterns appear across projects. If chain-associated reviews consistently differ from isolated reviews, then chain-level signals may be useful for future review analytics and tooling. Because the study is observational, we interpret the results as recurring associations rather than direct causal effects of chaining. RQ3 then examines which *intra-chain* features drive the differences identified in RQ2 (chain position, base-change activity, structural evolution), turning the chain from a binary attribute into a set of fine-grained signals that downstream review-support tools (recommendation systems, dashboards, CI schedulers) could consume. Limitations are discussed in Section 7.

## 4.2 Phase I: Data Extraction

We selected three Gerrit ecosystems (OpenStack, Wikimedia, ONAP) as representative large ecosystems where coordination across dependent changes is needed, and where prior MCR research has established the platform as a reliable empirical setting [29, 23, 39, 8]. The three differ on dimensions likely to interact with chain behaviour: review culture, language and domain, and CI-gating strictness, letting us separate effects that are general properties of chains from those tied to a specific development context. All three use the same review platform with the same chain-detection mechanism (patchset-level parent-SHA links), so cross-ecosystem comparisons rest on a uniform data model. Within each ecosystem, we required publicly accessible review history, at least 1,000 completed changes, and active

development spanning multiple years, following prior MCR conventions [29, 23, 3]. Table 1 summarizes the corpus. For each project, we queried the Gerrit REST API in five passes covering change metadata, patchset revisions with parent SHAs, file-level diffs, review messages (distinguishing humans from CI bots), and review labels.

**Table 1** Overview of the studied Gerrit corpus across the OpenStack, Wikimedia, and ONAP ecosystems. Per-project counts of total changes, merged and abandoned outcomes, and reconstructed relation chains.

| Ecosystem | Project | Changes | Merged | Aband. | Chains |
|---|---|---|---|---|---|
| OpenStack | nova | 42,781 | 31,145 | 11,636 | 3,682 |
| | neutron | 29,151 | 22,430 | 6,603 | 2,015 |
| | cinder | 18,797 | 13,793 | 4,094 | 1,104 |
| | horizon | 13,654 | 10,503 | 3,058 | 406 |
| | heat | 12,446 | 10,047 | 2,299 | 498 |
| Wikimedia | mw/core | 84,626 | 72,884 | 10,276 | 10,036 |
| | ext/Wikibase | 28,839 | 25,692 | 2,972 | 3,662 |
| | ext/VE | 17,194 | 16,080 | 986 | 1,291 |
| | ext/MF | 15,365 | 13,830 | 1,501 | 1,341 |
| | ops/puppet† | 118,257 | 110,366 | 7,891 | 3,012 |
| ONAP | so | 5,208 | 4,439 | 699 | 680 |
| | sdc | 4,728 | 4,157 | 543 | 846 |
| | oom | 5,743 | 4,812 | 904 | 588 |
| | cps | 2,524 | 2,264 | 243 | 184 |
| | ccsdk/cds | 1,943 | 1,809 | 131 | 235 |
| **Total** | | **401,256** | | | **29,580** |

†ops/puppet's chain count includes one auto-generated chain of depth 59,945 from its config-as-code workflow; we exclude it from aggregate statistics.

## 4.3 Phase II: Chain Detection and Metric Computation

A *relation chain* is a set of Gerrit changes linked by parent–child dependencies at the *patchset* level. Every patchset is a full git commit with a parent SHA; Gerrit detects a chain link whenever a patchset's parent SHA matches the latest revision SHA of another in-review change in the same project. Because each change has its own evolving patchset sequence, the parent SHA can change across patchsets, the mechanism by which chains restructure during review (Section 5.3). For chain detection (step 2), we follow Gerrit's convention and link changes by the parent SHA of each change's latest patchset. A change with no in-review parent and no in-review children is classified as *solo*.

We label each chain member by position: the *base* has no in-review parent, the *top* has no in-review descendant, and *middle* members are neither. In a chain of $n \geq 3$, exactly one base, one top, and $n - 2$ middle members exist; branching chains produce one top per branch. *Solo* is a fourth label for changes outside any chain. For each change we compute six *per-change* metrics (step 3). **#Revisions** is the number of distinct patchset revisions, from the Gerrit `revisions` endpoint [29, 23, 38]. **#Rebases** is the subset of patchsets whose `kind` is `NO_CHANGE` or `TRIVIAL_REBASE`, isolating dependency-driven rebases from substantive revisions. **Review duration (hours)** is the time from first patchset upload to final state, computed across merged and abandoned changes to avoid survivorship bias [8, 47]. **Discussion messages** is the count of top-level human review messages, excluding accounts on a per-project bot allowlist (top-50 commenters, CI usernames such as `zuul`, `jenkins`) [29, 46]. **Inline comments** is the count of human-authored code-anchored comments, filtered with the same allowlist. **CI/CD jobs** is the count of verification messages from accounts in the bot allowlist [27, 9]. To account for change size as a confound, changes are bucketed by Gerrit size category (XS: $\leq 9$ lines; S: 10–29; M: 30–99; L: 100–999; XL: $\geq 1000$) [29, 23].

At the chain level (step 4) we compute four *per-chain* metrics. *Chain depth* is the number of members ($\geq 2$). *Submission gap* and *merge gap* are computed for each consecutive pair $(c_i, c_{i+1})$ as the time between uploads and between merges. For each chain with at least two merged members, we compute the *base-change* and *descendant-mean* values of each per-change metric, supporting correlation analyses. For chain-evolution analysis we compare each member's parent SHA at Patchset 1 against its parent SHA at the final patchset, classifying any non-trivial-rebase change as a structural evolution event.

## 4.4 Phase III: Analysis

We use non-parametric tests throughout because code-review metrics are right-skewed [4, 5]. All tests are two-sided. For RQ1's temporal trend (step 5), monthly prevalence violates independence because consecutive months share contributors, release cadences, and backlogs. We therefore use the Mann–Kendall test [14], robust to autocorrelation, and report Sen's slope [37] in percentage points per year (pp/yr), both established in SE temporal studies [42, 22]. $H_0$: no monotonic trend; $H_1$: an increasing or decreasing trend.

For chain-vs-solo comparisons (RQ2, step 6), we report Mann–Whitney U [28, 14] and Cliff's $\delta$ [13], using Romano et al.'s thresholds [36]: $|\delta| < 0.147$ negligible, $< 0.33$ small, $< 0.474$ medium, and $\geq 0.474$ large. $H_0$: a random chain member and solo change are equally likely to be larger; $H_1$: one is stochastically greater. Because large samples can make significance misleading, we treat Cliff's $\delta$ as the primary measure of practical magnitude and emphasize directional consistency across projects and ecosystems.

For per-chain base-vs-descendant correlations (RQ3, step 7), we report Spearman's $\rho$ with two-sided $p$-values [14], which captures monotonic association without assuming linearity or normality. $H_0$: base and descendant-mean metrics are rank-independent; $H_1$: they are monotonically associated.

Significance markers are $^{***}$ $p < 0.001$, $^{**}$ $p < 0.01$, $^{*}$ $p < 0.05$, and ns otherwise. We apply no multiple-comparison correction because each project is an independent observational unit and interpret each effect by its sign and magnitude.

# 5 Results

## 5.1 RQ1: Prevalence and Structure

Table 2 summarizes per-project chain-prevalence trends; Figure 4 illustrates two contrasting exemplars. Table 3 reports per-project chain-depth statistics, and Figure 5 shows monthly mean chain depth per project.

**Finding #1.1: Relation-chain prevalence varies across projects and ecosystems.** Excluding the `operations/puppet` outlier, the proportion of changes in a chain ranges from 5.1% in OpenStack `Horizon` to 48.5% in ONAP `sdc`, with a median of 17% across the remaining 14 projects. Variation differs by ecosystem: ONAP 11–49%, OpenStack 5–32%, Wikimedia 12–22%. Chain usage is therefore not uniform but reflects differences in development practices and tooling conventions.

**Finding #1.2: Relation-chain adoption evolves over time, with most projects showing increasing usage.** The Mann–Kendall trend test (Table 2) yields significant monotonic trends in 14 of 15 projects: 10 increasing, 4 decreasing. The only project without a significant trend is `ccsdk/cds`, which has the shortest observation window (38 months). All OpenStack

**Table 2** Per-project chain-prevalence trends (Mann–Kendall test on monthly prevalence series). *Chained %* is the proportion of project changes that belong to a relation chain. Sen's slope reports the trend magnitude in percentage points per year.

| Ecosystem | Project | Chained % | Months | Sen's slope (pp/yr) | MK $p$ |
|---|---|---|---|---|---|
| OpenStack | Nova | 31.5% | 175 | +1.83 | *** |
| | Neutron | 10.8% | 176 | +2.44 | *** |
| | Cinder | 11.0% | 168 | +2.81 | *** |
| | Horizon | 5.1% | 174 | +0.76 | *** |
| | Heat | 7.5% | 159 | +2.23 | *** |
| Wikimedia | mw/core | 19.1% | 170 | +1.93 | *** |
| | ext/Wikibase | 21.9% | 167 | +2.76 | *** |
| | ext/VisualEditor | 13.2% | 170 | +1.54 | *** |
| | ext/MobileFrontend | 12.1% | 170 | +0.43 | *** |
| | ops/puppet† | 97.3% | 170 | +0.27 | *** |
| ONAP | so | 27.1% | 81 | −3.42 | ** |
| | sdc | 48.5% | 89 | −8.02 | *** |
| | oom | 16.9% | 104 | −1.99 | *** |
| | cps | 11.2% | 65 | −1.53 | * |
| | ccsdk/cds | 25.0% | 52 | −1.59 | ns |

†`ops/puppet`'s near-100% prevalence reflects auto-generated config-as-code chains, not human-authored review.

projects exhibit increasing trends (+0.8 to +2.8 pp/yr, $p < 0.001$), and four of five Wikimedia projects follow the same pattern. Several ONAP projects display decreasing trends (−8.0 to −1.5 pp/yr), notably `oom` (Figure 4b), where monthly prevalence drops from over 60% in 2018–2019 to below 20% by 2024.

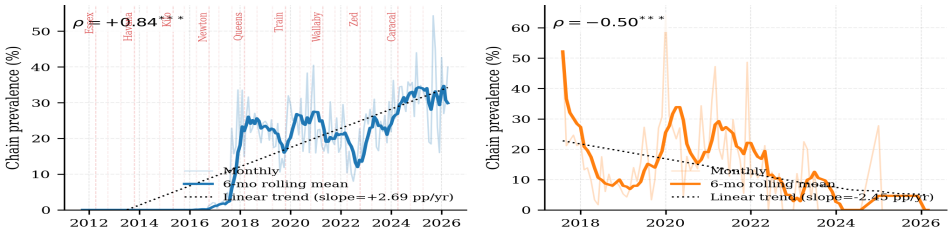

**Figure 4** Monthly chain-prevalence exemplars: (a) increasing trend in OpenStack Neutron; (b) decreasing trend in ONAP `oom`. Bold line: 6-month rolling mean; dotted line: linear trend.

ONAP `oom` change 137529,[3] which introduces Kafka support across multiple policy charts in a single 2024 change, illustrates this evolution. Similar cross-component modifications in earlier years were often decomposed into linked chains, suggesting a gradual shift away from chain-oriented coordination; we revisit potential explanations in Section 6.

**Finding #1.3: Relation chains are dominated by short pair-like structures, with project-specific deep tails and one auto-generated outlier.** Per-project depth statistics show similar central tendencies across ecosystems (Table 3): 12 of 15 projects have median depth 2, 14 of 15 have Q1 of 2, and 11 of 15 have Q3 $\leq 4$. Thus, most chains are pair-like structures or short sequences of two to four members. Mean depth is low (2.3–6.1), with standard deviation below 4 in 12 of 15 projects. The tails vary substantially: maximum depth ranges from 5 (`cps`) to 98 (`sdc`), and seven projects contain at least one chain deeper than 30. ONAP `sdc` has the deepest profile (mean 6.1, Q3 of 7, maximum 98), whereas `cps` has

[3] `https://gerrit.onap.org/r/c/oom/+/137529`

maximum depth 5 and standard deviation 0.6. The `ops/puppet` project is an outlier: its maximum depth of 59,945 comes from a single auto-generated chain in its config-as-code workflow (Table 1), which we exclude from aggregates.

**Table 3** Per-project chain-depth statistics. `ops/puppet`'s maximum reflects a single auto-generated config-as-code chain (Table 1).

| Ecosystem | Project | $n$ | Min | Q1 | Median | Mean | Q3 | Max | Std |
|---|---|---|---|---|---|---|---|---|---|
| OpenStack | nova | 4,985 | 2 | 2 | 2 | 2.7 | 3 | 56 | 1.8 |
| | neutron | 2,015 | 2 | 2 | 2 | 3.1 | 3 | 26 | 2.5 |
| | cinder | 1,104 | 2 | 2 | 2 | 4.8 | 5 | 38 | 5.4 |
| | horizon | 406 | 2 | 2 | 2 | 3.6 | 4 | 22 | 3.3 |
| | heat | 498 | 2 | 2 | 2 | 3.5 | 4 | 29 | 3.0 |
| Wikimedia | mw/core | 10,036 | 2 | 2 | 2 | 3.2 | 4 | 31 | 2.1 |
| | ext/Wikibase | 3,662 | 2 | 2 | 2 | 3.4 | 4 | 34 | 2.8 |
| | ext/VisualEditor | 1,291 | 2 | 2 | 2 | 3.0 | 3 | 12 | 1.6 |
| | ext/MobileFrontend | 1,341 | 2 | 2 | 3 | 3.4 | 4 | 22 | 2.3 |
| | ops/puppet | 3,012 | 2 | 3 | 5 | 38.2 | 9 | 59,945 | 1244.4 |
| ONAP | so | 680 | 2 | 2 | 2 | 3.2 | 4 | 21 | 2.3 |
| | sdc | 846 | 2 | 2 | 3 | 6.1 | 7 | 98 | 7.8 |
| | oom | 588 | 2 | 2 | 2 | 3.4 | 3 | 46 | 3.6 |
| | cps | 184 | 2 | 2 | 2 | 2.3 | 2 | 5 | 0.6 |
| | ccsdk/cds | 235 | 2 | 2 | 2 | 3.5 | 4 | 18 | 2.7 |

**Finding #1.4: Mean chain depth shows no systematic temporal trend in most projects.** Grouping chains by the month their base was created (Figure 5), Spearman correlations between calendar month and monthly mean depth range from $-0.34$ to $+0.33$ and are non-significant in 12 of 15 projects. Exceptions are ONAP `so` ($\rho = -0.57$, $p < 0.001$) and `sdc` ($\rho = -0.53$, $p < 0.001$), where chains become shallower over time, consistent with declining prevalence in Finding #1.2, and OpenStack Cinder, which shows the opposite trend ($\rho = +0.32$, $p < 0.01$). Thus, outside these cases, chain *shape* remains stable while *adoption* grows: the increase in Finding #1.2 reflects more chains, not longer ones.

**Finding #1.5: Depth spikes correspond to coordinated engineering campaigns, not noise.** Figure 5 also reveals months where mean depth rises to several times the project's long-run median. We identified 14 spike months (mean depth above the project median plus two standard deviations); 13 are multi-chain bursts in which three to nineteen chains, several deep, are created together. For example, OpenStack Horizon created seventeen chains in December 2018 with a mean depth of nine and a maximum of twenty-two, driven by a single author decomposing a project-wide `pylint` cleanup[4] into dependent chains. Similar spikes occur during architectural migrations and refactoring sweeps (full list in the replication package), indicating that depth spikes mark coordinated multi-chain campaigns.

**RQ1 summary**

Relation chains are a common but ecosystem coordination mechanism in Gerrit-based development, with prevalence ranging from 5% to 49% across projects (median 17%). Chain adoption is increasing in most projects. Chains are typically shallow (median depth 2), and their structural characteristics remain stable despite changing adoption rates. Deeper chains, when they occur, are associated with engineering workflows such as sequential refactoring and diagnostic branching.

[4] `https://review.opendev.org/q/topic:pylint+project:openstack/horizon`

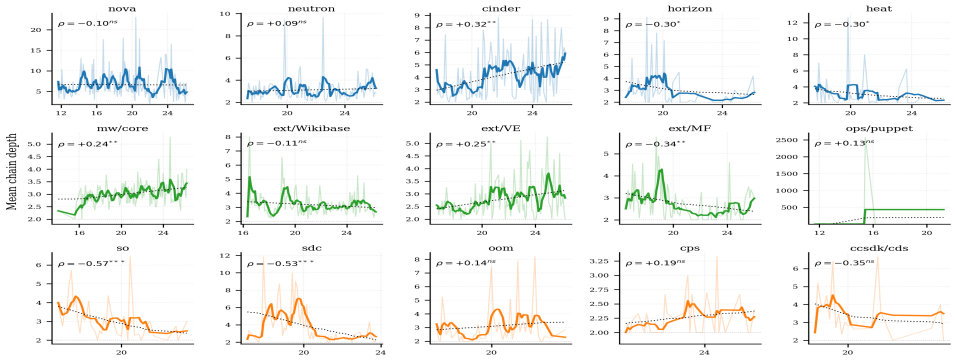

**Figure 5** Monthly mean chain depth per project (6-month rolling mean; dotted line = linear trend). Horizontal dotted line at depth 2 marks the pair floor.

## 5.2 RQ2: Review Outcomes

Table 5 reports descriptive statistics and Mann–Whitney effect sizes for chain-vs-solo comparisons across six metrics and five Gerrit size buckets. Table 4 breaks down the same metrics by chain-position label. Figure 6 shows per-project patchset count by chain position.

**Finding #2.1: Relation chains introduce synchronization overhead through additional revisions, rebasing activity, and longer review duration.** Across all five Gerrit size buckets, chain members take a median of 2.6× longer to merge and undergo 1.5× more revision rounds than comparable solo changes (Mann–Whitney U, $p < 0.001$; Table 5). Cliff's $\delta$ is *small* in four of five buckets and *large* only in the XL bucket ($\delta = 0.49$), showing that the strongest overhead is concentrated among very large changes. This reflects repeated rebasing, validation, and merge-order coordination across dependencies. The OpenStack Horizon December 2018 `pylint` cleanup[5], which created seventeen dependent chains in one month, illustrates this effect: each chain accumulated its own review iterations plus dependency-related coordination overhead.

**Finding #2.2: Chain members do not attract more top-level discussion than solo changes, but receive significantly more code-anchored inline comments in OpenStack and Wikimedia.** In OpenStack and Wikimedia, solo changes attract more median discussion messages than middle- or top-of-chain members (Table 4). In contrast, OpenStack chain members receive significantly more inline comments across all five size buckets (Cliff's $\delta = 0.21$–$0.34$, all *small*, $p < 0.001$; Table 5). Wikimedia shows significant differences in every bucket but with mixed direction, while ONAP shows the smallest and least consistent effect. Overall, feedback appears to shift from top-level discussion toward code-anchored scrutiny and synchronization/validation maintenance.

**Finding #2.3: Relation chains exhibit a CI amplification effect under strict gating regimes.** Chain members run a median of 10–23 CI/CD jobs depending on position, against fewer than two for solo changes in the same ecosystem (Table 4). The split is largest in OpenStack, where base, middle, and top members each trigger a test pipeline on every patchset under the project's gating policy [27, 9]; the accumulation matches the multi-hour merge gaps

[5] `https://review.opendev.org/q/topic:pylint+project:openstack/horizon`

reported in Finding #3.1. ONAP, with lighter CI gating, shows the smallest split (chain CI medians of 0–2 versus solo medians of 2). The OpenStack Neutron `[OVN]` migration of November 2019[6], with nine dependent chains advancing the same migration, illustrates the cumulative cost: each member's revisions retriggered the CI suite. We call this recurring downstream validation workload the *CI amplification effect*, where revisions to one chain member trigger repeated validation across dependent descendants.

**Table 4** Per-ecosystem chain-position breakdown of six review metrics. For each ecosystem (OpenStack, Wikimedia, ONAP), each metric is split across the three chain-position labels (Base, Middle, Top) and summarised as Min, Q1, Median, Mean, Q3, Max. `ops/puppet` is excluded from the Wikimedia rows (see Table 1).

| | | Base | | | | | | Middle | | | | | | Top | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Metric | Min | Q1 | Med | Mean | Q3 | Max | Min | Q1 | Med | Mean | Q3 | Max | Min | Q1 | Med | Mean | Q3 | Max |
| OpenStack | #Revisions | 1 | 1 | 3 | 5.61 | 6 | 126 | 1 | 2 | 3 | 5.72 | 7 | 103 | 1 | 1 | 3 | 4.78 | 5 | 114 |
| | #Rebases | 0 | 0 | 2 | 4.61 | 5 | 125 | 0 | 1 | 2 | 4.72 | 6 | 102 | 0 | 0 | 2 | 3.78 | 4 | 113 |
| | Review dur. (h) | 0.18 | 63.9 | 270 | 1167 | 990 | 60,844 | 0.28 | 116 | 362 | 1181 | 1143 | 47,431 | 0.40 | 105 | 324 | 1011 | 964 | 38,658 |
| | Discussion msg. | 0 | 1 | 8 | 30.4 | 27 | 1,796 | 0 | 0 | 4 | 25.4 | 19 | 951 | 0 | 0 | 4 | 15.6 | 16 | 1,185 |

**Finding #2.4: Middle-of-chain members function as synchronization bottlenecks within dependency-linked review workflows.** Middle-of-chain members function as synchronization bottlenecks within dependency-linked review workflows. Across all three ecosystems, middle-of-chain changes show higher median #Revisions, more #Rebases, and longer review duration than the base or the top of the same chain (Table 4). The per-project view confirms the pattern: in nearly every project, #Revisions medians at middle positions sit at or above those at the base and the top (Figure 6). This matches bottom-up merge enforcement: a middle member is simultaneously blocked by its predecessor and blocking its successor, accumulating the iteration cost of waiting for changes below while continuing to receive feedback from above. As a result, middle members effectively function as synchronization bottlenecks that absorb the highest coordination burden within the chain. Reviewers internalise this dependency: on a 17-member ONAP `sdc` chain (change 88612[7]), one held back approval with "*waiting for parent to be verified.*"

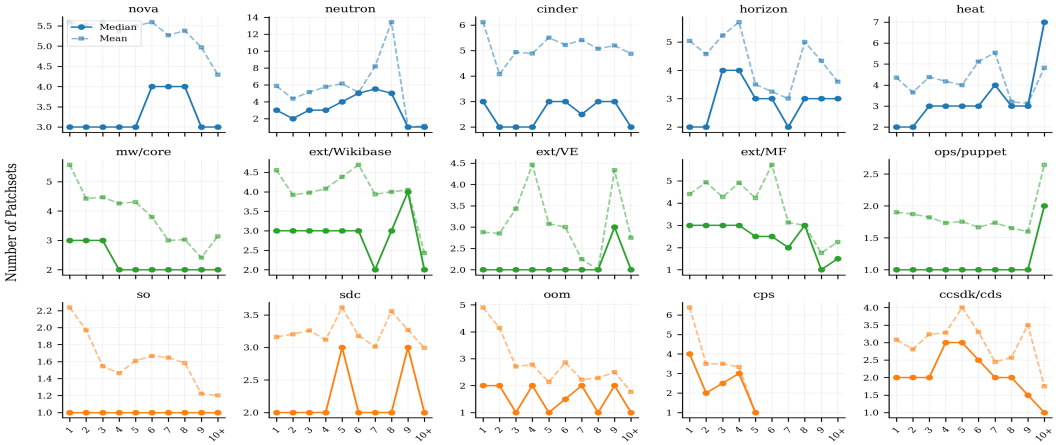

**Figure 6** Patchset count by chain position-from-base, per project. Solid line: median; dashed line: mean.

**RQ2 summary**

Relation chains introduce synchronization overhead through increased revisions, rebasing activity, review duration, and amplified CI workload compared to isolated changes (Finding #2.1). These coordination costs emerge primarily from dependency management rather than increased conversational review activity (Finding #2.2). Under strict CI-gating regimes, relation chains exhibit a *CI amplification effect*, where revisions to one member repeatedly retrigger validation across dependent descendants (Finding #2.3). Within chains, middle members function as synchronization bottlenecks that absorb the highest coordination burden due to simultaneous upstream and downstream dependency constraints (Finding #2.4).

## 5.3 RQ3: Structural Factors

Table 6 reports submission and merge gaps between consecutive chain members. Figure 7 shows Spearman correlations between base-change and descendant-mean review metrics.

**Finding #3.1: Chain throughput is set by the project's CI gating regime rather than chain mechanics.** Relation chains unfold in two timing regimes: a *submission gap* (time between uploads of consecutive members) and a *merge gap* (time between merges). Submission is fast on aggregate: pooled median 14 minutes, with project medians from near-zero in OpenStack `Horizon` and `Heat` to roughly six hours in ONAP `sdc` and `cps` (Table 6); these reflect developer work patterns, since a multi-step refactor prepared offline appears within minutes while incremental uploads widen the spread. Merge gaps separate ecosystems more sharply: medians sit below one hour for most Wikimedia and ONAP projects but between two and ten hours for every OpenStack project (`Horizon` 2.23 h to `Neutron` 9.82 h). The split tracks CI-gating regimes [27, 9]: OpenStack runs a per-member test pipeline before each descendant's submission completes, while Wikimedia and ONAP permit descendants to follow within minutes once the base has merged. The Horizon `pylint` cleanup of December 2018[8] shows this at chain level: chains assembled offline (small submission gaps) produced merge gaps in hours because each descendant waited for its predecessor's CI pipeline on the rebased revision. The same dependency structure therefore produces substantially different coordination costs under different CI-gating regimes.

†Excluded from aggregate statistics (see Table 1).

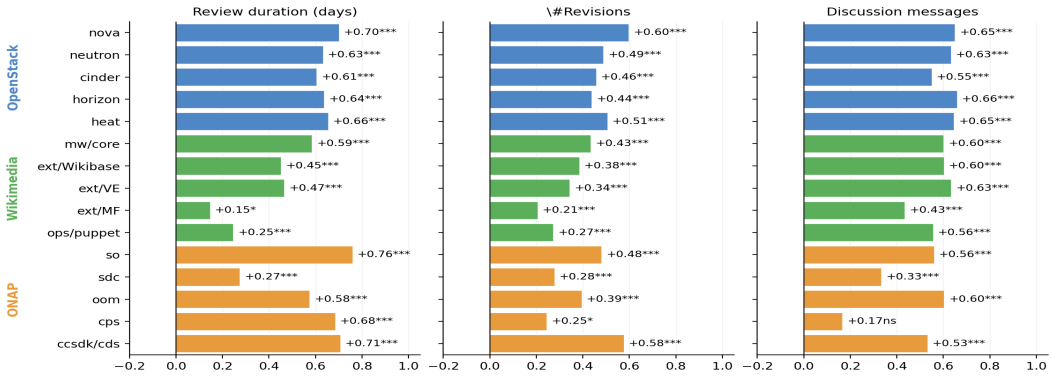

**Figure 7** Foundation effect: per-chain Spearman correlation between base-change and descendant-mean review metrics, computed within each project.

**Finding #3.2: Higher review activity on base is associated with higher review activity on chain descendants.** Spearman correlations between the base change's review metrics and the mean of its descendants' metrics are positive across all three metrics: review duration (median $\rho = +0.61$, significant in 15/15 projects), discussion messages ($\rho = +0.60$, 14/15), and #Revisions ($\rho = +0.43$, 15/15) (Figure 7). We refer to this regularity as the *foundation effect*: chains with high-effort bases have high-effort descendants, and chains with low-effort bases have low-effort descendants. Because our metrics measure review activity rather than code quality, we describe the correlation as review-effort propagation, not evidence of base quality. The Nova SDK migration chain (change 659691)[9] illustrates the pattern: its base accumulated 38 #Revisions and 17 discussion messages, and its 14 merged descendants each required additional review activity.

[9] `https://review.opendev.org/c/openstack/nova/+/659691`

**RQ3 summary**

The median merge gap between consecutive chain members varies by roughly three orders of magnitude across ecosystems and is explained by the project's CI-gating regime rather than chain mechanics (Finding #3.1). The *foundation effect*: base-change review activity correlates positively with descendant review activity (Spearman $\rho = 0.43$–$0.61$) in 14–15 of 15 projects (Finding #3.2).

## 6 Discussions and Implications

Although many observed effect sizes are small according to Romano et al.'s Cliff's $\delta$ thresholds, the directional consistency of the results across projects and ecosystems suggests that relation-chain membership captures recurring coordination patterns rather than isolated project-specific anomalies.

**Implications for Researchers.** The change-level unit of analysis common in code-review research does not capture review dynamics in ecosystems where a substantial share of changes belong to chains; modern review workflows increasingly operate as dependency-aware coordination systems rather than collections of independent review units. When a chain is present, the review process involves decisions across dependent changes (which member to review first, whether to wait for a predecessor, how to handle merge ordering) invisible from any single change. Studies of reviewer load, reviewer assignment [40, 31], and review latency [47, 48] that treat reviews independently may not represent the full process, and predictive models built on change-level features alone omit chain-level signals (chain position, depth, base-change activity, chain dynamism) that our data show correlate with the same outcomes they aim to predict.

Two further chain-level properties deserve attention. First, chains are not static dependency graphs but continuously evolve throughout review, a behaviour we refer to as *dynamic dependency restructuring*: 33.5% of chain members undergo a structural change in their parent SHA before merging, most often by detaching from an in-review parent (40% of evolution events), with rates of 25.0% (OpenStack), 39.7% (Wikimedia), and 50.2% (ONAP). Reviewers describe these dynamics in our metadata: on Wikimedia `mediawiki/core` change 530540[10], one noted that "*the chain is now just blocked on the MediaWikiTestCaseBase thing*," treating the chain as a unit gated by a single member. Second, chains persist across multi-year timespans: submission gaps reach ∼4.8 years in OpenStack `Nova` and merge gaps ∼2.85 years in `Neutron` (Table 6). Chain-aware tooling must continuously recompute dependency topology throughout the review lifecycle.

The foundation effect (Finding #3.2) shows base-change review activity correlates with descendant-change activity. Possible mechanisms include scrutiny applied to descendants of a heavily reviewed base, descendants inheriting architectural decisions, and reviewers accumulating context across the chain; our observational data does not distinguish between them, and because our metrics measure review activity rather than code correctness we do not interpret the correlation as evidence of base quality. LLM-based review agents [25, 41, 21] process changes independently of chain dependency, yet chain position is associated with differences in review effort (Finding #2.4) and one third of chain members restructure during review; a natural extension is to provide such tools with chain-level inputs: position, base

[10] `https://gerrit.wikimedia.org/r/c/mediawiki/core/+/530540`

review state, and recent dependency-graph evolution. Chain prevalence, evolution rates, and median merge gaps also vary across ecosystems by amounts comparable to chain-vs-solo differences within a single ecosystem (Findings #1.2, #3.1), correlating with submit-type and CI-gating configuration [27, 9]; replications should evaluate chain practices per setting rather than pooling across ecosystems.

**Implications for Practitioners.** Our findings argue against the current default in review tooling, which processes each change as an independent unit [40, 31, 25, 41]: when changes belong to a relation chain, their review outcomes are quantitatively linked. The foundation effect (Finding #3.2) is the central evidence: Spearman $\rho = 0.43$–$0.61$ in 14–15 of 15 projects show base review activity predicts descendant activity. The practical consequence is a single high-leverage intervention point per chain. Concentrating reviewer attention on the base (through earlier reviewer assignment, dedicated review slots, or AI-assisted summarisation of the base's open discussion) is associated with lower per-descendant review effort, multiplying the effect across every member. The Nova SDK migration chain (change 659691) illustrates the scale: 38 #Revisions and 17 discussion messages on the base, with 14 merged descendants each absorbing additional review activity that would likely have been smaller had the base resolved with less friction.

Within chains, middle-of-chain changes show the highest median review effort (Finding #2.4), since a middle change is simultaneously blocked by its predecessor and blocking its successor. Review dashboards and reviewer-assignment systems [40, 31] could use chain position as an input, prioritising changes whose merge unblocks the largest number of downstream changes. Chain-aware CI could reorder test-resource scheduling. Consider the Horizon `pylint` cleanup of December 2018: its seventeen chains were assembled in one afternoon (Finding #3.1), but descendants queued behind each other for hours, each waiting for its predecessor's CI pipeline. A chain-aware scheduler could have given higher priority to the base (gating seventeen downstream pipelines) and lower priority to any single descendant (gating none until the base merges), turning hours of serialised wait into parallel queueing once the base passes. The principle generalises: OpenStack chain members run 10–23 CI/CD jobs per position against fewer than two for solo changes (Finding #2.3), so wasted resources on superseded patchsets are a recurring property of strict-gating regimes.

Finally, a chain's dependency graph is not fixed during review: 33.5% of chain members restructure before merging, most often by detaching from an in-review parent. Tools that read the graph once and assume it stable (reviewer recommendation, CI scheduling heuristics, dashboards) produce results based on a graph no longer holding in about one-third of cases. A practical mitigation is to recompute chain-dependent state on every patchset upload, not only at chain creation; the long-tail timing in Table 6 further suggests chain-aware tooling should preserve coordination state across dormant periods rather than discarding context after fixed timeouts.

## 7 Threats to Validity

**Construct validity.** We measure review effort (latency, patchset count, comment count) rather than review quality; the foundation effect is therefore framed as propagation of review activity, not of code quality. Chain detection relies on parent-SHA matching, validated against Gerrit's Relation Chain panel, with the operations/puppet auto-generated deep chain excluded from aggregates and chain evolution distinguishing true structural changes from trivial rebases (same Change-Id). Human-vs-bot distinction in discussion and CI/CD

metrics relies on a per-project allowlist; while this convention is standard in Gerrit-based MCR research [29, 46], residual misclassification at the long tail of commenters cannot be excluded. The Nova patchset-level data was extracted through a replication package rather than our own pipeline; we verified that the same Change-Id-based exclusion was applied, and removing Nova does not qualitatively change the results.

**Internal validity.** We compare chain members and solo changes within size strata but cannot exclude task complexity as an unmeasured confounder, so the latency overhead is treated as an association rather than a causal effect [5]. We do not apply multiple-comparison corrections to per-project tests because projects are independent observational units, and the consistency of sign and magnitude across the corpus is the primary finding.

**External validity.** The corpus spans three open-source Gerrit ecosystems, dominated by infrastructure and platform software. Industrial settings, other platforms (GitHub [48], Phabricator, Graphite), and different Gerrit submit types may exhibit different dynamics. Replication on those platforms is a natural next step.

## 8 Conclusion

We characterized 29,580 relation chains across 401,256 reviewed changes in three open-source Gerrit ecosystems. Chains are prevalent (5–49% of changes, increasing in 14 of 15 projects) and impose measurable coordination costs: members take a median of 2.6× longer to merge than solo changes, exhibit a *CI amplification effect* under strict gating, and place *synchronization bottlenecks* on middle members. The *foundation effect* (Spearman $\rho = 0.43$–$0.61$) shows base-change review activity propagates to descendants, and *dynamic dependency restructuring* reshapes one third of chain members mid-review, sometimes across multi-year intermittent timespans.

These regularities suggest a lever for chain-aware tooling: invest review attention in base changes, and the benefit propagates through the chain. Future work should evaluate targeted interventions (base-review checkpoints, chain-aware reviewer assignment [40, 31], dependency-graph-aware CI scheduling) and replicate the analyses on platforms beyond Gerrit (Phabricator, Graphite, GitHub stacked PRs).

## Data Availability Statement

To facilitate replication and extension, we share data and scripts in our replication package [1]. The package contains raw Gerrit REST API outputs for the 15 studied projects, processed per-change and per-chain CSVs used as inputs to all analyses, and Jupyter notebooks that reproduce every figure and table reported in this paper, organised by research question. A README documents environment setup and provides a finding-to-cell mapping from each result in Sections 5.1–5.3 to the specific notebook cell that produced it.

## Abstract

**Background.** Automated Machine Learning (AutoML) is increasingly embedded in software and data engineering workflows, automating the design and optimization of machine learning (ML) pipelines. AutoML has been extensively synthesized through secondary studies that map tools, algorithms, and evaluation practices. However, these reviews predominantly reflect a research-centric perspective and provide limited evidence on how AutoML is actually used, adapted, and experienced in practice. Traditional surveys and interviews capture only a narrow slice of the practitioner community, leaving open how well academic claims about AutoML align with day-to-day engineering realities.

**Aims.** This study aims to (i) assess to what extent AutoML practices and challenges reported in existing secondary studies reflect practitioners' experiences, and (ii) identify mismatches between research and practice by empirically comparing academic claims with practitioner experiences shared on YouTube.

**Method.** Following established guidelines for multivocal literature reviews in software engineering, we conduct a multivocal evidence synthesis combining 16 peer-reviewed secondary studies (systematic and multivocal literature reviews) with 30 practitioner-created YouTube videos in which engineers, data scientists, and ML practitioners describe their AutoML workflows, workarounds, and pain points.

**Results.** Our analysis reveals a marked imbalance: academic reviews emphasize algorithm selection, search strategies, and benchmarking, whereas practitioners foreground data quality and cleaning, resource and cost constraints, tool robustness, scalability, and integration into production pipelines. We also observe areas of alignment, for example around hyperparameter optimization and the need for reproducible workflows.

**Conclusions.** Treating YouTube videos as curated gray literature under established multivocal review guidelines, our study shows that they provide complementary, practice-grounded evidence about AutoML adoption. The identified gaps and alignments suggest concrete directions for empirical AutoML research that more directly address operational and organizational constraints in real-world software engineering settings.

## 1 Introduction

Machine learning (ML) has become a foundational technology across modern industries, powering applications in healthcare, finance, manufacturing, and digital services [23, 27]. Its success has led to the emergence of AI engineering, a discipline that bridges software engineering and artificial intelligence to design, deploy, and maintain ML-enabled systems [23]. Despite the rapid progress of ML, many organizations still struggle to operationalize ML systems because of their heavy dependence on scarce expert knowledge and the high cost of developing, tuning, and maintaining models [23, 21, 11]. Traditional ML workflows require practitioners to manually handle tasks such as data preprocessing, feature engineering, model selection, and hyperparameter optimization – each demanding extensive domain knowledge and iterative experimentation. This dependency on expert intervention has created a bottleneck in industrial adoption, limiting innovation and scalability in organizations lacking skilled data scientists [23]. Building an effective ML model requires navigating a large design space of algorithms, encodings, and hyperparameters under constraints of accuracy, memory, and runtime; exhaustively exploring this combinatorial search space through manual experimentation is computationally expensive and often yields suboptimal results due to the limitations of human-guided search [5, 23]. These technical and operational pressures collectively strengthen the case for automation in configuration, search, and data preparation processes.

**Automated Machine Learning (AutoML)** has emerged as a response to these limitations by automating the end-to-end design and optimization of ML pipelines [15, 23, 5]. AutoML systems automate processes such as data preprocessing, feature engineering, algorithm and hyperparameter selection, and performance evaluation to produce optimized models with reduced human intervention [3, 27, 21]. Unlike traditional ML, where experts manually engineer and tune models, AutoML systems algorithmically explore search spaces of models, hyperparameters, and architectures to identify high-performing configurations. This paradigm aims to democratize ML – making it more accessible to non-experts – while improving reproducibility, scalability, and efficiency [11, 14, 33].

In parallel with advances in AutoML technology, the literature has witnessed a growing number of secondary studies that survey AutoML tools, algorithms, and evaluation practices [6, 8, 15, 16]. While these reviews provide a valuable map of the research landscape, they predominantly reflect a research-centric perspective and give limited attention to how AutoML is actually used, adapted, and experienced in real projects [15, 23]. Existing studies rarely capture the fine-grained practices, workarounds, and frustrations that arise when teams integrate AutoML into complex socio-technical environments. Traditional empirical methods such as surveys and interviews, although important, typically reach only a narrow slice of the practitioner community, raising questions about how well academic claims about AutoML align with day-to-day engineering realities [12, 34].

At the same time, many ML engineers, data scientists, and practitioners now openly share their AutoML experiences on social media platforms, notably YouTube, where they discuss implementation challenges, best practices, and lessons learned from applied projects. YouTube is one of the most visited websites worldwide, with more than two billion users and hundreds of hours of video uploaded every hour, and it has increasingly been used as a data source in qualitative and mixed-methods research [32, 19]. Prior work has shown that user-generated YouTube videos can serve as a qualitative research asset and a rich source of naturally occurring data, provided that search strategies, sampling decisions, and contextual limitations are made explicit [9, 30, 17]. These studies highlight both the opportunities

and the methodological challenges of working with YouTube data, for example the need to document search terms, ranking mechanisms, and inclusion criteria to approximate real viewing behavior [30, 32]. Motivated by this body of work, we treat practitioner-created YouTube videos as curated gray literature that can complement traditional sources when studying AutoML in practice.

In software engineering, guidelines for multivocal literature reviews (MLRs) explicitly advocate combining formal literature (e.g., journal and conference papers) with gray literature (e.g., blog posts, white papers, and videos) to obtain a more complete picture of both the state of the art and the state of practice [13]. MLRs extend systematic literature reviews by incorporating such gray sources under a structured protocol for searching, quality assessment, and data extraction [13, 23]. Building on these guidelines, we conduct a multivocal evidence synthesis that integrates findings from peer-reviewed secondary studies on AutoML with practitioner experiences shared on YouTube. This design allows us to empirically examine to what extent AutoML practices and challenges reported in academic reviews are reflected in practitioners' accounts, and where they diverge.

In this study, we conduct a multivocal evidence synthesis that comparatively analyzes AutoML practices and challenges across 16 literature reviews and 30 practitioner-created YouTube videos [13]. This design allows us to systematically contrast research and practice perspectives on AutoML and to derive implications for both communities. Our contributions are threefold: (i) we synthesize AutoML practices and challenges reported in existing secondary studies and in YouTube practitioner content; (ii) we assess where these two sources converge or diverge; and (iii) we derive implications for researchers and practitioners based on the observed gaps and alignments

## 2 Background and Related Work

Over the last decade, AutoML has evolved from research prototypes to an ecosystem of open-source frameworks (e.g., Auto-Sklearn, TPOT, FLAML) and commercial platforms offered by major providers such as Google, AWS, IBM, and Microsoft [23, 10]. These tools enable users to build, train, and deploy models through graphical interfaces or APIs while supporting scalability across on-premise and cloud infrastructures [10, 33]. Within the ML workflow, AutoML can trigger automatic retraining and monitoring, thereby improving reliability and maintainability [23]. In specialized domains such as medical imaging, AutoML techniques like Neural Architecture Search (NAS), Hyperparameter Optimization (HPO), and Automatic Data Augmentation (ADA) have produced architectures that compete with or exceed manually designed neural networks [3]. Similarly, AutoML has been applied in robotics [27], unsupervised learning [21], and other domain-specific settings, underscoring its expanding applicability.

AutoML has also been the subject of several secondary studies, including systematic literature reviews, mapping studies, and multivocal reviews; a systematic mapping of this body of work is provided in a recent tertiary study [25]. These reviews consolidate terminology regarding the scope and phases of AutoML [6, 8], provide overviews of pipeline structures and key components [15, 16], and evaluate well-known AutoML tools, frameworks, and algorithms through benchmarks and reported experiences [38, 33, 23]. Other reviews focus on specific phases of the AutoML process, such as HPO [18, 24], feature engineering [26, 22], and NAS [28, 29], or on application domains and use cases including healthcare, finance, and industrial IoT [36, 34, 4, 37, 7, 5, 3]. A few empirical studies complement these reviews with interviews and case studies on AutoML adoption and usage [35, 31]. Overall, this literature

offers a broad and deep account of AutoML concepts, techniques, and tool ecosystems, but it largely foregrounds algorithmic innovation and benchmark performance, and provides only limited, fragmented insight into how AutoML is actually practiced in day-to-day engineering work.

Beyond software engineering, there is a growing body of methodological work on using YouTube as a data source for qualitative and mixed-methods research. Systematic reviews of health-related YouTube studies highlight that, when search strategies, sampling procedures, and inclusion criteria are transparently reported, YouTube can serve as a reproducible and informative medium for studying practices, perceptions, and communication patterns [30, 32]. Other work explicitly positions user-generated YouTube videos as a qualitative research asset and a repository of naturally occurring data that can inform both teaching and research [9]. More broadly, reviews of social-media-based qualitative research document YouTube alongside platforms such as Twitter and Facebook as a common source for content analysis and observational studies, while also emphasizing the need to acknowledge platform-specific biases and engagement mechanisms [17, 19]. These studies collectively argue that YouTube can be used as a legitimate empirical source, provided that researchers carefully design and document their search, sampling, and analysis procedures.

In software engineering, guidelines for multivocal literature reviews explicitly advocate combining formal literature (e.g., journal and conference papers) with gray literature (e.g., blog posts, white papers, practitioner talks, and videos) to obtain a more complete picture of both the state of the art and the state of practice [13]. MLR guidelines specify concrete procedures for identifying, selecting, and assessing gray sources, and they highlight the value of practitioner material for revealing real-world constraints, trade-offs, and work practices that are under-represented in academic publications [13, 23]. So far, only one multivocal literature review has addressed AutoML in depth [23]. However, that study primarily synthesizes practitioner- and academic-oriented sources at a relatively coarse level, and it does not explicitly compare the frequency of specific practices and challenges across source types. To the best of our knowledge, no prior AutoML study has systematically treated practitioner-created YouTube videos as gray literature under these guidelines, nor explicitly contrasted the distribution of practices and challenges between academic secondary studies and YouTube content.

Against this backdrop, our work focuses on the *state of practice* of AutoML as communicated by practitioners on YouTube, and on how this state aligns with or diverges from the AutoML landscape portrayed in academic secondary studies. We build on the existing AutoML review literature and MLR guidelines, but extend them in two key ways: (i) we treat practitioner-created YouTube videos as a curated gray-literature corpus, sampled and analyzed following established recommendations for YouTube research and MLRs; and (ii) we perform a comparative, cross-source analysis that explicitly quantifies and interprets similarities and differences in reported practices and challenges between academic and practitioner sources. In doing so, we provide a more fine-grained and empirically grounded picture of how AutoML is actually used, adapted, and experienced in real-world software and data engineering projects.

## 3 Study Design

In this study, we conduct a comparative analysis of evidence from 16 literature reviews and 30 practitioner-created YouTube videos. Following a multivocal evidence synthesis approach [13] that bridges white and gray literature, we compare these sources to identify where research assumptions align or diverge from real-world practice.

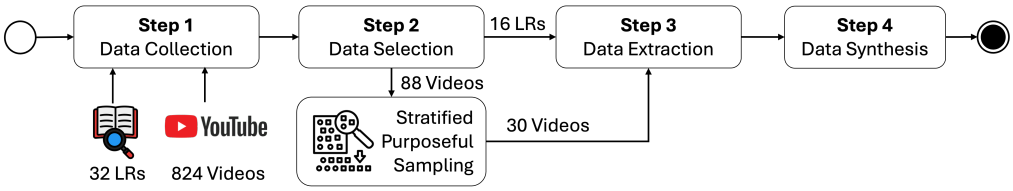

**Figure 1** Overview of the multivocal literature review process, spanning data collection, selection, extraction, and synthesis across LR and YouTube corpora.

## 3.1 Research Questions

To explore the alignment and divergence between these perspectives, we formulate the following research questions (RQs):

**RQ1: What AutoML practices are reported in the existing literature and on YouTube?** *Rationale.* This question identifies and categorizes practices associated with AutoML across research and practice. It examines how the literature describes methods and strategies for designing, implementing, and optimizing AutoML pipelines, and contrasts these accounts with the hands-on practices reported by practitioners in real-world projects.

**RQ2: What challenges are reported in the existing literature and on YouTube?** *Rationale.* This question identifies and categorizes limitations, barriers, and risks encountered in AutoML development and deployment. It compares how the literature conceptualizes technical, organizational, and ethical challenges with the difficulties and pain points expressed by practitioners.

**RQ3: To what extent do practices and challenges discussed in the literature align with those reported on YouTube?** *Rationale.* Building on RQ1 and RQ2, this question investigates the degree of convergence and divergence between academic and practitioner perspectives. It evaluates whether research priorities reflect the realities encountered in practice and pinpoints areas where theoretical assumptions may overstate, overlook, or underestimate practical concerns in AutoML adoption.

## 3.2 Research Process

The overall research process – from data collection and selection to data extraction and synthesis is summarized in Figure 1.

### 3.2.1 Data Collection

This study integrates two complementary sources of evidence: *literature reviews*, which provide theoretically grounded and aggregated knowledge, and *YouTube videos*, which capture practical, experiential, and up-to-date insights from practitioners. Together, these sources offer a broader and more grounded perspective on AutoML by combining white and gray literature [13].

**Literature Review Dataset.** The literature review dataset was derived from our recent tertiary study on AutoML [25], which synthesized evidence from existing systematic and multivocal literature reviews. In that study, a total of 32 reviews were identified through a

structured search and selection process that treated secondary studies as primary units of analysis. For the present work, we reused this curated dataset and focused on the subset of 16 reviews (more than 400 primary studies) that contained explicit information on AutoML practices and challenges – the key dimensions relevant to our comparative analysis. Reusing this validated dataset ensures methodological consistency with prior work and provides a robust foundation for examining how reported practices and challenges in the literature compare with those discussed by practitioners.

**YouTube Videos Dataset.** We collected practitioner-created YouTube content in two rounds. The first dataset, retrieved on 7 April 2025, served as a pilot and contained 540 videos. A second search on 16 June 2025 added 284 new videos published in 2025, resulting in a combined pool of 824 videos. Using the YouTube Search API, we queried each search term individually and retrieved up to 100 videos per term listed below.

```
["AutoML","Automated Machine Learning","AutoML practices","AutoML
challenges","AutoML pipelines","AutoML tools comparison","AutoML
automation tools","AutoML case studies","AutoML in real-world projects"]
```

To minimize personalized search bias and support reproducibility, all API calls were performed without authentication and mirrored incognito usage, and the same query parameters were applied across both collection rounds [32, 30]. No restrictions were imposed on publication year or geographic region to ensure broad coverage of AutoML-related content.

### 3.2.2 Data Selection

**Literature reviews.** The 32 reviews identified in our prior tertiary study [25] were already the result of a structured search and selection process. For this work, we further restricted this set to the 16 reviews that explicitly reported AutoML practices and/or challenges because these dimensions are central to our comparative analysis. The 16 AutoML-focused secondary studies collectively synthesize findings from more than 400 primary studies, where primary-study counts were reported.

**YouTube Videos.** Video filtering was carried out in two stages using both automated and manual screening. In the first stage, we applied the inclusion (I) and exclusion (E) criteria in Table 1 to the 824 collected videos. Automated filtering based on video metadata (title, description, duration, and language tags) reduced the dataset to 144 candidate videos.

**Table 1** Inclusion (I) and exclusion (E) criteria for YouTube videos.

| Inclusion criteria (I) | Exclusion criteria (E) |
|---|---|
| **I1** Content related to Automated Machine Learning (AutoML) (e.g., videos referring to AutoCAD or other non-AI automation topics were excluded). | **E1** Purely promotional or marketing content (e.g., product advertisements, discount announcements, sponsored "buy now" videos). |
| **I2** Duration longer than one minute (to exclude YouTube Shorts and very short clips). | **E2** Non-informative content (e.g., vlogs, reactions, entertainment, or non-technical news coverage). |
| **I3** Content in English. | **E3** Duplicate uploads of the same video. |

The rest 144 candidate videos were manually inspected for relevance. We kept only videos that presented at least one concrete AutoML workflow or project and explicit discussion of practices and challenges (e.g. rationales for design decisions, trade-offs between tools or settings, and reflections on what worked or failed); we excluded videos that were dominated by tool marketing, very brief GUI click-through demonstrations with no discussion of workflow decisions. This manual screening resulted in 88 videos.

In the second stage, we applied a *stratified purposeful sampling* strategy [20] to ensure that the final sample reflected the diversity of AutoML topics represented in the corpus. Specifically, we grouped the 88 videos into five strata according to the parent terms assigned to their search queries: *AutoML*, *AutoML pipelines*, *AutoML automation tools*, *AutoML case studies*, and *AutoML practices*. The largest strata covered general AutoML overviews and pipeline-focused content, whereas automation-tool, case-study, and practice-focused videos were fewer but conceptually central to our research questions. From this frame, we drew a stratified purposeful sample of 30 videos, aiming for a minimum number of information-rich cases in each stratum and deliberately oversampling the smaller yet theoretically important strata (automation tools, case studies, and practices). This follows Patton's notion of stratified purposeful sampling, where purposeful samples are nested into strata along key dimensions to capture major variations and enhance the credibility and heterogeneity of qualitative findings, while acknowledging that such samples are not intended for statistical generalization [20]. The final sample of 30 practitioner-created videos has a total running time of approximately 637 minutes (around 11 hours) of content, which we subjected to detailed data extraction and coding.

## 3.3 Data Extraction

A unified extraction protocol was applied to both datasets to ensure consistency across sources. We systematically extracted information on AutoML practices and challenges, guided by the following operational definitions:

- 🔵 **Practice:** Actions, processes, or workflow strategies used to design, implement, or optimize AutoML pipelines, including methods for data preparation, hyperparameter tuning, model evaluation, and human-in-the-loop integration.
- 🟥 **Challenge:** Limitations, risks, or barriers encountered in the use or adoption of AutoML, encompassing technical issues (e.g., scalability, reproducibility), organizational barriers (e.g., lack of expertise, integration difficulties), and ethical or regulatory concerns (e.g., bias, explainability, compliance).

For the literature reviews, one author conducted the initial extraction and two other authors independently checked the extracted items against the primary texts. Metadata such as paper ID, title, venue, year, and type of study were retained, and all extracted practices and challenges from the 16 reviews were organized in structured spreadsheets.

For the YouTube dataset, we used the automatically generated transcripts as the primary analysis material, complemented when necessary by viewing relevant video segments to clarify ambiguous statements. We first conducted a small pilot on two videos to calibrate the application of the above definitions and refine the extraction guideline. The standardized protocol was then applied across the full dataset, with each of the 30 videos independently extracted by one author and subsequently validated by a second author. Discrepancies in extracted practices or challenges were discussed in joint sessions until consensus was reached, and the guideline was updated when new decision rules emerged. All extracted data were consolidated in spreadsheets to support cross-source comparison, and the full extraction artifacts are available in our replication package [2].

## 3.4 Data Synthesis

Open and thematic coding were conducted separately for the literature reviews and the YouTube dataset to preserve the original framing and emphasis of each source. The initial codebook was seeded from the AutoML pipeline phases identified in [25], which provided

the core stages of AutoML workflows. In each dataset, an initial round of open coding was performed by one author, who assigned descriptive labels to the extracted practices and challenges. A second researcher then independently reviewed the assigned codes and their underlying excerpts, assessing coding consistency and the interpretation of emerging categories. Disagreements were resolved through discussion, and the shared codebook was revised accordingly.

Within each dataset, we iteratively applied a constant-comparison strategy, clustering individual codes and merging recurring or conceptually similar practices and challenges to derive higher-level thematic groups. This process reduced redundant open codes (e.g., minor wording variations referring to the same underlying practice) while retaining distinctions that were meaningful for analysis. The code list was continuously refined throughout the synthesis to ensure comprehensive coverage of all extracted practices and challenges. Conducting coding and theme development separately for academic and practitioner sources enabled a more reliable comparison between research and practice perspectives. The unified thematic codebook used in this study, along with a description of each theme and example excerpts, is provided in the replication package [2].

# 4 Results

This section presents the synthesized results from both datasets, integrating quantitative counts and qualitative insights on AutoML practices and challenges. The findings are organized per RQ.

## 4.1 RQ1: AutoML Practices

The analysis identified a total of **229 actionable AutoML practices**, organized into **12 thematic groups** and **89 subgroups**. These practices were synthesized from two complementary knowledge sources: Literature Reviews (LR) drawing on 16 peer-reviewed publications, and a practitioner-oriented corpus of 30 YouTube (YT) educational videos. The distribution across sources was markedly asymmetric. Of the 229 practices, 199 (86.9%) originated exclusively from YouTube content and 23 (10.0%) exclusively from the academic literature, with only 6 (2.6%) corroborated by both. In aggregate, YouTube videos contributed to 205 practices (89.5%) and LR papers to 29 (12.7%) – proportions that reflect not a mere difference in corpus size, but a fundamental divergence in what each knowledge channel chooses to document. Academic publications concentrate on formally defined, theoretically grounded problems – neural architecture search, meta-learning, adversarial robustness, and domain-specific clinical applications – whereas practitioner video content engages extensively with applied, tool-specific, and workflow-level concerns that constitute the daily reality of AutoML adoption. This structural difference is reflected in the thematic distribution shown in Figure 2. Optimization emerged as the most extensively documented group (34 practices, 9 subgroups), followed by Pipeline & Orchestration (29, 14 subgroups), Data Preparation (28, 11 subgroups), and Deployment (21, 7 subgroups) – all dominated by YouTube sources and collectively accounting for 48.9% of all identified practices, reflecting the operational emphasis practitioners place on search efficiency, pipeline management, and production readiness. At the other end, Task Formulation (6 practices) and Human-Centric Design (8 practices) were the least represented. Notably, Human-Centric Design was the only group drawing comparably from both sources (4 LR, 4 YT), suggesting that human–AutoML interaction remains an active concern across both communities despite its limited overall representation.

**Figure 2** Taxonomy of AutoML practices: 229 practices organized across 12 thematic groups and 89 subgroups, synthesized from 16 LR papers and 30 YouTube videos. Group labels indicate total practice count per group.

Table 2 presents representative actionable practices for the three most densely documented thematic groups – Optimization (34 practices), Pipeline & Orchestration (29 practices), and Data Preparation (28 practices) – which together account for 39.7% of all identified practices. These three groups were selected not only on the basis of volume, but because they illustrate the breadth of the theory–practice divergence most clearly: Optimization is the group with the strongest academic footprint, while Pipeline & Orchestration and Data Preparation are almost entirely practitioner-driven. For each group, three subgroups are presented, each populated with three representative practices drawn from the full catalog, accompanied

by their source attribution (LR = literature; YT = YouTube). Within the Optimization group, the subgroups span from foundational hyperparameter tuning strategies and search space design to more specialized concerns such as neural architecture search, meta-learning warm-starting, and business-constrained objective design. The Pipeline & Orchestration subgroups highlight the operational scaffolding practitioners build around AutoML runs – modular component design, artifact provenance tracking, and end-to-end pipeline structure – none of which appear meaningfully in the academic literature. Data Preparation practices similarly reflect practitioner-led concerns: systematic imputation strategies, column-type-aware preprocessing, and structured data loading workflows that academic treatments rarely operationalize at this level of specificity. In compliance with ESEM's open science policy, the complete catalog of all 229 actionable practices across all 12 thematic groups and 89 subgroups is provided as a structured online appendix [1].

**Table 2** Representative AutoML practices from the two dominant thematic groups. Subgroups selected based on practice count and source coverage (LR = literature review; YT = YouTube). LR/YT[*] denote source indices; the complete list of source list is provided in the online appendix [1].

| | Subgroup | | Actionable Practice |
|---|---|---|---|
| Optimization | Search Space Design & Acceleration | P1 | Design search spaces balancing compactness and comprehensiveness, incorporating human prior knowledge to reduce wasteful exploration. Use cell-based search and structured approaches as practical defaults. [LR5] |
| | | P2 | Apply acceleration techniques (e.g., weight sharing, NASP) to reduce search time, especially in AutoDL where final architecture evaluation often far exceeds the discovery cost. [LR5] |
| | | P3 | Use NAS-Bench datasets (NAS-Bench-101, NAS-Bench-201, NAS-Bench-NLP) to decouple algorithm design from expensive evaluation, enabling faster iteration on optimization strategies. [LR8] |
| | Neural Architecture Search (NAS) | P4 | Use differentiable architecture search (DARTS) for gradient-based NAS, and explore joint HPO + architecture optimization to find both architecture and hyperparameters in a single pass. [LR8, YT29] |
| | | P5 | Combine meta-learning with NAS to reuse and transfer architectures across tasks, enabling fast adaptation to new problems. Extend NAS to few-shot and unsupervised settings where labelled data is scarce. [LR8] |
| | | P6 | Apply NAS with reinforcement learning to automate the discovery of optimal layer counts and neuron configurations for deep learning models, replacing iterative manual architecture design. [YT21] |
| | Business-Aware & Constraint-Driven Optimization | P7 | Design or select AutoML systems that explicitly balance accuracy, efficiency, scalability, and flexibility – these four criteria should guide both tool selection and evaluation. [LR13] |
| | | P8 | Incorporate business constraints into modelling – e.g., monotonicity requirements from regulations, prediction range constraints, or weighted learning when some examples matter more than others. [YT18] |
| | | P9 | Automate target distribution analysis to recommend an appropriate mathematical objective suited to the data. Apply multi-objective fine-tuning where relevant. [YT18, YT22] |
| Pipeline & Orchestration | Artifact Storage & Provenance Tracking | P10 | Store all pipeline artifacts (datasets, models, hyperparameters, code, accuracy scores) in cloud storage to support reproducibility, debugging, and model deprecation. Enable artifact reuse across pipeline components. [LR2, YT25] |
| | | P11 | Document and maintain provenance records for error tracing and auditing. Store artifacts from original model runs in tracking servers (e.g., MLflow) for documentation and regulatory compliance. [LR2, YT9] |
| | | P12 | Track full model lineage – log all inputs, outputs, hyperparameters, and training data references throughout the pipeline to answer provenance questions and identify what changed between runs. [YT25] |
| | Component-Based Pipeline Design | P13 | Design pipelines as modular, component-based workflows where each step is defined by exactly one component with well-specified inputs and outputs. Components can perform preprocessing, training, evaluation, or deployment. [YT25] |
| | | P14 | Chain transformers and estimators sequentially to build pipeline models: transformers operate row-by-row on columns, estimators learn from full columns, and outputs feed into the next stage. [YT8] |
| | | P15 | Reuse prebuilt pipeline components (e.g., Google Vertex AI prebuilt components) before building custom ones. Share components across projects and teams via repositories (e.g., AI Hub). [YT25] |

**Table 2** Representative AutoML practices (continued).

| | | |
|---|---|---|
| End-to-End ML Pipeline Structure | P16 | Structure ML projects as end-to-end pipelines: data collection → cleaning/feature engineering → model selection → evaluation → deployment. Automate as many stages as possible while maintaining human oversight at key decision points. [YT10, YT29, YT17, YT9] |
| | P17 | Use comprehensive AutoML frameworks that automate model selection, HPO, data cleaning, and feature engineering as part of one unified pipeline, reducing the need for separate tool integration. [YT29] |
| | P18 | Build complete pipelines that include imputation, feature selection, classification, and calibration – not just prediction models. Enable pipeline-aware feature engineering matched to the specific pipeline being searched. [YT4, YT18] |

## 4.2 RQ2: AutoML Challenges

The analysis identified a total of **177 AutoML challenges**, organized into **12 thematic groups** and **75 subgroups**, drawing from the same corpus of 16 LR papers and 30 YouTube videos. The source distribution for challenges reverses the pattern observed for practices: the academic literature contributed to 103 challenges (58.2% of all challenges, counting shared entries once per source) and YouTube content to 83 (46.9%), with 9 challenges (5.1%) corroborated by both. This reversal is structurally revealing. Whereas practitioners are the primary documenters of *what to do* in AutoML workflows, the formal literature more extensively captures *what goes wrong* – particularly in areas that require systematic evaluation, theoretical analysis, or longitudinal observation to surface. This asymmetry suggests that failure modes in AutoML are not always immediately visible to practitioners during hands-on adoption; many manifest only at scale, under rigorous experimental conditions, or across multiple deployment cycles.

Figure 3 presents the full taxonomy of AutoML challenges across all 12 groups and 75 subgroups. The most extensively documented challenge groups are Process (23 challenges), Optimization (22 challenges), and Deployment (20 challenges), together accounting for 36.7% of all identified challenges and collectively capturing the central difficulty of AutoML adoption: despite advances in automation, building complete, reliable, and maintainable pipelines remains fundamentally hard. Scope & Applicability (18 challenges) and Data Preparation (18 challenges) follow closely. The latter is noteworthy: all 18 Data Preparation challenges originate exclusively from YouTube, confirming that data-level friction – fragmented sources, imputation complexity, format diversity, and business logic drift – is a practitioner reality the academic literature has largely left untheorized. Transparency (8 challenges), Feature Engineering (6 challenges), and Ethics, Safety & Compliance (9 challenges), while smaller in volume, carry disproportionate weight for real-world deployment: the interpretability deficit directly undermines clinical adoption and regulatory compliance, while unresolved ethical and fairness risks grow more consequential as AutoML systems are deployed in high-stakes domains.

Table 3 presents representative challenges for the three most extensively documented groups – Process (23 challenges), Optimization (22 challenges), and Deployment (20 challenges) – accounting for 36.7% of all identified challenges. These groups were selected because they represent distinct failure modes across the AutoML lifecycle: process-level breakdowns in pipeline automation and team coordination, optimization-level failures in search efficiency and model selection, and deployment-level gaps in production monitoring and CI/CD integration. Within the Process group, challenges are shared across both sources but articulated differently – the literature frames them as systemic design failures, while practitioners describe them as operational pain points. The Optimization group reveals a persistent tension between what AutoML promises and what it delivers under time, memory,

**Figure 3** Taxonomy of AutoML challenges: 177 challenges organized across 12 thematic groups and 75 subgroups, synthesized from 16 LR papers and 30 YouTube videos. Group labels indicate total challenge count per group.

and budget constraints. The Deployment group exposes a blind spot common to both sources: drift detection, monitoring failures, and missing CI/CD abstractions are identified by both communities, yet neither offers mature solutions. The complete catalog is provided in the online appendix [1].

**Table 3** Representative AutoML challenges from the two dominant thematic groups. Subgroups are selected based on challenge count and source coverage (LR = literature review; YT = YouTube). LR/YT[*] denote source indices; the complete list of source list is provided in the online appendix [1].

| | Subgroup | Challenge | |
|---|---|---|---|
| Process | Incomplete End-to-End Pipeline Automation | C1 | AutoML systems fail to automate the entire ML pipeline – many stages still require human effort. Task Formulation is not currently automated, and defining the right prediction goal remains more important than algorithm choice. [LR6, LR9] |
| | | C2 | AutoML may deliver suboptimal performance due to poor automation decisions in some tasks. Even when automation is available, existing tools require human interventions to achieve production-quality results. [LR6, YT24] |
| | | C3 | Predictive modelling cannot be completely automated – some detection and risk assessment tasks require human judgment even when AutoML provides partial support. [YT18] |
| | Scalability & Deployment Process Limitations | C4 | Deploying a single model traditionally requires many data engineers, scientists, and engineers – this process does not scale as each new model demands a large team. Building integrations across data collection, training, and deployment remains the central challenge. [YT8] |
| | | C5 | The training stage is highly iterative and effort-intensive, requiring extensive time and experimentation to converge on a good solution. ML pipeline implementation is consistently time-consuming across organisations. [YT17, YT25] |
| | | C6 | Organisational and process barriers – including expertise scarcity, process sluggishness, and diverse stakeholder expectations – compound the difficulty of delivering ML projects at scale. [LR10] |
| | Incomplete & Fragmented Pipeline Coverage | C7 | Most AutoML libraries only focus on parts of the pipeline – preprocessing and post-processing remain underexplored. Integration gaps exist across ML pipeline stages, with a lack of intelligent automation in decision-making. [LR8, LR7, LR6] |
| | | C8 | AutoML tools lack transparency, flexibility, adequate documentation, and regulatory compliance support, making their integration into existing organisational processes complex. [LR6] |
| | | C9 | ML workflow acceleration focuses on one-time execution, neglecting gradual and continuous development. Long development cycles (months to years) persist even for experienced teams. [LR10] |
| Deployment | Compute & Memory Burden at Scale | C10 | Scaling AutoML to handle big data efficiently is an ongoing challenge. AutoML tools face scalability issues with large datasets due to training inefficiencies and high compute requirements – especially for hyperparameter tuning. [LR22, LR6] |
| | | C11 | AutoML can crash or fail due to memory limitations on large or complex datasets. For deep learning with millions of rows, more powerful servers are required to complete training in reasonable time. [LR6, YT20] |
| | | C12 | AutoML training is excessively time-consuming across frameworks. Excessive training time is a universal complaint regardless of tool, dataset size, or model type. [YT21, YT29, YT28] |
| | Missing CI/CD & Automated Post-Deployment Support | C13 | AutoML lacks native support for modern CI/CD pipelines, limiting reliability and maintainability. AutoML tools also do not provide automated solutions for monitoring and updating models after deployment. [LR6, LR7] |
| | | C14 | Organisations face deployment challenges due to high compute requirements, infrastructure setup costs, and limited cross-environment deployment support across different real-world environments. [LR6] |
| | | C15 | RL-trained models are often impractical to deploy due to infeasible answers in real use cases. Deploying ML systems on the cloud raises difficulties around portability, cost management, and operations. [LR10] |
| | Production Monitoring & Data Drift | C16 | Model evaluation in AutoML platforms is typically done offline, raising concerns about performance monitoring once models are in production. Continuous dashboards and alerts for tracking performance over time are often absent. [YT16, YT7] |
| | | C17 | Detecting data drift, transform inconsistencies, and latency pattern shifts during execution is critical for reliability. Feedback loop detection in production – where deployed models influence future training data – remains an open challenge. [YT7, YT18] |
| | | C18 | The world changes over time – models will eventually encounter data they have never seen during training. Automated drift detection and adaptation are essential but remain largely underbuilt in current AutoML tools. [YT18] |

## 4.3 RQ3: Alignment and Divergence across Literature and Youtube

Building on the taxonomies established in RQ1 and RQ2, this section examines convergence and divergence between academic and practitioner AutoML knowledge, drawing on source attribution data across all 406 coded items (229 practices, 177 challenges) and supported by Figures 4 and 5. The overarching finding is one of structural misalignment: only 6 shared practices (2.6%) and 9 shared challenges (5.1%) were corroborated by both sources – reflecting a genuine and systematic divergence in what each community attends to, how it frames problems, and what it considers worth documenting.

**Alignment and Divergence in Reported Practices.** Figure 4 reveals that meaningful alignment between the literature and YouTube is confined to a small number of thematic groups. *Optimization* is the clearest point of convergence: both sources document practices related to hyperparameter search, neural architecture search, and meta-learning warm-starting, reflecting a shared recognition that search efficiency is central to AutoML. *Evaluation* and *Tool Usage* also appear across both sources, indicating that validation reliability and operational framework use represent common ground – practitioners and researchers alike are invested in knowing whether a pipeline works and which tools make it work. *Transparency* represents a subtler form of alignment: academic treatments frame it as explainability and model interpretability as design properties, while YouTube content addresses it through practical tooling (e.g., SHAP values, feature importance dashboards), but both communities recognize that AutoML outputs must be interpretable to be trustworthy. Beyond these areas, the divergence is sharp and consistent. YouTube content dominates *Deployment* (21 practices, 0 from LR), *Data Preparation* (28 practices, 0 from LR), and *Pipeline & Orchestration* (29 practices, 2 from LR) – groups that collectively account for 34.1% of all identified practices yet are almost entirely absent from the academic literature. These are not peripheral concerns: they represent the operational scaffolding without which no AutoML system reaches production. The literature, by contrast, concentrates its practice-level contributions in *Human-Centric Design* (4 of 8 practices from LR), *Model Selection* (5 of 16 from LR), and *Optimization* (8 of 34 from LR) – areas characterized by theoretical framing and algorithmic novelty. In short, academic publications tend to document AutoML improvement as a methodological pursuit, while practitioners approach it as an engineering discipline of efficiency, maintainability, and operational reliability.

**Alignment and Divergence in Reported Challenges.** The challenge data presents a partial but important reversal of this pattern. As shown in Figure 5, the literature and YouTube converge more meaningfully around challenges than around practices, particularly in *Optimization*, *Process*, and *Human-Centric Design*. The shared recognition of HPO difficulty, incomplete pipeline automation, and the persistent need for domain expertise suggests that certain failure modes are visible to both communities, even if they are encountered through different routes – researchers through systematic benchmarking, practitioners through hands-on deployment. *Scope & Applicability* also emerges as a shared concern: both sources acknowledge that AutoML is not one-size-fits-all, that it overemphasizes HPO and feature engineering relative to the full pipeline, and that terminology confusion around AutoML, AutoAI, and AutoDS creates misaligned expectations. Divergence persists, however, and follows a predictable pattern. The literature contributes disproportionately to *Data Quality* (10 challenges, 0 from YouTube), *Ethics, Safety & Compliance* (6 LR vs. 4 YT), and *Evaluation* (8 LR vs. 4 YT) – challenge areas that require sustained empirical investigation, controlled experimental conditions, or regulatory awareness to surface. Practitioners, by contrast,

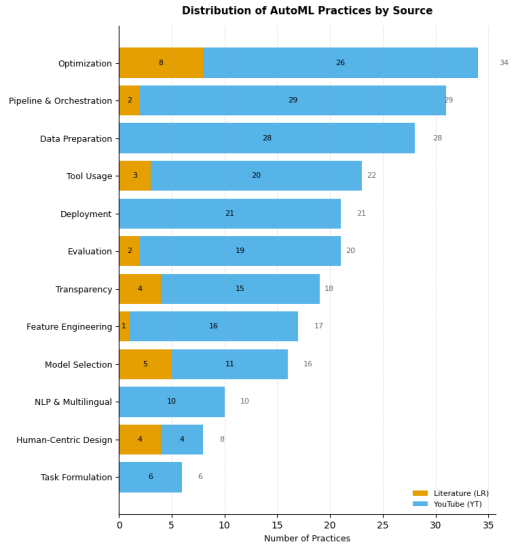

**Figure 4** Distribution of AutoML practices per thematic group by source (LR vs. YouTube). Groups ordered by total practice count.

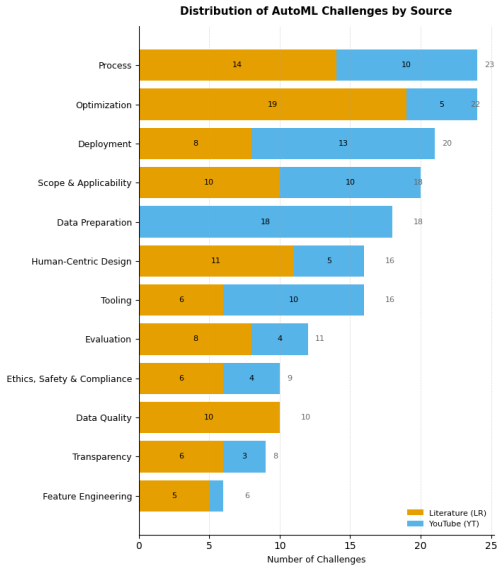

**Figure 5** Distribution of AutoML challenges per thematic group by source (LR vs. YouTube). Groups ordered by total challenge count.

are the sole documenters of *Data Preparation* challenges (18 challenges, 0 from LR), and contribute substantially to *Tooling* (10 YT vs. 6 LR) and *Deployment* (13 YT vs. 8 LR). The complete absence of Data Preparation challenges from the academic literature is particularly striking: issues such as fragmented data sources, business logic drift, imputation complexity, and format diversity are reported consistently and in granular detail by practitioners, yet remain essentially untheorized in the formal literature. This represents one of the clearest instances of the theory–practice gap this study documents.

**Cross-theme Reflections.** Examining practices and challenges together reveals a recurring and important structural pattern: the thematic areas where practitioners are most active in developing operational knowledge are precisely the areas where the literature most underrepresents challenges – and vice versa. *Optimization* illustrates this duality most clearly. It is simultaneously the group with the broadest practice documentation (34 practices, spanning HPO, NAS, meta-learning, and edge-aware deployment) and a source of persistent, well-documented challenges (22 challenges around search cost, generalization failures, and performance–cost trade-offs). Both communities recognize optimization as central to AutoML, but the literature frames it as a frontier research problem while practitioners treat it as a configurable workflow component – a distinction that shapes what each community considers a solution. *Data Preparation* presents the inverse pattern. Practitioners document it extensively as both a practice domain (28 practices) and a challenge domain (18 challenges), yet the literature contributes to neither. This bilateral absence from academic sources is not explained by the topic's simplicity – the granularity and specificity of practitioner-reported data preparation challenges (MNAR imputation, schema drift, multilingual NLP preprocessing) indicate that these are non-trivial engineering problems deserving formal treatment. *Human-Centric Design* exhibits yet another pattern: it is documented as a challenge primarily in the literature (11 of 16 challenges from LR), yet appears as a practice

relatively infrequently and predominantly in academic sources (4 of 8 practices from LR). This suggests that human-centered concerns are well-theorized but rarely operationalized – practitioners are not yet systematically building the human-in-the-loop mechanisms that the literature identifies as necessary.

Taken together, these findings confirm that AutoML research and practice operate in largely parallel, non-communicating worlds. The literature theorizes optimization, robustness, and human-AI interaction at a conceptual level, while practitioners have independently developed an extensive, operationally grounded body of knowledge around deployment, data preparation, and pipeline orchestration that research has scarcely acknowledged. This gap is not merely a communication problem – it reflects a structural misalignment in research priorities that risks making AutoML scholarship increasingly disconnected from the practitioners it purports to serve.

# 5 Discussion

Drawing on the synthesis across RQ1–RQ3, this section identifies open issues and research opportunities, and practical implications for AutoML researchers and practitioners.

## 5.1 Open Issues and Research Opportunities

Several open issues emerge from our analysis that warrant sustained attention from the research community. *Theory-practice gap.* The most immediate open issue is the absence of academic engagement with a large and coherent body of practitioner knowledge. Entire thematic areas – Data Preparation, Deployment, and Pipeline & Orchestration – are documented almost exclusively through practitioner sources, yet the challenges within these areas are neither trivial nor solved. Research that formalizes, evaluates, and builds upon this practitioner knowledge base – through empirical studies, tool evaluations, and replication studies in real-world settings – would substantially reduce this gap.

*Human-centered AutoML remains under-operationalized.* The literature consistently identifies human oversight, interpretability, and trust as critical requirements, yet practitioner content reveals that these properties are rarely built into AutoML workflows in practice. This gap calls for research into concrete mechanisms – human-in-the-loop interfaces, explainability-by-design frameworks, and participatory evaluation protocols – that translate human-centered principles into implementable AutoML components.

*Ethics, fairness, and compliance are structurally underserved.* With only 9 challenges identified in Ethics, Safety & Compliance and limited practitioner engagement with fairness and bias, this study finds that ethical dimensions of AutoML remain at the periphery of both research and practice. As AutoML systems are increasingly deployed in high-stakes domains – healthcare, finance, criminal justice – the absence of standardized fairness evaluation protocols, privacy-preserving automation techniques, and accountability mechanisms represents a risk that the community must proactively address.

## 5.2 Implications for Practice

The findings carry concrete implications for practitioners integrating AutoML into production.

**Treat AutoML as a continuous process, not a one-time automation task.** The dominance of Deployment, Data Preparation, and Pipeline & Orchestration in practitioner-reported practices reflects a mature understanding that AutoML value is realized over time, through

structured experimentation, versioned artifacts, and automated retraining pipelines – not through a single tool invocation. Practitioners should invest in CI/CD integration, metadata capture, and automated monitoring from the outset.

**Resource management is a first-class concern.** Optimization-related challenges – excessive training time, memory failures, and cost–performance trade-offs – are reported consistently across practitioner sources. Rather than relying on tool defaults, practitioners should define explicit computational budgets, employ adaptive early stopping, and conduct cost-effectiveness analysis throughout the AutoML lifecycle. Hardware-aware scheduling and parallelization strategies represent immediately actionable mitigations.

**Operationalize interpretability before deployment, not after.** The literature's strong emphasis on transparency and human-centric design offers practitioners a clear prescriptive signal that is currently underheeded. Embedding explainability dashboards, model lineage tracking, and human-in-the-loop validation checkpoints throughout the AutoML lifecycle – rather than as post-hoc additions – is particularly critical in regulated or high-stakes domains where auditability is not optional.

## 6 Threats to Validity

This study follows established guidelines for multivocal literature reviews in software engineering [13], and addresses construct, internal, external, and conclusion validity threats as deliberate methodological considerations rather than residual limitations. **Construct validity.** The primary threat concerns operationalizing *practices* and *challenges* across heterogeneous sources that differ in terminology, abstraction, and communicative intent. We mitigated this by defining a unified extraction protocol and shared codebook before data collection and refining constructs through pilot coding. Multiple researchers independently assigned codes, and thematic groupings were reconciled through structured discussion, with disagreements resolved by returning to the source material to keep codes evidence-grounded rather than merely negotiated. **Internal validity.** Two sources of selection bias warrant acknowledgment. First, the LR dataset is restricted to secondary studies (i.e., literature reviews and surveys) meeting our inclusion criteria. Second, the gray literature corpus is intentionally scoped to YouTube, excluding other practitioner channels such as blogs, forums, and webinars. The YouTube dataset is subject to platform visibility bias, as search rankings reflect engagement metrics and recency rather than epistemic quality. We mitigated this by conducting all searches in incognito mode to minimize personalization effects, and by making all search strings, inclusion and exclusion criteria, and sampling decisions fully explicit and reproducible. **External validity.** Findings characterize AutoML knowledge as represented in peer-reviewed secondary literature and publicly available English-language practitioner videos. Generalizability is bounded in three respects: results may not transfer to proprietary industrial environments; they exclude non-English-speaking communities that may exhibit distinct adoption patterns; and they omit other gray-literature channels such as blogs, forums, and webinars. The multivocal design partially mitigates this by triangulating white and gray literature, but we make no claim of statistical representativeness. **Conclusion validity.** Reported counts are frequency indicators from a qualitative coding process, not statistical prevalence estimates. Thematic distributions are presented through bar charts and taxonomy figures to reveal structural patterns rather than confirm hypotheses. We mitigated confirmation bias through independent coding, iterative codebook refinement, and full documentation of the analysis, all available in the replication package [2].

## 7 Conclusion

This study conducted a multivocal literature review synthesizing 16 peer-reviewed publications and 30 practitioner YouTube videos, identifying 229 actionable AutoML practices across 12 thematic groups and 177 challenges across 12 thematic groups. The central finding is a striking structural asymmetry: only 6 practices (2.6%) and 9 challenges (5.1%) were corroborated by both sources. Practitioners are the near-exclusive documenters of operational knowledge – Deployment, Data Preparation, and Pipeline & Orchestration – while the literature disproportionately covers theoretically grounded challenges in Data Quality, Ethics & Compliance, and Evaluation. The result is two coherent but largely non-communicating knowledge bases: one theoretically sophisticated, the other operationally rich. This structural misalignment risks making AutoML scholarship increasingly disconnected from the practitioners it purports to serve. Key open issues include incomplete end-to-end pipeline automation, underdeveloped human-centered design, inadequate benchmarking infrastructure, and a near-total lack of academic engagement with data preparation challenges. In future work, we plan to extend the corpus to complementary gray-literature channels (blogs, forums, conference talks) and validate findings through interviews with AutoML practitioners.

## Data Availability Statement

The replication package [2] includes the search strings, inclusion and exclusion criteria, extracted data, and the codebook with definitions and representative examples, made openly available to support transparency, auditability, and replication. The online appendix [1] provides the complete browsable catalog of all 229 actionable practices and 177 challenges across all 12 thematic groups and subgroups, intended as an open reference for researchers and practitioners.

## Abstract

**Background.** Agents have recently improved LLM-based vulnerability detection through retrieval, iterative analysis, and verifier modules. However, existing evaluations mainly report improvements in detection performance without determining whether these improvements reflect more reliable vulnerability reasoning or access to retrieved context.

**Aims.** This study investigates how different agent components affect the reasoning-oriented evaluation dimensions of agent-based vulnerability detection.

**Method.** We present a controlled measurement framework with six conditions and evaluate it on six base models. The conditions progress from plain single-pass prompting through matched-context replay and ReAct-style tool use to self-review, trace-isolated verification, and multi-role decomposition, allowing us to separate context effects, iterative orchestration, and added agent modules under a shared protocol. Beyond vulnerability detection performance metrics, our framework evaluates three reasoning-oriented dimensions: *robustness* under semantics-preserving perturbations, *resistance* to misleading non-causal context, and *grounding* in concrete code evidence.

**Results.** The full agent often achieves higher accuracy or F1 than plain single-pass prompting, but these improvements do not consistently extend to the three measured behavioral dimensions of robustness, resistance, and grounding. The models are not consistently more stable under harmless code changes, are often misled by non-causal prompt cues, and rarely cite the exact code lines that explain the vulnerability. In the strongest improvement case, much of the accuracy change already appears when the model receives the same retrieved tool outputs without the full agent process; after that context is held fixed, the remaining agent effect is mainly associated with predicting vulnerable more often.

**Conclusions.** Higher detection performance should not be taken as direct evidence of better vulnerability reasoning. In our experiments, better performance metrics can reflect retrieved context or changes in how often the model predicts vulnerable, rather than a clear improvement in stable, evidence-based vulnerability reasoning. Future evaluations should report these behavior checks alongside performance metrics.

## 1 Introduction

Vulnerability detection is a semantic judgment about code, not only a binary classification task. A detector must decide whether reachable behavior can violate a security property by following dependencies, recognizing guards or sanitizers, locating dangerous operations, and understanding patch effects. Classical work grounds such judgments in data/control flow, source–sink relations, and patch behavior [35, 13, 1]. Recent LLM evaluations show why this matters: models can appear accurate while relying on identifiers, formatting, surrounding snippets, or other shallow cues instead of the causal code path [29, 19, 25].

We use *reliable vulnerability reasoning* as an operational term grounded in observable detector behavior. A detector is more reliable when it bases its decisions on security-relevant semantics and causal evidence. Examples include data or control flows to dangerous operations, guards and sanitizers, causal reasoning, and patch effects, rather than surface cues or non-causal context. We operationalize this notion through three dimensions used throughout the paper: *robustness* to semantics-preserving code changes, *resistance* to misleading non-causal context, and *grounding* in concrete code evidence and consistent rationale. These dimensions follow prior evaluations that separate semantic code analysis from pattern matching [19] and check whether explanations match the true root cause [29].

LLM-based vulnerability detection has advanced rapidly. Agent detectors combine tools, retrieved context, iterative analysis, verification, and multi-role decomposition, and often report higher precision, recall, or F1 than plain prompting [37, 9, 20, 32, 34, 24, 28, 23]. However, a full-agent-versus-plain-baseline comparison changes several factors at once: the available information, how it is selected and processed, the organization of model calls, and potentially the predicted-label distribution. Existing studies usually compare complete systems or remove individual modules without holding the agent-selected tool observations fixed. This leaves a specific evaluation gap: aggregate improvements cannot be attributed to retrieved information, residual iterative processing over that information, or a shift toward one label. JITVUL's report that some configurations predict "vulnerable" on more than 90% of inputs illustrates the risk: recall and F1 can rise without better pair-level discrimination [37]. Without such attribution, higher end-to-end metrics do not establish more reliable vulnerability reasoning or show whether added orchestration is warranted.

**Research questions.** Motivated by this gap, we ask: **RQ1.** How well do agent-based conditions preserve their verdicts under semantics-preserving repository changes? **RQ2.** How well do agent-based conditions resist non-causal repository distractors and opposite-label prompt cues? **RQ3.** How well are agent-based vulnerability predictions grounded in code evidence and consistent under paired patches? These questions operationalize robustness, resistance, and grounding, respectively.

**Approach.** To answer these questions, we combine a matched attribution chain with three behavioral evaluations. The chain compares plain single-pass prompting (C1), matched-context single-pass replay (L1), and the corresponding interactive ReAct agent (C2). L1 receives exactly the observations selected by the matched C2 agent. Because C1→C2 changes both the available context and the process used to select and analyze it, C1→L1 captures change recoverable from the C2-selected trace, whereas L1→C2 estimates the conditional residual of interactive execution under C2's retrieval policy.C3–C5 test common extensions beyond the basic ReAct condition: self-review, trace-isolated verification, and plan–execute–verify role decomposition. They assess whether self-correction, independent re-analysis, or role specialization adds value beyond the basic agent condition [20, 32, 23].

We apply the six conditions to JITVUL across six base models. Repository-synchronized semantics-preserving perturbations address RQ1, misleading-context interventions address RQ2, and evidence localization, CWE classification, and paired-patch counterfactuals address RQ3. SecVulEval and SV-TrustEval-C provide complementary grounding and semantic-change checks. RQ1 and RQ2 are label-preserving, while the paired-patch component of RQ3 tests response to a causal label change.

**Evaluation.** We conduct a controlled, matched, cross-model evaluation. Within each contrast, the base model, analysis instance, repository snapshot, output schema, and execution controls are held fixed. This design combines aggregate detection metrics with controlled behavioral checks and tests whether the observed patterns recur across base models.

Applying this framework, we find that reported improvements in vulnerability detection should be interpreted cautiously. The central pattern is not that additional agent components reliably improve the measured reasoning-oriented dimensions, but that improvements in aggregate detection metrics are model-dependent and partly entangled with predicted-vulnerable-rate shifts. In the strongest aggregate-metric-improvement replication, DeepSeek-V3.2 improves by +0.279 F1, while pair-level accuracy changes by only +0.054; on the full matched sample, much of the C1→C2 pair-level accuracy change is already present after replaying the C2-selected tool trace, although the exact recovery ratio is stratum-sensitive. These improvements also do not consistently lift the reasoning-oriented dimensions: perturbation flip rates rise on five of six base models, self-review increases rather than reduces sensitivity, and grounding remains near the floor across conditions.

**Contributions.** This paper makes the following contributions:

- **Measurement Framework.** We define a reusable measurement framework that attributes observed changes to the portion recoverable through replaying an agent-selected tool trace and the residual associated with interactive execution over that trace. It organizes robustness, resistance, and grounding as complementary behavioral evaluation dimensions centered on a matched-context single-pass baseline. We will release the framework implementation and experimental artifacts as a public replication package.

- **Controlled Empirical Evaluation.** We apply the framework in a controlled cross-model study with six executable conditions and three intervention families. JITVUL serves as the main paired benchmark, while SecVulEval and SV-TrustEval-C provide the grounding and semantic-change checks used to answer RQ1–RQ3.
- **Empirical Analysis of Agent Gains.** Our experiments show that adding agent components does not consistently improve robustness, resistance, or grounding. Across six base models, reported gains co-vary with predicted-vulnerable-rate shifts, and matched-context replay reveals that a substantial portion of pair-level accuracy change already emerges after replaying the C2-selected tool trace.

# 2 Background and Related Work

## 2.1 Tool-Using LLM Agents

Agent-based vulnerability detection augments a target-function prompt with repository-level tool use. A ReAct-style agent alternates reasoning, tool calls, and observations before issuing a verdict [36]; tools may retrieve repository evidence such as definitions, dependencies, data-flow facts, or patch context [17, 37, 9]. We distinguish *retrieved context*, the evidence returned by tools, from *iterative reasoning*, the process that selects tools and updates the analysis. This distinction creates an attribution problem: improvements in aggregate detection metrics may come from the selected tool trace, the residual ReAct-loop effect, self-review or verification, or a predicted-vulnerable-rate shift. Section 3 therefore defines matched-context conditions that hold the C2-selected tool trace fixed.

## 2.2 Plain-LLM Vulnerability Detection

LLM-based vulnerability detection builds on earlier ML and deep-learning work on graph-based detectors, CVE-derived datasets, and vulnerability-detection baselines [39, 7, 3]. Recent plain-LLM work improves vulnerability detection through prompting, model adaptation, and context enhancement [10, 14, 27, 38, 6, 22, 16, 33]. These studies improve end-task performance, but a complementary diagnostic line asks what detectors actually rely on. Perturbation and semantic-reasoning benchmarks expose weak causal grounding; results vary sharply by model and prompt; and syntactic metrics can match or manipulate detector predictions [29, 19, 25, 21, 31]. These findings motivate tests of stability under semantics-preserving changes, resistance to non-causal context, and root-cause grounding.

## 2.3 Agent-Based Vulnerability Detection

Repository-level analysis has pushed vulnerability detection from single LLM calls to tool-using agents. JITVUL, RepoAudit, and recent multi-agent systems add ReAct loops, memory or validators, role decomposition, routing, parallel agents, or confidence-based escalation [37, 9, 32, 20, 34, 24, 28, 23]. Existing ablations are useful for testing whether a module matters, but they usually remove validators, rounds, or escalation stages from the full pipeline. They therefore do not separate the value of the selected tool trace from the residual value of iterating over that trace on the same input. Related agent benchmarks also show that aggregate performance can depend strongly on architecture or implementation choices [2, 18]. Table 1 summarizes these gaps and our coverage.

# 3 Methodology

We use a paired, matched design in which each contrast fixes the analysis instance, repository snapshot, tool suite, and output schema while varying only the condition or intervention. L1 is the central matched-context control, and three intervention families evaluate robustness, resistance, and grounding.

## 3.1 Conditions

We study six conditions that isolate design primitives commonly varied in current agent-based vulnerability detectors: tool access, iterative reasoning, self-review, independent verification, and multi-role decomposition. Figure 1 summarizes the paired instances, condition family, and interventions. The main attribution chain is C1→L1→C2. C3, C4, and C5 test additional agent components. We reserve C-labels for independently executable detector configurations; L1 denotes a matched trace-replay baseline because it is defined only after C2 has selected a tool trace.

**C1** (plain CoT) sees only the target function and emits a single-pass verdict. **L1** receives exactly the tool observations that C2 retrieved on the same input, in the same order, and then emits a single-pass verdict. **C2** (ReAct agent) iterates through thought–action–observation cycles with dynamic tool calls. **C3** adds self-review on top of C2: the model inspects its own reasoning after the verdict and revises only if it identifies a concrete mistake. **C4** adds an external, trace-isolated verifier that sees neither the detector's verdict nor its reasoning trace; the detector and verifier use the same output schema, and an evidence-aware merge rule produces the final verdict while preserving both intermediate records for audit. The merge keeps the detector verdict when detector and verifier agree; when they disagree, it selects the verdict whose record cites at least one target-file evidence line and has higher confidence, falling back to the verifier verdict if neither side provides target-file evidence. **C5** implements a plan–execute–verify multi-role architecture [20, 32, 23]. We treat C5 as a bundled-architecture comparison rather than a single ablation step.

The C1-vs-C2 contrast mixes two effects: the information contained in the C2-selected tool trace and the residual effect of the ReAct loop over that trace. L1 fixes the tool trace selected by C2, following prior work that treats access to retrieved information and reasoning over that information as distinct capabilities [12, 30]. The step C1→L1 measures how much of the C2 change is recoverable once the model is given the same tool trace selected by the agent. The L1→C2 step captures the remaining difference between static trace replay and interactive execution, including the tool-selection dynamics embedded in C2's trajectory. The chain therefore provides an attribution under the agent's retrieval policy: C1→L1 is the replay-recoverable component, and L1→C2 is the interactive residual. A fixed-policy retriever, such as call-graph retrieval, would provide a complementary attribution under a different selection policy (§ 6).

RQ1 uses C1→L1→C2 as its primary chain, with C3–C5 supplementary; RQ2 compares C1, C2, and C4-aware/blind under D1–D2; and RQ3 evaluates all six conditions, with patch consistency restricted to eligible reruns (Table 2).

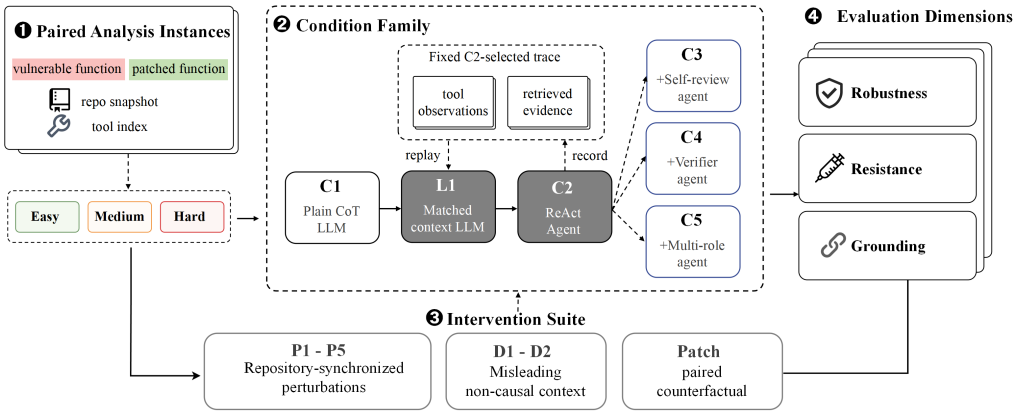

**Figure 1** Study framework. Paired vulnerable–patched instances feed the condition family; P1–P5, D1–D2, and patch counterfactuals audit robustness, resistance, and grounding.

## 3.2 Interventions

The intervention families map directly to the RQs: RQ1 uses P1–P5 for robustness, RQ2 uses D1–D2 for resistance, and RQ3 combines paired-patch counterfactuals with evidence and CWE analyses for grounding. P1–P5 and D1–D2 preserve the ground-truth label and target reachability. Code-changing interventions rebuild prompts and tool indices; patch replacement is the only label-changing intervention and is evaluated separately for RQ3.

**Table 2** Research-question-to-design mapping.

| RQ | Datasets | Conditions | Interv. | Measures | Analysis | Interp. |
|---|---|---|---|---|---|---|
| RQ1 | JITVUL; SV-TrustEval-C (aux.) | C1→L1→C2; C3–C5 | P1–P5 | FR; Δ-Acc; PFC | matched; CIs | robustness |
| RQ2 | JITVUL | C1; C2; C4 aware/blind | D1–D2 | FR; cue response; reversals | McNemar; directional | resistance |
| RQ3 | JITVUL; SecVulEval | C1; L1; C2–C5 | paired patch | CWE Top-1/3; evidence F1; Faith | est.; corr.; audit | grounding |

**Repository perturbations (P1–P5).** For RQ1, Table 3 summarizes five semantics-preserving changes: renaming identifiers (P1), changing function names (P2), adding unreachable code (P3), inserting dead functions (P4), and formatting changes (P5). These perturbations test *robustness*: whether detectors maintain consistent predictions under small, semantics-preserving code changes. Together they cover surface signals that vulnerability detectors may overuse: lexical cues in identifiers and function names, visible but non-causal code within or outside the target function, and presentation-level formatting. All edits run on temporary repository copies with the tool index rebuilt. P1 and P2 rename variables and functions consistently across prompt, repository, and call sites. P3 inserts syntactically valid `if (0)` blocks containing vulnerability-looking operations, P4 adds unused helper functions with vulnerability-like patterns, and P5 applies AST-preserving whitespace normalization. After each perturbation, definition lookup, caller/callee tracing, and file-level retrieval all operate on the same perturbed snapshot shown to the model. We validate perturbations by checking that the target function remains locatable, the repository index can be rebuilt, and the ground-truth vulnerable/safe label remains unchanged; failed materializations are excluded from the matched denominator for both members of the comparison.

**Misleading non-causal context (D1–D2).** For RQ2, Table 3 summarizes two interventions that test *resistance*. D1 injects unrelated repository code and rebuilds the corresponding tool index, so the distractor is available through the same retrieval interface as other repository content. The injected code is drawn from a different project or non-overlapping module, contains vulnerability-looking tokens or API calls, is not reachable from the target function, and is checked not to modify the target function, patch, call graph, or ground-truth label. D2 adds a one-sentence opposite-label prompt cue (vulnerable samples are framed as safe, and safe samples are framed as vulnerable). This is an adversarial stress test for non-causal task framing: realistic workflows may contain fallible cues such as issue reports, review comments, static-alert summaries, or commit messages, and D2 intentionally instantiates the worst-case opposite-label version of such a cue. The D2 cue is not evidence and does not modify the repository, patch, call graph, or label; it tests whether the model follows a non-causal prompt cue over code evidence. The RQ2 analysis focuses on C1, C2, and C4 because these conditions separate plain prompting, tool-using agent analysis, and independent verification. For C4, we distinguish *aware* verification (the verifier sees the misleading signal) from *blind* verification (the verifier sees only the clean target). This contrast tests whether verification helps through re-analysis or through controlled exposure.

**Patch counterfactuals and grounding checks.** For RQ3, this intervention tests *grounding* through the vulnerable–patched pair structure. Unlike P1–P5 and D1–D2, it is not label-preserving. For vulnerable samples, we replace the target function with its paired patched version and rebuild the corresponding prompt and tool index. We then evaluate grounding along three aspects. Evidence localization asks whether the cited code overlaps vulnerability-relevant code. CWE classification asks whether the predicted weakness type matches the ground truth. Patch-based counterfactual consistency asks whether a `vul` verdict changes to `safe` after the paired patch removes the vulnerability. Detailed evaluation procedures are described in § 4.4. Table 3 summarizes the three intervention families.

**Table 3** Intervention taxonomy.

| Dim. | ID | Change and signal tested |
|---|---|---|
| Rob. | P1 | Rename local identifiers; tests variable/parameter lexical cues. |
| | P2 | Rename target functions and call sites; tests function-symbol lexical cues. |
| | P3 | Add an unreachable block inside the target; tests local, visible but non-executable code. |
| | P4 | Add an unused helper outside the target; tests repository-level code off the call path. |
| | P5 | Reformat code without AST changes; tests presentation-only cues. |
| Res. | D1 | Inject unrelated repository code; tests retrievable but non-causal code evidence. |
| | D2 | Add an opposite-label prompt cue; tests prompt cues without code evidence. |
| Grd. | Patch | Replace vulnerable target with paired patch; label-changing causal counterfactual. |

# 4 Experimental Setup

## 4.1 Research Questions

As introduced in Section 1, the study is organized around three research questions corresponding to robustness, resistance, and grounding. This section operationalizes them through the interventions and condition comparisons defined in Section 3.

**RQ1. How well do agent-based conditions preserve their verdicts under semantics-preserving repository changes?** This RQ focuses on understanding whether agent-based vulnerability detectors are robust to semantics-preserving code perturbations. We examine P1–P5 perturbations and use the C1→L1→C2 attribution chain to distinguish robustness changes already present after replaying the C2-selected tool trace from residual changes introduced by the ReAct loop. We also use an external semantic-change check to ensure that stability under semantics-preserving changes does not simply reflect insensitivity to real semantic changes. The semantic-change check is auxiliary rather than part of the matched JITVUL perturbation experiment.

**RQ2. How well do agent-based conditions resist non-causal repository distractors and opposite-label prompt cues?** In this RQ, we examine whether tool-using agents and verifier-based conditions can ignore misleading non-causal context that is visible to the model but not related to the vulnerability. We analyze repository-level distractors, opposite-label prompt cues, and the aware/blind verifier contrast for C4 to separate independent verification from controlled exposure to the misleading signal.

**RQ3. How well are agent-based vulnerability predictions grounded in code evidence and consistent under paired patches?** With this RQ, we examine whether verdict-level gains are accompanied by stronger observable grounding in vulnerability evidence. We evaluate grounding through evidence localization, CWE classification, and patch-based counterfactual consistency when vulnerable code is replaced by its paired patch.

## 4.2 Datasets and Sampling

**Dataset roles.** We use three datasets with distinct experimental roles. JITVUL is the main dataset for all RQs because it provides repository-level context, vulnerable–patched function pairs, and CWE annotations. This structure supports perturbation tests, misleading non-causal context tests, and patch-based counterfactuals on the same paired units. SecVulEval is used for the RQ3 evidence-localization analysis because it provides statement-level evidence labels, which allow us to evaluate whether cited evidence overlaps with vulnerability-relevant code. SV-TrustEval-C is used as an external semantic-change check for RQ1. It is not merged into the matched JITVUL perturbation experiment; instead, it checks whether conditions that appear stable under semantics-preserving perturbations still respond to genuine semantic changes.

**Difficulty-stratified paired sampling.** Our main sample uses difficulty-stratified paired sampling over eligible JITVUL pairs with complete repository snapshots. For each pair $p$, we compute a pair-level competence score $s(p) \in \{0, \ldots, 6\}$ by counting correct zero-shot CoT predictions across the vulnerable and patched versions under three reference models: gpt-5.4, Claude Sonnet 4.6, and DeepSeek-V3.2. We partition pairs into $\mathcal{S}_{\text{easy}} = \{s \in \{4, 5\}\}$, $\mathcal{S}_{\text{med}} = \{s = 3\}$, and $\mathcal{S}_{\text{hard}} = \{s \in \{0, 1, 2\}\}$. We then draw 50 pairs from each stratum. The resulting JITVUL sample contains 150 pairs, or 300 function instances. These pairs define the statistical units of the main study. Each pair is reused across conditions, perturbation states, misleading-context variants, base models, and patch-based counterfactual reruns. The experiment therefore estimates behavioral changes within pairs.

**Rationale.** The paired design requires a detector to distinguish a vulnerable function from its patched counterpart rather than rely on project-level, style-level, or vulnerability-prior shortcuts. Stratification serves a separate purpose. It ensures that the experiment covers cases that current LLMs usually solve, cases on which they disagree, and cases that all reference models find difficult. This prevents the mechanism analysis from being dominated by the natural difficulty distribution of the dataset.

**Supplemental stratified evidence set.** For SecVulEval, we construct a difficulty-stratified supplemental sample with 50 instances per stratum. This set is used only for the RQ3 evidence-localization analysis, where statement-level labels are needed to measure evidence localization directly. JITVUL remains the primary dataset for pair-level verdicts, CWE evaluation, and patch-based counterfactuals.

**Voting/evaluation overlap.** gpt-5.4 and DeepSeek-V3.2 appear in both the voting pool and the evaluation pool. We therefore interpret difficulty-stratified results through within-model condition contrasts. The voting procedure defines strata before the agent conditions are compared; it does not affect the matched within-model contrasts reported here.

## 4.3 Models and Execution Pipeline

**Model selection.** We selected six base models to span three dimensions relevant to agent-based vulnerability detection: model access, scale, and code specialization. The pool includes closed-weight frontier models, large open-weight general-purpose models, and smaller code-specialized models. Open-weight models range from 14B to 671B parameters, covering small,

mid, and large tiers. One additional closed-weight frontier model is used only for difficulty stratification (Table 4). We treat a finding as cross-model only when its direction holds for a majority of the six base models.

**Execution controls.** All matched conditions use the same repository snapshot, tool suite, output schema, deterministic decoding setting ($T$=0), fixed per-sample seed, and versioned repository index. The tool suite includes target-function lookup, caller/callee tracing, symbol search, file-content retrieval, and static-alert retrieval when available. Each tool-using role runs under the same per-role tool-call budget; if the budget is exhausted, that role must produce its output from the observations already collected. Multi-role conditions can therefore cost more overall, but no individual role receives a larger retrieval budget. Prompt templates and tool descriptions are identical across base models, with no model-specific tuning. These controls keep the comparison focused on condition design rather than differences in infrastructure or prompting.

**Output schema and parsing.** Every condition is parsed into the same structured record: `verdict` in {`vulnerable`, `safe`}, numeric `confidence`, `evidence_lines`, `evidence_files`, `evidence_functions`, ranked `cwe_top3`, and a free-text rationale. Agent conditions also store the full thought–action–observation trace and tool errors; C4 additionally stores the detector and verifier records before the merge. We score only parsed records with a valid binary verdict. Data errors such as a missing target function or failed snapshot materialization are removed pairwise from the affected matched comparison rather than imputed as wrong predictions, so condition denominators can differ slightly; each table reports them.

## 4.4 Evaluation Protocol

**Experimental procedure.** The main JITVUL experiment uses 150 vulnerable–patched pairs (300 function instances) as the statistical units. Each instance is evaluated under the six conditions using the same repository snapshot, tool suite, and output schema. We then reuse the same paired units for matched intervention runs: P1–P5 for RQ1, D1–D2 for RQ2, and patch-based counterfactual reruns for RQ3. Supplemental SecVulEval and SV-TrustEval-C runs are evaluated separately for statement-level evidence and semantic-change checks. Intervention runs add observations, not independent samples.

**Matched analysis.** All primary comparisons are within-model contrasts on matched samples. For detection performance, we report instance-level metrics and pair-level accuracy (pAcc), where a pair is correct only if both the vulnerable and patched versions are classified correctly. For condition effects, we compare predictions made by the same base model on the same sample and snapshot. We report both pooled results over the 150 JITVUL pairs and stratified results by difficulty. Cross-model claims are based on whether the direction of the within-model effect holds for a majority of base models.

**Measures and statistical support.** Clean detection uses Acc, Precision, Recall, F1, MCC, pAcc, and VulBias. VulBias is the predicted-vulnerable rate, i.e., the fraction of valid instances predicted `vulnerable`; pAcc is pair-level accuracy and is correct only when both members of a vulnerable–patched pair receive the expected labels. RQ1 reports flip rate (FR), accuracy change ($\Delta$-Acc), and pairwise flip consistency (PFC). RQ2 reports FR, susceptibility to the injected cue, and D2 reversal direction, including clean-correct cases destroyed, denoted

CC→WH, and clean-wrong cases repaired, denoted CW→Corr. RQ3 reports CWE Top-1/Top-3 accuracy, evidence F1 against SecVulEval statement labels, and patch-replacement consistency (Faith), following rationale/evidence and faithfulness evaluation work [4, 11]. Faith is an auxiliary subset-dependent diagnostic computed on eligible vulnerable instances that are initially predicted `vulnerable`.

For matched binary verdicts, we use McNemar's exact test; for other metrics, we report bootstrap confidence intervals. Reported $p$-values support planned matched contrasts, not a multiple-comparison discovery procedure. Cross-cell patterns are interpreted through effect sizes, available intervals, and directional consistency across matched units. With $N = 150$ pairs, we treat small effects as interval estimates rather than definitive null results.

# 5 Experimental Results

This section first calibrate aggregate performance and then evaluate RQ1–RQ3. Unless stated otherwise, claims are within-model matched contrasts; cross-model statements require a recurring direction across the six complete JITVUL pipelines.

## 5.1 Baseline Calibration

**Result.** The C2 ReAct agent reproduces improvements in aggregate detection metrics on several base models, but the same C1→C2 transition shows heterogeneous patterns: clear positive pair-level accuracy change on some base models, near-neutral change on others, and change dominated by a shift in the predicted-vulnerable rate on others. These aggregate improvements therefore need to be examined alongside robustness, resistance, and grounding before they can support claims about reasoning reliability. The conditional L1 contrast estimates the residual ReAct-loop effect over a fixed C2-selected trace.

The clearest replication is DeepSeek-V3.2. F1 increases from 0.351 to 0.630, while pAcc moves only from 0.068 to 0.122. The matched-context replay condition changes the interpretation: on the full matched sample, replaying the C2-selected observations in L1 reproduces much of the observed C1→C2 pAcc change, while the remaining L1→C2 pAcc change is only +0.007 and is not detected by the matched test at this scale, with $p = 1.0$. C2's larger visible effect is instead a predicted-vulnerable-rate shift, with DeepSeek's VulBias moving from 0.270 at C1 to 0.805 at C2.

The other base models show why the calibration matters. The same agent scaffold improves pair-level detection for Qwen3.6-27B and Qwen2.5-Coder-14B, leaves it approximately unchanged for gpt-5.4 and DS-Coder-V2-Lite, and degrades it through a safe-side collapse for gpt-oss-120b. C5 follows the same model-dependent pattern, so role decomposition alone does not explain the aggregate gains.

The main C1→C2 direction persists across strata, but L1's exact recovery ratio is stratum-dependent; aggregate metrics alone therefore do not establish better robustness, resistance, or grounding.

## 5.2 RQ1: Robustness to Semantics-Preserving Perturbations

**Result.** The condition chain does not make verdicts more stable under semantics-preserving edits in our matched perturbation runs. From C1 to C2, aggregate flip rate increases on five of six complete pipelines. The exception is gpt-oss-120b, whose lower FR co-occurs with its collapse toward `safe`, not with better discrimination. The important pattern is repeated reversibility: for the four most affected base models, more than half of evaluable samples flip under at least two of the five semantics-preserving perturbation families.

**Table 5** Clean JITVUL performance, pooled across difficulty strata. ΔpAcc/F1/VulBias are computed against the same model's C1. ↑/↓ mark pAcc change against the preceding step in C1→L1→C2. **L1** is the matched-context baseline. C2 shading marks clear pair-level gain sage, strong predicted-vulnerable-rate shift or collapse coral, and near-neutral change gray. C5 is a bundled multi-role reference condition, not part of the C1→L1→C2 ablation chain.

| | | Absolute metric (clean baseline) | | | | | Delta vs. C1 | | |
|---|---|---|---|---|---|---|---|---|---|
| **Model** | **Cond.** | Acc | F1 | MCC | pAcc | VulBias | ΔpAcc | ΔF1 | ΔVB |
| DeepSeek-V3.2 | C1 | 0.500 | 0.351 | +0.000 | 0.068 | 0.270 | – | – | – |
