**Exclusion criteria.** However, our study focuses specifically on software projects, excluding repositories that serve educational, demonstrative, or curatorial purposes. Therefore, we removed projects whose name or description contained any of the following terms: *scratch, papers, paper, colab, education, course, tutorial, guide, example, lessons, list, sample, notebook, deprecated, abandoned, articles, notes, doc, or demo.* This list was constructed inductively by manually reviewing the names and descriptions of the initial set of 1281 projects and identifying terms commonly associated with non-software or auxiliary content.

Additionally, some repositories matched our initial criteria but were unrelated to LLMs due to ambiguous terminology. For example, the term “gpt” may refer to the GUID Partition Table, rather than to Generative Pretrained Transformer. To mitigate such false positives, we refined the selection by requiring that a project include at least three of the following LLM-related topics: *ai, chatgpt, dall-e, generative-ai, generativeai, gpt, llm, chatbot, transformers, language-model, Chatbots, llms, agent, gemini, llama, app, ui, claude, artificial-intelligence, Large-language-models, lora, mistral, Langchain, Assistant, Ollama, agents, bert.* This list was compiled by examining the complete set of topics present across all 1281 initially collected repositories. After applying these additional topic-based and content-based filters, the final dataset consisted of 565 software projects that are suitable for our empirical analysis.

### 3.2.2 LLM Parameter Extraction

Large Language Model parameters are configuration settings that govern how a model produces text during prediction. These parameters allow developers to finetune model behavior, influencing characteristics such as creativity, determinism, verbosity, and lexical diversity. Understanding how these parameters are configured in realworld software projects provides insight into usage patterns and developer preferences.

In this work, we analyze how developers modify LLM parameters within their software repositories. We focus on the parameters that modern large language models commonly support, namely: temperature, top-k, top-p, min-p, frequency penalty, presence penalty, repetition penalty, and maximum tokens [8, 11].

To extract these configurations, we clone each selected Python project and statically analyze its source code using Python's built-in `ast` module. AST-based parsing detects parameter values accurately across variable assignments, function calls, dictionary structures, and class instantiation patterns. This approach ensures robust identification while avoiding false positives caused by comments, examples, or documentation. Each extracted parameter instance is represented as a row in our dataset and includes: **project name, file path, line number, parameter name, and assigned value**.

**Path exclusions.** To ensure that we capture only parameters relevant to the actual system behavior, we exclude files whose paths contain any of the following terms: *doc*, *test*, *readme*, *fixture*, *benchmark*, *example*, *deprecated*, *not_working*, *demo*, *beta*, *migrations*, *sample*, *lock*, *evaluation*, or *result*. These directories typically contain non-production or auxiliary artifacts. After applying these path exclusions, our final dataset contains **7892 LLM parameter definitions** extracted from **363 projects**. It should be noted that when extracting the parameters from the 565 selected projects, solely 363 projects remained because others: (i) defined the parameters in some path that we excluded or (ii) only used the model with default parameters.

## 4 Results

**RQ1: Which LLM parameters are defined by developers in real-world software projects?** To answer this question, we obtained the number and percentage of projects that define each parameter from our dataset. Table 1 shows this information. We can highlight that the *temperature* parameter is defined in a majority of projects (90.36%), followed by the *max_token* and *top_p* parameters, which are defined in slightly more than half of the projects, and the *top_k* parameter, which is defined in 42.70% of the projects. We can observe that the penalty parameters (*repetition_penalty, presence_penalty, and frequency_penalty*) are used much less frequently (20.11%, 19.28% and 18.46% respectively). Finally, the *min_p* parameter is defined in only 16 projects (4.41%). These figures suggest that, in practice, developers prioritize sampling diversity/length controls over penalty-style regularization.

Findings (RQ1).

Most projects explicitly define *temperature*; over half define *max_tokens* and *top_p*, while penalty parameters are defined much less frequently. Overall, developers tend to control sampling and output length more often than repetition-related penalties.

**Table 1 Definition of parameters in projects.** Number and percentage of projects that define each parameter.

| Parameter | # Projects | Projects (%) |
|---|---|---|
| temperature | 328 | 90.36% |
| max_tokens | 206 | 56.75% |
| top_p | 181 | 49.86% |
| top_k | 155 | 42.70% |
| repetition_penalty | 73 | 20.11% |
| presence_penalty | 70 | 19.28% |
| frequency_penalty | 67 | 18.46% |
| min_p | 16 | 4.41% |

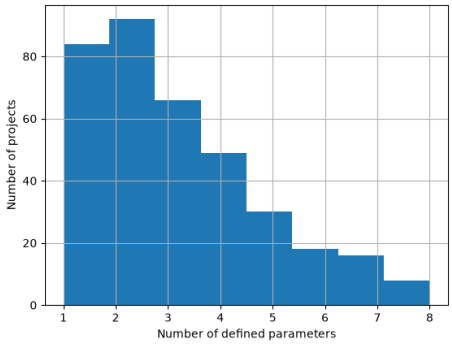

**Figure 2** Histogram of projects based on the number of parameters they define.

**RQ2: How complex are LLM configurations at the project level, and how is this complexity structured across parameters?** To understand the complexity of LLM configurations at the project level, we first examine the number of parameters defined in each project. Figure 2 shows the histogram of projects based on the number of parameters they define. We can observe that almost half of the projects define one or two parameters (176 projects). Next, there are 66 projects that define three parameters, followed by 49 projects that define four parameters, and 30 that define five parameters. Finally, there are 18 projects that define six parameters, 16 projects that define seven parameters and 8 that define eight parameters. Furthermore, the average number of parameters defined in a project is 3. These results suggest that most repositories adopt *lightweight* configurations, with relatively few projects engaging in broader, multi-parameter tuning.

Furthermore, to understand how the complexity of parameter configurations is structured, we are interested in knowing which groups of parameters are defined in the projects. For example, for projects that define two parameters, we want to understand which ones they typically configure. We are also interested in knowing the number of projects and the percentage in which each group of parameters is defined, to determine if there are parameter groups that developers tend to be more interested in. It should be clarified that we are not talking about configurations here, but about groups of parameters that are defined in the project.

Table 2 shows, for projects that define exactly $k$ parameters, the groups of size $k$ that appear within those projects, and reports the number and proportion of projects in which each group is defined. We emphasize that this is *project-level co-definition*, not guaranteed co-use in a single invocation. For projects that define exactly two parameters, the most common groups are {*max_tokens*, *temperature*} (59.78%) and {*temperature*, *top_p*} (15.22%), followed by {*temperature*, *top_k*} (13.04%). For projects with three parameters, the groups {*temperature*, *top_k*, *top_p*} (31.82%), {*max_tokens*, *temperature*, *top_k*} (27.27%), and {*max_tokens*, *temperature*, *top_p*} (19.70%) are the most frequent. For four parameters, {*max_tokens*, *temperature*, *top_k*, *top_p*} dominates (38.78%), and for five parameters the configuration {*frequency_penalty*, *max_tokens*, *presence_penalty*, *temperature*, *top_p*} is most common (50.00%). Taken together, these observations suggest that *temperature* appears in the most frequent groups across $k$, with *max_tokens* and one of *top_p*/*top_k* often accompanying it as the group size grows.

**Table 2 Parameter groups defined in projects.** Number and percentage of projects that define each group of parameters.

| # Defined parameters | Defined parameters | # Projects | Projects (%) |
|---|---|---|---|
| 1 | temperature | 59 | 70.24% |
| | max_tokens | 17 | 20.24% |
| | top_k | 5 | 5.95% |
| | repetition_penalty | 2 | 2.38% |
| | top_p | 1 | 1.19% |
| 2 | max_tokens, temperature | 55 | 59.78% |
| | temperature, top_p | 14 | 15.22% |
| | temperature, top_k | 12 | 13.04% |
| | max_tokens, top_k | 6 | 6.52% |
| | top_k, top_p | 4 | 4.35% |
| | presence_penalty, temperature | 1 | 1.09% |
| 3 | temperature, top_k, top_p | 21 | 31.82% |
| | max_tokens, temperature, top_k | 18 | 27.27% |
| | max_tokens, temperature, top_p | 13 | 19.70% |
| | repetition_penalty, temperature, top_p | 10 | 15.15% |
| | max_tokens, repetition_penalty, temperature | 3 | 4.55% |
| | repetition_penalty, temperature, top_k | 1 | 1.52% |
| 4 | max_tokens, temperature, top_k, top_p | 19 | 38.78% |
| | repetition_penalty, temperature, top_k, top_p | 13 | 26.53% |
| | frequency_penalty, presence_penalty, temperature, top_p | 8 | 16.33% |
| | max_tokens, repetition_penalty, temperature, top_p | 4 | 8.16% |
| | max_tokens, min_p, temperature, top_p | 1 | 2.04% |
| | max_tokens, repetition_penalty, temperature, top_k | 1 | 2.04% |
| | max_tokens, presence_penalty, temperature, top_p | 1 | 2.04% |
| | max_tokens, frequency_penalty, temperature, top_p | 1 | 2.04% |
| | max_tokens, frequency_penalty, temperature, top_k | 1 | 2.04% |
| 5 | frequency_penalty, max_tokens, presence_penalty, temperature, top_p | 15 | 50.00% |
| | max_tokens, repetition_penalty, temperature, top_k, top_p | 8 | 26.67% |
| | frequency_penalty, max_tokens, temperature, top_k, top_p | 2 | 6.67% |
| | max_tokens, presence_penalty, temperature, top_k, top_p | 1 | 3.33% |
| | frequency_penalty, presence_penalty, temperature, top_k, top_p | 1 | 3.33% |
| | max_tokens, presence_penalty, repetition_penalty, temperature, top_p | 1 | 3.33% |
| | max_tokens, min_p, temperature, top_k, top_p | 1 | 3.33% |
| | frequency_penalty, max_tokens, presence_penalty, temperature, top_k | 1 | 3.33% |
| 6 | frequency_penalty, max_tokens, presence_penalty, temperature, top_k, top_p | 11 | 61.11% |
| | frequency_penalty, presence_penalty, repetition_penalty, temperature, top_k, top_p | 3 | 16.67% |
| | max_tokens, presence_penalty, repetition_penalty, temperature, top_k, top_p | 2 | 11.11% |
| | max_tokens, min_p, repetition_penalty, temperature, top_k, top_p | 1 | 5.56% |
| | frequency_penalty, max_tokens, presence_penalty, repetition_penalty, temperature, top_p | 1 | 5.56% |
| 7 | frequency_penalty, max_tokens, presence_penalty, repetition_penalty, temperature, top_k, top_p | 11 | 68.75% |
| | frequency_penalty, min_p, presence_penalty, repetition_penalty, temperature, top_k, top_p | 2 | 12.50% |
| | max_tokens, min_p, presence_penalty, repetition_penalty, temperature, top_k, top_p | 1 | 6.25% |
| | frequency_penalty, max_tokens, min_p, presence_penalty, temperature, top_k, top_p | 1 | 6.25% |
| | frequency_penalty, max_tokens, min_p, presence_penalty, repetition_penalty, temperature, top_p | 1 | 6.25% |
| 8 | frequency_penalty, max_tokens, min_p, presence_penalty, repetition_penalty, temperature, top_k, top_p | 1 | 100.00% |

Findings (RQ2).

Projects typically define a small set of parameters (mean $\approx 3$), and it is uncommon to find repositories that configure more than five parameters. This points to a prevalent *minimalist* configuration practice. Furthermore, across projects, the most common groups nearly always include *temperature*, frequently paired with *max_tokens* and either *top_p* or *top_k*. As the number of defined parameters increases, groups tend to expand around this core set.

**RQ3. What values do developers assign to the LLM parameters they define?** In this research question, we are interested in understanding the specific values that developers define for each parameter. To do this, we obtain the different values that are defined for each parameter in each project. Figure 3 shows the defined values for each parameter. To focus on dominant choices, we display the most frequent values that jointly account for 90% of the observations for that parameter and aggregate the remainder into an "other" bin.

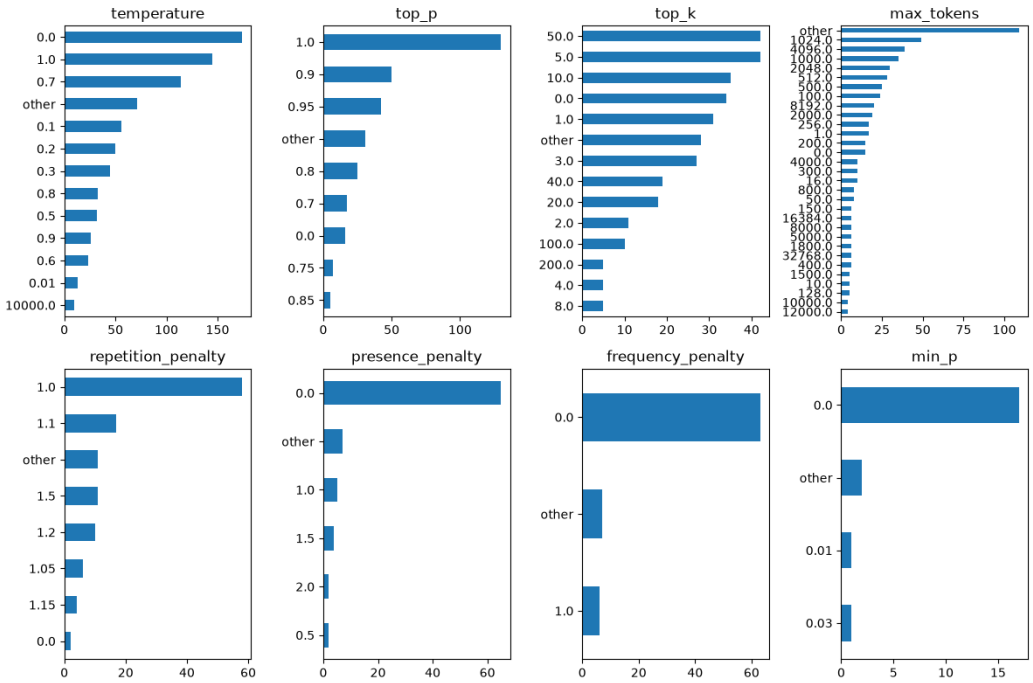

**Figure 3** Parameters values. Each sub-figure corresponds to one of the parameters where each bar represents the number of projects that define the indicated value for the parameter.

The distributions reveal that developers tend to adopt a relatively narrow band of values for the most frequently defined parameters. Regarding temperature, we observe that the values 0.0 and 1.0 were frequently defined, followed by 0.7. Temperatures in the ranges 0.1-0.6 and 0.8-0.9 being less frequent, suggest a general preference for deterministic results in some projects and more creative results in others. For *top_p*, values higher than 0.9 dominate, indicating that most developers rely on a standard nucleus-sampling threshold rather than fine-grained tuning. Similarly, *top_k* values tend to fall within a small range (0–50), which suggests an emphasis on moderate vocabulary restriction. For *max_tokens*, the most common settings appear in a set of rounded values, likely reflecting conventional generation lengths or example defaults from popular libraries. *Presence_penalty* and *frequency_penalty* are most often defined at 0.0 while *repetition_penalty* is frequently defined at 1.0. The *min_p* parameter is defined in very few projects and is frequently set to 0.0.

Findings (RQ3).

Developers converge on a narrow set of values for key parameters. *Temperature* is most often set to 0.0, 0.7 and 1.0, while *top_p* clusters around 0.9 and *top_k* around moderately small values. Common choices for *max_tokens* correspond to values of the form $2^k$, suggesting conventional or template-driven usage. In general, the penalty parameters are configured to penalize repetition, presence, and frequency only slightly. Overall, the distributions reveal emerging *defaults-in-practice* for high-frequency parameters and scattered exploration for less commonly used ones.

## 5 Threats To Validity

**Internal validity.** Our results depend on the correct extraction of LLM parameter definitions from Python source code using AST-based static analysis. Project-specific wrappers, dynamic configuration patterns, aliasing of parameter names, or indirection through configuration files may lead to false negatives or, less frequently, false positives. In addition, parameters defined conditionally or overridden at runtime may not be captured by our static approach. To mitigate these risks, we adopted conservative extraction rules, excluded non-production paths, retained full provenance (project, file, and line) for each extracted instance, and performed randomized spot checks on the dataset.

**Construct validity.** We operationalize a parameter as being *defined* when an explicit value assignment appears anywhere in a repository, and we interpret parameter groups as sets of parameters co-defined at the project level. This construct does not imply that parameters are used together in a single LLM invocation, nor does it capture dynamic overrides, environment-driven defaults, or provider-side implicit defaults. We address this threat by aligning our research questions, analysis, and interpretations strictly with project-level definitions, and by explicitly avoiding claims about runtime behavior or causal effects.

**External validity.** Our corpus consists of open-source Python projects hosted on GitHub, selected using topic filters and a popularity threshold. This sampling strategy may bias the dataset towards active, visible repositories and may under-represent private, industrial, or less popular projects, as well as ecosystems using other programming languages. We mitigate this threat by making all selection criteria explicit and grounding them in prior MSR literature that uses stars as a proxy for maturity and visibility.

**Conclusion validity.** Our analyses are descriptive in nature and should not be interpreted as causal evidence about configuration effectiveness, output quality, or developer intent. Given the number of parameters and value choices inspected, some patterns may appear salient by coincidence, particularly for infrequently used parameters. To reduce this risk, we emphasize high-support patterns, report complete tables and distributions, avoid causal language, and interpret results conservatively.

## 6 Conclusion

This paper provides a repository-based view of how developers *define* LLM parameters in real-world software projects. Using AST-based extraction over open-source Python repositories, we addressed three questions on prevalence (RQ1), configuration complexity and its structure (RQ2), and value distributions (RQ3). We find that *temperature* is the parameter most frequently defined, with *max_tokens* and *top_p* also common, while penalty-style parameters are comparatively rare. Projects typically define few parameters (mean $\approx 3$), the most frequent project-level defined parameter groups consistently include *temperature* with *max_tokens* and either *top_p* or *top_k*, and value distributions suggest emerging *defaults-in-practice* (e.g., *temperature* $\sim$ 0.0, 0.7 and 1.0, *top_p* $\sim$ 0.9, moderately small *top_k*, and rounded *max_tokens* such as 256/512/1024). These descriptive results make configuration practices visible and measurable, supporting clearer reporting and reproducibility in LLM-in-SE studies, and offering practical baselines for tools and education.

## 6.1 Future Directions

This section describes the future lines of research that stem from the findings presented in this paper.

**Understanding *why* developers make these choices.** Our evidence characterizes *what* is defined, but not the underlying rationale. Future work should investigate the *causes* behind observed practices, including (a) developer intent and mental models (*e.g.,* interviews/surveys with practitioners), and (b) the role of examples and library templates (*e.g.,* LangChain/Ollama/vLLM code templates).

**Longitudinal evolution of configurations.** Another promising direction is to study *how* configurations evolve over time within each project. Mining commit histories and release tags can reveal adoption curves (*e.g.,* when *top_p* first appears), churn (frequency of parameter changes), stability of value ranges, and responses to upstream API changes.

**Task- and domain-specific patterns.** Future work can consider task inference (*e.g.,* RAG[3], agents, evaluation, TTS[4]/ASR[5], vision) and quantify whether certain tasks are associated with distinctive configuration profiles (*e.g.,* lower *temperature* for evaluation pipelines, higher *max_tokens* for drafting/long-form generation).

**From "defaults-in-practice" to outcomes.** Distributions suggest conventional bands (*e.g.,* *temperature* $\sim$ 0.0, 0.7 and 1). A key extension is to relate these bands to *outcomes*: output quality, diversity, stability, cost/latency. Controlled experiments on representative tasks and models – using values mined from repositories as treatments – can test whether defaults-in-practice are well-calibrated, suboptimal, or context-dependent.

## Data Availability Statement

The dataset supporting this study, including the mining scripts, raw repository data, and analysis notebooks, is openly available on Zenodo at `https://doi.org/10.5281/zenodo.21456738` under a CC-BY 4.0 license. The replication package contains all materials necessary to reproduce our findings.

## Abstract

**Background.** Interview-based studies are widely used in empirical software engineering to investigate human, organizational, and socio-technical phenomena, yet interview sample adequacy and saturation are reported inconsistently across the literature.

**Aims.** This paper investigates how interview sample adequacy and saturation are reported in empirical software engineering research.

**Method.** We analyzed 427 papers published between 2016 and 2025 across major software engineering venues, focusing on interview sample sizes, saturation discussions, and sample adequacy justifications.

**Results.** Preliminary findings indicate substantial variation in interview sample sizes, ranging from highly specialized small-sample studies to broader investigations involving large interview datasets. Studies involving 12 or fewer interviewees were common and frequently associated with specialized industrial contexts or constrained organizational access. However, the most common range was 13 to 24 interviewees, suggesting that moderate-sized samples represent the most common configuration in empirical software engineering research. Saturation and sample adequacy justifications were heterogeneous, with many studies relying on implicit or contextual reasoning rather than explicit methodological discussion.

**Conclusions.** Our findings provide empirical insights into methodological reporting practices in interview-based software engineering research and contribute to ongoing discussions on qualitative rigor and transparency.

## 1 Introduction

Qualitative research is an established component of empirical software engineering, particularly for investigating human, organizational, behavioral, and socio-technical aspects of software development [22, 8, 19]. Interview-based studies (e.g., case studies, surveys, and grounded theory) are widely used to investigate developer experiences, team interactions, organizational practices, decision-making processes, and perceptions that quantitative measures alone cannot capture [22, 15]. Interviews therefore play an important role in empirical software engineering because they support contextual understanding, triangulation across data sources, and exploratory investigation of socio-technical phenomena [22, 15, 19].

Methodological guidelines for qualitative software engineering research emphasize transparency, reflexivity, triangulation, sampling adequacy, and saturation [22, 8, 23, 19, 10]. These guidelines additionally caution against applying quantitative expectations, such as statistical representativeness, to qualitative work [10]. Nevertheless, previous reviews indicate that saturation is discussed inconsistently and qualitative quality criteria are reported unevenly in software engineering publications [19]. These issues carry practical consequences for researchers. Qualitative and interdisciplinary software engineering studies continue to face challenges during peer review and publication, with interview-based work sometimes dismissed as out of scope or *"too soft"* [16]. Reviewer concerns frequently target the number of interviewees, methodological legitimacy, and unfamiliarity with qualitative or interdisciplinary methods [16]. Such concerns may become particularly pronounced in studies involving marginalized populations, senior professionals, leadership roles, or specialized industrial contexts, where recruitment is inherently difficult, and smaller samples may still provide substantively meaningful insights.

The broader qualitative methodology literature has addressed these tensions more directly. While software engineering guidelines have generally avoided prescribing exact interview sample sizes [22, 8, 10, 19], interdisciplinary qualitative research has discussed interview numbers, stopping criteria, and empirical saturation ranges in greater detail [12, 11, 14, 13]. Prior work suggests that saturation may occur in relatively few interviews within homogeneous contexts while also cautioning against rigid numerical interpretations of adequacy [12, 14, 13, 4, 9]. However, despite these broader methodological discussions, there is still limited empirical evidence regarding how software engineering studies operationalize and report interview sample adequacy and saturation in practice.

The goal of this paper is to investigate how interview sample size adequacy and saturation are operationalized and reported in empirical software engineering research, with the purpose of characterizing current practices, identifying reporting patterns, and providing empirical insights into methodological decisions surrounding interview-based studies. To achieve this goal, we investigate the following research question: *How are interview sample size and saturation operationalized in software engineering interview studies?* To answer this question, we conducted a large-scale review of 427 software engineering papers employing interviews, characterized interview sample size practices, explored how studies justified sample adequacy, and conducted a preliminary mapping of how saturation is discussed across the field.

Our preliminary results show that interview-based software engineering studies vary substantially in sample size, ranging from single-participant studies to investigations with more than 100 interviewees. Across 427 papers, we identified 7,407 reported interviews, with an average of 17.35 participants per study. The most common range was 13 to 24 interviewees, followed closely by studies with 5 to 12 interviewees. Discussions of saturation and sample adequacy were heterogeneous, with many papers relying on implicit or contextual justifications rather than explicit methodological explanations. Our study contributes to

an empirical characterization of interview sample-size practices in software engineering and provides initial evidence to support more transparent reporting of saturation and sample adequacy in interview-based studies.

## 2 Background

As discussed previously, software engineering methodological guidelines have generally avoided prescribing exact interview sample sizes, instead emphasizing saturation, methodological adequacy, triangulation, reflexivity, and alignment between research goals and qualitative procedures [22, 8, 19, 10]. While this flexibility is methodologically principled, it can create practical difficulties for researchers justifying interview adequacy during peer review, in particular, in studies involving difficult-to-recruit populations, interdisciplinary topics, or specialized industrial contexts [16].

On the other hand, qualitative methodology literature outside software engineering has engaged with these challenges more directly, offering explicit discussion of interview numbers, saturation thresholds, stopping criteria, and sample adequacy across fields such as psychology, health research, nursing, education, and the social sciences [12, 11, 7, 14, 13, 3, 2]. The aim of such discussions is generally practical: to improve transparency in qualitative reporting, support saturation procedures, and establish shared expectations for publication [11, 7, 2].

The numerical recommendations that emerge from this literature vary considerably. For relatively homogeneous samples, recommendations range from 6 to 8 interviews [2], with some studies reporting saturation within the first 12 interviews and basic metatheme elements emerging within approximately 6 [12]. Another commonly discussed stopping criterion consists of an initial sample of 10 interviews followed by 3 consecutive interviews without new themes [11]. Beyond these general thresholds, some studies distinguish between different forms of saturation: code saturation may occur within approximately 9 interviews, whereas meaning saturation may require between 16 and 24 [14]. Others report that common themes in relatively homogeneous groups may emerge within approximately 16 interviews, while cross-cultural metathemes may require between 20 and 40 [13].

Broader numerical ranges reflect differences in methodological design, participant heterogeneity, and analytical goals. Phenomenological studies are commonly associated with approximately 5 to 25 interviews, grounded theory studies with 20 to 30, and ethnographic studies with 30 to 60, depending on scope and heterogeneity [2]; publication-oriented discussions have additionally proposed 25 to 30 interviews as a practical minimum for grounded theory journal submissions [7]. At the lower end, 15 interviews have been identified as the smallest acceptable qualitative sample size in some contexts, while at the upper end, studies exceeding approximately 150 interviews may become analytically difficult to manage [2].

Despite this range of guidance, several researchers caution against rigid numerical interpretations, arguing that interview adequacy ultimately depends on study scope, participant heterogeneity, data richness, analytical depth, and interpretive goals rather than fixed thresholds [4, 3, 2, 9], yet numerical guidance and saturation-oriented recommendations continue to appear frequently in qualitative methodology literature, reflecting an ongoing tension between methodological flexibility and the practical demands of publication.

## 3 Method

In this study, we followed a process conceptually similar to a systematic mapping study [18, 21, 17]. We aimed to identify software engineering papers that used interviews as part of their empirical data collection process. We did not adopt an automatic search strategy because the

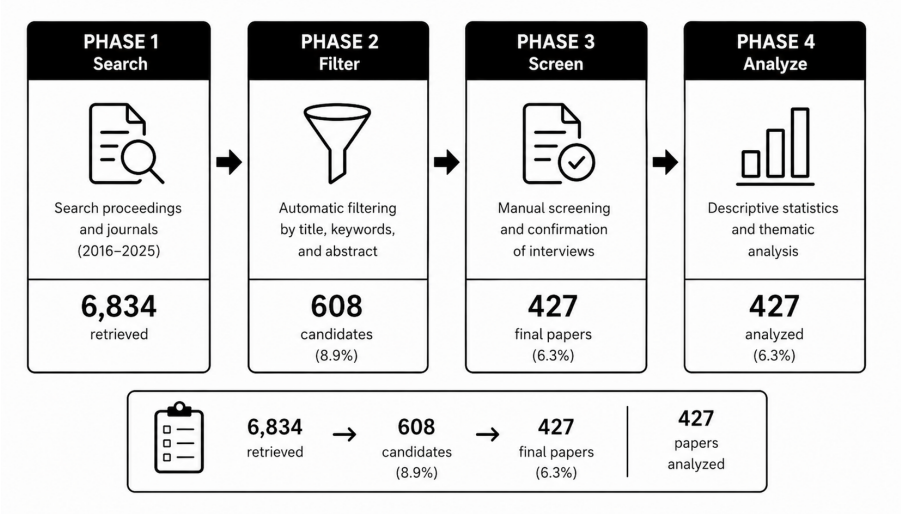

**Figure 1** Overview of the methodological process.

scope of the topic was intentionally broad, namely, studies in software engineering involving interviews. Preliminary attempts indicated that conventional search strings would retrieve an excessively large and noisy corpus requiring extensive manual filtering. Therefore, we adopted a manual search strategy, which is commonly used in secondary studies in software engineering when automatic retrieval is impractical or insufficiently precise [17]. Our process consisted of four main stages: (1) manual identification of papers from selected software engineering venues, (2) automatic filtering of potentially qualitative studies through title, keyword, and abstract inspection, (3) manual full-text screening to confirm the actual use of interviews, and (4) preliminary descriptive and thematic analysis of the resulting corpus. Figure 1 summarizes the overall methodological process adopted in this study.

**Search Strategy.** We manually searched papers published between 2016 and 2025 in the proceedings of the International Symposium on Empirical Software Engineering and Measurement (ESEM), the International Conference on Evaluation and Assessment in Software Engineering (EASE), the International Conference on Software Engineering (ICSE), and the ACM Joint European Software Engineering Conference and Symposium on the Foundations of Software Engineering (FSE), as well as in the Empirical Software Engineering journal (EMSE). We selected these venues because of their relevance to empirical and industrial software engineering research. ESEM, EASE, and EMSE are recognized for publishing studies with strong methodological and empirical emphasis, while ICSE and FSE were selected for their broad influence within the software engineering community and strong participation by industry practitioners, which frequently results in empirical studies involving interviews. To support the collection process, we developed a Python script to retrieve the proceedings and issues for each selected venue over the ten-year period. For conferences, we included main research tracks, industry tracks, and thematic tracks such as Software Engineering in Society (SEIS) and the Education track (SEET). We excluded co-located events and workshops. For the journal, we included both regular and special issues. This initial corpus comprised 6,834 papers.

**Selection Process and Data Extraction.** We then developed a second script to automatically identify papers potentially involving qualitative research methods. This process analyzed titles, keywords, and abstracts. Papers describing methods commonly associated with

interview-based qualitative research, such as case studies, grounded theory, and related qualitative approaches, were automatically selected and exported to a spreadsheet for further inspection. This stage reduced the dataset from 6,834 papers to 608 candidate papers. Next, two authors manually inspected the full text of all candidate papers to confirm whether interviews had actually been conducted as part of the empirical study. We considered this manual verification step necessary because many papers referenced qualitative methods without necessarily collecting interview data. The final corpus comprised 427 papers.

**Data Analysis and Synthesis.** In this paper, we present emerging results identified in our analysis. So far, we have relied primarily on descriptive statistics [5] to characterize the distribution of interview sample sizes and other basic study characteristics across the identified corpus. To support interpretation, we organized interview sample sizes into characteristic ranges derived from discussions available in the qualitative research literature:

- **Fewer than 5 interviews:** highly specialized, exploratory, elite, or difficult-to-access contexts [16].
- **5 to 12 interviews:** homogeneous samples, focused studies, and early thematic saturation discussions [12, 2].
- **13 to 24 interviews:** meaning saturation and deeper interpretive analysis [14].
- **25 to 40 interviews:** heterogeneous, multisite, cross-cultural, and grounded theory-oriented investigations [13, 7, 2].
- **41 to 60 interviews:** broader ethnographic and exploratory qualitative studies involving larger datasets [2].
- **More than 60 interviews:** very large qualitative datasets and discussions regarding analytical manageability and extensive qualitative coverage [2].

To investigate how saturation and sample-size justification were discussed in practice, we also conducted a preliminary qualitative analysis [6]. Since this paper reports emerging results, we have not yet qualitatively analyzed the full corpus of 427 papers. Instead, we adopted an exploratory stratified selection strategy to capture variation across interview sample sizes while maintaining a manageable scope for this preliminary stage of the study. For this preliminary exploratory analysis, we analyzed 14 papers: 12 papers randomly selected from the interview-sample-size ranges, plus the paper with the highest number of interviews and one randomly selected paper from the two papers reporting the lowest interview count.

Random selection within each range was performed using an online randomization tool based on the paper identification codes assigned during data extraction. This strategy was adopted to obtain an initial overview of how saturation and sample size justification were discussed across studies involving substantially different interview samples, ranging from highly specialized interview settings to large qualitative datasets. The selected papers were then inspected to investigate whether and how authors discussed saturation, justified interview sample sizes, described participant accessibility, and characterized the adequacy of their interview samples. The analysis focused on methodological descriptions and reporting practices presented by the authors rather than on evaluating the objective adequacy of the interview samples themselves. Preliminary insights emerging from this exploratory analysis are discussed in this paper. In future work, we plan to extend the qualitative extraction and analysis process to the full corpus of 427 papers, enabling a broader characterization of saturation practices, reporting strategies, and approaches to sample size justification in software engineering interview studies.

**Threats to Validity.** **Construct Validity.** One threat to construct validity concerns the identification of papers that actually used interviews as part of their empirical data collection process. Because interview studies are described inconsistently across software engineering papers, some studies may not explicitly mention interviews in titles, keywords, abstracts, or methodological descriptions. To reduce this threat, we combined automatic filtering with manual full-text inspection conducted by two authors. Another construct-related threat concerns the categorization of interview sample size ranges. These ranges were derived from discussions available in the qualitative research literature and should not be interpreted as strict or universally accepted thresholds for adequacy or saturation. **Internal Validity.** The automatic filtering process relied on methodological terminology commonly associated with interview-based qualitative research, such as case studies, grounded theory, and surveys. Consequently, studies using interviews without explicitly describing their methods through these terms may have been missed during the automatic filtering stage. In addition, the preliminary thematic analysis reported in this paper was conducted on a reduced exploratory subset of papers rather than the full corpus. Although this strategy was intentionally adopted to support an emerging results paper, the current findings should be interpreted as preliminary and exploratory rather than exhaustive. **External Validity.** Our study focused on papers published in ESEM, EASE, ICSE, FSE, and EMSE between 2016 and 2025. Although these venues are influential within software engineering research and include substantial empirical and industry-oriented work, the findings may not generalize to all software engineering venues, related disciplines, or qualitative research communities outside software engineering. Similarly, practices associated with interview saturation and sample size justification may differ in other contexts not represented in our study. **Reliability.** Manual screening and qualitative interpretation involve researcher judgment, which may introduce inconsistencies during paper selection and thematic analysis. To reduce this threat, two authors manually reviewed the candidate papers during the interview confirmation stage and resolved conflicts using consensus meetings. We also describe our methodological process, filtering stages, and analysis procedures in detail to support transparency and reproducibility. In the complete version of this study, we plan to extend the extraction and thematic analysis process to the full corpus of 427 papers and further refine the coding process through iterative discussion among the authors.

## 4 Results

Our sample comprised 427 software engineering papers employing interviews published between 2016 and 2025. Publication counts by year were: 24 papers in 2016, 25 in 2017, 37 in 2018, 45 in 2019, 60 in 2020, 42 in 2021, 44 in 2022, 53 in 2023, 44 in 2024, and 53 in 2025. These counts point to a rise in interview-based studies after 2018, with publication rates remaining relatively stable in subsequent years. Regarding venues, EMSE contributed the largest share (n=139), followed by FSE (n=85), ICSE ( n=83), ESEM (n=62), and EASE (n=58), indicating that interview-based empirical research is distributed across multiple major software engineering venues rather than concentrated in a single outlet. Figure 2 presents the combined distribution across publication years and venues.

The identified studies also varied in interview type. Semi-structured interviews were the dominant approach, appearing in 407 papers, followed by structured interviews (n=9) and unstructured interviews (n=3). We additionally identified 5 interview surveys or qualitative surveys, 2 focus group interviews, and 3 studies combining multiple interview types. Regarding interview mode, in-person interviews appeared in 82 papers, remote interviews in 58, and

**Figure 2** Distribution of interview-based studies.

video-call interviews in 54. Mixed formats appeared in 65 papers and email interviews in 9. A substantial portion of the analyzed papers did not report how interviews were conducted, pointing to variability and incompleteness in methodological reporting practices.

## 4.1 Interview Sample Size Characteristics

Interview sample sizes varied substantially across the analyzed studies. Across the 427 papers, we identified 7,407 reported interviews, with an average of 17.35 participants per study. The smallest studies relied on a single participant, while the largest reported 100 interviewees. Figure 3 presents the distribution of interviewee counts across the analyzed papers. Studies involving 13 to 24 interviewees were the most frequent (n=152), followed closely by studies with 5 to 12 interviewees (n=150). Studies involving 25 to 40 interviewees appeared in 64 papers, while studies with fewer than 5 interviewees appeared in 39 papers. Studies involving 41 to 60 interviewees were identified in 14 papers, and studies employing more than 60 interviewees were comparatively rare (n=8).

These results indicate that interview based software engineering research spans a broad range of sample sizes rather than converging around a single dominant range. The analyzed studies cover multiple sample size ranges discussed in the qualitative methodology literature, from small homogeneous samples to moderate sized qualitative investigations and broader exploratory studies. Studies with 13 to 24 interviewees were the most prevalent, suggesting that moderate sized interview samples are common in empirical software engineering research. Studies with 5 to 12 interviewees also appeared frequently, indicating that smaller interview studies remain widely used across the field. The substantial number of studies involving 25 to 40 interviewees further suggests that larger qualitative and exploratory investigations also represent an important segment of the literature. These ranges should not be interpreted as prescriptive methodological thresholds, but rather as interpretive groupings informed by the qualitative research literature. The observed variation likely reflects differences in research objectives, participant accessibility, methodological approach, analytical scope, study context, and publication practices.

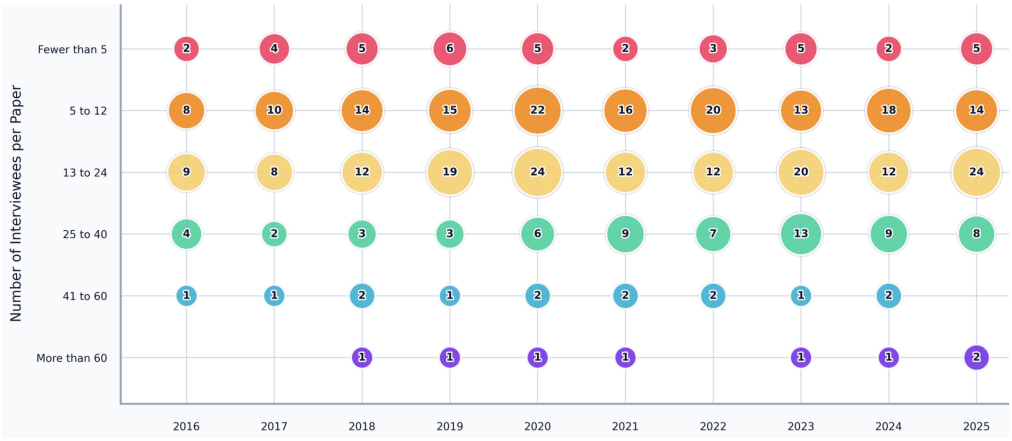

**Figure 3** Distribution of interview sample size ranges.

## 4.2 Preliminary Analysis of Sample Size Justification and Saturation

Among the 14 papers randomly selected for this preliminary exploratory analysis, the full list is provided in the supplemental material due to space restrictions. Authors often provided some explanation of participant selection, even when explicit methodological justification for the final sample size was limited. These explanations tended to focus on contextual, organizational, or practical recruitment considerations rather than formal qualitative sampling guidance. Explicit saturation discussions were comparatively rare, appearing in only four papers, two of which were grounded theory investigations, a methodology that relies heavily on iterative sampling and theoretical saturation.

**Sample Justification.** The analyzed papers showed heterogeneous approaches to describing and justifying interview sample sizes. Smaller studies typically justified participant selection by the specificity of the investigated context, the uniqueness of participants, or the limited availability of individuals directly involved in the phenomenon under study. For example, an investigation involving a single hacker participant or release managers responsible for patch uplift decisions. Studies with moderate sample sizes more commonly emphasized variation across organizational contexts, products, stakeholder groups, or technical perspectives. One study involving 21 interviews framed the work as a qualitative survey intended to capture variation across industrial settings rather than conduct an in-depth analysis of a single case. Another involving 23 interviews deliberately included API producers associated with both adoption and non-adoption of lambda support to capture contrasting perspectives within the Java ecosystem. Larger studies typically justified participant counts through broader organizational coverage, multisite designs, or heterogeneous stakeholder groups. The studies involving 42 and 75 interviews relied on grounded theory procedures with iterative recruitment and theoretical sampling. A study involving more than 100 interviews defined recruitment as part of a customer discovery process covering workflows, onboarding practices, and organizational adoption challenges across multiple professional roles. Although explicit methodological justification was often limited, most studies still provided contextual reasoning for participant selection.

**Saturation.** Explicit discussion of saturation was infrequent in the analyzed subset. The two grounded theory studies described iterative data collection, theoretical sampling, and continuous refinement of interview questions until theoretical saturation was reached, oper-

ationalized as the point at which additional interviews no longer produced new analytical insights. Outside grounded theory, saturation was discussed less systematically. One study treated saturation as the recurrence of previously identified codes and used this observation to iteratively adapt the interview guide, rather than as a stopping criterion for recruitment. Another explicitly acknowledged that theoretical saturation was not achieved, arguing that saturation may have limited temporal validity in rapidly evolving security contexts where attacker behavior continuously changes. Explicit saturation reporting thus remains relatively uncommon in this subset of software engineering interview studies. When discussed in methodological detail, it was primarily associated with grounded theory investigations involving iterative recruitment and theoretical sampling.

### 4.3 How are interview sample size and saturation operationalized in software engineering interview studies?

Considering both the quantitative characterization of interview sample sizes and the preliminary qualitative analysis of reporting practices, our findings indicate that software engineering interview studies employ highly variable sample sizes, ranging from single-participant studies in highly specialized contexts to investigations involving more than 100 interviewees. Currently, the most common range in empirical software engineering is 13 to 24 interviewees, with an average of 17.35. However, no single interview sample size can be considered universally appropriate for software engineering interview studies. Sample sizes appear to be strongly dependent on research objectives, methodological approach, analytical depth, participant accessibility, organizational scope, and the nature of the phenomenon under investigation. Interview sample adequacy is therefore highly context-dependent rather than determined by fixed numerical expectations. Yet, researchers tend to provide only contextual explanations for participant selection, and explicit justification for why a specific number of interviews was considered sufficient remains limited. Saturation discussion, in turn, is largely confined to grounded theory investigations involving iterative recruitment and theoretical sampling. These emerging results suggest that interview sample adequacy, justification, and saturation deserve greater methodological attention in empirical software engineering research.

## 5 Discussion

Our emerging results suggest that software engineering interview research partially aligns with broader qualitative research traditions while also diverging from them in important ways. Similar to qualitative research in psychology, health, education, and the social sciences, software engineering studies frequently rely on contextual reasoning when defining interview samples, with participant accessibility, organizational scope, technical specialization, and the nature of the investigated phenomenon all influencing sample adequacy decisions. This aligns with broader qualitative understandings that adequacy depends on research goals, heterogeneity, and analytical depth rather than fixed numerical thresholds [3, 2, 4, 13, 14].

At the same time, qualitative methodology literature in other fields has increasingly emphasized explicit reporting of saturation procedures, stopping criteria, and sample adequacy rationale [11, 14, 2]. In contrast, our findings suggest that many software engineering studies rely primarily on implicit or contextual justification without systematically articulating why the selected number of participants was considered analytically sufficient. This divergence may partially reflect the historical development of empirical software engineering, where methodological reporting has often prioritized technical artifacts, evaluation procedures, and empirical outcomes over theorized discussion of interpretive adequacy, reflexivity, or saturation logic [16, 1].

Organizational realities also play a role. Many empirical studies investigate industrial environments characterized by restricted access, confidentiality constraints, non-disclosure agreements, and difficult-to-recruit populations, such as senior architects, security specialists, or release managers who are directly responsible for specific technical decisions. In these contexts, recruiting even a small number of highly knowledgeable participants may require substantial effort, organizational permissions, and sustained professional relationships [15, 1]. Our findings further suggest that participant availability is frequently a binding constraint rather than a methodological choice, and sample sizes may therefore reflect what was realistically achievable rather than what was theoretically optimal. Under these conditions, contextual justification is not only pragmatic but also necessary, and evaluating such studies against numerical expectations derived from less-constrained research environments may be inappropriate. Software engineering interview research may therefore be closer to applied and organizational qualitative research, where access constraints strongly influence study design and where the depth and relevance of participant knowledge often matter more than the number of participants recruited.

Despite these realities, our findings suggest several areas for improvement. Greater transparency in sample adequacy reasoning would benefit peer review and replication without requiring fixed numerical recommendations. Software engineering research would also benefit from broader engagement with contemporary saturation concepts beyond grounded theory, including code saturation, meaning saturation, and information power [14, 3, 20], and from stronger qualitative-specific reporting expectations within existing methodological guidelines [10, 1]. Our findings also indicate that studies involving fewer than 5 specialist participants, or between 5 and 12 interviewees, are common and methodologically legitimate in software engineering research. Small samples should not be used as grounds for paper rejection or negative reviews, provided authors offer clear justification for their sample size and, preferably, engage with saturation. The methodological quality of an interview study cannot be reduced to participant count alone [4, 1].

Finally, we caution against applying sample-size recommendations from other disciplines without accounting for the contextual particularities of software engineering research. The observed variability suggests that interview adequacy depends heavily on industrial access, participant specialization, and methodological design. That said, if a reference point is needed, our findings suggest that 13 to 24 interviewees represent the most empirically common range in software engineering, and may serve as a practical starting point for researchers planning interview studies. Numerical guidance from broader qualitative literature may serve better as interpretive reference points than prescriptive requirements [4, 13, 14]. The central challenge is not identifying a universally correct number of interviews, but improving transparency about how adequacy decisions are made and how they connect to the goals of empirical investigation.

## 6 Conclusions and Future Work

We investigated how interview sample size adequacy and saturation are operationalized in empirical software engineering research. Sample sizes vary substantially, with 13 to 24 interviewees representing the most frequent range, while studies with 12 or fewer participants were also common. Very small samples were commonly linked to specialized industrial contexts, expert populations, or constrained organizational access, and should not be dismissed on participant count alone, provided adequate justification is offered. Larger samples, by contrast, were more frequently associated with broader organizational coverage, heterogen-

eous participant groups, multisite investigations, and exploratory designs requiring wider contextual representation. Adequacy decisions thus appear strongly dependent on contextual, organizational, and methodological factors rather than shared numerical criteria. Saturation and explicit sample-adequacy justification were heterogeneous and comparatively uncommon outside grounded-theory studies, suggesting methodological transparency in interview-based software engineering research deserves greater attention.

**Future Work.** We plan to extend the analysis to the full corpus of 427 papers, investigating how justification practices, saturation operationalization, and recruitment decisions vary across methodologies, venues, industrial contexts, and participant profiles. These steps aim to support clearer methodological guidance, improve transparency in qualitative reporting, and support more consistent, context-sensitive evaluation of qualitative studies by researchers, reviewers, and editors.

## Abstract

Microservice architectures are increasingly becoming the standard design for cloud-native applications, yet their complex dependency structures make architectural understanding a challenge. Our research explores how Large Language Models (LLMs) can be leveraged to automatically reconstruct microservice architectures directly from source code, a task that requires both high-level architectural reasoning and fine-grained code understanding. We introduce a Minimum Viable Agent (MVA) as a single-agent that combines tool-assisted repository exploration with role-guided prompting to infer the services, inter-service connections, and exposed endpoints in Java microservice systems. We evaluate two state-of-the-art LLMs, GPT-4o and Llama4-16:17B, on 17 open-source microservice applications with 20 independent runs per system. GPT-4o achieves a mean F1 score of 0.604, outperforming Llama4 (F1 = 0.254). Both models show higher precision than recall, suggesting a tendency to under-represent architectural relationships rather than hallucinate them. Results also reveal substantial variation across applications and architectural element types. Analysis by architectural element indicates that service-to-service connections are the most challenging to recover for both models, while large performance differences emerge from endpoint reconstruction. Overall, our findings suggest that LLMs show promise for automated architecture recovery, but current capabilities remain insufficient for fully reliable reverse engineering. We discuss implications for integrating LLMs into architecture analysis workflows and outline directions for future research.

## 1 Introduction

Architectural recovery enables software engineers to understand, maintain, and evolve complex software systems. Documentation often becomes outdated, forcing developers to reconstruct system structure directly from implementation artifacts. This challenge is particularly pronounced in distributed systems, where the absence of an up-to-date architectural view contributes to architectural drift and erosion, increasing maintenance effort and reducing reliability [5, 16]. Microservice architectures amplify these difficulties: functionalities are distributed across independently deployable services that communicate through network-based interfaces [5, 7], with service boundaries, interactions, and endpoints scattered across

© Venla Liljas, Matteo Esposito, Valentina Lenarduzzi, and Davide Taibi;
licensed under Creative Commons License CC-BY 4.0

source code, configuration files, and infrastructure artifacts. Reconstructing a complete architectural view therefore requires synthesizing information from multiple heterogeneous sources, making manual reconstruction labour-intensive at scale [15].

Static analysis tools have been developed to automate this task through dependency analysis, call-graph extraction, and configuration parsing. While effective in certain contexts, these approaches remain limited for microservices, where service interactions are often defined through runtime configuration, service discovery or asynchronous messaging rather than explicit source-code dependencies. As a result, existing tools often produce incomplete or fragmented architectural views [3, 23]. Large Language Models (LLMs) have recently achieved promising results across a range of software engineering tasks, including code generation, defect localization, and automated issue resolution [1, 11, 28]. Their competence in reasoning over natural language and source code suggests potential for higher-level tasks requiring synthesis of diverse artifacts.

Agentic LLM systems capable of planning actions, interfacing with external tools, and revising outputs based on intermediate results [12] provide a practical mechanism for applying LLMs to such tasks, enabling iterative analysis that more closely resembles how human engineers investigate unfamiliar systems. Despite growing interest in applying LLMs to software architecture recovery, the application of LLM-based agents remains largely underexplored. Existing studies primarily combine LLMs with static analysis [17, 10], leaving the capabilities of standalone LLM agents largely unexamined. We base our single-agent design on the Minimum Viable Agent (MVA) principle, which has emerged from industry practice as a design philosophy for building the smallest agent capable of completing a target task[1,2]. Accordingly, our agent consists of a single LLM reasoning engine and a minimal tool set for repository navigation, without external memory, a planner, or sub-agent coordination. We evaluate the design on the microSecEnD dataset [21] of open-source Java microservice applications. We examine the reconstruction accuracy of two state-of-the-art LLMs across multiple architectural element types. This provides initial evidence of the feasibility and limitations of LLMs as an MVA-based LLM agent for automated microservice architecture recovery.

To summarize, we contribute (i) an MVA design for architecture reconstruction based solely on iterative repository navigation and tool use, (ii) an empirical evaluation of 17 open-source Java microservice systems comparing a closed-weight model (GPT-4o) and an open-weight model (Llama 4), and (iii) a fine-grained analysis of reconstruction accuracy across architectural element types (components, connections, and endpoints), enabling comparison between LLM-only reconstruction and existing static-analysis approaches on the same benchmark.

and textual requirements without access to source code addressing architecture generation from requirements, whereas we investigate architecture recovery directly from implementation artifacts. Pan et al. [17] introduce ArchAgent, a framework that augments LLM reasoning with static analysis and adaptive code segmentation to derive multi-view architectural representations from large-scale legacy systems. In contrast, our approach relies solely on LLM-driven tool use via an MVA-style agent, without static analysis support. Hatahet et al. [10] propose a hybrid approach to software architecture description generation that combines reverse engineering with LLM analysis, recovering both static and behavioural views by passing source code directly to GPT-4o with few-shot, role-based prompting. A key limitation they identify is the model context window: when source code exceeds the input limit, recovery degrades, constraining applicability to larger systems. They identify agentic prompting as a promising future direction, a gap our study addresses by employing an MVA-style agent loop that navigates repositories incrementally through tool use, avoiding the need to pass the full codebase at once.

Siala & Lano [22] propose LLM4Models, applying LLMs to reverse engineering by abstracting Object Constraint Language (OCL) specifications from Java and Python source code. Using a fine-tuned Mistral-7B-v0.1, they report improved accuracy, consistency, and F1 over the base model, with Mistral outperforming Llama 2 13B on 20 evaluation examples. Their focus is on OCL extraction from individual programs, whereas our study targets distributed architectural elements spanning multiple services, connections, and endpoints across full repositories. In our study, the choice of GPT-4o reflects its established strong performance on instruction-following and structured output tasks [6], while Llama4-16×17B represents a capable open-source alternative deployable without API dependency, providing a practically relevant option for environments with strict data privacy policies or cost constraints.

Overall, existing studies focus on architecture generation from requirements rather than recovery from implementation artifacts [6], LLM-assisted reverse engineering of code or software models [22], and hybrid approaches that combine LLMs with static analysis [17, 10] for architecture recovery. Our work complements these directions by isolating the capabilities of a lightweight MVA-style LLM agent that relies solely on iterative tool use to recover microservice architectures from source code repositories. This enables us to assess the feasibility and limitations of LLM-only architecture recovery without static analysis as a confounding factor.

## 3 Empirical study design

This section presents the empirical study design, including the study goal and research questions, the study context, the data collection methodology, and the data analysis approach [26]. An overview of the study design is described in Figure 1.

### 3.1 Goal and Research Questions

Our goal for this work is to analyze the use of LLMs in a single-agent workflow for reconstructing a microservice architecture, including the components, connections and endpoints with respect to their agreement and accuracy and limitations in the context of open-source Java based microservice architectures.

To achieve our goal, we formulate the following research questions (RQs):

**$RQ_1$** How accurate LLMs are in reconstructing a microservice architecture?

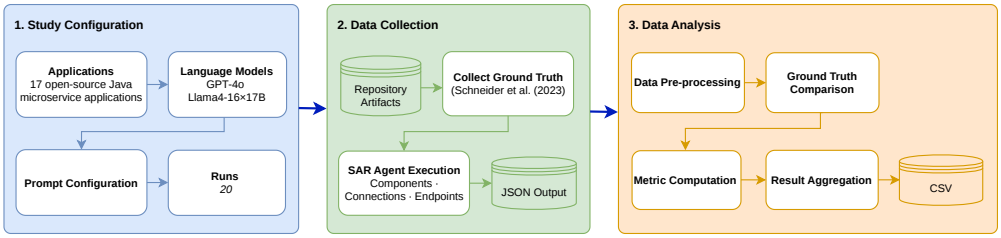

**Figure 1** Study Design Overview.

Our research question aims to evaluate the ability of simple LLM agents to accurately and reliably reconstruct microservice software architectures. Accuracy metrics provide quantitative evidence of how well these models can identify true components, connections and endpoints within the architectures while minimizing falsely identified entities. The results from $RQ_1$ will provide insights into how LLMs, considering their probabilistic and semantic nature, can compare with or complement current predominantly deterministic methods consisting of static analysis tools while demonstrating the capabilities between the two LLMs for excelling in this task. We therefore formulate the following hypotheses:

- $H_{01}$: The choice of LLM **does not affect** the LLMs accuracy of reconstructing a microservice architecture.
- $H_{11}$: The choice of LLM significantly **affects** the LLMs accuracy for reconstructing a microservice architecture.

**$RQ_2$** Does the architectural element type of the microservice architecture affect the LLMs accuracy for reconstructing a microservice architecture?

The complexity of large software systems may introduce cognitive biases in LLMs, potentially weakening their ability to perform precise reasoning when analyzing microservice architectures. This challenge also affects context handling, as models may introduce non-existent components or interactions when attempting to fill gaps in incomplete or ambiguous information. The risk of false inferences becomes particularly relevant given the different architectural elements in microservice architectures. Identifying high-level components, inter-service connections, and concrete API endpoints requires progressively finer-grained reasoning and deeper contextual integration. As the level of detail increases, the task may become more cognitively demanding for LLMs, which may influence reconstruction accuracy. To examine whether this granularity affects the performance of the LLMs, we formulate the following hypotheses:

- $H_{02}$: The architectural element type **does not affect** the LLMs accuracy of reconstructing a microservice architecture.
- $H_{12}$: The architectural element type significantly **affects** the LLMs accuracy for reconstructing a microservice architecture.

## 3.2 Study Context

Schneider et al. [21] introduced the microSecEnD dataset, which provides a collection of open-source microservice-systems represented as dataflow diagrams. The dataset consists of open-source Java microservice applications implemented using the Spring framework

and hosted on GitHub. For each application, the available artifacts include the source code, configuration files, and a manually validated reference architecture describing the services, their inter-service connections, and exposed endpoints. The selected systems vary in scale, ranging from 604 to 14,527 lines of code and comprising between 2 and 14 services. Architectural complexity, quantified by the total number of nodes and edges in the corresponding data flow diagrams (DFDs), spans from 29 to 246 elements across the dataset. Schneider et al. [20] used microSecEnD to benchmark state-of-the-art static analysis tools for microservice architecture recovery. Their evaluation reported an overall F1-score of 0.86 for the strongest individual tool, which increased to 0.91 when multiple tools were combined. We adopt microSecEnD as the primary dataset to investigate whether the same reconstruction task can be performed using an LLM-based agent.

## 3.3 Agent Architecture

The architecture consists of a lightweight MVA agent workflow that enables the LLM to process the entire application directory and produce a single, consolidated output in a standardized JSON format. The agent system programmatically inspects the source code and associated artifacts of each microservice application. Its behavior is organized around a role-based prompt provided with a static analysis context.

- **Source Code Access**: The agent is provided with the full path to the application repository with the ability to reference all files, source code, configuration and when constructing the prompt ensuring that the LLM has complete architectural context.
- **Tools**: The LLM can request the use of three tools: one to list subdirectories and files in each repository, one to read the complete content of any file, and one to search for text patterns across all files in the repository.
- **Prompt Construction**: Based on the given prompting strategy, the LLM receives a common set of instructions that require it to report strictly from file evidence, avoid assumptions or prior knowledge, and comply with specific formatting rules when presenting its findings. We experimented with different prompt approaches and chose the best performing, single role-based prompting approach for subsequent analysis, as follows:
  - Role-based: The agent is assigned an expert role in static code analysis. The prompt depends on the domain-specific heuristics associated with that role, without using explicit task decomposition or step-by-step reasoning. To promote reliable results, the prompt instructs the LLM to report only those findings that can be directly supported by the source files, without requiring the supporting evidence to be included in the output.
- **Output**: The agent retrieves the LLM's response, parses the JSON, and stores both the architecture and the reasoning for subsequent evaluation. It repeats this workflow for each application and prompt strategy, supporting comparative analysis of reasoning quality and extraction accuracy. Invalid outputs trigger an iterative re-prompting loop.

## 3.4 Data Collection

To assess how well large language models can reconstruct microservice architectures, we experimented with various prompt engineering techniques across multiple LLM providers to assess their effectiveness in restoring the microservice architecture from 17 open-source Java repositories. We obtained all necessary code artifacts and ground-truth architecture specification for each application, enumerating all validated microservice components, their

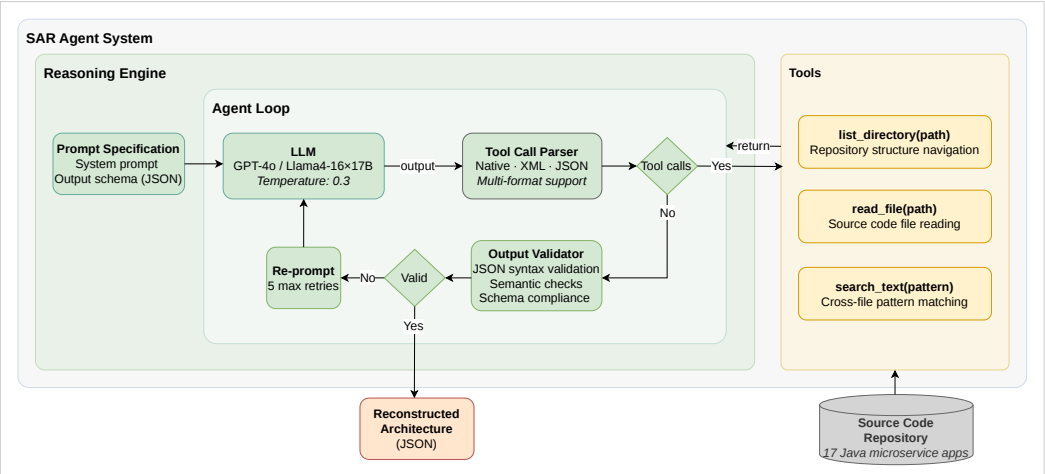

**Figure 2** A minimum viable SAR agent. LLMs iteratively navigate the repository using the provided tools until a valid, structured architecture reconstruction is produced.

connections, and endpoints. We then executed our agent on each application, with a role-based prompt and two LLMs. GPT-4o was accessed via the OpenAI API alias, which resolved to snapshot gpt-4o-2024-08-06 during our runs (2026-03-14). Llama4-16×17B was served via OpenAI-compatible inference endpoints on Danish HPC infrastructure. Both models were queried with temperature = 0.3 and other decoding parameters at provider defaults. The agent analyzed the application directory and generated structured outputs that described every inferred component, connection, and endpoint.

## 3.5 Data Analysis

For each of the 17 open source microservice applications, we performed an automated comparison against the groundtruth architecture. We executed 25 runs per model to provide redundancy against transient API and network errors. We retained 20 runs per model for the analysis, yielding 340 observations per model (17 applications × 20 runs). Within the 20 runs, application-level observations that fail to produce a parseable extraction due to missing output, malformed JSON format or schema errors, are retained in the analysis and scored as zero rather than excluded. The analysis included the following steps:

- **Data pre-processing:** We parsed and normalized the data by converting both the LLM-generated outputs and the ground-truth specifications into a canonical representation, harmonizing naming conventions to enable a fair comparison.
- **Metric Computation**: For each application, we evaluated accuracy by computing standard information retrieval metrics consisting of precision, recall, and F1-score separately for components, connections, and endpoints.
- **Result Aggregation**: We consolidated the evaluation metrics across all applications, runs and LLM providers, and exported the aggregated results to a CSV file for subsequent analysis and visualization.
- **Error Analysis**: We investigated instances with low or zero metric values to uncover recurring failure patterns, investigating such outputs for inconsistent naming patterns or incomplete extractions.

**LLM Accuracy for Microservice Reconstruction ($RQ_1$).** For each subject system, LLM, architectural element type, and run, we compute precision, recall, and F1-score against the ground truth. We then compute the macro-average across the three element types for each run, yielding a system-averaged score per run that represents overall reconstruction accuracy. We report descriptive statistics (mean, median, standard deviation) on the system-averaged accuracy metrics per run. Following standard empirical software engineering practice [26], we test data normality using the Anderson–Darling test [2, 24]. If normality is not rejected, we apply a two-sided paired t-test with Cohen's $d_z$ as effect size; otherwise, we apply a two-sided Wilcoxon signed-rank test [25] with the rank-biserial correlation $r = (W^+ - W^-)/(W^+ + W^-)$ as effect size [13]. We conduct inferential tests on per-application mean scores aggregated across repeated executions, treating the application as the experimental unit. We set significance level $\alpha = 0.05$ and apply the procedure separately for each metric ($n = 17$ paired observations).

**The Impact of Architectural Element Type on Accuracy ($RQ_2$).** For each subject system, we compute precision, recall, and F1-score for three element categories (components, connections, endpoints), separately for each LLM and metric. Following the same procedure as $RQ_1$[26], we assess normality using the Anderson–Darling test [2, 24]. If normality is not rejected, we apply repeated-measures ANOVA [9] with partial $\eta^2$ as omnibus effect size; otherwise, the Friedman test [8] with Kendall's $W$. Following a significant omnibus test, for normally distributed data, we conduct post-hoc pairwise comparisons using parametric paired t-tests with Cohen's $d_z$ or the non-parametric Wilcoxon signed-rank tests with the rank-biserial correlation $r = (W^+ - W^-)/(W^+ + W^-)$ if normality is rejected [13]. To control the family-wise error rate across nine post-hoc comparisons (three element type pairs $\times$ three metrics), we apply a Bonferroni correction at $\alpha = 0.05$, yielding an adjusted threshold of $\alpha = 0.0056$. A pairwise difference is considered practically meaningful when significant after correction and reaching at least a medium effect size ($d_z \geq 0.5$ or $r \geq 0.3$) [4, 14]. Because the goal is comparative evaluation, we do not define an absolute threshold for acceptable reconstruction accuracy.

## 4 Results

This section presents the accuracy of GPT-4o and Llama4 in reconstructing microservice architectures from source code, and examines whether architectural element type influences the accuracy. Results are based on 17 subject systems executed across 20 repeated runs per model, reporting precision, recall, and F1-score against ground-truth annotations.

**LLM Accuracy for Reconstructing a Microservice architecture ($RQ_1$).** The Anderson–Darling test rejected normality for both LLMs across all metrics (Precision: $A^2 = 21.91$ for GPT-4o, 13.09 for Llama4; Recall: $A^2 = 3.19$ and 6.28; F1: $A^2 = 5.74$ and 4.60; all $p < 0.0001$), motivating the use of the non-parametric Wilcoxon signed-rank test. Across the experiments, GPT-4o exhibits substantially higher scores than Llama4 across all accuracy metrics. Notably, GPT-4o achieves high precision, indicating that the majority of extracted elements are correct, while its mean F1 score is more than twice that of Llama4, with substantial gaps in both precision and recall. The Wilcoxon signed-rank test confirms a statistically significant difference in favour of GPT-4o across all three metrics, indicating that GPT-4o outperformed Llama4 on every paired observation. Due to GPT-4o outperfoming Llama4-16x17B on every one of the 17 applications for Precision, Recall and F1, the three

Wilcoxon signed-ranked tests yield identical statistics ($S = -76.5$, $r = 1.000$, $p < 0.001$), interpreted as a single sign-test-like confirmation of complete dominance rather than as three independent statistical confirmations. Full descriptive statistics and Wilcoxon signed-rank test results are provided in Table 1.

**Table 1** Descriptive statistics on system-averaged scores ($n = 340$ per model) and Wilcoxon signed-rank test results on per-application aggregated means ($n = 17$ paired observations, two-sided, Bonferroni $\alpha = 0.017$).

| | GPT-4o | | | Llama4 | | | Wilcoxon | | |
|---|---|---|---|---|---|---|---|---|---|
| **Metric** | **Mean** | **Median** | **Std** | **Mean** | **Median** | **Std** | **S** | **p** | **r** |
| Precision | 0.846 | 0.915 | 0.181 | 0.452 | 0.583 | 0.292 | −76.5 | <0.001* | 1.000 |
| Recall | 0.514 | 0.533 | 0.168 | 0.200 | 0.176 | 0.161 | −76.5 | <0.001* | 1.000 |
| F1 | 0.604 | 0.655 | 0.171 | 0.254 | 0.261 | 0.189 | −76.5 | <0.001* | 1.000 |

* Significant after Bonferroni correction ($\alpha = 0.017$).

**Architectural Element Type in Reconstructing a Microservice architecture ($RQ_2$).** As the Anderson–Darling test rejected normality of the raw accuracy scores in every architectural element type–metric–model combination ($A^2$ ranging from 2.26 to 80.95, all $p < 0.0001$), we chose the non-parametric Friedman test for the statistical analysis. Described in Table 2, the Friedman test indicates a significant effect of architectural element type on reconstruction accuracy for both models. The effect is large for GPT-4o for F1 and Recall, and moderate for Llama4. Precision shows no significant architectural element type effect for GPT-4o.

**Table 2** Friedman test results for Precision, Recall, and F1 scores across architectural element types.

| **Model** | **Metric** | $\chi^2$ | **p-value** | **Kendall's $W$** |
|---|---|---|---|---|
| GPT-4o | Precision | 2.362 | 0.307 | 0.069 |
| | Recall | 22.776 | <0.001 | 0.670 |
| | F1 | 22.776 | <0.001 | 0.670 |
| Llama4 | Precision | 9.556 | 0.008 | 0.281 |
| | Recall | 15.394 | <0.001 | 0.453 |
| | F1 | 15.636 | <0.001 | 0.460 |

Post-hoc Wilcoxon signed-rank tests with Bonferroni correction reveal distinct patterns between models, highlighted in Table 3. For GPT-4o, connections perform significantly worse than both components and endpoints for F1 and Recall. No significant difference is observed between components and endpoints. For Llama4, components significantly outperform both connections and endpoints for F1 and Recall while connections and endpoints do not differ significantly. For Precision, none of the pairwise comparisons reach significance after correction. These results lead to rejection of $H_{02}$: architectural element type significantly affects reconstruction accuracy for both models, though the nature and magnitude of the effect differ between GPT-4o and Llama4. Figure 3 reveals additional distributional patterns. GPT-4o's interquartile range for endpoint precision indicates high precision in the majority of runs rather than as isolated outliers. Llama4's F1 distribution is bimodal, the model either performs moderately or fails completely, and for endpoints, more than half of all runs yield zero across all three metrics. Across both models, connections exhibit a precision-recall asymmetry, with high precision coexisting alongside consistently low recall.

**Table 3** Post-hoc Wilcoxon signed-rank results per architectural element pair ($n = 17$, Bonferroni $\alpha = 0.0056$).

| Model | Metric | | Component vs. Connection | Component vs. Endpoint | Connection vs. Endpoint |
|---|---|---|---|---|---|
| GPT-4o | F1 | $S$ | 0 | 42 | 1 |
| | | p-value | <0.001* | 0.109 | <0.001* |
| | | $r$ | 1.000 | 0.451 | 0.987 |
| | Recall | $S$ | 0 | 32 | 3 |
| | | p-value | <0.001* | 0.035 | <0.001* |
| | | $r$ | 1.000 | 0.582 | 0.961 |
| Llama4 | F1 | $S$ | 0 | 13 | 63 |
| | | p-value | <0.001* | 0.001* | 0.548 |
| | | $r$ | 1.000 | 0.830 | 0.176 |
| | Precision | $S$ | 29 | 19 | 24 |
| | | p-value | 0.433 | 0.006 | 0.013 |
| | | $r$ | 0.256 | 0.752 | 0.686 |
| | Recall | $S$ | 0 | 14 | 72 |
| | | p-value | <0.001* | 0.002* | 0.854 |
| | | $r$ | 1.000 | 0.817 | 0.059 |

* Significant after Bonferroni correction ($\alpha = 0.0056$).

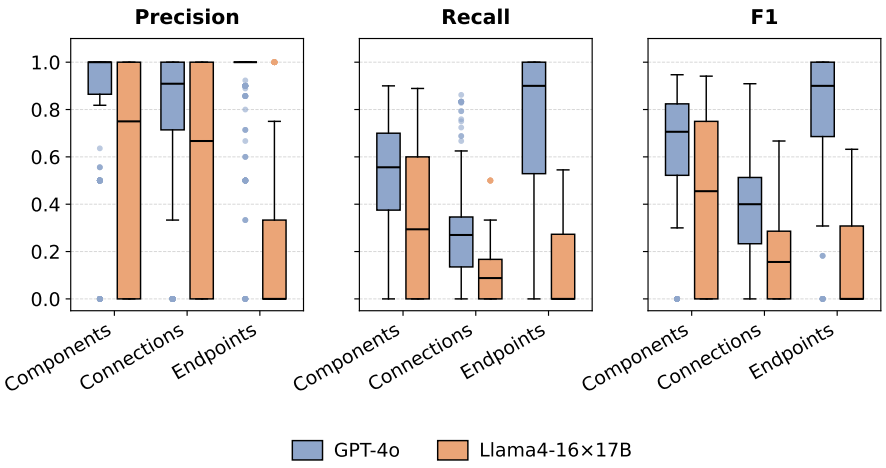

**Figure 3** Distribution of Accuracy Metric by Architectural Element Type.

## 5 Discussions

Our research indicates that reconstruction accuracy is significantly affected by both the choice of LLM and the architectural element type being recovered. The two factors shape the outcome differently as the LLM choice determines the overall achievable level of accuracy while the element type shapes the pattern of strengths and weaknesses within both models. **The performance gap between GPT-4o and Llama4 is consistently large across all metrics and element types, indicating that model capability is a major factor of reconstruction quality**.

**Beyond the difference in accuracy, the two models fail in qualitatively different ways.** GPT-4o is consistently conservative by identifying fewer architectural element types than the ground truth but the elements it identifies are frequently correct. Llama4, by contrast, exhibits compound failure modes including inconsistent naming and malformed outputs. This distinction has relevance for downstream use. GPT-4o's incompleteness can be addressed by augmenting the extracted architecture, but Llama4's structural unreliability undermines the use of its outputs. Reconstruction accuracy also varies systematically across architectural element types. Endpoints, typically defined through REST annotations, are recovered most reliably, followed by components identifiable from class structure and naming conventions. Connections are the most difficult element type for both models, likely because they rely on indirect implementation details such as messaging middleware, gateway routing, or runtime configuration. However, GPT-4o and Llama4 differ in which element types they recover most reliably, suggesting that model capability also influences which architectural information can be extracted. Together, these findings indicate that **the limits of LLM-based SAR depend on both model capability and the observability of architectural information in static source code**.

Besides raw capability, **tool use behaviour can influence the observed differences**. Architectural reconstruction is fundamentally an exploratory task requiring iterative repository navigation [18, 19]. Llama4's tendency to underuse available tools, requiring explicit re-prompting to elicit exploration [27], may explain its weak recall. Our observations suggest that equipping LLMs with reliable agentic exploration strategies can be a critical aspect of the task. Across both models and all element types, precision exceeds recall, often substantially, indicating that **the principal limitation lies in completeness rather than correctness**. This positions LLMs as suitable for complementing architecture recovery but insufficient as a standalone source of truth in our study configuration.

## 6 Threats to Validity

This section discusses the threats to validity explaining the different adopted tactics [26].

**Construct Validity.** We acknowledge that the reliance on LLMs for information extraction assessment introduces a potential construct validity concern. We operationalise reconstruction quality using Precision, Recall and F1 on components, connections and endpoints computed against a benchmark dataset of open-source Spring-based microservice systems with manually validated ground-truth annotations. This captures element-level extraction correctness but does not measure semantic aspects such as protocol correctness or the downstream usefulness of the reconstructed model. The ground-truth annotations themselves may be incomplete or inconsistent for individual applications.

**Internal Validity.** Each evaluated project is represented by a single canonical architectural reference. While this ensures analytical consistency, it may exclude alternative decompositions that would also be considered architecturally sound. Additionally, models may show preferences for specific tools, introducing evaluation bias.

**External Validity.** The study scope is limited to open-source microservice codebases written in Java and retrieved from GitHub. Although the selected projects span a range of sizes, application domains, and implementation styles, the findings may not transfer to proprietary systems, codebases developed in other programming languages, highly specialised domain contexts, or architectural patterns that fall outside those represented in our sample.

**Conclusion Validity.** Several factors may influence the reliability of the statistical conclusions. LLM outputs are inherently stochastic, which can lead to variation across repeated runs. To mitigate this, we used a low temperature setting (0.3), and performed multiple runs per application; however, minor variability may still remain. Tool execution may introduce additional noise when outputs fail to conform to the expected format. Finally, the reproducibility of the study may be affected by the evolution of external LLM APIs and open-source model versions over time.

## 7 Conclusions

We present an empirical evaluation of a simple MVA-based agent for reconstructing microservice architectures from source code, comparing the accuracy of a commercial and an open-source language model and the effect of architectural element type on the accuracy. GPT-4o substantially outperformed Llama4 across all accuracy metrics, with statistically significant differences for precision, recall, and F1. GPT-4o demonstrated high precision while recall remained moderate for both models, indicating that LLM-based reconstruction produces reliable but incomplete extractions. Architectural element type also had a statistically significant effect on reconstruction accuracy for both models. GPT-4o achieved its strongest performance on endpoints and moderate degradation on components and connections, whereas Llama4 achieved acceptable performance for components and degraded substantially on connections and endpoints. LLM-based reconstruction appears reliable for explicit, local architectural elements such as services and annotated endpoints, but less reliable for global structural relationships.

When compared with the strongest static-analysis approaches evaluated on the same microSecEnD benchmark [20], GPT-4o achieved a lower overall F1-score (0.604 versus 0.86 for the best individual tool and 0.91 for the combined approach). These results indicate that, although an LLM-only MVA can recover substantial architectural information, it does not yet match the completeness and overall accuracy of state-of-the-art static-analysis techniques. Specifically, the single-agent setup consistently under-performs on implicit inter-service dependencies and favors models with strong instruction-following capability. Future work should investigate agentic workflows with explicit task decomposition and self-refinement particularly to address the trade-off between completeness and reliability of architectural extraction.

## Declaration on the use of generative AI

The authors used ChatGPT for suggestions on improving textual clarity. All research design, data analysis, interpretations, and manuscripts were created by the authors themselves.

## Data Availability Statement

We provide all raw data, scripts, model prompts, and analysis configurations in a FAIR [3] replication package on Zenodo [4].

## Abstract

Large language models (LLMs) are increasingly used for code translation, yet existing evaluations often collapse results across language pairs, thereby obscuring the direction of transfer. We present an emerging empirical study that treats multilingual code translation as a directed transfer problem. Our study uses 100 programming problems, each with reference implementations in eight languages, yielding a complete directed graph of 56 ordered source-target translation directions. Five contemporary LLMs generate candidate translations, which are evaluated through execution in the target language. The results reveal substantial directional asymmetry. In model-averaged pass@5, reversing a language pair changes the translation success rate by as much as 27.4 percentage points. We also observe systematic differences between source and target roles: Python3 and Java achieve higher average performance when used as source languages, whereas JavaScript, Rust, and Golang achieve higher average performance when used as target languages. These findings show that aggregate scores and unordered language-pair averages can conceal practically important transfer behavior. Rather than establishing a definitive model ranking, this study provides preliminary evidence that code-translation evaluations should preserve ordered source-target results, distinguish source and target language roles, and explicitly report directional gaps. This direction-aware perspective provides a more informative basis for subsequent failure analysis and the evaluation of realistic cross-language migration scenarios.

## 1 Introduction

Large language models (LLMs) have made code generation a mainstream research topic [1, 3, 5]. However, many practical software engineering scenarios require translating existing programs rather than producing new implementations from natural-language requirements [13, 6]. Developers translate code when migrating legacy systems, porting algorithmic implementations, reusing software across language ecosystems, teaching programming concepts in multiple languages, or moving prototypes toward production-oriented platforms [4]. Recent repository-level benchmarks further demonstrate that code migration is a practical software engineering problem rather than merely a programming-contest task [14, 15]. In these settings, an LLM must understand an existing source program, preserve its intended behavior, and realize that behavior as an executable implementation in a different programming language.

This paper argues that LLM-based code translation should be studied as a *directed* transfer problem. Translating from Java to JavaScript is not necessarily equivalent to translating from JavaScript to Java. The former starts from explicit type information and class structure and produces an implementation in a more flexible language, whereas the latter may require the model to recover types, interfaces, and data-structure choices that are implicit in the source code. Similar directional differences may arise between Python3 and Rust, C and Golang, or C++ and C#. Consequently, treating a language pair as unordered can hide important empirical behavior: a single pair-level average may conflate two translation tasks that impose different requirements on the model.

We conduct an emerging empirical study of direction-aware code translation across eight programming languages: Python3, Java, C, C++, Rust, JavaScript, C#, and Golang. Our evaluation set contains 100 programming problems, each with reference implementations in all eight languages. This design induces a complete directed translation graph in which programming languages are nodes and the 56 ordered source-target pairs are directed edges. For each evaluated model, problem, and translation direction, the model generates candidate programs in the specified target language. The resulting programs are submitted to the corresponding target-language execution environment, so correctness is determined through execution rather than textual similarity, following the broader movement toward execution-based code evaluation [3, 8, 7]. Because the same 100 problems are used across all translation directions, differences between source-target pairs can be examined under matched problem semantics.

Figure 1 summarizes the study setting. The central empirical object is the directed translation graph rather than a single aggregate model score. Each edge represents a concrete translation direction, such as Java-to-JavaScript or JavaScript-to-Java. Preserving this ordered relation throughout the evaluation allows us to examine whether opposite directions exhibit similar performance, which directions are comparatively difficult, and whether individual languages behave differently when serving as sources and targets.

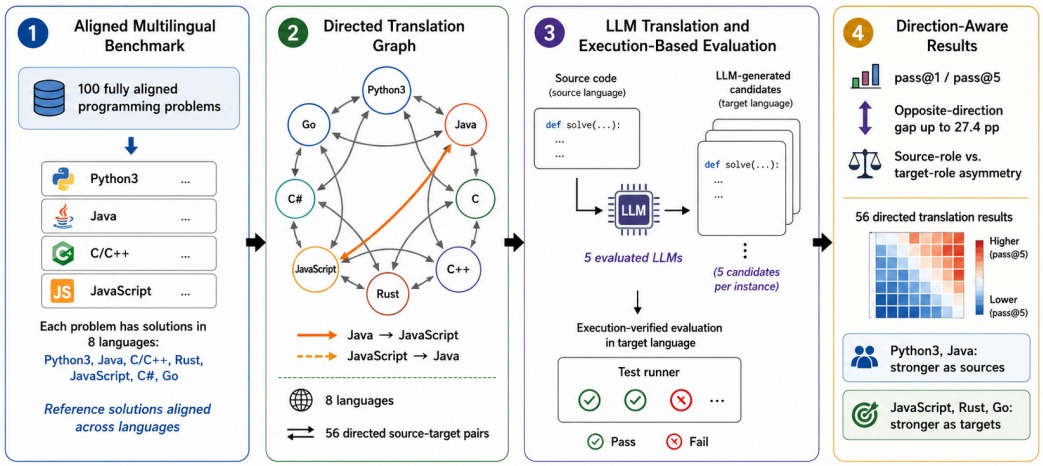

**Figure 1** Overview of our direction-aware code translation study. Using 100 aligned multilingual problems across 8 languages, we form 56 directed source-target pairs, evaluate LLM outputs by execution, and analyze the resulting matrix for opposite-direction gaps and source/target role asymmetries.

As an emerging-results study, we center our investigation on one overarching question: *what does the 56-edge translation graph reveal about the behavior of LLM-based code translation?* Our results show that the graph is uneven, asymmetric, and role-dependent. Although the evaluated models differ in overall translation performance, aggregate model scores do not reveal where translation succeeds or fails. In model-averaged pass@5 results, several pairs exhibit opposite-direction differences exceeding 20 percentage points, with the largest observed gap reaching 27.4 percentage points. We also find that some languages achieve higher average performance when used as source languages, whereas others achieve higher average performance when used as target languages. These observations indicate that translation difficulty cannot be adequately characterized by an unordered language pair or by a single language-level score.

This paper makes two main contributions:

- We formulate multilingual code translation as a direction-aware evaluation problem, representing programming languages as nodes and ordered source-target translation tasks as edges in a directed graph.
- We provide execution-verified empirical evidence from 100 programming problems, eight languages, 56 directed translation pairs, and five contemporary LLMs, showing that aggregate translation scores can conceal substantial opposite-direction gaps and distinct source/target language roles.

Based on these findings, we derive reporting implications for empirical evaluations of LLM-based code translation. In particular, translation studies should preserve ordered source-target results, report source and target language roles separately, and distinguish first-attempt performance from multi-candidate translation success.

## 2 Code Translation as a Directed Transfer Problem

### 2.1 Direction-Aware Translation Perspective

Code generation and code translation are related but distinct capabilities. Code generation maps a natural-language problem description to an implementation in a target language and has been extensively studied through benchmarks such as HumanEval and its multilingual

extensions [3, 2, 20]. Broader code-intelligence datasets further support multilingual and multi-task evaluation [21, 7]. Code translation, by contrast, starts from an existing implementation and asks a model to preserve its behavior while realizing an executable program in another language. This task has motivated dedicated translation methods, datasets, and evaluation studies [12, 6, 18, 14]. A successful translation therefore requires the model to understand the source program, preserve its intended semantics, and satisfy the syntactic, type, library, and execution constraints of the target language. The broader challenge of preserving intent across representations also arises in LLM-assisted formal specification generation, where informal requirements are transformed into machine-checkable specifications [11, 10, 9]. Although code translation and specification generation produce different artifacts, both require semantic constraints expressed in one representation to be faithfully reconstructed in another.

These coupled requirements make the direction of transfer important. Translating from language $A$ to language $B$ is not necessarily equivalent to translating from $B$ to $A$, because the two directions may expose different information and impose different reconstruction requirements. For example, a dynamically typed source may leave type information implicit, making translation into a statically typed target more demanding. A low-level source may expose memory management, indexing, or pointer-related details that must be re-expressed using higher-level abstractions. Conversely, translating from a high-level language into a systems language may require explicit choices concerning data structures, ownership, interfaces, and resource management. An aggregate score over an unordered language pair can therefore conflate two empirically and practically different translation tasks.

We model multilingual code translation as a weighted directed graph. Each programming language is represented as a node, and each ordered source-target pair is represented as a directed edge. For eight languages, the resulting graph contains $8 \times 7 = 56$ directed edges. This graph supports three complementary levels of analysis. At the *edge level*, we examine the translation success of an individual source-target direction. At the *pair level*, we compare two opposite edges, such as Java-to-JavaScript and JavaScript-to-Java, to quantify directional asymmetry. At the *role level*, we aggregate outgoing and incoming edges to study how a language behaves when used as a source or as a target.

This perspective complements conventional aggregate reporting. A model-level score over all translation instances remains useful as a coarse indicator of overall capability, but it does not answer the practical question faced by developers: *can this model translate from the language I have to the language I need?* Direction-aware evaluation addresses this question by preserving the ordered source-target relation throughout the analysis. It also complements execution-based multilingual code evaluation [7] by shifting attention from model-level or target-only averages to the edge-, pair-, and role-level structure of multilingual transfer.

## 2.2 Formal Problem Definition

Let $\mathcal{L} = \{\ell_1, \ldots, \ell_m\}$ denote a set of programming languages and $\mathcal{P} = \{p_1, \ldots, p_n\}$ denote a set of programming problems. Each problem $p \in \mathcal{P}$ has a reference implementation $s_{p,\ell}$ in every language $\ell \in \mathcal{L}$. A directed code-translation instance is represented as a triple $(p, \ell_s, \ell_t)$, where $\ell_s, \ell_t \in \mathcal{L}$ and $\ell_s \neq \ell_t$. Its input consists of the source program $s_{p,\ell_s}$ and the specified target language $\ell_t$. The expected output is a target-language program $\hat{s}_{p,\ell_t}$ that preserves the behavior of $s_{p,\ell_s}$ and is executable in the target-language evaluation environment.

We view an LLM $M$ as a stochastic translator:

$$M(s_{p,\ell_s}, \ell_t) \rightarrow \{\hat{s}^{(1)}_{p,\ell_t}, \ldots, \hat{s}^{(k)}_{p,\ell_t}\},$$

where $k$ denotes the number of generated candidates. Correctness is determined by an execution oracle $E$:

$$E(p, \ell_t, \hat{s}) = \begin{cases} 1, & \text{if } \hat{s} \text{ passes the target-language tests for } p, \\ 0, & \text{otherwise.} \end{cases}$$

Execution provides a uniform and practical correctness criterion, but its judgment is necessarily limited to the available test cases. Recent work on LLM-assisted formal specification generation suggests a complementary direction in which machine-checkable behavioral properties could support stronger validation of semantic preservation beyond test execution [16, 17, 19].

For a directed instance $(p, \ell_s, \ell_t)$, empirical pass@$k$ indicates whether at least one of the first $k$ candidates is accepted:

$$\text{pass@}k(p, \ell_s, \ell_t, M) = \mathbb{I}\left[\max_{1 \le i \le k} E(p, \ell_t, \hat{s}^{(i)}_{p,\ell_t}) = 1\right].$$

This measure represents empirical best-of-$k$ success over the generated candidates. It differs from the unbiased pass@$k$ estimator commonly used when a larger candidate pool is sampled.

The edge weight for an ordered source-target pair $(\ell_s, \ell_t)$ is defined as the average empirical pass@$k$ over the problem set:

$$w_k(\ell_s, \ell_t, M) = \frac{1}{|\mathcal{P}|} \sum_{p \in \mathcal{P}} \text{pass@}k(p, \ell_s, \ell_t, M).$$

This definition induces a model-specific weighted directed graph $G^M_k = (\mathcal{L}, \mathcal{E}, w_k)$, where

$$\mathcal{E} = \{(\ell_s, \ell_t) : \ell_s, \ell_t \in \mathcal{L}, \ell_s \neq \ell_t\}.$$

When results are aggregated over a set of evaluated models $\mathcal{M} = \{M_1, \ldots, M_r\}$, we define the model-averaged edge weight as

$$\bar{w}_k(\ell_s, \ell_t) = \frac{1}{|\mathcal{M}|} \sum_{M \in \mathcal{M}} w_k(\ell_s, \ell_t, M).$$

To quantify asymmetry between two languages, we compare the corresponding opposite edges:

$$\Delta_k(\ell_a, \ell_b) = \left|\bar{w}_k(\ell_a, \ell_b) - \bar{w}_k(\ell_b, \ell_a)\right|.$$

A small $\Delta_k$ indicates that the two directions exhibit similar translation success under the evaluation setting, whereas a large value indicates that reversing the source and target languages substantially changes the observed performance.

We further characterize the source and target roles of a language $\ell$ by averaging its outgoing and incoming edges:

$$\text{Src}_k(\ell) = \frac{1}{|\mathcal{L}| - 1} \sum_{\ell_t \in \mathcal{L} \setminus \{\ell\}} \bar{w}_k(\ell, \ell_t),$$

$$\text{Tgt}_k(\ell) = \frac{1}{|\mathcal{L}| - 1} \sum_{\ell_s \in \mathcal{L} \setminus \{\ell\}} \bar{w}_k(\ell_s, \ell).$$

Here, $\text{Src}_k(\ell)$ measures the average translation success when $\ell$ provides the source program, whereas $\text{Tgt}_k(\ell)$ measures the average success when $\ell$ is the requested target language. Their difference, $\text{Tgt}_k(\ell) - \text{Src}_k(\ell)$, indicates whether a language obtains higher performance in the target or source role.

In the remainder of the paper, we apply these definitions to the complete 56-edge translation graph. Our analysis proceeds from overall model performance to directed edge behavior, opposite-direction gaps, and source/target language roles.

**Table 1** Direction-aware code translation setting.

| Item | Setting |
|---|---|
| Problems | 100 fully aligned programming problems |
| Languages | Python3, Java, C, C++, Rust, JavaScript, C#, Golang |
| Translation graph | 8 language nodes and 56 directed source-target edges |
| Candidates | 5 candidates per problem-source-target setting |
| Candidates per model | 28,000 translated programs |
| Evaluation protocol | Target-language execution-based checking |
| Main metrics | Accepted rate, pass@1, pass@5, opposite-direction gap |

# 3 Study Design

## 3.1 Research Questions

Guided by the direction-aware formulation in Section 2.2, we organize the study around three research questions.

**RQ1: How effectively do LLMs perform execution-verified code translation across eight programming languages?** This question examines the overall translation capability of the evaluated models before considering individual source-target directions.

**RQ2: To what extent does code-translation performance depend on the source-target direction?** This question analyzes the 56 directed source-target edges and compares each edge with its reverse direction to quantify directional asymmetry.

**RQ3: How do programming languages differ in their source and target roles?** This question aggregates outgoing and incoming translation edges separately to examine whether a language behaves differently when providing the source program and when serving as the target language.

## 3.2 Evaluation Set and Translation Graph

The study evaluates 100 online-judge programming problems across eight programming languages: Python3, Java, C, C++, Rust, JavaScript, C#, and Golang. Each problem has a reference implementation in every language, allowing each language to serve as the source and every other language to serve as the target. The same 100 problem identities are used for all translation directions, ensuring that source-target pairs and their reverse directions are evaluated under matched problem semantics. This controlled design reduces the influence of problem-set composition when comparing translation directions.

Under the formulation in Section 2.2, $|\mathcal{L}| = 8$ and $|\mathcal{P}| = 100$. The eight languages form a complete directed graph with $8 \times 7 = 56$ ordered source-target edges. Each edge represents one translation direction, such as Java-to-JavaScript or JavaScript-to-Java, and each evaluation instance is a problem-source-target triple $(p, \ell_s, \ell_t)$. The resulting evaluation contains $100 \times 56 = 5{,}600$ directed translation instances per model before candidate sampling. Table 1 summarizes the study setting.

## 3.3 Models and Prompting

We evaluate five contemporary code-capable LLMs: qwen3-coder-480b-a35b-instruct, gpt-4o, glm-4, deepseek-v3.2, and claude-3-5-haiku-20241022. For each problem and ordered source-target pair, the prompt provides the reference implementation $s_{p,\ell_s}$ in the source language and instructs the model to produce an equivalent implementation in the target language

$\ell_t$. The instruction template remains fixed across all translation directions; only the source program and target-language name vary. This common prompting protocol ensures that the 56 directed edges are evaluated under the same task formulation.

Each model generates five candidates for every problem-source-target instance. Consequently, one model produces $100 \times 56 \times 5 = 28{,}000$ translated programs, and the five evaluated models collectively produce 140,000 candidates. The complete prompt templates, model invocation configurations, and decoding parameters are provided in the accompanying artifact.

### 3.4 Execution-Verified Evaluation

Model outputs are converted into executable submissions using the corresponding target-language templates. When an output contains Markdown fences, post-processing selects the first complete code block matching the target language. Otherwise, it uses the first complete code block or the cleaned raw output. The extracted program is then inserted into the target-language submission template. Post-processing does not repair imports, rename identifiers, edit types, modify input-output logic, or manually correct algorithms.

A candidate is accepted only if the execution oracle returns $E(p, \ell_t, \hat{s}) = 1$. We report three complementary correctness measures: candidate-level accepted rate, empirical pass@1, and empirical pass@5. The acceptance rate is computed over all generated candidates. Pass@1 indicates whether the first candidate for a problem-source-target instance is accepted, whereas pass@5 indicates whether at least one of its five candidates is accepted. Thus, accepted rate is a candidate-level measure, while pass@1 and pass@5 are instance-level best-of-$k$ measures.

For each model, the overall pass@5 result is computed over the 5,600 problem-source-target instances. The corresponding 95% confidence interval is estimated from these instance-level binary outcomes. Reporting both pass@1 and pass@5 allows us to distinguish first-attempt reliability from the benefit of generating multiple translation candidates.

For the direction-level analyses in RQ2 and RQ3, we use the model-averaged edge weight $\bar{w}_5(\ell_s, \ell_t)$ defined in Section 2.2. Opposite-direction asymmetry is measured using $\Delta_5(\ell_a, \ell_b)$, while source and target language roles are characterized using $\mathrm{Src}_5(\ell)$ and $\mathrm{Tgt}_5(\ell)$. Unless otherwise stated, these analyses average pass@5 over the five evaluated models. The resulting edge-, pair-, and role-level values are interpreted as empirical observations about the evaluated 56-edge translation graph rather than as intrinsic rankings of programming languages.

## 4 Preliminary Results

### 4.1 RQ1: Overall Translation Performance

We first examine overall execution-verified translation performance before analyzing the structure of individual source-target directions. Table 2 reports the results of each model aggregated over the 5,600 problem-source-target instances defined by the 56 directed translation edges. Among the evaluated models, qwen3-coder-480b-a35b-instruct achieves the highest pass@5 at 90.5%, followed by gpt-4o at 85.8%. The other models also demonstrate nontrivial translation capability: glm-4 reaches 73.8%, while deepseek-v3.2 and claude-3-5-haiku-20241022 achieve 60.5% and 59.0%, respectively.

Figure 2 compares first-attempt translation success with best-of-five success. Although accepted rate and pass@1 are numerically similar for several models in Table 2, they are computed over different units. Accepted rate is the proportion of successful candidates

**Table 2** Overall results for directed code translation.

| Model | Candidates | Accepted | Accepted Rate | Pass@1 | Pass@5 | 95% CI |
|---|---|---|---|---|---|---|
| qwen3-coder-480b-a35b | 28,000 | 24,433 | 87.3% | 87.5% | 90.5% | [89.7, 91.2] |
| gpt-4o | 28,000 | 17,295 | 61.8% | 61.8% | 85.8% | [84.9, 86.7] |
| glm-4 | 28,000 | 15,141 | 54.1% | 54.3% | 73.8% | [72.6, 74.9] |
| deepseek-v3.2 | 28,000 | 12,215 | 43.6% | 43.8% | 60.5% | [59.2, 61.8] |
| claude-3-5-haiku | 28,000 | 10,477 | 37.4% | 37.4% | 59.0% | [57.7, 60.3] |

Note: qwen3-coder-480b-a35b abbreviates qwen3-coder-480b-a35b-instruct.

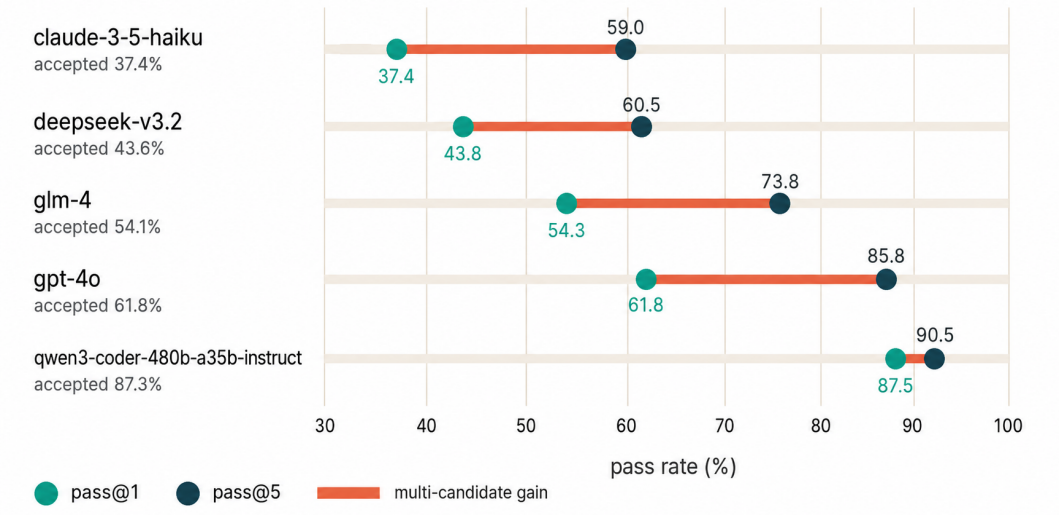

**Figure 2** Overall pass@1 and pass@5 of the five evaluated LLMs across the 56 directed translation edges.

among all 28,000 generated programs per model, whereas pass@1 is the proportion of the 5,600 problem-source-target instances for which the first candidate is accepted. The more informative sampling comparison is therefore between pass@1 and pass@5.

For qwen3-coder-480b-a35b-instruct, pass@5 exceeds pass@1 by only 3.0 percentage points, indicating that most of its successful translation instances are already solved by the first candidate. In contrast, gpt-4o improves from 61.8% pass@1 to 85.8% pass@5, a gain of 24.0 percentage points. glm-4 and claude-3-5-haiku-20241022 gain 19.5 and 21.7 percentage points, respectively. These differences show that first-attempt reliability and multi-candidate success capture distinct aspects of translation capability. A model with a relatively modest pass@1 may still achieve substantially higher coverage when several candidates are available.

**Finding 1.** The evaluated LLMs achieve substantially different levels of execution-verified translation success across eight languages. Moreover, the gains from pass@1 to pass@5 vary considerably across models, showing that first-attempt reliability and best-of-$k$ success should be reported separately.

## 4.2 RQ2: Directed Source-Target Effects

The aggregate results in RQ1 summarize overall model capability but collapse the 56 source-target directions into a small number of model-level scores. To expose the directional structure behind these aggregates, Figure 3 reports the model-averaged edge weight $\bar{w}_5(\ell_s, \ell_t)$ for every

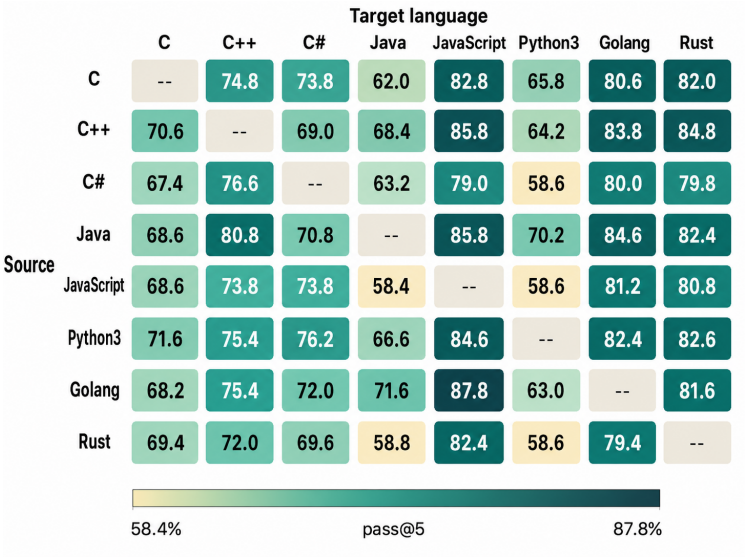

**Figure 3** Model-averaged pass@5, $\bar{w}_5(\ell_s, \ell_t)$, for each directed source-target edge. Diagonal cells are excluded.

**Table 3** Largest observed opposite-direction gaps in code translation, with pass@5 averaged over the five evaluated models.

| Direction Pair | Forward Pass@5 | Reverse Pass@5 | Gap |
|---|---|---|---|
| Java to JavaScript vs. JavaScript to Java | 85.8% | 58.4% | 27.4 pp |
| Python3 to JavaScript vs. JavaScript to Python3 | 84.6% | 58.6% | 26.0 pp |
| Python3 to Rust vs. Rust to Python3 | 82.6% | 58.6% | 24.0 pp |
| Java to Rust vs. Rust to Java | 82.4% | 58.8% | 23.6 pp |
| Python3 to Golang vs. Golang to Python3 | 82.4% | 63.0% | 19.4 pp |

ordered source-target pair. The resulting matrix shows substantial variation across edges. It is also visibly asymmetric: reversing the source and target languages can markedly change the observed translation success rate.

Table 3 and Figure 4 further report the largest opposite-direction differences, measured by $\Delta_5(\ell_a, \ell_b)$. For example, Java-to-JavaScript reaches 85.8% model-averaged pass@5, whereas JavaScript-to-Java reaches 58.4%, producing a gap of 27.4 percentage points. Python3-to-JavaScript and JavaScript-to-Python3 differ by 26.0 percentage points. Similarly, Python3-to-Rust reaches 82.6%, while Rust-to-Python3 reaches 58.6%, yielding a gap of 24.0 percentage points. An unordered average for any of these language pairs would merge two empirically different translation settings and conceal which direction presents the greater difficulty.

The observed gaps should be interpreted as diagnostic evidence rather than as causal explanations. They identify language pairs for which source comprehension and target realization appear to impose different empirical burdens. For example, the JavaScript-to-Java direction may involve reconstructing explicit types, method signatures, and target-library choices that are less explicit in the source implementation. Likewise, translation between Python3 and Rust may involve substantial differences in typing, ownership, data structures, and implementation conventions. However, the edge-level pass@5 results alone cannot determine which language features or model behaviors cause a particular gap. Establishing such mechanisms would require direction-specific failure analysis and controlled experiments.

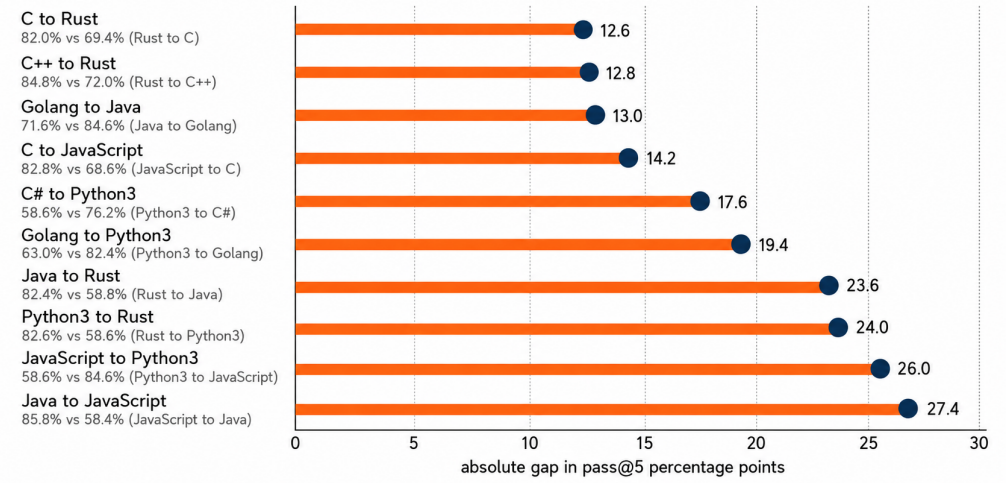

**Figure 4** The ten largest opposite-direction gaps in model-averaged pass@5, ranked by $\Delta_5(\ell_a, \ell_b)$.

**Table 4** Average pass@5 when each language is used as source or target in directed translation, averaged over the five evaluated models.

| Language | As Source | As Target | Target–Source |
|---|---|---|---|
| Python3 | 77.1% | 62.7% | -14.4 pp |
| Java | 77.6% | 64.1% | -13.5 pp |
| C | 74.5% | 69.2% | -5.3 pp |
| C++ | 75.2% | 75.5% | 0.3 pp |
| C# | 72.1% | 72.2% | 0.1 pp |
| Golang | 74.2% | 81.7% | 7.5 pp |
| Rust | 70.0% | 82.0% | 12.0 pp |
| JavaScript | 70.7% | 84.0% | 13.3 pp |

**Finding 2.** The evaluated translation graph exhibits substantial source-target asymmetry. Several opposite directions differ by more than 20 percentage points in model-averaged pass@5, demonstrating that translation results should preserve ordered source-target pairs rather than collapse them into unordered pair averages.

## 4.3 RQ3: Source and Target Language Roles

RQ2 examines asymmetry between opposite edges of individual language pairs. We next aggregate outgoing and incoming edges to determine whether each language behaves differently in its source and target roles. Following the definitions in Section 2.2, Table 4 reports $\mathrm{Src}_5(\ell)$, $\mathrm{Tgt}_5(\ell)$, and their difference for each language.

Python3 and Java obtain substantially higher averages when used as source languages than when used as target languages. Python3 achieves 77.1% in the source role and 62.7% in the target role, while Java achieves 77.6% and 64.1%, respectively. C also obtains a moderately higher source-role average.

The opposite pattern appears for JavaScript, Rust, and Golang. JavaScript achieves 70.7% when used as a source but 84.0% when used as a target. Rust increases from 70.0% in the source role to 82.0% in the target role, while Golang increases from 74.2% to 81.7%. C++ and C# are comparatively balanced, with source-target differences close to zero.

This role-level analysis complements the opposite-edge comparisons in RQ2. Directionality is not confined to a small number of exceptional language pairs; it is also reflected in systematic differences between the outgoing and incoming edges associated with individual languages. The results therefore caution against characterizing a programming language as simply "easy" or "hard" for code translation. A language may yield relatively high success when its implementations provide the source representation but substantially different results when the same language is requested as the translation target.

These role differences should nevertheless be interpreted as properties of the evaluated models, problems, prompts, and execution environments rather than as intrinsic properties of the programming languages themselves. Accordingly, direction-aware evaluations should report source-role and target-role results separately.

**Finding 3.** Programming languages exhibit distinct source and target roles in the evaluated translation graph. Python3 and Java achieve higher source-role averages, whereas JavaScript, Rust, and Golang achieve higher target-role averages. C++ and C# remain comparatively balanced across the two roles.

# 5 Discussion and Threats to Validity

## 5.1 Implications for Direction-Aware Evaluation

Our results show that LLM-based code translation should not be summarized solely by an aggregate pass@$k$ score. Although such a score provides a coarse measure of overall capability, it conceals variation across ordered source-target directions. This distinction matters in practice because translating an existing JavaScript implementation into Java is a different task from translating Java into JavaScript.

We derive three reporting implications. First, translation evaluation should be *direction-aware*: source-target settings should be reported as ordered pairs rather than collapsed into unordered language-pair averages. Second, it should be *role-aware*: a language's performance as a source should be distinguished from its performance as a target. Third, it should be *sampling-aware*: pass@1 and pass@$k$ should be reported separately because first-attempt reliability and multi-candidate success can produce different assessments of model capability.

These analyses complement rather than replace aggregate model-level results. Model-level scores support broad comparison, while edge-, pair-, and role-level results reveal where translation performance varies. The directed graph therefore serves not only as a visualization, but also as an organizational structure for source-target-specific evaluation and validation.

## 5.2 Interpreting the Translation Graph

An evaluation over eight languages induces $8 \times 7 = 56$ distinct translation directions rather than merely eight target-language settings. Each edge may involve a different combination of source comprehension and target realization requirements, including typing, memory management, ownership, library conventions, class structure, and submission interfaces.

The role-level results should be interpreted as evaluation indicators rather than language rankings. The Target–Source column in Table 4 measures the difference between a language's target-role and source-role averages. A negative value indicates higher observed performance in the source role, whereas a positive value indicates higher performance in the target role. For example, Python3 and Java obtain higher source-role averages, while JavaScript, Rust,

and Golang obtain higher target-role averages. These observations do not imply that a language is intrinsically easy or difficult to translate. Instead, they indicate that source understanding and target implementation should be treated as distinct empirical roles.

Likewise, large opposite-direction gaps should be viewed as diagnostic signals rather than causal explanations. A gap such as JavaScript-to-Java versus Java-to-JavaScript may be associated with type recovery, interface reconstruction, or library mapping, but the aggregate results do not identify the underlying mechanism. Establishing such explanations requires direction-specific failure analysis and controlled experiments.

## 5.3 Relation to Practical Migration

This study uses online-judge programming problems because they provide multilingual reference implementations and executable correctness oracles, a design also adopted in multilingual code-evaluation benchmarks [7]. Using the same problems across all ordered source-target pairs enables controlled comparison of translation directions under matched problem semantics.

However, online-judge translation differs substantially from repository-level software migration. Real migration tasks involve multi-file structure, dependencies, build systems, framework APIs, test suites, performance constraints, maintainability, and human review [14]. Our findings should therefore be interpreted as evidence of direction-dependent behavior in controlled executable tasks rather than as a complete assessment of industrial migration quality.

Nevertheless, the direction-aware perspective extends naturally to repository-level settings. Future evaluations can treat each migration direction as a distinct configuration and report build success, test passing, API compatibility, performance, and maintainability separately for each source-target direction.

## 5.4 Threats to Validity

**Study scope.** The evaluation uses 100 online-judge programming problems with reference implementations in all eight languages. Although this design enables matched comparison across 56 translation directions, the problems may not represent the full range of difficulty levels, algorithmic topics, or language-specific idioms. The results should therefore be interpreted as preliminary evidence from the evaluated setting rather than as definitive benchmark rankings.

**Evaluation setting.** Online-judge tasks provide executable oracles and controlled multilingual comparison, but they do not capture the structural and organizational complexity of repository-level migration, including dependencies, build configurations, framework APIs, and maintainability requirements.

**Implementation choices.** Prompt wording, decoding parameters, post-processing rules, target-language templates, and source-implementation style may affect the measured results. We apply a common prompting and post-processing protocol across all directions, but the absolute pass rates may remain sensitive to these design choices.

**Training exposure and correctness oracle.** The public programming problems and reference implementations may have appeared in model training data, potentially affecting absolute performance and individual languages unevenly. Moreover, execution-based checking is

limited by the available tests and does not establish full semantic equivalence. These limitations caution against over-interpreting absolute scores, while leaving the observed need for direction-aware reporting intact.

## 6 Conclusion

This paper studied LLM-based code translation as a directed multilingual transfer problem. Using 100 fully aligned problems across eight languages, we evaluated 56 ordered source-target directions through execution-based checking. The results reveal substantial opposite-direction asymmetries and distinct source/target language roles, showing that aggregate scores can conceal important translation behavior. These findings motivate direction-aware reporting and further analysis of the causes of translation asymmetry.

# Software Supply Chains Are Dead: Use-Case-Oriented Regeneration

**Tanmay Singla**
Purdue University, West Lafayette, IN, USA

**James C. Davis**
Purdue University, West Lafayette, IN, USA

## Abstract

Modern software development relies on an increasingly doubtful premise: that the up-front implementation savings from adopting a dependency outweighs the maintenance costs. Two changes are reshaping the build-*vs.*-reuse calculus: software supply chain attacks have raised the cost of external reliance, while generative AI has lowered the cost of local implementation. In this vision paper, we discuss *use-case-oriented regeneration* as a new software sourcing paradigm that shifts the supply chain from external trust to local verification. We evaluate an agentic workflow that synthesizes only the specific slice of dependency functionality that a repository exercises. Our measurements across 180 repository–dependency pairs suggest that this approach is feasible: the replacements preserve 99.8% of repository-observed behavior across baseline validation checks and reduce the exported API surface by 93%. Software sourcing may evolve toward verifiable repository-specific code synthesis, especially when the required functionality is narrow, stable, and well tested.

## 1 Introduction

For over two decades, software reuse has been increasingly organized around package-level dependency adoption. When software engineers need functionality, the default posture is to depend on upstream packages, even when the repository uses only a small part of that package's behavior. This artifact-centric model helped make reuse inexpensive and scalable [39, 41], but it also creates a persistent granularity mismatch: downstream repositories adopt, validate, and maintain entire upstream artifacts to obtain narrow pieces of functionality. That mismatch has become increasingly costly as repositories accumulate transitive dependency graphs and inherit upstream vulnerabilities, maintenance decisions, compatibility constraints, and ecosystem-level risks [2, 21, 13]. At the same time, generative AI and coding agents are lowering implementation costs as they become more capable of inspecting repositories, executing validation tools, and iteratively refining code [40, 36, 11, 4]. Together, these changes reopen the build-*vs.*-reuse decision: for narrow, stable uses of a dependency, relying on the full upstream artifact may no longer be the best choice.

We envision *use-case-oriented regeneration* as a new software sourcing paradigm that shifts dependency management from external trust to local verification. Instead of taking on a full dependency, an engineer can now use an agentic workflow to synthesize only the

specific functionality that is actually needed as a local, repository-owned implementation. Building on prior regeneration work, we shift the unit of analysis from the upstream package to the *repository–dependency pair*. We report on the feasibility of this regenerative paradigm, evaluating regeneration across 180 repository–dependency pairs spanning nine diverse JavaScript/TypeScript dependencies. Our results show that agentic workflows can successfully replace full dependencies with narrow, local implementations while preserving 99.8% of repository-observed behavior across baseline validation checks. When successful, these generated replacements shed the unused code, transitive dependencies, and maintenance obligations that accompany artifact-centric reuse.

The shift to regeneration creates new responsibilities – it moves the trust problem from evaluating a persistent upstream maintainer [12] to validating the correctness and maintainability of locally synthesized code. This paradigm shift introduces open challenges regarding validation coverage, semantic equivalence, and how developers can establish trust in regenerated code. In sum, this paper makes the following contributions:

- We propose *use-case-oriented regeneration* as a repository-centric sourcing strategy that competes with conventional full-artifact reuse. We demonstrate its feasibility through an evaluation of 180 repository–dependency pairs, observing behavioral preservation with substantial footprint reduction.
- We outline a research agenda for synthesize-and-verify reuse, focusing on appropriateness, behavioral validation, provenance, and refresh practices for generated replacements.

## 2 Background and Motivation

### 2.1 Dependency-Mediated Reuse and the Build-*vs.*-Reuse Tradeoff

Package ecosystems have made reuse cheap by shifting functionality into upstream artifacts. Instead of building every component from scratch, developers assemble applications from packages distributed through ecosystems such as npm, PyPI, Maven, and Cargo [39, 41]. Industry reports estimate that open-source components underpin most modern software – Black Duck reports that 96% of audited commercial codebases contain open-source components [16, 33], and the Linux Foundation suggests a substantial footprint, with OSS comprising 70–90% of modern software. Third-party package dependencies are a primary mechanism by which software functionality is obtained, shared, and maintained.

Package reuse imports obligations beyond the functionality used. A downstream repository inherits not only the immediate functionality of a dependency, but also its transitive dependency graph, release practices, maintenance state, compatibility constraints, and vulnerabilities [20, 34, 10]. Dependencies evolve independently of the downstream projects that rely on them. A package update may fix a vulnerability, introduce a breaking change, or require downstream adaptation, while failing to update may leave a project exposed to known defects [7, 9]. Package ecosystems have also become attack surfaces: Sonatype reports more than 1.23 million known malicious open-source packages across major registries, including more than 454,000 newly identified during 2025 [32]. Dependency reuse is therefore a sourcing, maintenance, and assurance commitment.

The insight underlying this paper is that *dependencies are often adopted at a coarser granularity than they are used*. Package ecosystems distribute reusable artifacts as general-purpose packages, but a downstream repository may exercise only a small subset of a package's API or behavior. The repository must still adopt, validate, and maintain the full artifact to obtain that subset. This mismatch motivates us to move beyond reactive reduction techniques and reconsider whether continued runtime reliance on full-package artifacts remains necessary for narrow dependency use cases [38, 1, 17].

This granularity mismatch changes the build-*vs.*-reuse tradeoff. Software sourcing is traditionally framed as a choice between implementing functionality locally or obtaining it from an external component [3]. Building locally gives the downstream project control over implementation, integration, review, and evolution, but requires design, implementation, and testing effort. Reusing an external package reduces the initial cost of acquiring functionality, but introduces costs related to integration, assurance, updates, and dependency management [15]. The tradeoff is therefore not only whether code exists, but who owns the implementation, how it is validated, and how it evolves.

The software engineering community is biased toward reuse; even the US Department of Defense approves of open-source software. We believe generative systems demand that we revisit that tradeoff. Large language models can inspect repositories, execute validation tools, and iteratively refine code, reducing the acquisition cost of local implementation by generating code for the surrounding repository context [36, 40, 19]. Reuse becomes less attractive when one's repository uses a narrow and stable slice of the package, or when the package introduces transitive dependencies and security exposure that exceed the value of the functionality it provides [25]. By lowering the cost of code creation, generative systems expose another sourcing option: regenerating the verified slice of dependency functionality that the repository needs.

## 2.2 Motivating Example: A Case Study in Generative Sourcing

For a concrete illustration of this concept, let us share a recent experience. We were developing an automated accessibility tool [5] that needed to manipulate mathematics in Microsoft Office documents. The system had MathML and needed to render it as OMML for native support in Microsoft Office. Under the traditional sourcing model, we initially treated this as a dependency-selection problem. MathML-to-OMML conversion is not a trivial formatting task: it requires handling structured mathematical constructs, including operators, fractions, matrices, fences, scripts, annotations, and other element types. We therefore assessed existing implementations, including open-source converters, document-editor subprocesses, and commercial options.

Some candidates were plausible under the conventional reuse calculus: credible provenance, acceptable licensing, or good pilot behavior on our fixtures. However, that calculus assumes that the costs of taking on the dependency are lower than the cost of developing it ourselves. In our case, adding an external converter would have entailed more elaborate component vetting, licensing concerns, and bloating our Google Cloud images with the JVM.[1] We therefore considered an alternative: using an AI coding agent to implement the converter locally. We asked Claude about the complexity of MathML, which it characterized as involving roughly thirty relevant node types; and about the feasibility of a straightforward tree-transducer approach (whether each type could convert cleanly to OMML without reasoning over an intermediate representation). Receiving positive answers to each, we asked Claude to construct a MathML-to-OMML library of our own, backed by fixtures and validation against Office's OpenXML SDK. After Claude spent an hour on it, the resulting library worked on the first try with our validation fixtures. Claude's library has 1.4 KLOC, accompanied by 1.5 KLOC of unit and property-based tests. On inspection, the library code is of good quality – structured and concise. The library has been in use for the past two months with no reported functional defects. It was refactored once to extract helpers for sharing, and touched five times by repo-wide automated code modifications.

[1] Image bloat would reduce our service's peak scalability under our current Cloud tenant memory quota.

**Table 1** Comparison of dependency reduction and replacement strategies. Use-case-oriented regeneration differs because it targets the repository-used slice of functionality as the unit of sourcing and replacement.

| Approach | Starts from | Main goal | Relies on full upstream artifact? |
|---|---|---|---|
| Debloating | Adopted artifact | Remove unnecessary code and reduce attack surface | Yes, typically |
| Tree shaking / DCE | Adopted artifact and build graph | Remove unreachable shipped code | Yes |
| Vendoring | Upstream artifact | Internalize code for local control and patching | Yes, conceptually |
| Full regeneration (*e.g.*, HARP, Lexo) | Upstream artifact | Synthesize a full replacement of the package | No |
| *Use-case-oriented regeneration* | Repository–dependency pair | Replace repository-used functionality with local impl. | Not necessarily |

This anecdote is not evidence that every converter should be regenerated. Rather, it illustrates the changed decision problem for package selection when the needed behavior is bounded and testable. *Is relying on existing packages still preferable once agent-assisted local synthesis makes a small, auditable, product-specific implementation cheap enough to create?*

## 2.3 Dependency Reduction and Internalization Strategies

Several existing strategies already attempt to mitigate the cost or exposure associated with overly broad dependencies. Debloating, for instance, removes unnecessary code from software artifacts or deployed systems while attempting to preserve required behavior [26]. Tree shaking and dead-code elimination remove code that is statically unreachable from a particular build, bundle, or execution path [37, 18]. Vendoring internalizes a dependency by copying the upstream source code directly into the downstream repository, often to improve control, reproducibility, or availability [24]. These strategies are highly useful because they explicitly recognize that the full adopted dependency often exceeds what a downstream project actually needs.

More recently, *full regeneration* strategies, such as HARP [35] and Lexo [14], have emerged to eliminate supply-chain attacks by leveraging program inference and LLMs to synthesize complete, semantically equivalent replacements for upstream packages.

However, as highlighted in Table 1, these strategies generally begin *after* a dependency has already been adopted as an upstream artifact, or they treat the *upstream package* as the fundamental unit of analysis. Debloating and tree shaking reduce unused code from an existing dependency, while vendoring moves upstream source into the downstream repository but still relies on the upstream implementation as the starting point. Full regeneration attempts to replace the artifact entirely, but still aims to synthesize a general-purpose, 1-to-1 package equivalent of the third-party library.

# 3 Use-Case-Oriented Regeneration

We propose *use-case-oriented regeneration* to address the structural liabilities of artifact-centric reuse. We define this approach as the local synthesis of only the specific dependency functionality that a downstream repository actually exercises, treating the *repository–dependency pair* as the fundamental unit of replacement. Crucially, this targets *repository-*

*observed equivalence* rather than full semantic equivalence with the upstream package. A generated replacement implements only the behaviors directly exercised by the repository, allowing unused API surfaces to be discarded, and success to be evaluated by whether the repository's validation artifacts continue to pass.

In this context, we define a "use case" as the specific, bounded slice of a dependency's API that is actually invoked by the downstream repository's first-party code. This functionality is strictly bounded by the execution paths, configurations, and arguments exercised by the repository's existing validation artifacts (e.g., its test suite). Therefore, the goal is not to broadly recreate the dependency, but to synthesize a minimal local implementation that perfectly satisfies these observed boundaries.

We can view use-case-oriented regeneration as a projection problem. Let $P$ denote an upstream package, and let $R$ denote a downstream repository that uses $P$. The repository induces an observation context $O_R$: the set of calls, inputs, configurations, validation artifacts, and execution paths through which $R$ exercises $P$. Unlike full regeneration [35, 14], which seeks a replacement $P'$ such that $P' \equiv P$ over the full package semantics, *use-case-oriented regeneration* seeks a local implementation $L_{R,P}$ such that

$$\pi_{O_R}(L_{R,P}) \equiv \pi_{O_R}(P),$$

where the projection $\pi_{O_R}$ projects package behavior onto the behaviors observable through $R$'s use of the dependency. Thus, the relevant equivalence class is defined by the repository–dependency pair, not by the upstream artifact alone.

This paradigm changes the locus of supply chain trust. In the current model, developers rely on external signals – such as package identity, ecosystem provenance, and maintainer reputation – that are often decoupled from the actual code executed [8, 6, 30]. Regeneration reduces runtime reliance on these external signals, shifting the trust problem from evaluating an upstream ecosystem to the *local verification* of synthesized code. The repository owner must therefore establish adequate evidence for the correctness, test coverage, and maintainability of a hyper-specialized local implementation.

## 4 Study Design

This section describes the empirical study used to evaluate use-case-oriented regeneration. We evaluate whether an agentic workflow can regenerate the functionality actually used by a client repository across a deliberately varied benchmark of repository–dependency pairs. Our study is a proof-of-concept: each successful regeneration provides evidence that a bounded slice of dependency functionality can be replaced by validated local code, while failures expose limits of the current workflow. Because regeneration is repository-specific and judgment-laden (cf. Section 2.2), the fully automated workflow described here is illustrative rather than prescriptive.

### 4.1 Research Questions and Evaluation Metrics

We ask three research questions, each paired with an evaluation metric:

**RQ1 (Feasibility).** Given a client repository and a dependency it uses, can an agent regenerate the exercised dependency functionality to remove first-party runtime reliance?
*Rationale: This evaluates whether generative AI can practically alter the traditional build-vs.-reuse tradeoff.*
*Metric: Successful removal of the target dependency from runtime code and the successful integration of an executable local replacement.*

**RQ2 (Behavioral Preservation).** To what extent do generated implementations preserve repository behavior across repository–dependency pairs?
*Rationale: Because regeneration shifts the trust model from upstream reputation to local verification, this evaluates how well generated code satisfies existing repository assumptions.*
*Metric: The aggregate pass rate of the repository's baseline validation checks (tests, builds, linters) before and after regeneration.*

**RQ3 (Size and Footprint).** How do generated implementations compare with the original dependency in terms of size and dependency footprint?
*Rationale: This contrasts use-case-oriented regeneration with reduction techniques like debloating, establishing whether repository-specific synthesis meaningfully reduces API exposure.*
*Metric: The measured reduction in exported API surface and implementation footprint compared to the original upstream package.*

Taken together, these metrics evaluate both whether regeneration works as a repository transformation and what kind of artifact it produces when it succeeds. This distinction is critical: a generated replacement may pass repository validation while still raising concerns about untested behavior or maintainability.

## 4.2 Subject Dependencies and Repositories

We evaluate use-case-oriented regeneration on nine JavaScript/TypeScript dependencies selected to vary in size, role, popularity, and expected regeneration difficulty. The dependencies span small utility packages, medium-sized libraries, and larger packages with broader API surfaces. This selection is not intended to be statistically representative of all npm packages; instead, it is designed to exercise regeneration across a range of dependency types for which repository-specific replacement may plausibly range from straightforward to difficult [39, 41].

**Table 2** Target dependencies used in the study, grouped by approximate package size.

| Size tier | Dependency | Type / role | Pairs |
|---|---|---|---|
| Small | `nanoid` | Identifier generation | 20 |
| Small | `change-case` | String case conversion | 20 |
| Small | `chalk` | Terminal string styling | 20 |
| Medium | `express` | Web server framework | 20 |
| Medium | `semver` | Version parsing and range handling | 20 |
| Medium | `postcss` | CSS transformation framework | 20 |
| Large | `lodash` | General-purpose utility library | 20 |
| Large | `axios` | HTTP client | 20 |
| Large | `zod` | Schema validation | 20 |
| *Total* | *9 dependencies* | | *180* |

For each dependency, we select 20 evaluable client repositories (180 pairs total). We identified candidate repositories through a code search over public GitHub repositories that imported the target dependencies. This initial pool was filtered to retain only repositories suitable for evaluation: they had to build in a clean environment, expose validation artifacts (such as test suites or executable scripts), and pass their baseline validation prior to any regeneration attempt. When multiple repositories were equally suitable, repository popularity

was used as a secondary preference signal. The primary unit of analysis remains the repository–dependency pair, as regeneration feasibility depends not only on the dependency itself but also on how deeply a particular repository uses it.

## 4.3 Regeneration Procedure

The experimental workflow is summarized in Figure 1. For each of the 180 pairs, we execute the following phases:

1. **Establish Baseline:** We clone the repository at a fixed revision, install its declared dependencies, and run its validation artifacts (e.g., `npm test`). Only repositories with successful baseline validation are retained, providing a strict behavioral denominator for comparison.
2. **Regenerate Agentically:** First, the agent performs *usage identification* by statically extracting all first-party imports of the target dependency to scope the required functionality. Then, the agent is provided a zero-shot prompt template that is dynamically injected with the repository path and target dependency. The agent operates with internet access and can directly inspect the original upstream dependency's source code within the local environment to guide its synthesis. It is permitted a maximum iteration budget of two attempts (one initial generation and one retry) to resolve any validation failures before terminating.
3. **Re-Validate & Measure:** This step represents the final evaluation. If the agent exhausts its iteration budget in Step 2 without satisfying the test suite, this step records a "Failed" outcome. If the final generated replacement passes all baseline checks without introducing new failures, it is recorded as a "perfect" preservation of repository-observed behavior. (Note: In Table 3, the baseline and after numbers reflect the raw count of individual assertions and tests passing). Finally, we measure the footprint differences of the successful replacements.

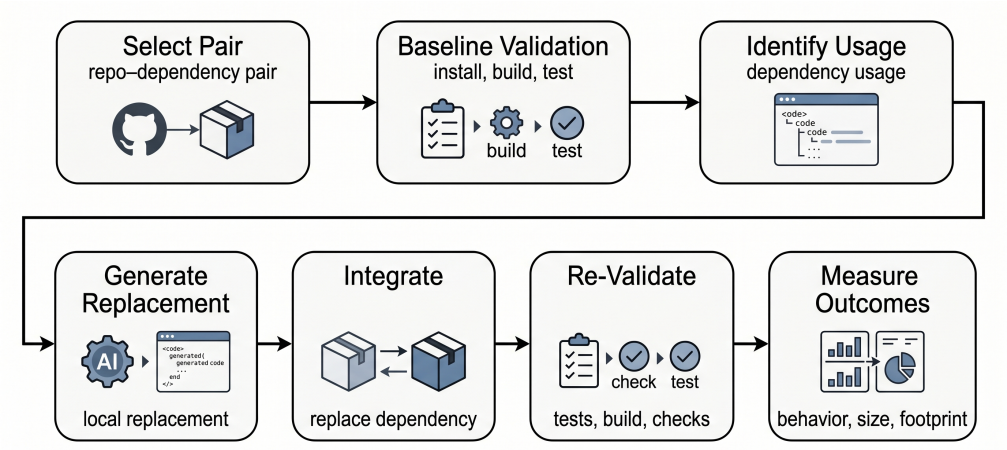

**Figure 1** Our experimental workflow. For implementation, see our artifact.

# 5 Results

This section reports results from our evaluation of use-case-oriented regeneration across 180 repository–dependency pairs. We interpret these results as a characterization of the feasibility and limits of repository-centered regeneration.

**Table 3** Summary of regeneration outcomes across 180 repository–dependency pairs. "Baseline" and "After" report the raw count of individual validation checks (e.g., assertions and tests) passing before and after regeneration. "Perfect" reports the number of repository–dependency pairs for which all baseline checks still pass after regeneration.

| Dependency | Repos | Baseline | After | Failed | Perfect |
|---|---|---|---|---|---|
| `nanoid` | 20 | 2,118 | 2,118 | 0 | 20/20 |
| `change-case` | 20 | 20,917 | 20,880 | 37 | 19/20 |
| `chalk` | 20 | 4,716 | 4,715 | 1 | 19/20 |
| `express` | 20 | 1,170 | 1,164 | 6 | 18/20 |
| `semver` | 20 | 5,111 | 5,109 | 2 | 18/20 |
| `postcss` | 20 | 2,292 | 2,289 | 3 | 18/20 |
| `lodash` | 20 | 12,804 | 12,700 | 104 | 16/20 |
| `axios` | 20 | 7,513 | 7,509 | 4 | 18/20 |
| `zod` | 20 | 7,993 | 7,993 | 0 | 20/20 |
| *Total* | *180* | *64,634* | *64,477* | *157* | *166/180* |

## 5.1 RQ1 & RQ2: Feasibility and Behavioral Preservation

As detailed in Table 3, use-case-oriented regeneration proved feasible and highly behavior-preserving across a substantial fraction of the evaluated pairs. In aggregate, generated replacements achieved a 99.8% validation pass rate, with 166 of the 180 pairs demonstrating perfect behavioral preservation. The agent identified first-party call sites, generated local replacement code, updated callers, and removed runtime reliance on the original packages.

However, outcomes varied by dependency. While highly bounded utilities like `nanoid` and `zod` saw perfect preservation across all client repositories, more complex or deeply integrated dependencies like `lodash` presented greater challenges. This variation confirms that feasibility depends heavily on both the target dependency's complexity and how specifically the downstream repository uses it.

Crucially, this high rate of preservation must be interpreted carefully. Because preservation is measured using each repository's existing validation artifacts, these results confirm that regeneration can seamlessly preserve *repository-observed* behavior. They do not prove full semantic equivalence across all possible inputs, as a generated replacement may pass available tests while omitting untested edge cases or undocumented compatibility behaviors. While preservation rates are high, the strength of the underlying validation artifacts varied. For instance, the average line coverage of the generated replacements executed by the repositories' existing test suites ranged from 92.5% for utilities like `change-case` to 40.8% for complex libraries like `lodash`, underscoring that passing existing tests does not guarantee all generated logic is strictly verified.

## 5.2 RQ3: Size and Dependency Footprint

Successful replacements were substantially narrower than their upstream counterparts. As shown in Table 4, the generated implementations exposed dramatically smaller interfaces – averaging a 93.1% reduction in exported API surface across the benchmark.

This reduction supports the central premise of use-case-oriented regeneration: downstream repositories typically rely on only a narrow slice of a dependency's behavior. To illustrate this footprint reduction, Figure 2 shows a generated replacement for `nanoid`.

**Table 4** API-surface reduction in generated replacements. The generated implementations expose substantially smaller interfaces than the original dependencies, reflecting repository-specific usage rather than full-package replacement. "Original exports" refers to the total number of publicly accessible functions, classes, and variables exposed by the upstream package's main entry point.

| Dependency | Original exports | Avg. regenerated | Reduction | Utilization |
|---|---|---|---|---|
| `zod` | 236 | 4.1 | 98.3% | 1.7% |
| `lodash` | 306 | 19.4 | 93.7% | 6.3% |
| `chalk` | 64 | 5.0 | 92.2% | 7.8% |
| `postcss` | 25 | 1.0 | 96.0% | 4.0% |
| `change-case` | 14 | 0.4 | 97.1% | 2.9% |
| `axios` | 33 | 6.4 | 80.6% | 19.4% |
| `semver` | 45 | 9.8 | 78.1% | 21.9% |
| `nanoid` | 5 | 1.4 | 73.0% | 27.0% |
| `express` | 11 | 3.2 | 70.9% | 29.1% |
| *Overall* | *82.1* | *5.6* | *93.1%* | *6.9%* |

```
const urlAlphabet =
  'useandom-26T198340PX75pxJACKVERYMINDBUSHWOLF'
  + '_GQZbfghjklqvwyzrict';

export function nanoid(size = 21) {
  const bytes = new Uint8Array(size);
  crypto.getRandomValues(bytes);

  let id = '';
  for (let i = 0; i < size; i++) {
    id += urlAlphabet[bytes[i] & 63];
  }

  return id;
}
```

**Figure 2** Use-case-regenerated replacement for `nanoid`.

The agent successfully extracted only the core random-byte generation logic required by the client, shedding the original package's unused CLI tools and custom alphabets. This reduces the dependent's unused API surface and transitive exposure.

Footprint reduction alone is an imperfect proxy for quality. A smaller replacement is easier to audit, but may omit behaviors that future repository evolution might require. The primary empirical signal here is that these replacements are significantly smaller *while still preserving the current validation behavior*, suggesting regeneration is most effective for narrow, stable, and well-tested usage slices.

## 5.3 Failure Modes and Limitations

Analyzing the 14 failed regeneration attempts clarifies the current limits of this approach. Failures strongly correlated with specific dependency characteristics and usage breadth, typically emerging when the target dependency provided broad, subtle, or highly dynamic behaviors that were difficult for the agent to infer strictly from static call sites. Specifically, we observed three primary failure modes:

1. *Semantic and edge-case mismatches*, such as failing to reproduce `semver`'s prerelease logic or `lodash`'s deep cloning and chained APIs. These failures occurred when the repository's usage breadth involved complex internal state that exceeded the validation suite's explicit coverage;

2. *Class identity mismatches*, where generated objects failed strict `instanceof` checks against native or cross-package prototypes (*e.g.*, in `zod` and `semver`); and
3. *Deep framework integrations*, where replacements could not satisfy complex internal tooling expectations, such as `express` middleware arity or `axios` mock interceptors.

In these scenarios, the agent successfully handled the common path but failed on nuanced edge cases exercised by the repository's test suite. These failures may also reflect the limitations of our validation setup. Repository validation artifacts can be brittle, environment-sensitive, or uneven in coverage. Passing a weak test suite might hide significant semantic deviations, while failing a flaky or snapshot-sensitive test might falsely indicate a broken replacement.

Detailed descriptions of these attempts are given in our accompanying artifact [29].

# 6 Discussion and Research Agenda

The results indicate that use-case-oriented regeneration is a potentially viable sourcing strategy for bounded slices of functionality. However, safely realizing this vision requires shifting the research focus from package-level synthesis to automated assurance and secure agent governance.

## 6.1 The Security of Generated Code

The central challenge for regeneration is behavioral confidence and security. Passing existing repository tests does not guarantee safety across unexercised edge cases, nor does it prevent the introduction of AI-generated vulnerabilities or hallucinations [23]. Regeneration changes the threat model: it replaces the risk of external supply-chain vulnerabilities with the risk of local AI-generated defects. Future work must prioritize the automated security verification of the generated slice, moving beyond existing test suites to incorporate proactive AI-assisted vulnerability scanning (similar to the deep dependency threat detection pioneered by platforms like Socket [31]), as well as coverage-guided validation and differential testing against the original dependency's behavior.

## 6.2 From Human Trust to Automated Assurance

Under conventional reuse, downstream projects rely on upstream maintainer reputation as a proxy for trust. Regeneration demands stronger, localized evidence. Simply expecting downstream developers to manually judge whether a dependency is narrow or stable enough for safe regeneration is insufficient and scales poorly. The research community must develop automated usage analysis and slice characterization tools to systematically determine regeneration suitability.

Furthermore, establishing trust in generative systems requires rigorous safety benchmarking for AI coding agents. The community needs standardized evaluation frameworks, such as DepDec-Bench [28], to systematically measure how safely, securely, and accurately different large language models handle dependency decomposition and synthesis before they are deployed in production environments.

For practitioners considering this approach today, we propose a preliminary heuristic checklist: regeneration should only be attempted if (1) the dependency serves a narrow, bounded role; (2) the repository possesses high-coverage validation artifacts specifically exercising that functionality; and (3) the downstream team is equipped to independently monitor the upstream package for relevant security advisories. If these conditions are not met, maintaining the standard upstream dependency remains the safer choice.

### 6.3 Governing AI Agents in the Software Supply Chain

Regenerated replacements capture a repository-specific slice of functionality at a single point in time, meaning they do not automatically inherit future upstream security patches or API clarifications. To manage this responsibly, we must develop secure regeneration workflows and centralized governance infrastructure.

Future software ecosystems will require a governance layer, such as AgentHub [22], that audits agent actions, manages the precise provenance of synthesized code, automatically monitors upstream changes for relevant security fixes, and enforces local security policies before any generated code is merged into the codebase. This infrastructure will shift the software supply chain from rigid upstream adoption to flexible, verifiable, and strictly governed repository-specific generation.

### 6.4 Implications for Engineering Processes

Use-case-oriented regeneration changes how downstream projects benefit from the "many eyes" of open-source reuse [27]. In conventional artifact-centric reuse, a widely used upstream package accumulates not only implementation fixes, but also specification knowledge: API conventions, clarified edge-case behavior, documentation, tests, examples, and compatibility expectations. These are precisely the properties that afford regeneration. A downstream project that continues to depend on the package can inherit this evolving specification through dependency updates. A regenerated replacement, by contrast, captures a repository-specific slice of that specification at generation time. It does not automatically inherit later semantic changes, security fixes, or API clarifications. Regeneration therefore entails an explicit refresh practice: monitoring upstream changes, deciding whether they affect the local API slice, and acting when they do. This situation demands regeneration provenance metadata. Without such metadata, maintainers cannot reliably determine whether a later upstream change is irrelevant, requires regeneration, or exposes an unsound local approximation.

## 7 Threats to Validity

As this is a vision paper with a limited measurement, several threats affect our findings:

- **Construct Validity:** Preservation is measured via existing repository tests, not formal proofs. We mitigate this by bounding claims strictly to *repository-observed* equivalence.
- **Internal Validity:** Outcomes rely on a specific agentic workflow (Claude Opus) and prompt. We isolated agent impact by requiring strict baseline pre-validation.
- **External Validity:** Evaluation is limited to JS/TS and to 9 dependencies. Feasibility may differ in ecosystems with different testing cultures or agent training data.

## 8 Conclusion

Modern software systems rely on complex dependency graphs with substantial ongoing maintenance costs. We argue that recent advances in generative AI warrant reexamining the traditional build-*vs.*-reuse tradeoff. We envision *use-case-oriented regeneration* as a strategy in which generative systems synthesize only the repository-specific slice of an upstream dependency that is actually required. Our evaluation of 180 repository–dependency pairs suggests that this approach is often technically feasible and can substantially reduce dependency footprint while preserving repository-observed behavior.

Whether regeneration ultimately proves preferable to conventional reuse in a given context will depend on more than implementation cost. Regenerated code forfeits some of the advantages of shared upstream artifacts, including continual optimization, community review, evolving specifications, and Raymond's "many eyes" effect that has historically improved mature open-source software. Conversely, it offers opportunities for repository-specific optimization, reduced attack surface, simplified auditing, and greater local control. Determining when these competing considerations favor regeneration over continued upstream dependence remains an important open research question. We therefore view use-case-oriented regeneration not as a replacement for software package ecosystems, but as a complementary sourcing strategy. Future work should develop principled methods for deciding when regeneration is appropriate, how regenerated implementations should be validated and refreshed, and how engineers can balance the long-term benefits of shared ecosystems against the flexibility of locally synthesized software. Ultimately, use-case-oriented regeneration has the potential to shift the software supply chain from rigid upstream adoption to more flexible, verifiable, and repository-specific generation, granting downstream projects greater control over the code they trust and maintain.

## Abstract

Contributors to Open Source Software (OSS) projects are vital to maintaining the health of both communities and projects. However, the number of projects experiencing core contributors' disengagement has increased to the point that it risks the projects' survival. Finding new contributors to replace the workforce is challenging and time-intensive due to several factors, including a lack of precise knowledge about potential candidates' competences, which may need to be confirmed through interviews and exams. Previous studies provided indications of the contributor's competences, although they lack depth in understanding competence levels, which can result in poor knowledge about the contributor's capabilities. To address this gap, we assess contributors' competence by collecting code metrics related to source code from contributions. We also propose a competence model able to predict the competence level required to solve tasks. By properly assessing contributors' competences, we can identify and train candidates to replace core contributors. Our replication package, including code, data, and documentation, is available at `https://doi.org/10.5281/zenodo.21605122`

## 1 Introduction

Open Source Software (OSS) exhibits increasing project counts, file counts, and churn, while the number of joiners remains stable or declines in most projects [34]. Many of the projects depend on a few core contributors, with numbers approaching 1 or 2 in about 70 of the most popular GitHub repositories [3], and projects tend to die when abandoned by maintainers due to vital technical debt [2].

Competence-based management is a key factor in Human Resources (HR) selection, development, planning, and performance management [25]; therefore, knowing the core contributors' competences can help recruit, onboard, and train new members. Competence is commonly described as a combination of attitude, skills, and knowledge [1]. However, it remains challenging to consistently identify, represent, and assess human competences [7]. Previous studies have demonstrated the importance of revealing the capabilities of the workforce and the existing tasks in OSS context. Liang et al. [22] used surveys to investigate skills that support the development of OSS projects. Dey et al. [10] showed that contributors

© Sabahat Younas, Márcia Moraes, and Fabio Santos;
licensed under Creative Commons License CC-BY 4.0

are more likely to join projects aligned with their competence and have pull requests accepted. The onboarding of newcomers to OSS projects and the selection of tasks using proxies for skills were also the subjects of studies [28, 29]. However, previous studies are limited in depth since they ignored: differences between programming languages [10], security vulnerability [10], and the intricacy of competence levels [10, 28, 29]. The depth limit affects the performance of predictive models used to suggest issues for contributors [8, 31], thereby mitigating a core contributor shortage and supporting expert recruitment.

To close the gap of competence depth, we present a case study using source code data to evaluate contributors' competence in OSS, including levels mined from 5,793 unique functions. Our approach combines Abstract Syntax Tree (AST)-based competence extraction, hierarchical competence modeling, code complexity metrics (13 Lizard metrics), and machine learning models to build contributors' profiles and predict competence levels from pull requests. The profiles can later be used to generate recommendations for training or search for contributors to replace workforce as needed. Considering that, we are interested in answering the following research questions (RQ1): To what extent can we predict the competences to solve issues? (RQ2): How can contributor competences be automatically identified and profiled?

By answering these RQs, this work aims to contribute with (1) a novel hierarchical approach for competence profiling that aggregates function-level complexity metrics to competences based on usage patterns, (2) preliminary validation on a manually verified set of pull requests from JabRef demonstrating up to 90% accuracy in predicting competence levels for well-represented technical domains using a reduced, leakage-aware set of code complexity features, (3) empirical evidence that code metrics and structure are stronger predictors of competence requirements, and (4) a scalable, automated method for profiling competences to later use for training, planning task allocation and replacement when core maintainers disengage, therefore contributing to the competence management.

## Related Work

The approach combines language-aware competence extraction with structural evidence and proficiency levels to address limitations in prior research. Unlike Dey et al. [10], who use vector representations from API changes, this approach preserves programming-language semantics and analyzes API and library usage through AST-level structure. It shifts the focus from task/issue skill signals [28, 29] to code contributions and models levels of competence using code complexity and structural metrics. Hannan et al. [16] used Large Language Models (LLMs) to identify competence and cosine similarity to match tasks and coders; however, the method did not reveal the level of competence. Additionally, unlike Liang et al.'s [21, 22] broad human-centered model, this study operationalizes competence in a measurable and automatable way from repository artifacts, aiding in scalable profiling and decision support for training and replacement when core maintainers disengage.

# 2 Methodology

## 2.1 Case Study Design

We designed a case study to explore archival data to create a competence model and build competence profiles looking for evidence of their utility in measuring OSS workforce competence [26].

Our approach follows a systematic workflow composed of four main components: (1) data mining, (2) competence and sub-competence extraction, (3) complexity analysis and level assignment, and (4) model training (Figure 1).

In the data collection section (Section 2.2), we detail the data gathering process including the justification for the data source, which was the OSS project targeted for this study and how our data was organized to find evidence of the competences based on the source code and their respective AST with the support of a taxonomy and a Large Language Model (LLM) for categorization. Next, we gathered static metrics from the source code to derive the levels using a composite score (Section 2.3). Finally, we built a prediction model (Section 2.4) to verify to what extent the proposed competence management can address the proposed motivation.

**Figure 1: Research Design Overview**

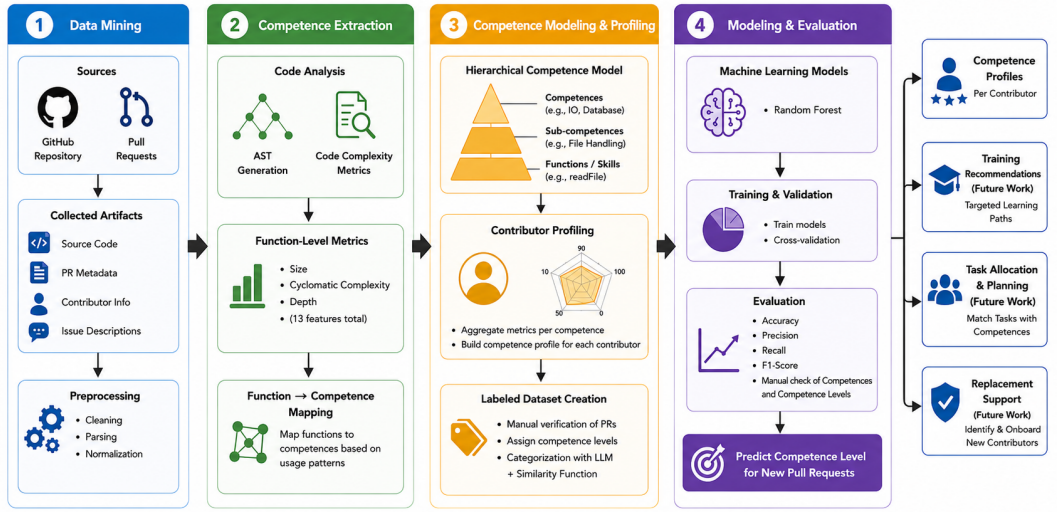

**Figure 1** Overview of the proposed competence profiling workflow.

## 2.2 Data Collection

Data collection comprised the mining process (Section 2.2.1) and competence extraction (Section 2.2.2)

### 2.2.1 Data Mining

We collect data from the JabRef GitHub repository, a mature OSS Java project used as a case study in this work. We selected JabRef based on its project maturity and the breadth of technical competences represented in its codebase (e.g., database management, UI, network communication, parsing), which is important for testing a competence taxonomy spanning multiple domains. It is a popular OSS Java-based reference management tool with over 4,000 stars on GitHub, more than 900 contributors, 4,500 closed issues, and a history of research collaboration, where maintainers and researchers find solutions for OSS projects. It also has a complex codebase spanning multiple technical competences including database management, user interface design, network communication, and bibliographic parsing. The broad range of competences is important for testing our predictive model. Finally, one

author contributed to JabRef, enabling concrete evaluation of the competences. For this case study, we limited the dataset size to allow a rigorous verification of the AST results and categorization. The dataset consists of 5,793 unique functions. The functions collected encompass 85 PRs where two authors (one JabRef contributor and one software engineer) could evaluate the competence categorization.

From the repository, we extract all source files modified in merged PRs together with PR metadata, including author information, timestamps, changed files, and contribution statistics. These data are used as input for competence extraction, complexity analysis, and model training.

We filter source files by removing non-code files and focusing on substantial code contributions which contain at least one parsable source code file from which AST structures and Lizard complexity metrics can be extracted. These filtered source files feed into our competence extraction pipeline, while the PR metadata is used for both competence extraction and model training phases. We sent the source code from the 5,793 unique functions to the competence-level extraction pipeline.

### 2.2.2 Competence Extraction

For each selected source file, we perform the following steps:

**Abstract Syntax Tree (AST) Generation.** We parse each source file into its AST representation, capturing the complete structural and syntactic information of the code.

**Extract APIs and Function Names.** From the generated ASTs, we traverse the tree structure to identify and extract all API calls, library imports, and function/method definitions used in the code.

**Competence Taxonomy.** Using the extracted APIs and function names, we build a hierarchical competence taxonomy [8] which contains 217 competences organized in two layers (31 competences in the first layer and 186 sub-competences in the second layer). This taxonomy organizes programming constructs into meaningful concepts (e.g., "Database - Backup," "IO - File Management," and "UI - Event Handler," where Database is the first layer, or the competence and Backup, the second layer, or the sub-competence).

**Competence Classification.** We classify each API and function into concepts from the taxonomy generated in the previous phase, producing classifications for each source file. This output maps each of the 5,793 unique functions declared in the source files to the competence taxonomy, capturing competence and sub-competence.

**LLM-based Categorization.** We used the zero-shot approach similar to SkillScope [8], but employing LLaMA-3.1-8B-Instant [13] via the Groq API to categorize APIs and functions into our competence taxonomy. We chose this approach because LLaMA-3.1-8B-Instant is an open-access model that offers a competitive cost-benefit. The LLM receives only taxonomy definitions without example classifications, using a near-zero temperature (temperature=0.1) to limit output variability while avoiding the degenerate or repetitive completions that strict determinism (temperature=0) can sometimes produce [20]. To mitigate hallucinations, we implement post-processing by ingesting the LLM output into spaCy [30] semantic similarity, to ensure outputs align with valid taxonomy entries. Complete prompt templates are available

in our replication package. Two authors evaluated a sample of 361 (from the 5,793 unique functions, using a 95% confidence level and 5% margin of error) functions to ensure correct classification.

The extracted PR metadata are combined with the competence and sub-competence categories defined in the taxonomy, using one-hot encoding, to create comprehensive training datasets that link contributors to their demonstrated competence.

## 2.3 Data Analysis

Using the Lizard static analysis tool [33], we extract comprehensive function-level code complexity metrics from each modified file in the pull request. Rather than relying solely on cyclomatic complexity, we employ a composite scoring approach that combines multiple complementary metrics to provide a more robust assessment of code difficulty and required competence.

Lizard computes cyclomatic complexity (CCN) by counting linearly independent paths through the code: each conditional statement (if, else if), loop (for, while, do-while), case in a switch statement, logical operator in conditions (and, or), and exception handler (catch) increments the CCN by one. Additionally, Lizard provides non-comment lines of code (NLOC), token count, parameter count, and function length metrics.

To avoid the limitations of single-metric approaches, we calculate a composite complexity score using weighted contributions from multiple metrics:

$$\text{Composite Score} = \sum_i w_i \times \frac{M_i}{T_i} \tag{1}$$

Where $M_i$ represents each metric value, $T_i$ is its normalization threshold, and $w_i$ is its weight. The metrics and their weights are: **CCN Metrics (30% total):** average CCN (10%), maximum function CCN (10%), and CCN density (10%). **Size Metrics (50% total):** total NLOC (10%), average NLOC per function (10%), average parameters (10%), average function length (10%), total tokens (5%), and average tokens per function (5%). **Structural Metrics (20% total):** number of functions (5%), number of files (5%), number of competences (5%), and number of sub-competences (5%).

Each metric is normalized to a 0-1 scale using empirically-derived thresholds based on JabRef data analysis. We use different normalization strategies depending on the metric distribution.

For metrics with highly skewed distributions and extreme outliers, such as NLOC and token counts, we use the 95th percentile as the normalization threshold to reduce the influence of unusually large pull requests. For example, NLOC is normalized by 100 (95th percentile observed: 52) and tokens by 200 (95th percentile observed: 435).

For metrics with more stable ranges and bounded behavior, such as CCN and function counts, we use empirically observed maximum reference values. CCN values are normalized by 30 (maximum observed: 78), while function counts are normalized by 100. This normalization strategy ensures that metrics with different scales contribute proportionally to the composite score while limiting distortion caused by extreme values.

We map composite scores to five competence levels: scores $\leq 0.25$ indicate simple code (Level 1), $0.25 < \text{score} \leq 0.45$ suggests moderate complexity (Level 2), $0.45 < \text{score} \leq 0.65$ indicates complex code (Level 3), $0.65 < \text{score} \leq 0.85$ represent very complex code (Level 4), and score $> 0.85$ denotes highly complex code requiring Level 5 competence.

This composite approach addresses the limitation that cyclomatic complexity alone may not fully capture all dimensions of code difficulty. For example, a function with moderate CCN but extremely high token count (indicating dense logic) or a function with low CCN but

spanning many lines (indicating structural complexity) would both be appropriately weighted in the final assessment. The weights were tuned using a Grid Search technique aiming to increase the accuracy of the prediction model and prioritize decision-making complexity while accounting for code size and project structure. The number of complexity levels and thresholds were inspired by the work of Liang et al. [21]. Previous studies have similarly used static analysis metrics obtained from source code to investigate code violations, cognitive complexity, and the security and quality characteristics of LLM-generated code [15, 19, 27], supporting the use of such metrics as a meaningful signal for competence assessment in this study.

Similar function-level combinations of static code metrics (NLOC, cyclomatic complexity, token count, and parameter count) alongside Term Frequency-Inverse Document Frequency (TF-IDF) features have been used effectively for lightweight software engineering classification tasks, such as vulnerability triage in C/C++ codebases [9], supporting the use of this metric family as an established, non-arbitrary foundation for our composite scoring approach.

To determine whether the surrogate model's predictive performance differs significantly from a naive baseline, rather than diverging only by chance, we apply McNemar's test [23], a non-parametric test for paired nominal data that is well suited to comparing two classifiers evaluated on the same set of samples, as recommended by Dietterich [11] for the statistical comparison of supervised learning algorithms.

## 2.4 Model Training

We implemented a hierarchical complexity extraction and prediction system using the Lizard static analysis tool to measure code complexity at multiple levels of granularity. Our system extracts 13 distinct complexity metrics and aggregates them hierarchically from the function level; of these, a reduced set of 6 structural metrics (Table 1) is used as input to the surrogate competence level model.

**Table 1** Features for Competence Level Prediction.

| Feature | Description | Competence Signal |
|---|---|---|
| Total NLOC | Sum of non-comment code lines | Contribution size |
| Total Tokens | Sum of lexical tokens | Lexical density |
| Num Functions | Count of modified functions | Breadth of change |
| Num Files | Count of modified files | Cross-file impact |
| Num Competences | Count of technical domains | Domain diversity |
| Num Sub-competences | Count of sub-domains | Fine-grained breadth |

**Hierarchical Aggregation.** We aggregate function-level metrics following a three-tier hierarchy: **Function Level:** Individual function metrics from Lizard. **Sub-competence Level:** Functions are grouped by API usage patterns (e.g., "Database → Query Execution", "User Interface → Layout Design"). For each sub-competence, we calculate: total CCN, total NLOC, total tokens, number of functions, average CCN, average NLOC per function, average tokens per function, and maximum function CCN. **Competence Level:** Sub-competences are aggregated into parent competences, and metrics are the sum of all sub-competence metrics within that competence.

**Composite Complexity Scoring.** We calculate a weighted composite score from all 13 metrics to assign competence levels. The composite score combines the metrics using equation (1) and competence levels (Section 2.2.2).

This multi-metric approach provides a more robust assessment than single-metric thresholds, as it captures multiple dimensions of code complexity.

**Machine Learning Models.** We adopt the one-vs-all strategy [24] to deal with the large number of categories in the multi-label problem aggravated by the data imbalance. One-vs-all strategy also enables the study to scale to more layers, potentially leading to an extreme multi-label problem in the future [32].

We train two complementary models:

*Competence Classification:* Predicts which technical areas are involved in a pull request using issue and linked PR text (title and description) processed through TF-IDF vectorization following previous research indicating best performance with lexical approaches instead of semantic for noisy text [16]. This multilabel model identifies which technical areas are involved.

*Competence Level Prediction Model:* Predicts the required competence level (1-5 scale) using both textual features and a surrogate model with six code complexity metrics [14]. The option for the surrogate model is twofold: it deals with the data leakage of predicting the levels using the same features used to obtain them, and enables the model to use only essential data available when the PR is submitted. This comparative feature-reduction approach follows standard practice in feature selection [14, 17].This multiclass model determines *who* (at what competence level) should work on the contribution.

The models work in tandem to provide comprehensive competence profiling: the competence model identifies technical scope, while the competence level model quantifies required experience. The predictive models demonstrate that the proposed metrics capture signals aligned with the requirements for identifying competence levels. We ran the models using Random Forest (RF) which reported competitive results in Software Engineering research [8, 28, 29, 31].

# 3 Results

In this section, we present the results of the study.

## 3.1 Dataset Characteristics

We successfully extracted complexity metrics from 19,005 function-level records (a function counted once for each commit in which it was modified), corresponding to 5,793 functions uniquely identified by name and file path across the dataset. From the 85 pull requests analyzed, we discarded 21 PRs that did not declare any source code and contained documentation or configuration-only updates. In total, this yielded 64 PRs that contained substantive code modifications with at least one extracted function and measurable complexity metrics. Table 2 summarizes the dataset characteristics.

Note that the 296.9 average functions per PR (Table 2) is computed from the 19,005 total function-level records, not the 5,793 uniquely identified functions, since a function modified across multiple commits is counted once per commit.

We organize technical knowledge using a two-level hierarchy composed of competences and sub-competences. Competences represent broad technical areas (e.g., User Interface, Network, Database), while sub-competences capture more specific activities within them (e.g.,

**Table 2** Dataset Summary Statistics (n=64).

| Metric | Value |
|---|---|
| Total PRs Analyzed | 85 |
| PRs with Code Changes | 64 (75.3%) |
| Empty PRs (docs/config) | 21 (24.7%) |
| Avg Functions per PR | 296.9 |
| Avg NLOC per PR | 4,411 |
| Avg Tokens per PR | 32,598 |
| Min Functions | 3 |
| Max Functions | 3,196 |
| Min Sub-competences | 1 |
| Max Sub-competences | 33 |

Layout Design, Connection Management, Query Execution). Each pull request may involve one or multiple competences and sub-competences depending on the APIs and functions identified during AST analysis and classification.

The dataset exhibits substantial variance in complexity, ranging from simple, single sub-competence changes (e.g., PR #34 with 8 functions in one sub-competence) to large architectural modifications (e.g., PR #80 with 2,156 functions across 33 sub-competences and 15 competences). This diversity enables robust model training across different competence levels.

McNemar's test confirmed the surrogate model's improvement over a majority-class dummy baseline was not due to chance: across 5,793 unique functions, the surrogate was correct where the dummy was wrong 981 times, versus 369 in the reverse, yielding a significant McNemar statistic of 276.53 ($p < 0.0001$).

## 3.2 Complexity Metrics Distribution

Table 3 presents the distribution of extracted complexity metrics across all 64 PRs with code changes.

**Table 3** Complexity Metrics Distribution.

| Metric | Mean | Min | Max |
|---|---|---|---|
| Cyclomatic Complexity | 3.32 | 1.00 | 78.00 |
| Lines of Code (NLOC) | 4,411 | 24 | 50,671 |
| Token Count | 32,598 | 175 | 367,105 |
| Functions per PR | 296.9 | 3 | 3,196 |
| Sub-competences per PR | 7.2 | 1 | 33 |
| Competences per PR | 5.1 | 1 | 15 |

The mean cyclomatic complexity of 3.32 indicates that most code in JabRef is moderately complex, falling into the Level 1 - Level 2 range. However, the maximum CCN of 78.00 suggests that some contributions require Level 5 competence. The wide range in NLOC (24 to 50,671) and tokens (175 to 367,105) reflects the diversity of contribution sizes, from small, low-line-count changes to major feature additions.

## 3.3 Model Performance

Despite the relatively small dataset, both models achieved strong performance. Table 4 summarizes the results.

The Competence Classification model achieved 92.91% accuracy in identifying which technical competences are involved in a PR. For competence level prediction, we adopted a surrogate model using six structural features to mitigate the risk of target leakage inherent

**Table 4** Model Performance Metrics.

| Model | Metric | Value |
|---|---|---|
| Competence Classification | Accuracy | 92.91% |
| | F1-Score | 75.80% |
| | Training Samples (functions) | 5,793 |
| Surrogate Model (6 features) | Test Accuracy | 69.23% |
| | F1-Score (weighted) | 67.18% |
| | CV Accuracy (3-fold) | 62.41% |
| | Training Samples (functions) | 5,793 |
| Dummy Baseline (Competence Level, most-frequent) | Accuracy | 38.46% |
| | F1-Score (weighted) | 21.37% |
| | Training Samples (functions) | 5,793 |

in predicting complexity levels from complexity-derived metrics themselves. The surrogate competence level model (69.23% accuracy, 67.18% F1) substantially outperforms the strongest naive dummy baseline (38.46% accuracy, 21.37% F1), supporting that it captures genuine predictive signal from code complexity metrics rather than exploiting class imbalance alone.

The competence level distribution across our 64 PR-level training samples was Level 1 (20.3%), Level 2 (30.8%), Level 3 (40.6%), Level 4 (6.2%), and Level 5 (2%), with contributions concentrated in the moderate-complexity range (Levels 2–3) and few reaching the highest complexity tiers. Note this reflects individual PR labels prior to aggregation; Section 3.6 reports a markedly different distribution once competence is aggregated to the contributor level using a maximum rule (Table 7).

## 3.4 Per-Domain Performance Analysis

To understand how the competence level prediction model performs across different technical domains, we analyzed prediction accuracy for each of the competences identified in our dataset. Table 5 presents the results, sorted by F1-Score.

**Table 5** Competence Level Prediction Accuracy (Surrogate Model), by Technical Domain.

| Domain | Accuracy | Precision | Recall | F1-Score | Samples | Avg Level |
|---|---|---|---|---|---|---|
| Databases | 90.00 | 91.67 | 90.00 | 89.45 | 10 | 2.30 |
| Error Handling | 85.71 | 89.29 | 85.71 | 84.35 | 7 | 2.14 |
| Operating System | 75.00 | 76.94 | 75.00 | 75.43 | 12 | 2.50 |
| Computer Graphics | 70.00 | 70.09 | 70.00 | 69.97 | 30 | 2.50 |
| Input-Output | 68.97 | 73.78 | 68.97 | 69.27 | 29 | 2.17 |
| Event Handling | 65.52 | 65.80 | 65.52 | 65.34 | 29 | 2.45 |
| Network | 63.64 | 69.26 | 63.64 | 64.69 | 11 | 2.55 |
| User Interface | 63.41 | 65.83 | 63.41 | 63.62 | 41 | 2.56 |
| Language | 57.14 | 65.00 | 57.14 | 60.32 | 14 | 2.71 |
| Data Structure | 56.25 | 56.35 | 56.25 | 56.00 | 32 | 2.41 |

The surrogate model achieved up to 90.00% prediction accuracy in the Databases domain, demonstrating its effectiveness in predicting contributor competence in specialized technical areas. Performance decreased in broader and more heterogeneous domains such as Language (57.14%) and Data Structure (56.25%), where the wider variety of development tasks and complexity patterns makes competence-level prediction more challenging. Overall, the results indicate that domain specialization enables more accurate prediction, whereas heterogeneous domains introduce greater classification uncertainty. Label cardinality is 7.1094 and label density is 0.0846, confirming the multilabel nature of the problem and the integrity of the learning process [4, 18].

## 3.5 Feature Importance Analysis

Feature importance analysis revealed that code complexity metrics substantially outperform textual features. Table 6 shows the top features.

**Table 6** Surrogate Model Feature Importance (6 Features).

| Feature | Importance |
|---|---|
| Total Tokens | 0.2725 |
| Total NLOC | 0.2324 |
| Num Files | 0.1561 |
| Num Functions | 0.1428 |
| Num Competences | 0.1058 |
| Num Sub-competences | 0.0904 |

Total token count emerged as the strongest predictor (importance: 0.2725), followed by total NLOC (0.2324) and number of files touched (0.1561). Structural breadth metrics (number of competences and sub-competences) contributed less, suggesting that raw contribution size and lexical density carry more signal for level prediction than the breadth of technical areas touched.

**RQ1 Answer.** The competence level can be predicted with up to 90% accuracy in the best-performing domain (Databases) using a reduced, leakage-aware surrogate model; the most influential predictors are total token count and total NLOC, indicating that contribution size and lexical density are stronger signals than technical breadth alone.

## 3.6 Contributor Profiling

Beyond analyzing individual pull requests, our approach enables the construction of comprehensive contributor profiles by aggregating competence across all contributions. For each contributor, we apply a maximum aggregation rule: the highest observed level in each sub-competence is retained in the contributor profile. This reflects the principle that when managers want to search for a contributor for a possible allocation, they can start by searching for the highest-skilled contributor, and then investigate the individual competence/sub-competence levels to reveal more details about the contributor's competences that demonstrate capability at a certain level.

**Contributor Analysis Results.** From 5,793 unique functions, we identified 16 contributors with varying competence levels. The contributor-level distribution below reflects, per contributor, the maximum level reached across their individual sub-competence scores, not the PR-level distribution reported earlier. Because each contributor spans many sub-competences (avg. 20.5, Table 8), a high level in even one area is enough to register, so contributor-level Level 5 rates run higher than PR-level rates. Table 7 presents the distribution of contributors by their maximum competence level achieved.

**Table 7** Contributor Distribution by Competence Level.

| Max Competence Level | Count | Percentage |
|---|---|---|
| Level 5 | 3 | 18.75% |
| Level 4 | 2 | 12.5% |
| Level 3 | 7 | 43.75% |
| Level 2 | 4 | 25.0% |

The distribution reveals that 56.25% of contributors (9 of 16) demonstrate Level 3 or Level 4 capabilities in at least one technical area, suggesting that a substantial proportion of contributors possess intermediate to advanced technical capabilities. This expertise distribution can help project maintainers identify contributors with similar technical capabilities when planning contributor replacement or assigning new tasks.

**Competence Breadth Analysis.** Contributors demonstrated competence across an average of 20.5 competence/sub-competence combinations (SD = 10.8, range = 6-43). Table 8 shows the most versatile contributors.

**Table 8** Top Contributors by Competence Breadth.

| ID | Areas | Max Lvl | PRs |
|---|---|---|---|
| d | 43 | 5 | 4 |
| c | 39 | 5 | 3 |
| 0 | 35 | 5 | 4 |
| b | 28 | 4 | 5 |

Contributor “d” demonstrated the broadest competence, achieving Level 5 proficiency in four competences while maintaining capabilities across 43 distinct sub-competence areas. This breadth-and-depth combination makes such contributors particularly difficult to replace, as finding candidates with comparable versatility requires matching not just peak competence but also the range of secondary competences.

**Competence Profile Example.** To illustrate the granularity of our profiles, Table 9 shows the competence distribution for contributor “a”, who achieved Level 4 status across multiple competences.

**Table 9** Competence Profile for Contributor "a".

| Level | Competence | Sub-competence | PRs |
|---|---|---|---|
| 4 | Computer Graphics | Image Rendering | 4 |
| 4 | Data Structure | Linear Structures | 5 |
| 4 | Event Handling | User Interactions | 5 |
| 4 | User Interface | Layout Design | 5 |
| 3 | Error Handling | Exception Handling | 1 |
| 3 | Input-Output | Data Reading | 3 |
| 3 | Network | Protocol Implementation | 1 |
| 3 | Operating System | Memory Management | 1 |
| ...and 19 additional areas at Levels 1-2 | | | |

This profile reveals that contributor “a” achieved Level 4 mastery in four core areas, Level 3 competence in four additional areas, and maintained working proficiency across 19 other technical competences at Levels 1–2. Such detailed profiles enable precise matching: if a project needs to replace this contributor, the search can prioritize candidates with demonstrated Level 4 capabilities in at least Computer Graphics and User Interface competences, rather than simply seeking “experienced Java developers.”

**RQ2 Answer.** The proposed method identified contributor profiles aggregated from historical contributions revealing competences, sub-competences and levels.

# 4 Discussion

## 4.1 Implications for OSS Sustainability

Competence modeling has been explored by the industry to understand how to improve performance with qualified personnel [6]. Our study mines data from OSS repositories aiming to build profiles to benefit OSS communities by utilizing contributor's competences to optimize task allocation towards populating an ontology to anchor the concepts [5, 7] for automatic matching [12] at the next stage of this research.

Our approach has several implications for OSS project sustainability. First, by enabling automated candidate search at scale, projects can proactively build contributor pipelines before disengagement occurs. Second, the deep competence profiling allows for more accurate matching, reducing onboarding friction and increasing the likelihood of successful integration. Third, maintainers can identify competence gaps in their current team and train or recruit strategically to improve project resilience.

## 4.2 Limitations

External Validity: Case studies are limited in generalization on their own. Internal Validity: Metrics derived from static code analyzers may not always accurately reflect real-world code complexity; nevertheless, they are widely used tools in industry to give feedback to coders. LLM categorization cannot ensure determinism. However, we mitigated this through a low sampling temperature (0.1) to reduce output variability, combined it with a similarity metric to filter out hallucinations, and we manually analyzed 361 samples (functions) to confirm the results. Construct validity: Competence management is a broad concept, and this study aims to explore one topic: the level of competence. We employed programming language libraries, functions, and static metrics as proxies for competence, which may not reflect the true theoretical meaning of the concept, and reflect task complexity, PR size, or legacy code structure rather than the contributor's actual capabilities.

# 5 Future Work and Conclusion

Future work will build profiles for AI coding agents as contributors' teammates and will explore competence levels with additional metrics, at scale across multiple repositories, applying data source triangulation to assess whether the composite scoring thresholds and predictive models generalize beyond JabRef while exploring diverse LLMs, temperature and tuning parameters. New metric thresholds will be evaluated with industry practitioners using card sort approach. We plan to validate our approach through multiple methods: comparing our competence profiles against self-reported competence and levels in developer profiles, conducting surveys and interviews with project maintainers to assess the relevance of recommended candidates, and conducting experiments to evaluate maintainers' and contributors' feedback about the competences, levels and allocation recommendations. The accuracy to infer training needs, search, and recruitment will be explored in future work, along with an estimation of the costs associated with applying this approach in practice. Future work will also explore the use of a competence ontology to map the task and contributor profile to perform allocation through ontology matching. This work presents an initial approach for building competence profiles to later support search, recruitment, and training for the OSS workforce. By implementing competence-based management, we aim to contribute to the sustainability of OSS projects by leveraging complexity level and competence prediction for allocation recommendation.

## Data Availability Statement

The replication package is available through Zenodo https://doi.org/10.5281/zenodo.21605122. It will be publicly available during the review process and after acceptance.

## Abstract

Soft skills are essential for software engineers. For example, effective communication and collaboration are critical for the design and delivery of software solutions. However, many organizations lack the resources to systematically support soft skills training. Although video-based training provides a flexible approach, it easily leads to shallow learning. To support engagement, active video watching integrates reflective activities, such as commenting on videos and reviewing peers' comments. Gamifying these activities can further increase engagement. However, effective gamified training must carefully consider the target audience of the training. Therefore, this emerging results paper investigates the impact of gamification on the engagement, learning, and attitudes of software professionals participating in video-based soft skills training. We conducted an experiment involving 48 software professionals who completed a presentation skills training program. Our findings indicate that gamified video-based training did not significantly improve engagement or learning when compared to a non-gamified training. Nevertheless, participants generally expressed more positive attitudes toward gamified training. Based on these findings, we discuss several design considerations for technology-supported professional development for software professionals.

## 1 Introduction

Soft skills are "intra- and inter-personal (socio-emotional) skills essential for social participation and workplace success [15]" and include competencies such as communication skills and the ability to work effectively in teams. Soft skills complement core software development

activities such as requirement elicitation, design and construction, and quality assurance, but software professionals often lack these skills [15]. Ways to train soft skills include seminars, coaching, and workshops [5]. However, such training is time-consuming and disrupts professionals' schedules, and many software organizations lack the resources for soft skills development [14]. As a result, self-guided e-learning, and in particular video-based training, has emerged for professional soft skills development [18]. Learners can attend the training at their own time, their own pace, and personalize the training [29]. However, video-based training leads to shallow learning if there is little interaction with the video-based content [8]. To mitigate passive learning, "active video watching" (AVW) includes reflective activities, such as commenting on videos and reviewing comments from other learners [8]. This allows learners to engage with the training material, including deciding what is relevant, organizing information, and integrating it with their existing knowledge.

Gamification, i.e., the use of game design elements (e.g., badges, points) in non-game contexts, can further increase engagement with these activities [20]. However, gamification must carefully consider the target audience of the training [10]. Therefore, our goal in this *Emerging Results* paper is to investigate the impact of gamification on video-based soft skills training of software professionals. We address the following research questions (RQs):

1. **Does gamification increase engagement and learning in video-based soft skills training of software professionals?** Prior research has shown that professionals are open to gamified training [28]. However, this does not mean that gamification is actually effective in soft skills training. We analyze the impact of gamification on the engagement and learning of software professionals.
2. **What are the attitudes of software professionals towards gamified video-based soft skills training?** To complement the insights about the *effect* of gamification, we explore the *attitudes* of software professionals toward gamified video-based soft skills training.

## 2 Background

### 2.1 Soft Skills

Inadequate soft skills impact software project success and many software companies emphasize soft skills during recruitment [33]. Prior works found that communication is the most prominent soft skill in software engineering, and highlighted that soft skills do not depend on organization size or business domain [19]. Some studies focused on specific software professional roles. For example, de Morais Leça and de Souza Santos [7] explore soft skills for data scientists in the software industry and found critical thinking and empathy as essential for addressing the ethical challenges in software engineering. Estes et al. [12] conclude that interpersonal and stakeholder communication, as well as written communication skills are essential for software product managers.

For training soft skills, Szilárd et al. [34] suggested e-learning, in-person workshops, roleplay, simulation, mentoring, and coaching. Paulisch et al. [27] recognize the importance of soft skills training for senior software architects and developed a program to train architects while acknowledging the necessary investment in time and resources for a training program. Still, most studies on soft skills training in software engineering cover academic education rather than professional development of software engineers in industry [9].

## 2.2 Video-based Training

Video-based training via platforms such as Coursera[2], Udemy[3] Harvard Online Learning[4], LinkedIn Learning[5] or YouTube tutorials has seen significant growth [29]. By incorporating audio and visual elements, videos offer structured and engaging training content for better understanding and knowledge retention [29]. Learners can pause and revisit content at their own pace [29]. It also removes physical and time barriers for training in a setting and at a time that best suits learners [29]. Video-based training also offers advantages for training providers through scalable delivery to larger audiences while reducing repetitive efforts [29]. However, only passively watching videos results in lower training effectiveness and knowledge retention [28]. *Active video watching* involves engaging in reflective activities: writing comments and reviewing comments from other learners [8] and can support professional training of software engineers in industry [14]. Gamifying such active video-based training can further increase learner engagement.

## 2.3 Gamification

Gamification is "the process of game-thinking and game mechanics to engage and solve problems [38]." Software developing organizations have started to adopt gamification in employee training [13]. Mahat et al. [24] examined gamified professional training across domains. The authors identified three strategies for gamifying professional training: (1) gamified computer training platforms, (2) face-to-face gamified training, and (3) blended gamified training (i.e., combining computer-supported and face-to-face activities). They also noted that points, levels, leaderboards, challenges, and badges are the most common game elements in professional training. Miller et al. [25] conducted a case study within an IT department. Leaderboards, levels and challenges increased engagement in technology training, and gamification was well received by the employees. Ayoup et al. [2] conducted a case study in a large-scale software development company, implementing a badge-based gamified DevOps training program. Gamification helped accelerate the adoption of DevOps practices and practitioners found badges beneficial for learning.

# 3 Research Method

In this section, we provide an overview of the research method used to carry out the experimental study. We received approval from our institution's ethics board. We adhered to the guidelines for conducting experiments in software engineering [36].

## 3.1 Hypotheses and Variables

We define the following **hypotheses** (for space reasons we do not include the alternative hypotheses). Hypotheses 1 and 2 relate to RQ 1, and Hypothesis 3 relates to RQ 2:

1. Engagement: $H1_0$ Software professionals who participate in gamified video-based soft skills training will not demonstrate significantly higher levels of engagement compared to those who participate in non-gamified training.

[2] https://www.coursera.org/
[3] https://www.udemy.com/
[4] https://pll.harvard.edu/
[5] https://www.linkedin.com/learning/

2. Learning: $H2_0$ Software professionals who participate in gamified video-based soft skills training will not demonstrate significantly higher levels of learning compared to those who participate in non-gamified training.
3. Attitudes: $H3_0$ Software professionals who participate in gamified video-based soft skills training will not demonstrate significantly more positive attitudes compared to those who participate in non-gamified training.

The **independent variable** was whether professionals used gamified training or not. We categorize the **dependent variables** according to the constructs we measured in the experiment. Table 2 shows the variables for *engagement* ($H1$).

For *learning* ($H2$) we calculated a Learner Model Score (LMS) which represents the current skill level of a learner. This was because assessing presentation skills using live presentations was impractical due to the large cohorts, time and location constraints. We employed an ontology-based LMS [4]. This approach models each learner's knowledge based on a structured ontology of Knowledge Components (KCs) related to the trained skill, and updates the KC-level as a score whenever learners interact with course materials. For example, if a learner writes the comment "The audience appreciates the use of diagrams", the score for KC *Visual Aids* is increased as keyword "diagram" shows awareness of the importance of visualizations in presentations. The resulting scores, normalized between 0 and 1, provide an estimate of knowledge acquisition, which we used as a proxy for learning [4]. The learner model is initialized based on the learner's answer to the conceptual knowledge questions provided in a pre-survey. During the learning process, each time a learner writes a comment or responds to a peer, the KC score is updated [4]. This update process continues throughout the learning activities, with each KC score capped at a maximum of 1 for full mastery.

For *attitude* ($H3$) the measurement constructs were primarily grounded in the Technology Acceptance Model (TAM) [6]. To better evaluate user attitudes in the context of gamified video-based soft skills training, we extended the TAM measures by incorporating additional constructs from previous studies [11, 37]: (1) Perceived Usefulness for Learning (PU): the extent to which soft skills training and supports learning activities. (2) Perceived Ease of Use (PEU): degree to which training is easy to follow and interact with. (3) Behavioral Intention (BI): intention to use and recommend the training for future training. (4) Task-technology Fit (TTF): extent to which the implementation of training supports learning tasks and meets soft skills training needs. (5) Enjoyment: degree to which the training experience is fun and pleasurable. (6) Negative Affect (NA): the extent to which users experience negative emotions during training. (7) Social Recognition (SR): importance placed on organizational and peer acceptance of the training for professional development. The measures were adapted for both the gamified and non-gamified conditions with minor wording modifications to ensure comparability across conditions. Responses were collected using a 7-point Likert scale ranging from 1 (*Strongly Disagree*) to 7 (*Strongly Agree*). Cronbach's alpha was used to assess the internal consistency of the scale items, while composite averages were calculated for each construct to represent respondents' overall perceptions. Optional free text comments were also allowed alongside each construct, allowing participants to explain the reasoning behind their ratings. The supplementary material provides the complete list of selected constructs and measurement items used in the study.

## 3.2 Experiment Design

**Study Participants.** To recruit professionals from industry, we used purposive sampling [3] and recruited professionals through personal contacts and by reaching out to software organizations. We did not constrain recruitment based on factors such as age, qualifications,

or years of professional experience, as long as professionals were employed in the software engineering industry. Participants were randomly assigned to treatment conditions. The design was balanced across the two treatment groups and followed a one-factor (gamification condition), two-treatment structure (control: not gamified; experiment: gamified).

**Study Environment.** The scope of the experiment was a video-based training exercise to develop presentation skills, one representative communication skill required by software professionals [15]. This context was selected to better reflect how the training would be used in real professional settings. The experiment was conducted within the context of AVW-Space [8], an active video watching platform where we added gamification features in form of badges. The platform contains three generic training activities: watching videos, commenting on videos as a means of reflection for deeper learning, and reviewing comments from other learners on the same videos for another opportunity of reflection and engagement. Learners might be familiar with these activities from platforms like YouTube. The selection of game elements in AVW-Space was informed by prior work involving software professionals [28]. In line with the theoretical findings of this earlier study, we selected badges as the primary game element, as they emphasize individual progress and rewards [28]. We intentionally limited the implementation to a single game element, since the inclusion of multiple game elements may confound experimental results. To ensure that practitioners would respond positively to both the visual design and awarding conditions of the badges, we designed them based on established badge design frameworks [16]. Table 1 presents the badge awarding conditions, while Figure 1 shows the interface used for training. Comment quality to award some of the badges was based on a comment quality assessment framework developed by others [26], which has since been adopted in subsequent studies [4, 23].

**Table 1** Badges and awarding conditions for presentation skills.

| Badge | Awarding Condition |
|---|---|
| Video Novice | After watching first video |
| Video Pro | After watching 4 videos (half the videos in no particular order) |
| Video Master | After watching all 8 videos |
| Comment Novice | After writing first high-quality comment |
| Comment Apprentice | After writing two high-quality comments for the first video |
| Comment Pro | After writing two high-quality comments for the next video |
| Comment Expert | After writing three high-quality comments each for the next 3 videos |
| Comment Master | After writing five high-quality comments each for the next 3 videos |
| Peer Review Master | After reviewing and rating 15 peer comments |
| Learning Luminary | After accumulating all other badges |

**Study Activities.** Participants completed a pre-survey that collected demographic information and assessed their conceptual knowledge of presentation skills (see Section 3.1). The professionals then used AWV-Space to complete a learner journey independently, in their own pace, i.e., they watched and commented on eight presentation skill videos. The videos[6] were selected by experts in software engineering and education technology based on the following criteria: (1) content relevance (for software engineering and presentation skills, e.g., covering structure, delivery and visual aids, or examples of presentations); (2) pedagogical value and

[6] An example video used in the study can be found at `https://www.youtube.com/watch?v=i68a6M5FFBc`.

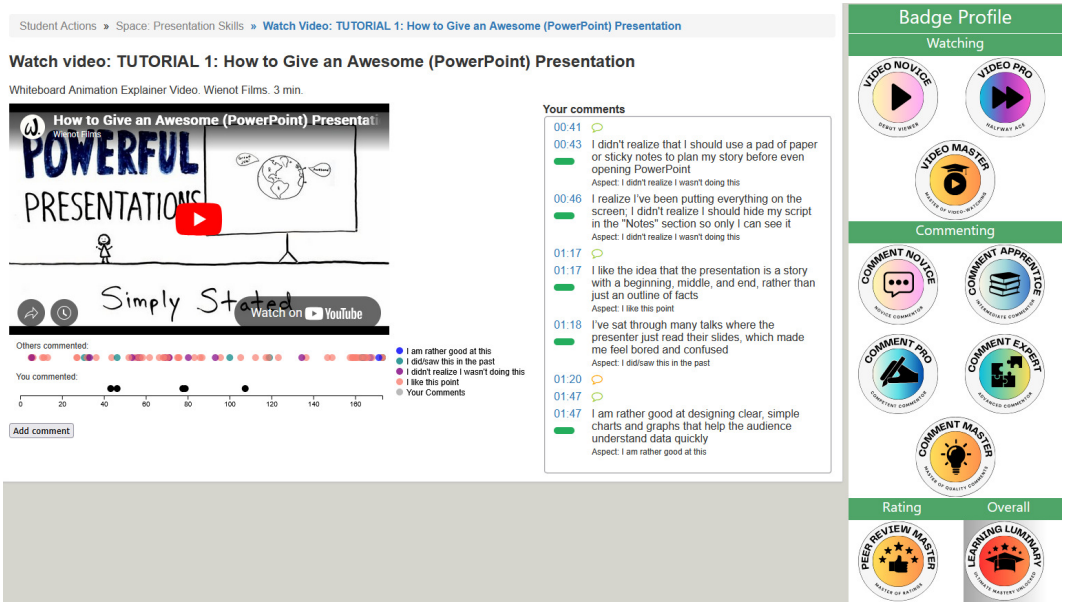

**Figure 1** Gamified prototype (user interface for watching and commenting on videos).

quality (e.g., delivery of video content); (3) length (no longer than 10 minutes to avoid fatigue); (4) gender balance in videos; (5) diversity of content (e.g., popular and not so popular examples based on YouTube ratings) [8], see supplementary material. Participants were also given access in AVW-Space to a set of pre-selected, anonymously published comments from a previous study involving a different group of software professionals (we could not use comments from the same participant group because participants went in their own pace and completed the learning activities at different times over a two-month period). Participants reviewed the anonymously published peer comments. Finally, participants completed a post-survey that captured their attitudes toward the use of gamified video-based training for professional development. The variables used to measure engagement and learning for $H1$ and $H2$ are automatically collected in AVW-Space. Attitudes ($H3$) were captured via a post-survey. The participants, from their point of view, did not primarily participate in an experiment; they were taking a soft skill training program. We offered a 17 US$ gift voucher in appreciation of their consent to the use of their data.

## 4 Results

The sample consisted of 27 software professionals who followed the gamified training and 21 who followed the non-gamified training, with the following demographics:

- **Age**
  - Gamified group: 24–29 ($n = 13$), 30–35 ($n = 14$)
  - Non-gamified group: 18–23 ($n = 1$), 24–29 ($n = 16$), 30–35 ($n = 3$), 36–41 ($n = 1$)
- **Gender**
  - Gamified group: Male ($n = 17$), Female ($n = 10$)
  - Non-gamified group: Male ($n = 16$), Female ($n = 5$)
- **Country**
  - Gamified group: Philippines ($n = 13$), Sri Lanka ($n = 7$), Malta ($n = 2$), Finland ($n = 1$), Germany ($n = 1$), Japan ($n = 1$), Malaysia ($n = 1$), New Zealand ($n = 1$)

  - Non-gamified group: Philippines ($n = 17$), Sri Lanka ($n = 1$), Singapore ($n = 1$), United Kingdom ($n = 1$), United States of America ($n = 1$)
- **Highest degree**
  - Gamified group: Bachelor's ($n = 26$), Master's ($n = 1$)
  - Non-gamified group: High School ($n = 1$), Bachelor's ($n = 20$)
- **Seniority**[7]
  - Gamified group: Junior (1–2 years, $n = 8$), Intermediate (3–5 years, $n = 14$), Senior ($> 5$ years, $n = 5$)
  - Non-gamified group: Junior (1–2 years, $n = 8$), Intermediate (3–5 years, $n = 5$), Senior ($> 5$ years, $n = 8$)

## 4.1 Engagement

Engagement data were not normally distributed (Shapiro-Wilk test), so we employed the Mann-Whitney U test to compare the gamified and non-gamified groups. However, we did not find any significant differences in the engagement metrics between the gamified training and the training without gamification (see Table 2). Effect sizes (rank-biserial correlation) for all engagement variables were small, and their 95% confidence intervals included zero, confirming that engagement did not differ significantly between the gamified and non-gamified groups. Therefore, the null hypothesis ($H1_0$), which states that there is no significant difference in engagement between gamified and non-gamified video-based training was not rejected. Software professionals who used gamified training did not exhibit higher engagement than those in non-gamified training.

## 4.2 Learning

We refer to the learner model score at the start of the experiment as $LMS_{Start}$, the learner model score at the end of the experiment as $LMS_{End}$ and the difference between $LMS_{Start}$ and $LMS_{End}$ as $LMS_{Diff}$. We used the Mann-Whitney U test and the independent sample t-test since $LMS_{Start}$ was not normally distributed (Shapiro-Wilk test). Despite differences in the distribution of age, country, education, and seniority, we found that both the gamified and non-gamified groups started with similar $LMS_{Start}$. However, we did not find any significant differences in $LMS_{End}$ or $LMS_{Diff}$ between the gamified and non-gamified groups (see Table 3). Learning outcomes did not differ significantly between groups, with small-to-moderate effect sizes (Cohen's d and rank-biserial correlation) and confidence intervals spanning zero. Therefore, the null hypothesis ($H2_0$), which states that there is no significant difference in learning outcomes between gamified and non-gamified video-based training among software professionals, was not rejected. Software professionals in gamified training did not exhibit higher learning than those in non-gamified training.

## 4.3 Attitudes Towards Gamified Video-based Training

Table 4 presents the reliability analysis along with the means and standard deviations of the constructs for the gamified group and non-gamified group. Since all constructs yielded Cronbach's alpha greater than 0.70, the instrument can be considered reliable [31]. The mean represents the average response over all professionals in a group, while the standard deviation indicates the degree of dispersion around the mean.

[7] Seniority is based on [22]

**Table 2** Engagement variables.

| | Gamified (N=27) | | Non-gamified (N=21) | | Significance | Effect size | 95% CI |
|---|---|---|---|---|---|---|---|
| | Mean (sd) | Median | Mean (sd) | Median | | | |
| Days logged into training | 3.30 (2.20) | 3 | 3.57 (2.80) | 3 | $U = 270.5$, $p = .784$ | r=-0.0459 | -0.3598, 0.2787 |
| # training sessions | 4.74 (3.98) | 4 | 4.86 (3.55) | 4 | $U = 255.5$, $p = .557$ | r=-0.0988 | -0.4110, 0.2311 |
| # videos watched | 6.67 (2.47) | 8 | 7.67 (1.53) | 8 | $U = 226.0$, $p = .066$ | r=-0.2028 | -0.4074, -0.0123 |
| # comments posted | 18.07 (15.43) | 15 | 20.57 (14.52) | 15 | $U = 248.0$, $p = .460$ | r=-0.1252 | -0.4427, 0.2081 |
| # high quality comments | 13.19 (11.72) | 11 | 15.62 (12.60) | 12 | $U = 252.5$, $p = .519$ | r=-0.1093 | -0.4392, 0.2275 |
| # comments reviewed | 25.63 (33.49) | 15 | 47.38 (50.48) | 30 | $U = 197.5$, $p = .074$ | r=-0.3034 | -0.6085, 0.0159 |

) *Note.* $r$ = rank-biserial correlation; 95% CI reported as lower limit, upper limit.

**Table 3** Learner Model Scores.

| | Gamified (N=27) | | Non-gamified (N=21) | | Significance | Effect size | 95% CI |
|---|---|---|---|---|---|---|---|
| | Mean (sd) | Median | Mean (sd) | Median | | | |
| $LMS_{Start}$ | 0.003 (0.003) | 0.003 | 0.003 (0.002) | 0.003 | $U = 260.5$, $p = .633$ | r=0.0811 | -0.2646, 0.4109 |
| $LMS_{End}$ | 0.100 (0.069) | 0.092 | 0.120 (0.067) | 0.122 | $t = 0.99$, $p = .326$ | d=0.289 | -0.2860, 0.8610 |
| $LMS_{Diff}$ | 0.097 (0.068) | 0.090 | 0.117 (0.067) | 0.119 | $t = 1.03$, $p = .309$ | d=0.300 | -0.2760, 0.8710 |

) *Note.* $r$ = rank-biserial correlation; $d$ = Cohen's $d$; 95% CI reported as lower limit, upper limit.

Practitioners in both groups expressed a positive attitude towards video-based soft skills training (see Table 4). Although gamified training showed a slightly higher overall mean (6.09 [$SD = 0.6040$]), no statistically significant differences were observed between the two groups. Therefore, the null hypothesis ($H3_0$), which states that there is no significant difference in attitudes between gamified and non-gamified video-based training programs among software professionals, was not rejected. Software professionals following the gamified training did not demonstrate more positive attitudes than those following the non-gamified training.

**Table 4** Measurement constructs for gamified group | non-gamified group.

| Construct | Cronbach's Alpha | Mean | Std. Deviation |
|---|---|---|---|
| PU | 0.866\|0.939 | 6.02\|6.25 | 0.7131\|0.9605 |
| PEU | 0.854\|0.928 | 6.27\|6.02 | 0.5884\|1.2306 |
| BI | 0.930\|0.974 | 6.28\|5.90 | 0.7819\|1.3250 |
| TTF | 0.892\|0.878 | 6.00\|5.95 | 0.8918\|1.0990 |
| Enjoyment | 0.923\|0.949 | 6.07\|5.60 | 0.8033\|1.6063 |
| NA | 0.895\|0.958 | 5.71\|5.88 | 1.1450\|1.6394 |
| SR | 0.871\|0.840 | 6.25\|5.78 | 0.6387\|1.0321 |
| Overall acceptance | – | 6.09\|5.91 | 0.6040\|1.0168 |

On the other hand, although the individual mean values across the gamified and non-gamified groups appear relatively similar, most constructs, including BI, PEU, and SR showed higher mean scores in the gamified group. This suggests a slight trend towards a positive difference, although the differences were not statistically significant.

# 5 Discussion

## 5.1 Implications of Findings

Our training solution was designed in line with established practices for professional development [27, 17]. It focuses on individual learning progress, incorporates active learning using self-reflective activities, and supports flexible, self-paced engagement. In addition, in the post-survey, participants in the gamified group generally reported positive attitudes toward badges in terms of how badges improve performance and the ease of use of badges with mean scores of 5.79 and 6.23 out of 7, suggesting that the game elements themselves were not perceived negatively. However, the experiment did not show a significant increase in engagement or learning for professionals who followed the gamified training. Although we observed a generally high overall acceptance of gamified video-based training for soft skills, there was also no significant difference between the gamified and non-gamified video-based training. Similar findings have also been reported for other types of learners, e.g., for students where gamification had less impact on engagement and learning [35]. On the other hand, the study also did not identify any significant detrimental effects of gamification. Several factors may explain the absence of a positive effect. One plausible explanation relates to the perceived relevance of the targeted soft skills. Software professionals may not view presentation skills as a critical soft skill that requires training, since they practice written and verbal communication on a daily basis anyway. This could have reduced their motivation to engage with the training regardless of whether it is gamified. Another possible explanation may be a general skepticism among software professionals regarding gamification for training. This skepticism was also evident in previous work [28], where software engineering

professionals were more doubtful than students that gamification could enhance learning. Practical constraints may have further limited engagement of software professionals. Since professionals have busy schedules, they may have felt less motivated to engage in this soft skill development. Furthermore, their work commitments may have caused interruptions, which might be a general challenge of professional development in the software industry [32]. Therefore, integrating additional incentives or support from organizations may be necessary to enhance engagement and learning among software professionals. For example, linking professional development to career progression, integrating it more directly into daily workflows, and associating rewards with formal recognition may improve both engagement and learning outcomes. This aligns with prior research in other domains, which highlights the importance of time constraints, employer support and motivation in professional development [1]. Finally, it should be noted that our sample was relatively broad in terms of professional seniority, and given its size, we could not detect any differences in outcomes based on seniority level.

With regard to the perceptions of software professionals on the use of gamified video-based training, the results indicated no statistically significant difference between the gamified and non-gamified video-based training. However, constructs such as PEU, BI, Enjoyment, and SR showed higher mean scores for the gamified group compared to the non-gamified group. This suggests that the gamified training may encourage more positive behavioural tendencies among software professionals toward training of soft skills. The higher scores for BI indicate a greater willingness to engage with and adopt the training (as one participant stated in the optional free text comments, "The rewards and challenges encourage consistent practice"). Additionally, the higher level of SR suggests that participants perceive that their peers and managers are likely to accept and support this type of training approach (e.g, one participant stated that "They likely appreciate that it offers measurable progress and helps employees improve in a flexible, self-paced way"). The higher PEU scores further indicates that the gamification did not create additional complexity or interruptions. Instead, gamification appears to function as a seamless enhancement to the training. The higher Enjoyment scores mean that professionals actually enjoyed the gamified training (e.g, one participant commented that that "The badges and progress tracking made the experience enjoyable by giving a sense of achievement"), which was one of the key motivational factors we found in previous studies [28].

## 5.2 Future Work

- **Further empirical research:** Future research should conduct additional studies with larger software professional groups to improve the generalizability of the results and to further examine the effectiveness of gamification. Larger-scale experiments may reveal behavioural or motivational effects that were not observable in the present study. Additionally, future studies should explore the intervention in a wider range of contexts to better understand the conditions under which gamification is most effective. For example, experiments could provide insights into whether certain workplace settings offer a more suitable context for gamified video-based professional development.
- **Refinement of the gamification intervention:** Future work could also focus on refining the gamification used in this experiment. In particular, improvements to badges may further enhance their motivational impact on software professionals. One potential direction is the integration of social gamification elements, such as peer visibility of badges or comparative progress indicators. Incorporating these social aspects into the existing badge implementation may strengthen engagement and provide additional motivational mechanisms beyond individual achievement. Additionally, future studies could explore other game elements, or combinations of multiple game elements rather than a single element, building on the recommendations provided by previous work [28].

### 5.3 Threats to validity

- **Construct validity:** Engagement was calculated using interaction metrics from the training platform. However, these behavioral indicators may not fully represent participants' cognitive or emotional engagement with the learning material, as learners may interact with the platform without being deeply engaged with the content. Similarly, learning was calculated using the LMS [4] as a proxy for the acquisition of soft skills. While this metric provides a structured quantitative measure of learner knowledge gain, it may not fully capture the multidimensional nature of soft skills competency, which often includes behavioral, interpersonal, and contextual elements that extend beyond what can be measured through system interactions alone.
- **Internal validity:** Differences in participants' baseline motivation and external workload demands may introduce a confounding variable that affects engagement independently of the gamified training. As a result, variations in participation in optional training activities may reflect pre-existing motivational differences or time constraints rather than the effect of the treatment itself. For example, the non-gamified group watched, on average, more videos and, on average, reviewed more comments. One possible explanation could be that professionals in the non-gamified group, who may have already had a high intrinsic motivation, continued engaging with videos and peer comments based on self-directed learning needs [21]. In contrast, gamified elements in the gamified group may have introduced explicit completion markers [30] (e.g., peer review master for reviewing 15 peer comments), which could have signaled task completion once acquired. This means that studies need to carefully control for the motivation and individual training needs of participants.
- **Conclusion validity:** One potential threat relates to the variability within the professional participant group, which included individuals from multiple countries and potentially diverse professional backgrounds. Such heterogeneity can increase variance in the data and reduce the ability to detect statistically significant effects. Another concern is the small sample size which may reduce statistical power and increase the likelihood of failing to detect meaningful effects of gamification.
- **External validity:** Our experiment focused specifically on video-based training for soft skill development and utilized a gamified implementation of a specific learning platform, AVW-Space. Although the platform incorporates common video-based learning activities, the design of the platform beyond the gamification features may influence how learners interact with the content. As a result, the findings may not generalize to other types of training platforms. Finally, our experiment examined only one of the soft skills, i.e., presentation skills as a representative communication skill. Therefore, the results may not necessarily generalize to other soft skills that may require different forms of training or assessment.

## 6 Conclusion

In this paper, we (1) explored the effectiveness of gamification in enhancing engagement, (2) examined its impact on learning, and (3) investigated the attitudes of software professionals toward gamified video-based training for soft skills development. Unlike Peiris et al. [28] which compared the perceptions and attitudes of different types of learners toward gamification, our study investigates the impact of gamification within one group of learners who actually experienced the gamified intervention.

The findings indicate that gamification did not lead to a statistically significant improvement in engagement or learning among professionals. Similarly, professionals in both the gamified and non-gamified groups reported generally positive attitudes toward video-based training for soft skills development across multiple measures, with no significant difference between the two groups. Given the relatively small sample size, these findings should be interpreted with caution and as preliminary, as the study may not have had sufficient statistical power to detect potential effects. Future research with larger professional samples is therefore needed to more conclusively determine the impact of gamification.

## Data Availability Statement

The dataset supporting this study, including study details and raw data, is openly available on Zenodo at `https://doi.org/10.5281/zenodo.20424284` under a CC-BY 4.0 license. The replication package contains all materials necessary to reproduce our findings.

## Abstract

AI coding agents such as GitHub Copilot and Claude Code are increasingly contributing pull requests (PRs) autonomously across large-scale software repositories. While prior research has primarily investigated the quality and acceptance of agent-generated artifacts, less is known about how sustained exposure to AI agents influences developers' own practices. Drawing on automation complacency theory, we investigate whether agent adoption is associated with changes in coding effort, testing discipline, and code review behavior. We conduct a longitudinal study of 669 developers across 103 repositories using the AIDev dataset and analyze behavioral changes before and after agent adoption across 11 metrics. To distinguish agent-associated effects from broader ecosystem trends, we complement within-subject analyses with a difference-in-differences (DiD) design using 228 control developers from repositories without agent activity. We find one large agent-associated effect: a 76.8% increase in PR description length ($r = 0.561$), alongside consistent but smaller improvements in testing discipline across all three testing measures. Coding effort remains stable. Although review behavior changes noticeably – reviews become faster, less detailed, and more permissive – these patterns are also observed in control repositories and therefore appear to reflect broader ecosystem trends rather than agent adoption. Overall, we find no evidence that developers reduce productive effort when working with AI agents. Instead, developers increase documentation and testing activity, while apparent declines in review thoroughness are better explained by wider changes in software development practice. These findings not only clarify how developers adapt to AI coding agents but also demonstrate how comparative causal designs help distinguish agent-associated behavioral changes from broader ecosystem trends.

**2012 ACM Subject Classification** Software and its engineering → Software creation and management; Computing methodologies → Artificial intelligence

**Keywords and phrases** AI Coding Agents, Automation Complacency, Developer Behavior, Pull Requests, Difference-in-Differences, Empirical Software Engineering, Longitudinal Study

**Funding** This research was fully funded by the Managed AI-powered Software Innovations (MAISA) project (Project No. 23B3C109YT10).

## 1 Introduction

AI coding agents such as GitHub Copilot, Cursor, and Claude Code are increasingly becoming part of everyday software development workflows. Beyond generating code suggestions, these agents now act as semi-autonomous collaborators that submit pull requests (PRs), generate tests, and respond to developer feedback [11, 10]. Large-scale datasets such as AIDev report hundreds of thousands of agent-authored contributions across diverse repositories [11], suggesting that AI agents are no longer experimental tools but an emerging

part of contemporary software engineering practice. As AI agents become increasingly integrated into development practice, an important question emerges: how does sustained collaboration with AI agents reshape developer behavior? Understanding this shift is important because software quality depends not only on generated artifacts, but also on how developers review, test, document, and maintain oversight during development.

Prior research has primarily focused on the outputs of AI agents rather than their influence on developers themselves. Existing studies have examined PR acceptance patterns [16, 22], code quality [9, 20], and testing practices in agent-generated contributions [25, 8]. Yet it remains unclear how sustained collaboration with AI agents influences developers' own practices over time. This question is methodologically challenging because developers who adopt AI agents may already differ from non-adopters, while behavioral changes over time may also reflect broader shifts in software development practices rather than the effects of AI agents themselves.

To understand this, we draw on automation complacency theory [14], which predicts reduced human monitoring and verification effort under reliable automation. In software engineering, this suggests that developers working alongside AI agents may change how they code, test, and review software over time. Accordingly, we investigate the following research question.

***RQ:*** *How does the observable adoption of AI coding agents reshape developers' coding effort, testing practices, and code review behavior?*

To answer this question, we conduct a longitudinal study of 669 developers across 103 repositories using the AIDev dataset and complement within-subject analyses with a (DiD) design using 228 control developers from repositories without agent activity. Our findings reveal selective behavioral adaptation rather than broad behavioral degradation. Agent adoption is associated with increased documentation effort and improved testing discipline, while changes in review behavior largely reflect broader ecosystem-wide trends rather than agent-associated effects. These findings make two contributions. Empirically, they show that developers maintain coding effort while strengthening documentation and testing practices when working with AI agents. Methodologically, they demonstrate that relying on within-subject analyses alone can misattribute broader ecosystem trends to AI-agent effects, highlighting the importance of comparative causal designs when studying AI-assisted software development.

## 2 Related Work

Prior research on AI-assisted software development has largely focused on short-term productivity gains and developer interactions with coding assistants. Controlled experiments show substantial improvements in task completion speed – for example, Peng et al. [15] report a 55.8% increase in task completion speed with GitHub Copilot, while Ziegler et al.[26] find similar perceived productivity benefits. However, complementary usability studies reveal a more nuanced picture: developers may accept AI-generated suggestions without thorough verification [21], exhibit varied interaction patterns [3], and face inefficiencies when evaluating generated code [13]. This literature is largely limited to short-term interactions and self-reported perceptions, leaving longer-term behavioral adaptation comparatively underexplored.

Beyond productivity, prior work has examined core development practices such as code review and testing, both of which are central to software quality. Code review research shows that practices converge across projects [17], serve broader functions such as knowledge transfer [2], and are strongly associated with software quality [12]. Additional work highlights the importance of factors such as comment specificity and reviewer familiarity [5].

Recent studies extend this line of inquiry to AI-generated contributions, showing differences in how developers review agent-authored PR [7]. Existing work, however, primarily examines the evaluation of agent-generated artifacts rather than broader changes in developers' review practices following sustained agent exposure. Similarly, testing practices have been studied through the lens of test–production co-evolution. Prior work shows that co-change between production and test files is a meaningful indicator of testing discipline and relates to downstream quality outcomes [19]. More recent studies investigate test generation by AI agents [25, 8], demonstrating variation across tools.

As with code review, this literature primarily focuses on agent-generated artifacts rather than longer-term developer adaptation. It remains unclear whether developers change their own testing behavior when working alongside agents. We therefore examine whether test inclusion and co-change patterns shift following agent adoption, and whether such changes are agent-associated or reflect broader ecosystem trends.

## 3 Research Method

We investigate the effects of AI agent adoption on developer behavior using a longitudinal within-subject quasi-experimental design, complemented with a DiD analysis [6] to better distinguish agent-related changes from broader ecosystem trends. For each treatment repository, we define the adoption point as the timestamp of the first observable agent-authored pull request, representing the earliest repository-level evidence of autonomous AI-agent participation. Behavioral changes are analyzed at the developer level, allowing each developer to serve as their own baseline while controlling for stable differences such as coding style, experience, and project context. To distinguish agent-related changes from broader temporal trends, we compare 103 treatment repositories with 148 control repositories that contain no agent activity. Because control repositories do not have a natural adoption event, we use the median pull request creation date as a pseudo-adoption point to partition repository history into balanced pre- and post-periods. This provides a consistent temporal reference for estimating developer-level behavioral changes while avoiding arbitrary calendar cutoffs and ensuring comparable pre/post partitions across repositories. We further assess the suitability of this construction by examining pre-adoption parallel trends between treatment and control groups (Figure 1).

**Dataset and Sampling.** Our analysis is based on the AIDev dataset [11]. We retain repositories that exhibit sustained agent activity spanning at least 90 calendar days, defined as a minimum of 90 days between the first and last agent-authored pull request, contain human-authored merged PRs in both pre- and post-adoption periods, and include at least one qualifying developer, yielding 103 treatment repositories. We retain developers who contributed at least five merged PRs in both periods within the same repository, a threshold chosen to balance statistical stability with sample retention. For the control group, we identify 148 repositories with no agent activity and apply the same developer criteria, yielding 228 qualified developers. To ensure data reliability, we remove invalid timestamps, exclude review turnaround times exceeding 720 hours (30 days), and retain only reviewers active in both periods. Coding-related metrics are filtered to reduce the influence of extreme values, and when developer-period groups exceed 20 PRs, we randomly subsample 20 to balance statistical stability and computational cost.

**Metric Operationalization.** We operationalize developer behavior using 11 metrics across three dimensions, aggregating all measures per developer per period using medians for volume-based metrics and means for proportions. Coding effort is captured through PR size, files changed, commits per PR, and PR description length. Testing discipline is measured via test file ratio, co-change rate, and production-conditioned co-change rate; test files are identified using standard filename heuristics (e.g., `test_`, `_test`, `.spec`, `/tests/`), which likely undercount modern co-located or implicit testing practices and therefore yield conservative estimates. Finally, review behavior is assessed through inline comments, review turnaround time, changes-requested ratio, and approval rate.

**Statistical Analysis.** We analyze behavioral changes using both non-parametric and parametric methods. Within-subject differences are tested using the Wilcoxon signed-rank test [23], which is robust to non-normal paired distributions and extreme values, with rank-biserial correlation ($r$) reported as the effect size. To distinguish agent-related changes from broader ecosystem trends, we evaluate per-developer DiD deltas using the Mann-Whitney U test. As an additional robustness check, we fit two-way fixed-effects models [24] of the form $y_{idt} = \alpha_i + \lambda_t + \beta(\text{Post}_{rt} \times \text{Treat}_r) + \epsilon_{idt}$ with repository-clustered standard errors, allowing us to account for stable unobserved differences across repositories and time periods. Because several outcomes are right-skewed, these models are used to validate the consistency of the findings rather than as the primary basis for interpretation. To further reduce selection bias between treatment and control repositories, we perform one-to-one nearest-neighbor propensity-score matching [18] based on programming language and log star count (caliper 0.2 standard deviations), achieving 83.2% language overlap and a median log star-distance of 0.52. We also conduct a dose-response analysis by dividing repositories according to the median level of agent activity (14 PRs) to examine whether stronger agent exposure is associated with larger behavioral changes. All $p$-values are adjusted using the Benjamini–Hochberg [4] procedure across 11 tests ($\alpha = 0.05$). Compared with within-subject analyses alone, the DiD design provides stronger evidence for agent-associated behavioral changes. However, the seven-month observation window captures only short-term behavioral changes; longer-term dynamics, including the gradual emergence of complacency effects predicted by classical theory, remain an important direction for future work.

## 4 Results

Our final dataset comprises 669 developer–repository pairs from 103 treatment repositories and 228 pairs from 148 control repositories. Table 1 summarizes the dataset.

**Table 1** Dataset summary for treatment and control groups.

| Property | Treatment | Control |
|---|---|---|
| Repositories | 103 | 148 |
| Developer–repo pairs | 669 | 228 |
| Enriched PRs | 22,792 | 6,656 |
| Reviews analyzed | 47,468 | 7,168 |
| Qualified reviewers | 532 | – |
| Median before/after (days) | 349 / 344 | – |
| Observation window | 7 months before/after first agent PR | Full history |
| Split criterion | First agent PR | Median PR date |

Figure 1 shows approximately parallel pre-adoption trends between treatment and control groups, supporting the validity of the DiD analysis.

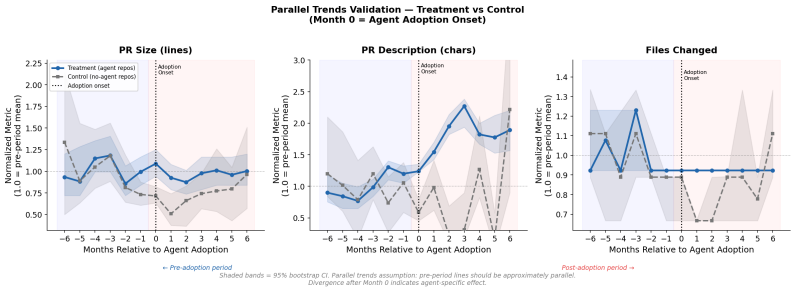

**Figure 1** Parallel pre-adoption trends for treatment repositories and median-split control repositories used in the Difference-in-Differences analysis.

Across our analyses, seven of ten within-subject significant findings do not survive DiD validation, corresponding to a potential 70% misattribution rate for within-subject-only designs in this setting. This suggests that within-subject analyses alone may incorrectly attribute broader ecosystem trends to agent adoption.

## 4.1 Coding Effort

We next examine how developers' coding effort changes after agent adoption. Figure 2 depicts the distributional shifts across all four coding effort metrics. Overall, coding effort remains largely stable, with one notable exception: a substantial increase in PR documentation. Detailed within-subject statistical results are available in the replication package [1].

**PR Size.** shows no significant change ($p_{adj} = 0.805$, $r = 0.011$, negligible). The near-equal split between developers who increase versus decrease PR size (49.8% vs. 50.2%) indicates the absence of any systematic directional shift. Despite agents generating substantial code in the same repositories, developers do not reduce the volume of code they personally write following the first observable agent-authored pull request. Similarly, **Files Changed and Commits per PR** shows statistically significant within-subject differences ($p_{adj} = 0.004$ and 0.022, small effects) despite identical medians. These effects reflect compression in the upper tails of the distribution: developers who previously submitted broader, multi-file PRs narrow their scope, while the majority remain stable. However, this same pattern is observed among control developers in the DiD analysis (Table 2), indicating that it reflects broader ecosystem trends rather than agent-associated effects.

Additionally, **PR Description Length** shows the largest effect among all coding effort metrics. The median increases from 304.0 to 537.5 characters (+76.8%, $p_{adj} < 0.001$, $r = 0.561$, large), with 65.3% of developers increasing their descriptions and a median paired difference of +117 characters. This represents a broad-based behavioral shift rather than an outlier-driven effect. Notably, this pattern runs counter to automation complacency: communication effort increases, rather than decreases, following agent adoption.

**DiD Validation.** The DiD analysis refines the within-subject findings: only PR description length remains significant when compared against the control group. Treatment developers increase descriptions by +121.5 characters, while control developers show no change ($p_{adj} < 0.001$, $r = -0.323$, medium effect). This effect is consistently supported across

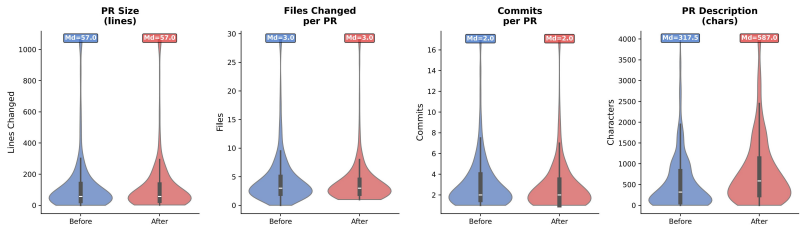

**Figure 2** Distribution of coding effort metrics before and after agent adoption.

**Table 2** DiD results for coding effort (BH-adjusted).

| Metric | Treat. Δ | Ctrl. Δ | DiD | $p_{adj}$ | $r$ | Agent-Sp. |
|---|---|---|---|---|---|---|
| PR Size | +0.0 | −10.5 | +10.5 | 0.053 | −0.101 | No |
| Files Changed | +0.0 | +0.0 | +0.0 | 0.877 | 0.007 | No |
| Commits/PR | +0.0 | +0.0 | +0.0 | 0.836 | −0.018 | No |
| PR Description | +121.5 | +0.0 | +121.5 | <0.001 | −0.323 | **Yes** |

analytical methods. To assess whether this increase reflects behavioral adaptation rather than mechanical adoption of agent-generated templates, we compare repositories with lower versus higher levels of agent-authored PR activity (low exposure: ≤14 agent PRs; high exposure: >14) to examine whether stronger agent exposure is associated with larger behavioral changes. Low-exposure developers increase description length by +67.5% ($p < 0.001$, $r = 0.601$), while high-exposure developers increase by +107.4% ($p < 0.001$, $r = 0.545$), a difference of +39.8 percentage points. The significant difference between low- and high-exposure repositories indicates that the effect scales with agent exposure, supporting the interpretation of behavioral adaptation rather than incidental template reuse.

**Key Findings**

*Agent adoption primarily affects how developers communicate their work rather than the amount of code they produce. Developers write more detailed PR descriptions, while coding effort remains largely unchanged and other apparent changes in coding activity are explained by broader ecosystem trends rather than agent adoption.*

## 4.2 Testing Discipline

We next investigate how developers' testing practices change following agent adoption. Figure 3 illustrates the distributional changes. In contrast to the expectations of automation complacency, all three testing metrics show consistent improvements, indicating increased rather than reduced testing discipline. Detailed within-subject statistical results are available in the replication package [1].

**Test File Ratio.** The median test file ratio is zero in both periods, indicating that most developers do not include test files in the majority of their PRs. Nevertheless, a statistically significant difference is observed ($p_{adj} = 0.021$, $r = 0.203$, small). This reflects a distributional shift above the median: among developers who include tests, inclusion frequency increases after adoption. Although only 16.9% of developers increase their test file ratio, the magnitude of those increases is sufficient to produce a meaningful rank-based effect, suggesting that testing improvements are concentrated within a subset of developers rather than uniformly

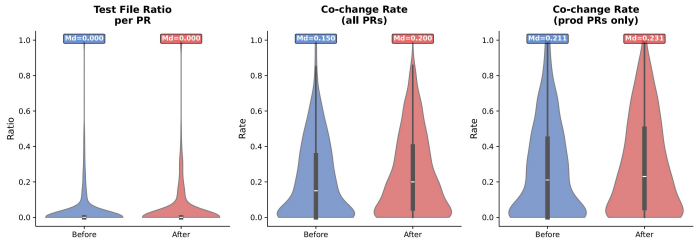

**Figure 3** Distribution of testing discipline metrics before and after agent adoption.

across the population. Similarly, **Co-change Rate:** The co-change rate increases from a median of 0.150 to 0.200, corresponding to a 33.3% relative increase ($p_{adj} = 0.008$, $r = 0.144$, small). The proportion of PRs that include both production and test changes rises, indicating that developers are more likely to couple code changes with corresponding test updates after agent adoption. Together, these findings indicate improved integration between development and testing activities. Additionally, **Production-Conditioned Co-change Rate:** When restricted to PRs that modify production code, the co-change rate increases from 0.211 to 0.231 (+9.6%, $p_{adj} = 0.010$, $r = 0.137$, small). This provides a more conservative estimate by focusing specifically on scenarios where testing is most relevant. The consistent increase across both unconditional and conditioned measures strengthens confidence that developers are more likely to include tests when modifying production code after agent adoption. The consistent improvement across all three metrics strengthens confidence in the observed testing-related changes. Because test-file detection relies on filename heuristics, the reported effects likely represent conservative estimates.

**DiD Validation.** To assess whether these improvements are associated with agent adoption, we perform a DiD analysis (Table 3). All three testing metrics remain significant after DiD validation, suggesting that the observed improvements are more strongly associated with agent adoption than broader ecosystem trends. Although the median change is zero for both treatment and control groups, the distributions of developer-level changes differ significantly. Treatment developers exhibit systematically more positive shifts than controls across all three testing metrics, indicating that the effect is distributional rather than a shift in the median. This consistent pattern strengthens confidence that testing improvements are associated with agent adoption rather than broader ecosystem evolution.

**Table 3** DiD results for testing discipline (BH-adjusted). All three effects remained significant after comparative validation.

| Metric | Treat. Δ | Ctrl. Δ | DiD | $p_{adj}$ | $r$ | Agent-Sp. |
|---|---|---|---|---|---|---|
| Test File Ratio | 0.0 | 0.0 | 0.0 | <0.001 | −0.158 | **Yes** |
| Co-change Rate | 0.0 | 0.0 | 0.0 | <0.001 | −0.157 | **Yes** |
| Prod. Co-change | 0.0 | 0.0 | 0.0 | 0.006 | −0.139 | **Yes** |

Key Findings

*Agent adoption is associated with stronger testing discipline. Developers become more likely to integrate testing into their development workflow, suggesting that AI agents reinforce verification-oriented behaviors rather than reducing attention to quality.*

## 4.3 Review Behavior

We next examine how developers' review behavior changes following agent adoption. Figure 4 illustrates the distributional changes. In contrast to the stability and improvements observed in coding and testing practices, all four review metrics show consistent changes: reviews become faster, less detailed, and more permissive after adoption. Detailed within-subject statistical results are available in the replication package [1].

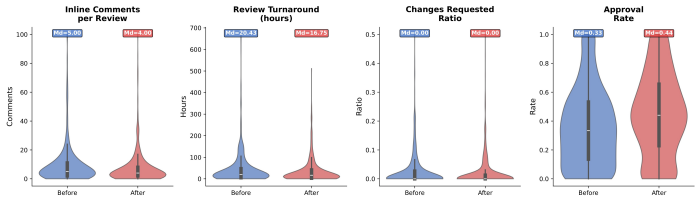

**Figure 4** Distribution of review behavior metrics before and after agent adoption.

**Inline Review Comments.** The median number of inline comments per review decreases from 5.0 to 4.0 ($-20.0\%$, $p_{adj} < 0.001$, $r = 0.244$). Only 34.8% of reviewers increase their commenting activity, indicating a broad reduction in review detail after adoption.

**Review Turnaround Time:** Median turnaround time decreases from 20.43 to 16.75 hours ($-18.0\%$, $p_{adj} < 0.001$, $r = 0.192$), with 57.0% of reviewers completing reviews more quickly. Together with reduced commenting activity, this suggests less thorough review behavior rather than purely improved efficiency.

**Changes Requested:** The proportion of reviews requesting changes declines ($3.5\% \rightarrow 2.6\%$, $p_{adj} < 0.001$, $r = 0.259$). Only 18.2% of reviewers increase their rate of requesting changes, indicating that most reviewers become less strict in enforcing revisions.

**Approval Rate:** The approval rate increases from 0.333 to 0.441 ($+32.2\%$, $p_{adj} < 0.001$, $r = 0.411$), representing the strongest within-subject effect in review behavior. A majority of reviewers (60.2%) approve a higher proportion of PRs after adoption, reinforcing the shift toward more permissive review practices. Taken together, these results initially appear consistent with automation complacency, where monitoring effort declines while productive effort remains stable.

**DiD Validation:** To determine whether these changes are attributable to agent adoption, we perform a DiD analysis (Table 4). However, the DiD results change this interpretation.

**Table 4** DiD results for review behavior (BH-adjusted). None remained significant after comparative validation.

| Metric | Treat. Δ | Ctrl. Δ | DiD | $p_{adj}$ | $r$ | Agent-Sp. |
|---|---|---|---|---|---|---|
| Inline Comments | −1.00 | +0.00 | −1.00 | 0.649 | −0.039 | No |
| Turnaround (h) | −1.59 | −0.05 | −1.54 | 0.090 | 0.094 | No |
| Changes Req'd | +0.00 | +0.00 | +0.00 | 0.828 | 0.022 | No |
| Approval Rate | +0.05 | +0.00 | +0.05 | 0.877 | −0.009 | No |

None of the four metrics remains significant after DiD validation. Control developers exhibit the same directional patterns as treatment developers, including fewer comments, faster reviews, and higher approval rates. All DiD effect sizes are negligible ($|r| \leq 0.039$ for three metrics). Turnaround time shows the largest treatment–control difference ($-1.54$

hours) but does not survive multiple testing correction ($p_{adj} = 0.090$). These findings suggest that the observed changes reflect broader ecosystem-wide trends rather than agent-associated effects. Without a control group, the within-subject results would likely have been incorrectly attributed to agent adoption. Because our analysis includes only reviewers active in both periods ($n = 532$), the findings likely represent conservative estimates of changes in review behavior. Longer-term dynamics may also differ beyond the seven-month observation window.

**Key Findings**

*Changes in review behavior are not uniquely associated with agent adoption. Although reviews become faster, less detailed, and more permissive over time, similar patterns are observed in repositories without agents, suggesting that these shifts reflect broader changes in software development practice rather than agent-associated adaptation.*

### 4.4 Synthesis of Findings

The results across all 11 metrics reveal a clear pattern: agent-associated changes are concentrated in productive development activities, whereas most review-related changes align with broader ecosystem trends. Table 5 summarizes the findings across all analyses. Only four metrics are consistently supported across analytical methods (bold rows in Table 5): PR description length and all three testing discipline measures. Across these dimensions, developers produce more detailed documentation and show stronger coupling between production and test changes following agent adoption. In contrast, the remaining seven metrics are not supported as agent-associated effects. PR size remains stable under both within-subject and DiD analyses, while files changed and commits per PR show within-subject differences that disappear under DiD validation, suggesting broader ecosystem trends rather than agent-associated effects. Most notably, all four review metrics remain highly significant in within-subject analyses but lose significance under DiD validation. Although overall directional patterns are clear, developers differ substantially in both the magnitude and direction of behavioral change. For example, 65.3% of developers increase PR description length after adoption, whereas 34.7% decrease it; similarly, 34.8% increase inline review comments while 65.2% decrease them. This heterogeneity suggests that responses to agent adoption are shaped by contextual factors such as repository norms, development practices, and developer roles. The exposure analysis strengthens the interpretation of the documentation effect. Developers in high-exposure repositories increase PR description length by +107.4%, compared with +67.5% in low-exposure repositories, indicating that the magnitude of the effect scales with agent usage. This gradient is consistent with behavioral adaptation rather than incidental template reuse. Overall, the findings support a pattern of selective behavioral adaptation. Agent adoption is associated with measurable changes in development behaviors, particularly documentation and testing practices, while evaluative review behaviors evolve alongside broader ecosystem dynamics independent of agent presence. Automation complacency, as classically defined, is therefore not supported by the observed comparative evidence.

## 5 Discussion

Across coding, testing, and review activities, our findings reveal a clear asymmetry: agent adoption is associated with changes in productive development behaviors, whereas most apparent changes in review behavior are better explained by broader ecosystem trends than by agent adoption itself.

**Table 5** Summary of within-subject and DiD findings across all metrics (BH-adjusted).

| RQ | Metric | $p_{WS}$ | $r$ | $p_{DiD}$ | Conf. | Conclusion |
|---|---|---|---|---|---|---|
| RQ1 | PR Size | 0.805 | 0.011 | 0.053 | 0/4 | No effect |
| RQ1 | Files Changed | 0.004 | 0.154 | 0.877 | 1/4 | Ecosystem trend |
| RQ1 | Commits/PR | 0.022 | 0.121 | 0.836 | 1/4 | Ecosystem trend |
| RQ1 | PR Description | <.001 | 0.561 | <.001 | **4/4** | **agent-associated (large)** |
| RQ2 | Test File Ratio | 0.021 | 0.203 | <.001 | **3/4** | **agent-associated (small)** |
| RQ2 | Co-change Rate | 0.008 | 0.144 | <.001 | **4/4** | **agent-associated (small)** |
| RQ2 | Prod. Co-change | 0.010 | 0.137 | 0.006 | **3/4** | **agent-associated (small)** |
| RQ3 | Inline Comments | <.001 | 0.244 | 0.649 | 1/4 | Ecosystem trend |
| RQ3 | Turnaround | <.001 | 0.192 | 0.090 | 2/4 | Ecosystem trend |
| RQ3 | Changes Req'd | <.001 | 0.259 | 0.828 | 1/4 | Ecosystem trend |
| RQ3 | Approval Rate | <.001 | 0.411 | 0.877 | 1/4 | Ecosystem trend |

**Revisiting the complacency hypothesis.** Automation complacency theory predicts reduced monitoring and verification effort when humans interact with reliable automated systems [14]. Our findings both challenge and refine this expectation in the context of AI-assisted software development. Developers do not appear to disengage from productive engineering activities following agent adoption. Instead, the observed improvements in documentation and testing practices suggest active behavioral adaptation, where developers invest additional effort in communication and verification when collaborating with AI agents. At the same time, the review-related changes initially resemble classical complacency patterns: reviews become faster, less detailed, and more permissive. However, these patterns are also present in repositories without agent adoption, suggesting that they reflect broader shifts in software development practice rather than direct effects of AI agents themselves. Our findings therefore do not support a classical automation complacency interpretation of code review behavior. Instead, they point toward a wider ecosystem shift in review practices, potentially driven by increasing development velocity, growing reliance on automated quality assurance tools, and evolving collaboration norms in modern software engineering.

**Explaining the observed effects.** Several mechanisms may explain the increases in documentation and testing effort. One possibility is social adaptation: developers repeatedly exposed to structured agent-authored contributions may gradually adopt similar practices themselves. Another possibility is compensatory behavior, where developers invest more effort in explanation and verification to reduce uncertainty around AI-assisted code changes. The stronger effects observed in high-exposure repositories are consistent with this interpretation. An alternative explanation concerns the timing of the intervention itself. Our adoption point corresponds to the first observable agent-authored pull request rather than the first use of AI-assisted programming tools within a repository. Developers may already have been using AI coding assistants such as GitHub Copilot, ChatGPT, or Cursor before autonomous agent-authored pull requests became visible. Consequently, our findings should be interpreted as behavioral changes associated with the transition to agent-based development workflows rather than the initial adoption of AI-assisted software development. Earlier exposure to AI coding assistants may also attenuate observable changes in coding-related metrics, such as pull request size, if behavioral adaptation had already begun before the observation window. Another possible explanation is that repositories adopting autonomous coding agents may simultaneously introduce new contribution templates, documentation practices, or workflow conventions that encourage more detailed pull request descriptions

and stronger testing practices. Although the observed exposure gradient is more consistent with behavioral adaptation than simple template reuse, these explanations cannot be fully disentangled using observational repository data. We also note that PR description length is an operationalization of communication effort rather than communication quality. Longer descriptions do not necessarily imply clearer or more useful documentation, and future work should complement quantitative measures with qualitative assessment of PR content. More broadly, the consistency of the testing improvements across multiple operationalizations suggests that the observed pattern is unlikely to be explained by measurement artifacts alone. In contrast, the review-related changes appear to reflect broader ecosystem evolution rather than agent-associated adaptation. Similarly, inline review comments, approval rates, and review turnaround time capture observable review behavior rather than review quality itself. These measures may also be influenced by factors such as pull request quality, team conventions, or increased use of automated quality assurance tools. Increasing development velocity, widespread adoption of CI/CD pipelines and automated quality tools, and shifting expectations around lightweight review processes may all contribute to faster and less detailed reviews across software projects generally. From this perspective, AI agents may coexist with these trends without necessarily driving them directly.

**Methodological implications.** Our findings highlight the importance of comparative research designs when studying AI-assisted software development. Several effects that appeared significant under within-subject analyses disappeared after comparison with control repositories, demonstrating that broader ecosystem changes can easily be misinterpreted as agent-associated behavioral effects when comparative controls are absent. Longitudinal within-subject analyses remain valuable for controlling developer-level heterogeneity, but our results suggest that they may be insufficient on their own for distinguishing agent-associated changes from concurrent ecosystem trends. Furthermore, because control repositories lack a natural intervention point, the pseudo-adoption date is based on the median pull request creation date. Although this enables balanced longitudinal comparisons, future work should investigate alternative constructions of comparable control windows (e.g., symmetric pseudo-observation windows or calendar-matched controls) and incorporate richer repository-level matching variables, such as project activity, contributor structure, CI practices, or review culture.

**Practical implications.** We find no evidence that agent adoption reduces productive engineering effort. Instead, developers maintain coding effort while improving testing and documentation practices. In contrast, declining review thoroughness appears to be an ecosystem-wide challenge rather than a challenge uniquely associated with agent adoption, suggesting that improving review quality will require broader process interventions rather than restricting agent use. At the same time, the observed increase in documentation practices may represent a valuable opportunity for improving knowledge transfer, onboarding, and maintainability in collaborative development environments.

## 6 Conclusion and Future Work

This study examined whether AI coding agent adoption changes how developers code, test, and review using a longitudinal within-subject design with comparative validation across 669 developer–repository pairs. Our findings reveal a pattern of selective behavioral adaptation. Agent adoption is associated with stronger documentation and testing practices,

while coding effort remains stable. In contrast, changes in review behavior reflect broader ecosystem-wide trends rather than agent-associated effects. More broadly, our findings challenge straightforward applications of automation complacency theory to AI-assisted software development. Developers do not appear to disengage from productive engineering activities when working with agents. Instead, the strongest agent-associated effects involve increased communication and verification effort. Methodologically, the study also highlights the importance of comparative research designs for distinguishing agent-associated behavioral changes from concurrent ecosystem evolution.

Several directions can extend this work. Future studies should strengthen causal identification under heterogeneous treatment timing, investigate the qualitative mechanisms underlying documentation and testing changes, and examine whether these behavioral patterns persist across longer time horizons, different agent types, and enterprise development settings.

## Abstract

**Background.** Infrastructure-as-Code (IaC) scanners detect cloud misconfigurations in Terraform and other IaC languages before deployment, but repairing the flagged configurations remains largely manual. Recent Large Language Model (LLM)-based repair approaches can repair some findings, but may hallucinate unsupported constructs or suppress warnings without fixing the issue.

**Aims.** We study whether tool grounding can improve LLM-based Terraform repair, and when a finding should be escalated because the required deployment-specific context is not available.

**Method.** We present `TerraRepair`, a prototype of a tool-grounded LLM agent for Terraform repair with structured escalation. `TerraRepair` retrieves dependency context from Terraform references, consults the installed provider schema, and re-runs the scanner before returning a candidate repair. When the required context is absent, `TerraRepair` escalates instead of fabricating a plausible fix.

**Results.** We evaluate our tool on two vulnerable-by-design Terraform repositories using two IaC security scanners, Checkov and Trivy, across AWS, Azure, and GCP. On the combined AWS benchmark, `TerraRepair` improves scanner-verified fix rates from 26.6% to 78.4% on Checkov and from 44.8% to 72.4% on Trivy, compared with a controlled one-shot baseline. It also reduces the baseline's 44.8–73.6 percentage point (pp) claimed-vs-verified repair gap to under 5 pp. In a sampled semantic audit covering AWS only, 78.9% of `TerraRepair`'s scanner-verified AWS repairs are labeled as correct under a majority-vote protocol with two LLM judges and one author.

**Conclusions.** These emerging results show that tool grounding can substantially improve scanner-verified LLM-based IaC repair on the studied benchmarks, while missing deployment-specific context remains the main knowledge boundary for full autonomy.

## 1 Introduction

Infrastructure as Code (IaC) is widely used to provision and manage cloud infrastructure through declarative configuration files, such as Terraform modules written in HashiCorp Configuration Language (HCL) [15, 7]. This practice improves repeatability, reviewability, and automation, but it also moves cloud security and reliability risks into code [5]. Misconfigured IaC can expose storage buckets, grant overly broad Identity and Access Management (IAM) permissions, disable encryption, or leave network access unrestricted. Prior work has studied such recurring weaknesses as IaC security smells [20].

IaC security scanners detect many of these issues before deployment by reporting policy violations over Terraform resources [5, 17, 2]. However, detection is only the first step. Developers must still determine how to modify the affected resource, whether related resources must also be changed, and whether the repair is valid for the installed Terraform provider version. Many repairs also require deployment-specific context, such as Key Management Service (KMS) keys, Classless Inter-Domain Routing (CIDR) ranges, logging destinations, certificates, or least-privilege IAM scopes.

LLMs offer a possible way to reduce this manual repair effort, following recent work on LLM-based program and vulnerability repair [18, 11]. In the IaC setting, Low et al. [13] showed that LLMs can repair many Terraform scanner findings, especially when human-provided context is available. However, it has been shown that LLM-based IaC repair can hallucinate Terraform constructs, introduce validation errors, or clear scanner warnings without fixing the underlying security issue [13]. This suggests that the main challenge is not only generating a plausible edit, but grounding the repair in the codebase, provider schema, scanner feedback, and available deployment context.

IaC repair differs from conventional program repair because IaC programs specify desired infrastructure state rather than local program behavior [22]. A syntactically valid HCL edit may still be invalid for the installed provider schema, undeployable in the target cloud environment, or unsafe for the intended deployment. Prior work on semantic checks for cloud IaC shows that IaC programs that pass compilation can still fail at deployment time because syntax alone does not capture deployment-relevant requirements [19]. For this reason, scanner success is an incomplete repair oracle. An autonomous IaC repair system needs a way to decide when a repair is sufficiently grounded and when the finding should be escalated.

To bridge such a gap, we present `TerraRepair`, a tool-grounded LLM agent for bounded Terraform repair. Given a scanner finding and the affected Terraform block, `TerraRepair` treats repair as a bounded tool-using process. The agent can query a dependency graph for cross-resource context, inspect the installed Terraform provider schema, and re-run the scanner on candidate repairs. If the required information is absent from the codebase, `TerraRepair` emits a structured escalation instead of fabricating a plausible repair.

To evaluate the effectiveness of tool grounding, its behavior across cloud providers, the contribution of individual components, and the limits of autonomous repair, we investigate the following research questions:

- ***RQ*$_1$*:*** How does `TerraRepair` compare with direct one-shot LLM prompting?
- ***RQ*$_2$*:*** How does `TerraRepair` vary across cloud providers?
- ***RQ*$_3$*:*** What is the individual contribution of each architectural component?
- ***RQ*$_4$*:*** What kinds of findings cannot be repaired autonomously?

To answer these questions, we evaluate `TerraRepair` on two vulnerable-by-design Terraform repositories used in prior IaC repair research, TerraGoat [4] and KaiMonkey [25]. The evaluation uses Checkov and Trivy across AWS, Azure, and GCP configurations. We

also construct a controlled one-shot baseline inspired by Low et al.'s autonomous first-pass prompt [13]. This baseline is not a reproduction of their 2024 environment. It isolates direct prompting under the same model, scanner versions, finding population, patching logic, and scoring procedure used for `TerraRepair`. On the combined AWS benchmark, `TerraRepair` improves scanner-verified fix rates, outperforming the considered baseline for both Checkov and Trivy. The ablation and escalation analyses show that provider-schema grounding and dependency retrieval are the main contributors to repair effectiveness, while missing deployment-specific context remains the main knowledge boundary for full autonomy.

As an emerging-results study, this paper makes the following contributions:

- We formulate Terraform security repair as a bounded tool-grounded process that returns either a scanner-verified candidate repair or a structured escalation.
- The introduction of the claimed-vs-verified repair gap as an operational measure of unsupported repair claims, characterizing a key failure mode of direct LLM repair.
- The `TerraRepair` tool as an empirical prototype that combines dependency-graph retrieval, provider-schema lookup, in-loop scanner verification, and escalation. To the best of our knowledge, this is the first tool of this type to tackle the issue.
- An initial empirical evaluation on vulnerable-by-design Terraform repositories across AWS, Azure, and GCP, comparing `TerraRepair` with a controlled one-shot LLM baseline.
- A replication package with the developed code and curated data has been published to foster open science [14].

## 2 Related Work

IaC security scanners detect policy violations before deployment, but most prior IaC analysis work focuses on detection and verification rather than repair. Rahman et al. [20] identify recurring IaC security smells, including hard-coded secrets, empty passwords, and unrestricted network access. Chiari et al. [5] survey static analysis for IaC, covering smell detection, defect prediction, and verification. InfraFix [22] addresses IaC repair by inferring a desired system state, repairing a normalized intermediate representation, and propagating changes back to the original script. `TerraRepair` instead repairs Terraform security findings reported by IaC scanners, using installed provider schemas, dependency references, scanner feedback, and escalation when required deployment context is absent.

`TerraRepair` also builds on automated program repair (APR) and recent LLM-based repair. APR generates patches with respect to evidence such as a test suite, crash, compiler error, or static-analysis warning [12], but a patch may overfit the repair oracle while failing to preserve intended behavior [24]. This issue is especially relevant for security repair because clearing a warning does not imply that the underlying vulnerability has been fixed. Recent LLM repair work has explored zero-shot vulnerability repair, static-analysis-guided and retrieval-augmented repair, tool-using repair agents, and repository-history-aware repair [18, 11, 3, 23]. `TerraRepair` follows this broader direction, but the artifact and oracle are different. It repairs Terraform configurations against scanner findings, provider schemas, dependency context, and explicit escalation conditions.

Several studies apply LLMs to IaC and configuration-security tasks. TerraFormer [10] studies Terraform generation and mutation from natural-language prompts using verifier-guided training over syntax, deployability, and policy compliance. LLMSecConfig [30] repairs Kubernetes container misconfigurations using static analysis, retrieval, prompting, and validation. Reyes et al. [21] construct a Terraform remediation dataset from Trivy findings and evaluate fine-tuning and in-context learning for open-source LLMs. Toprani and Madisetti [26]

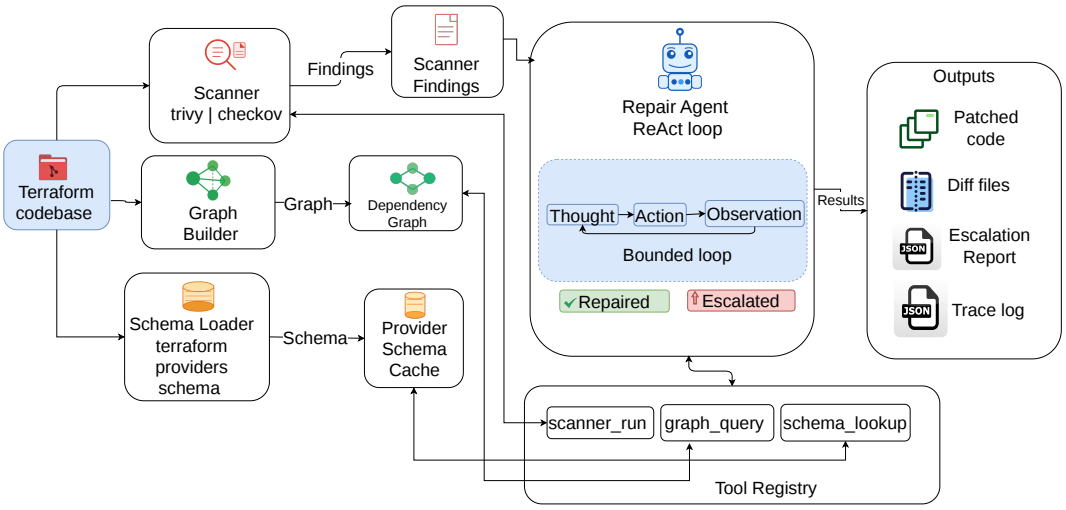

**Figure 1** TerraRepair architecture and repair workflow.

propose a multi-agent RAG workflow for detecting CloudFormation vulnerabilities and producing remediation guidance. NSync [28] addresses Terraform reconciliation rather than security repair by using cloud API traces to infer out-of-band infrastructure changes and synthesize Terraform updates. Together, these works show that LLMs can support IaC generation, configuration repair, vulnerability remediation, and cloud-state reconciliation.

Low et al. [13] are the closest prior work. They repair Terraform scanner findings by passing the flagged block and scanner output to an LLM, with a human-provided second pass for remaining findings. Their results show that LLMs can remove many scanner warnings, but may also hallucinate Terraform constructs, introduce validation errors, or clear warnings without fixing the underlying issue. TerraRepair targets this failure mode through provider-schema lookup, dependency retrieval, scanner feedback, and structured escalation.

## 3 TerraRepair: Proposed Approach

TerraRepair repairs Terraform scanner findings as a bounded tool-using process. Given a scanner finding, the flagged resource block, and the corresponding cause lines, TerraRepair returns either a scanner-verified candidate repair or a structured escalation. The escalation is used when the required information is not available from the codebase, provider schema, or scanner feedback, or when the bounded repair process does not converge.

The proposed approach is shown in Fig. 1. TerraRepair first runs a security scanner to obtain misconfiguration findings. It builds a dependency graph from HCL references in the codebase and loads the relevant Terraform provider schemas using the Terraform CLI provider-schema interface [8]. Each finding is then given to a single ReAct-style repair agent [29]. The agent receives the rule identifier, severity (if available), resolution hint, resource identifier, cause lines, and the complete original HCL block. We bound each repair attempt at ten agent steps. This fixed budget gives the agent room to query dependency context, inspect the provider schema, propose a patch, run the scanner, and revise when needed, while keeping repair attempts finite and comparable across findings. The agent has access to three tools. GRAPH_QUERY retrieves cross-resource information from the dependency graph, e.g., KMS key ARNs, network identifiers, and security group references. SCHEMA_LOOKUP retrieves the installed provider schema for the target resource type, so

**Table 1** Benchmark datasets and baseline finding counts.

| Dataset | Provider | Checkov | Trivy |
|---|---|---|---|
| TerraGoat | AWS | 158 | 113 |
| TerraGoat | Azure | 124 | 90 |
| TerraGoat | GCP | 55 | 49 |
| KaiMonkey | AWS | 69 | 55 |
| Combined AWS (primary) | – | 227 | 168 |
| Grand total | – | 406 | 307 |

that the agent can avoid unsupported attributes, invalid nested blocks, and assignments to provider-computed fields. SCANNER_RUN re-runs the scanner on the candidate repair and returns the result as feedback. If the scanner still reports the original finding, the agent may revise the patch. If the scanner no longer reports the original finding, the agent can terminate and emit the candidate repair.

The repair prompt defines the agent role, available tools, stopping criteria, and output schema. It specifies three constraints. First, the agent must consult the provider schema before using unfamiliar attributes or nested blocks. Second, the agent is instructed to obtain scanner verification before returning a candidate repair. Third, it must output exactly one repaired resource block. If a correct repair requires deployment-specific information that is absent from the codebase or provider schema, the agent is instructed to emit a structured escalation instead of fabricating a plausible repair. The full prompt templates, tool interfaces, and output schemas are included in the replication package [14].

## 4 Evaluation Methodology

The evaluation is organized around four research questions motivated in Section 1.

We use two vulnerable-by-design Terraform repositories used in prior IaC repair research, namely TerraGoat (commit `729f8da`) [4] and KaiMonkey (commit `3feb0bf`) [25]. TerraGoat contains AWS, Azure, and GCP configurations. KaiMonkey contains four AWS slices covering compute, network, storage, and a cross-module Server-Side Request Forgery (SSRF) scenario. These seven benchmark slices are evaluated with Checkov and Trivy, yielding 14 dataset–scanner configurations. The primary comparison dataset is the combined AWS subset, which contains 227 Checkov findings and 168 Trivy findings, as shown in Table 1. We use AWS as the primary comparison because Low et al.'s Terraform repair evaluation used AWS. Azure and GCP assess cross-provider behavior.

We use Checkov 3.2.510, Trivy 0.69.3, `gpt-4o-mini-2024-07-18` at temperature 0.0 [16], Terraform CLI 0.14.11, and python-hcl2 7.3.1 [1]. API inference may vary at temperature 0.0, so we repeat each `TerraRepair` configuration three times. The AWS configurations resolve the AWS provider at versions 4.67.0 for TerraGoat and 3.76.1 for KaiMonkey. The non-AWS configurations resolve the AzureRM provider at version 4.68.0 and the Google provider at version 7.27.0. Low et al. [13] used earlier scanner versions and also included Terrascan, which is now archived. Therefore, their published numbers are used only as historical context. We construct a within-study baseline based on Low et al.'s autonomous first-pass prompt [13]. The baseline uses the prompt from their Figure 2a verbatim and performs one LLM call per finding, with no dependency-graph retrieval, provider-schema lookup, or in-loop scanner verification. Both systems use the same model, scanner versions, finding population, file-patching logic, and post-run rescanning procedure. Within each run, a parity check confirms that both pipelines receive bit-identical scanner findings before repair.

The primary metric is the *scanner-verified fix rate*, the proportion of originally flagged findings that are no longer flagged when the same scanner is re-run on the repaired output. We also report the *claimed-vs-verified repair gap*, defined as the claimed repair rate minus the scanner-verified fix rate. For the baseline, a claimed repair is an LLM response with `is_fixed=true`. For `TerraRepair`, it is a final repaired status that typically follows in-loop SCANNER_RUN verification. Both systems are evaluated with the same final full-codebase rescan.

All `TerraRepair` configurations are executed three times. The controlled baseline is executed three times on the AWS configurations used for $RQ_1$. Each run first pools verified repairs across the relevant datasets, and the reported value is the mean and standard deviation of these pooled per-run rates.

Within each run, both systems are evaluated on the same initial finding population and repository commit, yielding paired binary outcomes. We apply the two-sided exact McNemar test per run on the discordant counts $n_{10}$ (`TerraRepair` repaired, baseline did not) and $n_{01}$ (the reverse), and report the paired risk difference $\mathrm{RD} = (n_{10} - n_{01})/N$, signed in `TerraRepair`'s favour. Although each attempt targets one finding, findings in the same block may share context or be affected by one block-level edit. We therefore estimate the 95% CI for the three-run mean effect using a cluster bootstrap ($B = 10{,}000$, seed 20260805) that resamples complete blocks and averages run-level RDs. We report one McNemar result per run rather than pooling the $3N$ repeated observations.

We assess Terraform validity using differential `terraform validate`, counting only newly introduced validation errors. We assess semantic correctness using a sampled jury-of-judges audit, informed by LLM-as-a-Judge work in software engineering [9]. From Run 3 AWS, whose fix rates are closest to the three-run mean, we sample 171 of 303 scanner-verified repairs using Cochran's formula with finite population correction [6]. The sample is allocated proportionally across dataset–scanner strata, and Wilson score intervals are used for the 95% confidence interval [27].

Each sampled repair is assessed by the first author and two LLM judges, Claude Sonnet 4.5 (`claude-sonnet-4-5-20250929`) and GPT-5.4 (`gpt-5.4-2026-03-05`). The first author inspects the original and repaired code with repository context, while the LLM judges use a conservative judging prompt that defaults to WRONG when the repair is ambiguous. Final labels are determined by majority vote. Since two raters are LLM judges and the human rater is an author, we treat this as a semantic audit rather than ground-truth correctness.

For $RQ_3$, we conduct a three-run leave-one-out ablation on TerraGoat AWS with Checkov ($n = 158$), removing GRAPH_QUERY, SCHEMA_LOOKUP, or SCANNER_RUN. We use the same paired tests and resource-block cluster bootstrap, with negative RDs indicating lower performance than the full system. For $RQ_4$, we classify structured escalations into missing external context, max-step termination, missing schema support, and unresolved Terraform variable or local references.

# 5 Experimental Results

## 5.1 $RQ_1$: How does `TerraRepair` compare with direct one-shot LLM prompting?

The controlled one-shot baseline described in Section 4 reproduces Low et al.'s autonomous first-pass prompt inside our repair harness. Table 2 reports the results on the combined AWS benchmark. The three Low et al. rows in Table 2 are historical context. They used different scanner versions, a different model, and a different finding population, and cannot be compared

**Table 2** Scanner-verified fix rates on the combined AWS benchmark. Mean±std over three runs. Low et al. rows are historical context.

| System | Approach | Checkov | Trivy |
|---|---|---|---|
| Low et al. GPT-3.5 pass 1 | autonomous, 2024 scanners | 9.0% | 17.1% |
| Low et al. GPT-4 pass 1 | autonomous, 2024 scanners | 27.4% | 44.2% |
| Low et al. GPT-4 pass 2 | human-assisted, 2024 scanners | 87.4% | 67.3% |
| Controlled baseline | one-shot, `gpt-4o-mini` | 26.6% ± 1.4 pp | 44.8% ± 1.4 pp |
| `TerraRepair` | agent+tools, `gpt-4o-mini` | **78.4% ± 0.8 pp** | **72.4% ± 4.0 pp** |
| **Gain over controlled baseline** | – | **+51.8 pp** | **+27.6 pp** |

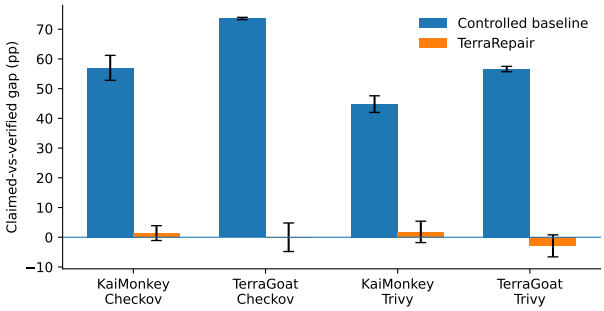

**Figure 2** Claimed-vs-verified repair gap on AWS configurations. Values closer to zero indicate better calibration. Negative values indicate finding-level underclaiming.

directly with the current experiment. The primary comparison is between `TerraRepair` and the controlled baseline, which share the same model (`gpt-4o-mini-2024-07-18`), scanner versions, finding population, file-patching logic, and scoring procedure. The controlled baseline achieves a scanner-verified fix rate of **26.6% ± 1.4 pp** on Checkov and **44.8% ± 1.4 pp** on Trivy. `TerraRepair` achieves **78.4% ± 0.8 pp** and **72.4% ± 4.0 pp**, respectively. The mean paired risk difference is **+51.8 pp** on Checkov and **+27.6 pp** on Trivy. The across-run cluster-bootstrap 95 % confidence intervals are [+34.3, +63.1] pp for Checkov and [+18.4, +38.3] pp for Trivy. The exact McNemar tests are significant in all three runs ($p < 0.001$ each).

The baseline also exposes a large gap between claimed and scanner-verified repairs. For the baseline, a claimed repair is an LLM response with `is_fixed=true`. For `TerraRepair`, a claimed repair is a final repaired status that typically follows in-loop SCANNER_RUN verification. As shown in Fig. 2, the one-shot baseline has a claimed-vs-verified gap of 44.8–73.6 pp across the AWS configurations. This means that the baseline frequently reports a repair as successful even though the same scanner still reports the original finding after patching and rescanning. `TerraRepair` reduces this gap to between −2.9 and +1.8 pp. A small negative gap means that the final scanner run cleared slightly more findings than `TerraRepair` explicitly claimed to repair. This can happen because Terraform repairs are applied at the block level, while claims are recorded per scanner finding. If several findings refer to the same block, one repair may clear more than one finding. Thus, we interpret small negative gaps as finding-level underclaiming, not as evidence of additional semantic correctness. Positive gaps can occur when a repair passes `TerraRepair`'s in-loop scanner check but the finding reappears during the final full-codebase rescan. Scanner verification does not prove semantic correctness, but it reduces this specific unsupported-claim failure mode.

**Table 3** Multi-cloud repair effectiveness and validity. Values are mean ± std across three runs. Validation errors are combined totals across both scanners and three runs.

| Dataset | Prov. | Checkov | Trivy | Val. | Main validity issue |
|---|---|---|---|---|---|
| TerraGoat | AWS | 83.1% ± 2.6 | 70.5% ± 2.8 | 0 | none observed |
| TerraGoat | Azure | 74.7% ± 1.2 | 72.2% ± 2.2 | 11 | missing required attrs. |
| TerraGoat | GCP | 71.5% ± 6.4 | 71.4% ± 2.0 | 15 | invalid provider fields |
| KaiMonkey | AWS | 67.7% ± 6.7 | 76.4% ± 7.3 | 0 | none observed |

Repair validity is assessed at two additional levels. First, on the AWS benchmark and across all three runs, `TerraRepair` introduces *zero* new `terraform validate` errors. This provides evidence that the repaired configurations remain syntactically valid and acceptable to Terraform validation on the primary benchmark, although `terraform validate` is not a complete semantic oracle. Second, in the sampled semantic audit, 135 of 171 scanner-verified AWS repairs are judged semantically correct by majority vote, giving an estimate of **78.9%** (95% CI [72.2%, 84.4%]). Inter-rater agreement is moderate (Fleiss' $\kappa = 0.54$), with 130/171 findings (76.0%) receiving unanimous verdicts. The judging prompt and rater-level labels are included in the replication package [14].

**Answer to RQ$_1$.** `TerraRepair` improves scanner-verified fix rate by +51.8 pp on Checkov and +27.6 pp on Trivy, reduces the claimed-vs-verified gap to within −2.9 to +1.8 pp, and has 78.9% of sampled scanner-verified AWS repairs judged correct.

## 5.2 RQ$_2$: How does `TerraRepair` vary across cloud providers?

Table 3 reports scanner-verified fix rates and validation errors across the four provider/dataset configurations. `TerraRepair` achieves broadly similar scanner-verified fix rates across the evaluated settings, with 67.7%–83.1% on Checkov and 70.5%–76.4% on Trivy. There is no clear drop that can be explained by provider alone. The observed variation appears to be influenced by dataset composition, especially KaiMonkey's concentration of wildcard IAM policy repairs and TerraGoat GCP's smaller finding population.

Repair validity, however, shows a cross-provider limitation that scanner-verified fix rates alone hide. Across the three runs, all 26 newly introduced `terraform validate` errors occur in Azure and GCP repairs. These errors cluster around provider-specific schema failures. Missing required attributes and unsupported or removed attributes account for 19/26 errors (73.1%). The remaining errors involve assignments to provider-computed fields, invalid enumeration values, and one block serialization failure. For example, for CKV_AZURE_7,[1] the agent generated `network_profile { network_policy = "calico" }`, which satisfies Checkov's network-policy check but omits the required `network_plugin` argument. Similarly, several GCP repairs used unsupported, removed, provider-computed, or invalid-enum attributes that were sufficient to address the scanner rule locally but invalid for the installed provider version. These cases show that provider-schema validity remains a separate repair requirement even when scanner-level behavior appears to generalize.

[1] CKV_AZURE_7 checks that an Azure Kubernetes Service cluster has a network policy configured.

**Table 4** Leave-one-out ablation on TerraGoat AWS with Checkov (mean±std over three runs).

| Configuration | Verified | Δ | Agent | Escalations |
|---|---|---|---|---|
| Full system | 83.1% ± 2.6 | – | 83.1% ± 2.2 | 26.7 ± 3.5 |
| No GRAPH_QUERY | 67.5% ± 4.5 | −15.6 pp | 68.1% ± 3.0 | 50.3 ± 4.7 |
| No SCHEMA_LOOKUP | 61.4% ± 2.5 | −21.7 pp | 59.1% ± 2.4 | 64.7 ± 3.8 |
| No SCANNER_RUN | 82.1% ± 2.2 | −1.1 pp | 81.4% ± 2.9 | 29.3 ± 4.5 |

**Answer to RQ$_2$.** `TerraRepair` varies mainly in repair validity rather than scanner-verified fix rate. Scanner-verified fix rates remain broadly similar across AWS, Azure, and GCP, but all new validation errors occur in Azure and GCP repairs. Thus, scanner-level repair transfers better than schema-correct repair.

## 5.3 RQ$_3$: What Is the Individual Contribution of Each Architectural Component?

Table 4 reports the leave-one-out ablation study on TerraGoat AWS with Checkov. Here, *Verified* denotes the post-run scanner-verified fix rate, and *Agent* denotes the agent's in-loop repaired status. The largest measurable contributions come from SCHEMA_LOOKUP and GRAPH_QUERY. Removing SCHEMA_LOOKUP reduces the scanner-verified fix rate by 21.7 pp (cluster-bootstrap 95 % CI [−30.2, −12.2] pp, $p < 0.001$ in all three runs) and more than doubles the mean number of escalations. This indicates that training-time model knowledge is insufficient for reliable Terraform repair. Removing GRAPH_QUERY reduces the scanner-verified fix rate by 15.6 pp (cluster-bootstrap 95 % CI [−24.2, −8.6] pp, $p < 0.001$ in all three runs) and similarly increases escalations.

Removing SCANNER_RUN reduces the mean verified fix rate by only 1.1 pp (cluster-bootstrap 95 % CI [−5.2, +3.5] pp, with McNemar tests nonsignificant in all three runs). This small delta reflects the fact that SCANNER_RUN is primarily a verification and calibration tool rather than a source of new repair context. It does not supply missing resource identifiers or schema information, and therefore contributes less to raw repair capability than GRAPH_QUERY or SCHEMA_LOOKUP. However, the controlled-baseline comparison in RQ$_1$ shows that scanner feedback is still important operationally as it reduces unsupported repair claims by preventing repairs that still trigger the original scanner finding from being reported as successful.

**Answer to RQ$_3$.** `TerraRepair`'s scanner-verified fix rate appears to be driven primarily by live provider-schema grounding and graph-based dependency resolution, while scanner feedback mainly supports verified termination and calibrated success reporting.

## 5.4 RQ$_4$: What Kinds of Findings Cannot Be Repaired Autonomously?

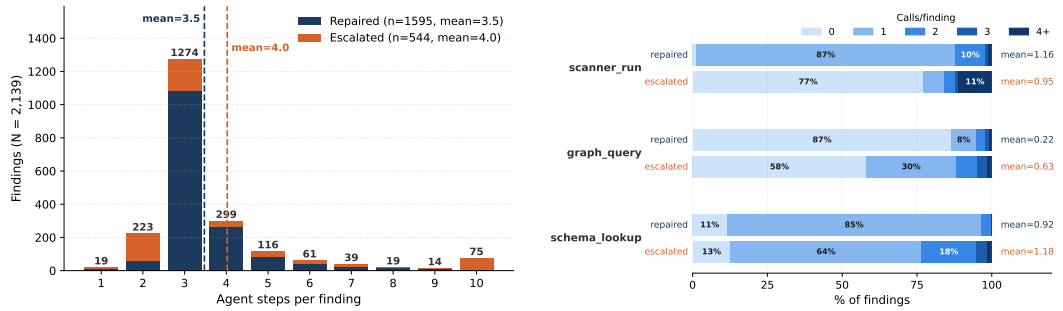
Across all 14 dataset–scanner configurations and three runs, `TerraRepair` escalates a mean of 181.3 findings per run. This corresponds to a stable escalation rate of 25.4% (std = 1.3 pp). Across the three runs, 544 findings are escalated in total. Table 5 summarizes the escalation taxonomy.

The category labels denote missing external context (`context_ext.`), max-step termination (`max_step`), missing schema support (`schema_unk.`), and unresolved Terraform variable or local references (`context_var.`). The dominant category is missing external context

**Table 5** Escalation categories across all runs (mean escalation rate: 25.4%).

| Category | R1 | R2 | R3 | Mean | % |
|---|---|---|---|---|---|
| context_ext. | 150 | 149 | 151 | 150.0 | 82.7% |
| max_step | 31 | 21 | 16 | 22.7 | 12.5% |
| schema_unk. | 8 | 6 | 7 | 7.0 | 3.9% |
| context_var. | 3 | 1 | 1 | 1.7 | 0.9% |
| **Total** | **192** | **177** | **175** | **181.3** | **100%** |

(82.7%). This includes absent cross-resource references and missing deployment-specific values, such as KMS ARNs, certificates, logging targets, secrets, disk-encryption sets, logging buckets, and network identifiers that cannot be inferred from the local codebase. Missing schema support and unresolved Terraform references account for another 4.8% of escalations.



A further 12.5% of escalations are max-step terminations. These should not be interpreted as graceful agent escalations. The repair process reached the 10-step budget while the agent was still trying to converge. Heredoc-containing blocks such as IAM policies and `user_data` scripts caused SCANNER_RUN parse failures that the agent treated as repair syntax errors (20 cases). Scanner feedback did not identify the unsatisfied condition (20 cases). SCHEMA_LOOKUP lacked enough nested-block detail (14 cases). The LLM produced invalid tool-call formatting before any repair was attempted (7 cases). Finally, the agent exhausted steps on tool lookups or emitted `FINISH` as an invalid tool action (7 cases). These causes indicate repair-loop limitations rather than missing deployment intent.

**Answer to RQ$_4$.** Most escalations are caused by unavailable or unresolved information, with missing external context alone accounting for 82.7% of escalations. A smaller set of escalations comes from max-step termination, where the bounded repair loop does not converge because of representation, scanner-feedback, or schema-detail limitations.

## 5.5 Operational Metrics

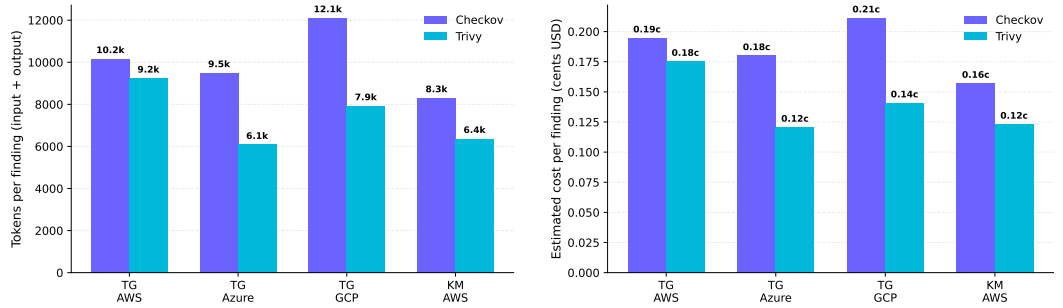


Fig. 3 reports `TerraRepair`'s operational metrics across all 14 dataset–scanner configurations and three runs ($N = 2{,}139$ finding-level repair attempts). Repaired findings require a mean of 3.5 agent steps, escalated findings a mean of 4.0, and only 0.4% of repaired findings (6 of 1,595) reach the 10-step budget (Fig. 3a). Fig. 3b breaks tool calls down by repair outcome. SCHEMA_LOOKUP is invoked about once per finding regardless of outcome (mean 0.92 repaired, 1.18 escalated). SCANNER_RUN is called at least once for 98.8% of repaired findings (mean 1.16) but only 22.8% of escalated ones (mean 0.95). GRAPH_QUERY shows the opposite pattern, with calls on 13.5% of repaired but 41.9% of escalated findings (means 0.22 and 0.63). Token consumption ranges from 6.1k to 12.1k per finding (Fig. 3c), an estimated 0.12–0.21 US cents with the `gpt-4o-mini-2024-07-18` API at the time of the experiment (Fig. 3d).

These figures quantify the RQ$_1$ effort gap: the one-shot baseline issues a single LLM call per finding, whereas `TerraRepair` spends a mean of 3.5 agent steps and several thousand tokens, for scanner-verified gains obtained under a quarter of a US cent per finding. Read against the RQ$_3$ ablation, SCHEMA_LOOKUP is invoked for 88.5% of repaired findings and produces the largest ablation delta ($-21.7$ pp when removed), whereas GRAPH_QUERY is invoked for only 13.5% yet costs 15.6 pp when removed. Cross-resource context is thus needed for a minority of findings, but decisive when required.

**(a)** Agent step distribution.

**(b)** Tool call distribution per finding by repair outcome.

**(c)** Tokens per finding (input + output).

**(d)** Estimated LLM API cost per finding (US cents).

**Figure 3** Agent operational metrics across all 14 dataset–scanner configurations and three runs ($N = 2{,}139$ finding-level repair attempts).

## 6 Discussion and Implications

The results suggest three design implications for LLM-based IaC repair. First, repair systems should distinguish generated, scanner-verified, and semantically reviewed outcomes. In-loop scanner feedback can prevent unsupported success claims, but scanner success should remain an intermediate validation signal rather than a complete correctness oracle.

Second, live provider schemas and repository dependency context should be treated as first-class repair inputs rather than relying only on training-time model knowledge. Access to the installed schema helps the agent select valid attributes and nested blocks, while dependency retrieval supplies values that are absent from the flagged resource.

Third, production deployment requires access to organization-specific context and a clear escalation path. Approved KMS keys, logging destinations, certificates, and IAM constraints are often unavailable from the local Terraform code. Integrating these knowledge sources may expand the set of findings that can be repaired autonomously, while structured escalation remains necessary when the required deployment context is unavailable.

## 7 Threats to Validity

**Construct validity.** Scanner-verified fix rate measures whether the original scanner finding disappears after repair, but it is not a complete measure of repair correctness. A scanner-verified repair may still be undeployable, invalid for the intended cloud environment, or inconsistent with the security policy. We therefore also report differential `terraform validate` results and a sampled semantic audit. The claimed-vs-verified repair gap is a reporting-calibration metric, not a correctness metric.

**Internal validity.** The semantic audit uses one author and two LLM judges, which may introduce author bias and model-judging bias. We mitigate this threat by using a structured judging prompt, reporting inter-rater agreement, and using majority vote. However, the audit should still be interpreted as an estimate under the jury protocol rather than as ground-truth repair correctness. LLM inference may also vary despite fixed settings; we therefore execute each configuration three times.

**External validity.** The evaluation uses TerraGoat and KaiMonkey, which are public and reproducible but vulnerable-by-design repositories. Production IaC may include private modules, custom providers, remote state, provider aliases, dynamic blocks, workspace-specific variables, and organization-specific deployment conventions. The experiments also use one repair model, `gpt-4o-mini-2024-07-18`, at temperature 0.0. Therefore, the fix rates, claim gaps, and ablation ordering should not be interpreted as model-independent properties of LLM-based IaC repair.

**Conclusion validity.** The primary $RQ_1$ comparison is a controlled within-study comparison, but it is an architecture-level comparison rather than an ablation of individual mechanisms. `TerraRepair` differs from the one-shot baseline in tool grounding, chain repair within blocks, in-loop scanner verification, and agent-oriented prompting. The leave-one-out ablation isolates the three tools within `TerraRepair`, but does not separately isolate prompting and repair-ordering differences. Only three runs were feasible, so we report McNemar tests per run and resource-block cluster-bootstrap intervals rather than pooling the $3N$ repeated observations. The McNemar tests do not adjust for within-block dependence, which is addressed by the cluster-bootstrap intervals.

## 8 Conclusion and Future Work

This paper presented `TerraRepair`, a tool-grounded LLM agent for bounded Terraform repair. `TerraRepair` retrieves dependency context, inspects the installed provider schema, and re-runs the scanner before returning a candidate repair. When required information is absent, it emits a structured escalation instead of fabricating a plausible fix.

In a controlled comparison with a one-shot baseline using the same model, scanner versions, finding population, patching logic, and scoring procedure, `TerraRepair` improves scanner-verified fix rate on Checkov and on Trivy on the combined AWS benchmark. It also reduces the baseline's repair gap. The ablation, audit, and escalation analyses suggest that provider-schema grounding and dependency retrieval are important contributors to repair effectiveness, while missing deployment-specific context appears to be a major knowledge boundary for autonomous repair.

The long-term goal is to extend `TerraRepair` to production-like Terraform repositories. Toward this goal, future work will address the observed failure modes by improving schema detail for nested HCL blocks and tool interfaces for heredoc-containing repairs. Future work will also integrate organization-specific knowledge sources, such as approved KMS keys, logging destinations, certificate inventories, and IAM policy templates, to support context-aware repair. Finally, semantic correctness should be assessed through independent review by IaC and cloud-security practitioners.

## Data Availability Statement

The replication package supporting this study is available in a public GitHub repository [14]. It includes the `TerraRepair` source code, evaluation scripts, semantic-audit artifacts, escalation labels, and instructions for reproducing the results. The benchmark datasets are available from the TerraGoat and KaiMonkey repositories at the commits listed in Section 4.

## Abstract

As Artificial Intelligence (AI) assistants and agents become increasingly integrated into software engineering work, concerns about the economic and environmental costs of AI usage continue to grow. Current discussions of computational efficiency focus primarily on model architectures, hardware optimization, and inference cost reduction. In this vision paper, we argue that computational efficiency should also be understood as a socio-technical phenomenon shaped by patterns of human-AI interaction within organizational settings. Motivated by ongoing dialogues with industry partners and informed by the Theory of Planned Behavior and Social Cognitive Theory, we introduce the concept of computational behavior to describe patterns of AI-assisted work that influence how computational resources are consumed, reused, coordinated, and amplified across software engineering activities. Building on this perspective, we propose a multilevel conceptual framework linking individual computational behaviors to emergent collective computational outcomes. We argue that individually rational AI usage behaviors may accumulate into either computational waste or collective computational efficiency depending on how interactions are shared, reused, and aligned across teams and workflows. While fragmented AI use may generate duplicated prompting, redundant generation, and coordination overhead, coordinated collective practices, such as reusable prompts, shared contextualization, and workflow integration may improve collective computational efficiency. We conclude by outlining a research agenda for studying computational coordination, including empirical and organizational AI governance in AI-assisted software engineering.

# 1 Introduction

Generative Artificial Intelligence (GenAI) is increasingly integrated into software development activities [7], and a large share of software engineers already use or plan to use AI tools in their daily work [36]. AI tools are increasingly efficient, but also complex and environmentally questionable, as they entail the often-overlooked consumption of enormous computational power and a significant carbon footprint for model training and deployment, as well as electronic waste associated with high hardware turnover and data center infrastructure [20, 43]. Therefore, assessments of AI's environmental outcomes and the responsible adoption of AI in industrial settings are important topics in today's reality [20].

While current optimization efforts focus primarily on model architectures, inference, hardware, and token reduction, computational efficiency is also shaped by how individuals and teams interact with AI systems. For example, software engineers may repeatedly regenerate outputs, independently rediscover similar prompting strategies, or default unnecessarily to more complex and expensive models. In contrast, organizations may reduce computational overhead through shared prompts, reusable workflows, and coordinated verification practices, to name a few examples. These examples suggest that computational efficiency, the extent to which computational behaviors produce desirable computational outcomes while minimizing unnecessary computational, organizational, and coordination costs, cannot be understood solely as a technical property of AI systems, but must also be studied as a socio-technical phenomenon.

In this vision paper, we argue that an important share of computational waste originates from the use of AI at the organizational level. We start with a summary of related work on computational efficiency from a technical perspective, followed by the motivation for why computational outcomes in organizational AI usage is also a socio-technical problem. We present our multi-level conceptualization of AI interaction behaviors across individual, group, and organizational levels. Particularly, our framework distinguishes between individual rationality and collective efficiency, between productive and wasteful redundancy, and between aggregated and socially amplified interactions. The vision paper concludes with a research agenda for empirical software engineering.

# 2 Background

## 2.1 Technical Perspective on Computational Efficiency

As GenAI grows in scale and adoption, sustainability concerns have become increasingly prominent. Green AI emphasizes advancing scientific progress while reducing resource consumption whenever possible [32].

Prior work has examined sustainability impacts across training and inference phases [19, 21, 30]. Proposed optimizations span the hardware, algorithmic, and systems levels, including phase-splitting architectures [27], distributed execution frameworks [33], and custom inference libraries [16, 41]. Current evidence suggests that LLM deployments can consume considerable amounts of electricity when inference demands are aggregated across millions of users [40]. Studies on heterogeneous data center architectures show that even modest improvements in task scheduling can meaningfully reduce inference energy usage, highlighting the resource-intensive nature of LLM workloads and the need for infrastructure-level optimizations [42]. Measurement remains challenging, as sustainability metrics are inconsistently defined across studies, which limits comparability and cumulative progress [2, 8, 19]. This inconsistency also makes it difficult to attribute computational outcomes to specific causes, including human interaction patterns.

Yet, as software engineering history repeatedly shows, seemingly technical challenges are rarely solved through technical improvements alone. Advances in programming languages, for example, have not eliminated persistent problems in software projects, partially because many outcomes depend on coordination, workflows, and organizational practices.

A similar shift is now needed in discussions of AI efficiency. Recent work has begun to extend efficiency concerns beyond infrastructure toward human interaction patterns [31]. While computational outcomes are treated as technical property of AI systems, they are also shaped by how people use those systems in practice [20]. For example, prior studies suggest that some LLM queries could be served by lower-cost alternatives, pointing to demand-side behavior as an important and underexplored lever for improving computational efficiency [13].

## 2.2 The Impact of Human-AI Interaction on Computational Outcomes

**Attitudes Toward AI.** Developers' attitudes toward AI tools range from enthusiastic early adoption to active skepticism and resistance, and this variation has direct computational consequences [29, 44]. However, attitudes do not operate in isolation: recent work shows that GenAI use is also shaped by compatibility with existing workflows, organizational support, and collective usage patterns within teams [37]. The Theory of Planned Behavior (TPB) [1] provides a principled frame: attitude toward a behavior, combined with perceived social pressure and perceived behavioral control, predicts behavioral intention and, in turn, behavior itself. AI enthusiasm, supported by documented productivity but amplified socially beyond what task demands justify, leads developers to shift to the most capable and expensive models regardless of task fit [28, 29]. This defaulting behavior resembles the Price-Quality Heuristic [11]: developers may implicitly treat more capable and expensive models as better choices even when the task does not require them. This tendency is especially concerning given longitudinal mixed-methods evidence showing no statistically significant correlation between developers' self-reported productivity change and changes in commit-based activity [38], suggesting that developers' subjective assessments of AI support may be poorly calibrated against its measurable effects. Within Social Cognitive Theory (SCT), according to Bandura [4, 5], this reflects uncalibrated outcome expectations, that is, beliefs that AI support with more powerful models always yield better results, regardless of the task at hand. On the other end, algorithm aversion [9] drives over-verification and redundant prompting, a pattern enforced by self-efficacy in developers who lack confidence in their own ability to evaluate AI outputs. Between these extremes, automation bias leads to uncritical acceptance of flawed outputs, downstream error loops and costly remediation [26, 35]. Indeed, in a recent study, Zhou et al. [46] assess that 48,8% of programmer actions in LLM-assisted development have been found to be biased, with automation and confirmation bias being dominant patterns. Together, these three attitude-driven pathways - overconsumption, over-verification, and under-verification followed by rework - illustrate why the TPB's multi-component structure matters, confirming that attitude-level interventions alone are insufficient if team practices and perceived behavioral controls are not properly addressed.

**Mental Models, Self-Efficacy and Outcome Expectations.** Users with more accurate mental models of AI achieve better outcomes in AI-assisted tasks [6, 10, 15], yet forming accurate mental models of LLM-based tools is particularly challenging [10, 24, 39, 45]. Commercial AI tools frequently combine LLM capabilities with tool-calling and knowledge base integration, blurring the boundary between what the model knows and what it can retrieve at inference time. O'Brien et al. [25] found that users frequently hold categorical misconceptions about which affordances are enabled for a given tool, leading to confusion

about what actions were taken before a response is returned. Such misconceptions have also been observed as cultural phenomena: folk prompting strategies such as tipping or threatening models persist despite producing no reliable performance gains [22]. These misconceptions translate into computationally costly behaviors. The monotonicity belief [12] that more context always improves performance, drives context window stuffing and wasteful token consumption. Misunderstandings about model memory lead to repeated re-injection of context across sessions, a pattern documented both among novice programmers and non-AI-experts [18, 45] and, in telemetry from professional developers, as frequent re-prompting to supply context the model lacked [23]. Further, categorical confusion about tool capabilities results in reliance on expensive general purpose models for tasks that are better suited for cheaper alternatives.

## 3 Conceptual Framework

In this section, we outline our multilevel conceptual framework of computational efficiency. The framework is organized according to guidelines for theory building [34] and describes our vision, constructs, propositions, theoretical grounding, and scope. The framework is inspired by ongoing dialogues with industry partners and theoretical concepts from social science.

### 3.1 The vision

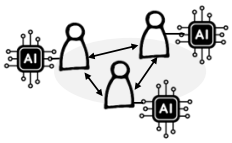
We argue that advances in sustainable and effective AI-assisted software engineering will require complementing technical optimization with a deeper understanding of computational efficiency from a socio-technical perspective. While existing focus on AI models, hardware infrastructure, and inference optimization remains important, it only partially explains how computational resources are consumed in the context of AI-assisted software engineering.

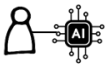
Computational cost is local, and the people who incur it are not aware of the overall impact of their actions on the organization. The individuals are aware of the tokens they personally consume, the organization sees the overall expenses, but neither can see which collaborative practices are beneficial, which redundancies are wasteful, or how differently individuals use resources to re-create the same contexts.

The vision that this paper presents is one in which computational cost is monitored, managed, and treated the same way maintainability, code quality, and technical debt are treated by mature organizations: good practice patterns are disseminated, awareness is encouraged, and tactics ensure that computational effort is used efficiently towards creating value while still allowing for the exploration and freedom that individual learning requires.

At the individual level, human-AI interactions may differ both in rationality and efficiency. Interactions that are locally rational in the sense that they align with an individual developer's immediate goals, constraints, and incentives may contribute to collectively inefficient outcomes when repeated independently across teams or workflows. At the group and organizational level, interaction behaviors may accumulate, amplify, or become coordinated through shared practices, producing emergent patterns of computational efficiency or waste (see Figure 1). From this perspective, *computational efficiency becomes an emergent socio-technical property rather than merely a characteristic of underlying technical systems.*

Finally, as software is increasingly operated by autonomous or semi-autonomous agents, computational behaviors of interest in our context extend beyond direct prompting to include how developers configure, delegate to, constrain, and supervise agentic workflows.





| Level of analysis | Human-AI interaction | Computational outcomes | Examples |
|---|---|---|---|
| Group and org level  | Socially amplified interaction | Wasteful use | Collaborative prompt spirals, Tokenmaxxing |
| | | Efficient use | Collaborative sensemaking, Shared contextualization |
| | Aggregated collective interaction | Wasteful redundancy | Redundant querying, Duplicated generation |
| | | Efficient redundancy | Parallel exploration, Redundant learning |
| Individual level  | Individual interaction | Irrational use | Prompt thrashing, Context window stuffing |
| | | Rational use | Exploratory prompting, Risk-aware verification |

**Figure 1** Multilevel conceptual framework of computational efficiency that distinguishes between individual rationality and collective efficiency and showing their possible computational outcomes.

## 3.2 Constructs

We propose to study *computational behaviors*, i.e., patterns of human-AI interactions that influence computational resource consumption during software engineering work.

Our overarching goal is to understand and improve *computational efficiency*, i.e., the extent to which computational behaviors produce desirable computational outcomes while minimizing unnecessary computational, organizational, and coordination costs.

In this context, *computational outcomes* refer to the consequences of computational behaviors, including resource consumption at the individual, group, and organizational levels (e.g., total time, token consumption) and the organizational and economic consequences produced (e.g., velocity, duplication).

We further introduce the concept of *computational waste*, referring to avoidable computational expenditure that produces limited additional value relative to organizational goals or outcomes achieved. Finally, *rationality* is the property of computational behavior of being logical/justified from the perspective of the actor who performs it.

## 3.3 Propositions (or relationships)

### 3.3.1 Individual level

At the individual level, we focus on observable computational behaviors through which individuals engage with AI systems to accomplish their work tasks, and which shape computational outcomes. These behaviors include prompting, verification, context provision, exploration, refinement, regeneration, and interpretation of AI-generated outputs. Such interactions influence computational outcomes by shaping how computational resources are consumed during software engineering work.

**Proposition 1: Individual Human-AI interactions vary in rationality.** The computational outcomes of AI-assisted software engineering are influenced by the ways in which individuals interact with AI systems, including how often they prompt, regenerate, verify, refine, or contextualize AI-generated outputs. To better understand these behaviors, we focus on the *rationality* of computational behaviors. We use rationality in a bounded sense, referring to whether an interaction is justifiable from the developer's local perspective, rather than to optimal decision-making in a formal sense. For example, repeated prompting and verification may be rational when developers face uncertainty, high-risk tasks, or opportunities for learning and exploration. In contrast, irrational interactions include repeated regeneration of

a prompt without converging on a usable result (*prompt thrashing*), redundant or unnecessary context provision (*context window stuffing*), or reliance on unnecessarily advanced and costly AI systems for tasks that can be more efficiently performed by simpler models or manually.

**Proposition 2: Rationality of individual computational behaviors is shaped, among others, by attitudes toward and mental models of AI capabilities.** Individual computational behaviors are influenced by developers' attitudes, expectations, and mental models regarding AI capabilities and limitations. For example, developers who perceive AI systems as highly capable may delegate larger portions of software engineering work to AI assistance, rely less on manual verification, or engage in extensive exploratory prompting. On the other hand, developers who distrust AI systems or underestimate their capabilities may avoid potentially beneficial AI-supported workflows or rely excessively on manual work. As a result, differences in attitudes and perceptions of capability may produce substantially different computational behaviors, even for similar tasks.

### 3.3.2 Group level

As software engineering work is highly collaborative, computational outcomes cannot be fully understood through individual behavior alone. At the group level, computational outcomes emerge through the accumulation and coordination of interaction behaviors across groups and workflows. We distinguish between aggregated and socially amplified computational behaviors.

**Proposition 3: Individually rational interactions may aggregate as collective waste.** Aggregated computational behaviors emerge through the accumulation of independently executed AI usage behaviors across collaborators, often without direct coordination. Such aggregation may introduce computational redundancy through repeated querying, duplicated generation, parallel experimentation, or fragmented AI-assisted workflows. For example, multiple developers independently exploring similar prompting strategies may each behave rationally from an individual perspective while collectively reproducing avoidable computational effort, i.e., collective waste. This mechanism extends to autonomous agents: when multiple agents or agentic pipelines independently spawn overlapping sub-tasks, retries, or parallel exploration branches, redundant computation can accumulate with no human coordination point at all. Redundancy becomes wasteful when it duplicates computational effort without producing a proportional increase in value. However, redundancy itself is not inherently inefficient. In some cases, it can serve valuable purposes such as enabling independent verification, improving resilience, supporting exploration, or facilitating collective learning. Organizations can e.g. have slow approval processes for new tools and processes. Allowing some experimentation, while often initially wasteful on an individual level, could aggregate to early evidence that motivates organizations to fast-track serious evaluation and approval of promising tools or processes in order to remain competitive

**Proposition 4: Socially amplified human-AI interactions can improve collective efficiency when managed well.** In addition to aggregated behaviors, software teams, groups, and communities may engage in socially amplified computational behaviors, in which Human-AI interaction with AI systems, prompts, contexts, workflows, or agents is shared or coordinated across multiple users. Unlike independent aggregation, socially amplified interactions involve interdependent AI-assisted collaboration or interaction behaviors. For example, collaborative

prompt repositories, shared contextualization practices, and coordinated AI workflows reduce duplicated inference and improve reuse across collaborators. In contrast, collaborative prompt spirals, persistent context expansion, excessive collective verification, or recursive agent interactions amplify computational waste. Multi-agent settings intensify this dynamic: when agents recursively delegate subtasks to other agents or re-invoke themselves without adequate stopping conditions, small inefficiencies compound across the execution trajectory rather than resetting at each turn [3]. Conversely, well-designed agent orchestration, e.g., shared memory across agents, explicit hand-off protocols, or bounded delegation depth, can reduce duplicated inference and convert multi-agent coordination into a source of collective efficiency rather than waste. Thus, at a group level, amplification may either improve or degrade collective computational efficiency. For example, collaborative prompt repositories, shared contextualization practices, and coordinated AI workflows reduce duplicated inference and improve reuse across collaborators. In contrast, collaborative prompt spirals, persistent context expansion, excessive collective verification, or recursive agent interactions amplify computational waste. Multi-agent settings intensify this dynamic: when agents recursively delegate subtasks to other agents or re-invoke themselves without adequate stopping conditions, small inefficiencies compound across the execution trajectory rather than resetting at each turn [3]. Conversely, well-designed agent orchestration, e.g., shared memory across agents, explicit hand-off protocols, or bounded delegation depth, can reduce duplicated inference and convert multi-agent coordination into a source of collective efficiency rather than waste. Thus, at a group level, amplification may either improve or degrade collective computational efficiency.

### 3.3.3 Organizational level

At the organizational level, computational behaviors shape broader patterns of computational alignment and misalignment across teams, workflows, and organizational structures.

**Proposition 5: Individualized AI adoption weakens organization-wide computational alignment.** When AI usage practices, computational expenditure, and collaborative workflows are insufficiently coordinated, organizational-level computational use is misaligned. Such fragmentation is more likely to surface in organizations that emphasize individual AI adoption over coordinated collective practices. As a result, hidden computational costs emerge through repeated interactions, duplicated inference, fragmented workflows, and weak institutionalization of efficient AI-assisted practices.

**Proposition 6: Management beliefs and top-down AI adoption initiatives amplify computational behaviors across workflows and teams.** Computational inefficiency does not only aggregate, it may also be amplified through top-down organizational dynamics. Management shapes AI-related norms, expectations, and governance structures that influence how employees interact with AI systems. For example, unrealistic expectations regarding the transformative capabilities of AI may encourage excessive AI usage or "Tokenmaxxing" behaviors [14], where employees increase visible AI interaction to signal productivity, innovation, or organizational alignment. Similarly, inaccurate organizational mental models regarding how AI systems function may lead organizations to deploy expensive general-purpose models in workflows better suited for deterministic computation or specialized tools, primarily to demonstrate AI adoption to stakeholders or customers.

## 3.4 Theoretical foundations

Our conceptual framework is grounded in the Theory of Planned Behavior (TPB) [1] and Social Cognitive Theory (SCT) [4, 5]. Together, these theories provide complementary explanations for how computational behaviors emerge, spread, and shape computational outcomes in AI-assisted software engineering, and can inform the design of empirical studies in this field.

As described in Section 2.2, TPB explains how individual attitudes, perceived social norms, and perceived behavioral control influence behavioral intentions and observable behavior [1]. In the context of AI-assisted software engineering, TPB helps explain why developers adopt different AI interaction behaviors, including prompting frequency, verification practices, context provision, regeneration strategies, and model selection. From this perspective, computational behaviors are not solely determined by technical necessity, but also by developers' beliefs regarding the usefulness, reliability, and expected value of AI assistance. TPB also highlights the importance of subjective norms within software engineering teams. Developers may adopt computational behaviors not only because they perceive them as effective, but also because such behaviors become socially expected, rewarded by the management, or normalized within work groups. As a result, computational behaviors may spread independently of their actual contribution to collective computational efficiency.

However, TPB's explanatory power has proven to be limited in situations when behaviors are automatic or habitual rather than reasoned [17]. This motivates pairing TPB with SCT.

SCT broadens the socio-technical lens for understanding how computational behaviors evolve collectively through learning, observation, reinforcement, and shared work practices [4, 5]. SCT emphasizes the role of self-efficacy, outcome expectations, and observational learning in shaping human behavior. In AI-assisted software engineering, developers' beliefs regarding their ability to effectively use AI systems influence whether they engage in exploratory prompting, careful verification, iterative refinement, or repetitive low-skill interaction patterns. Similarly, outcome expectations shape assumptions regarding the value and capabilities of AI systems, influencing model selection, escalation to more capable models, and the extent of computational effort invested in AI-assisted tasks. Importantly, SCT also explains how computational behaviors become socially reinforced and amplified within teams and organizations. Developers observe and imitate AI interaction practices used by peers, especially when such behaviors appear productive or are organizationally rewarded. Through repeated observation and reinforcement, individually rational computational behaviors may stabilize into shared collective practices regardless of whether they improve collective computational efficiency. This perspective is particularly important for understanding how computational outcomes emerge at the group and organizational levels.

## 3.5 Scope

The proposed conceptual framework focuses on computational behaviors emerging during AI-assisted software engineering work within organizational settings. The model is intended as a socio-technical complement to existing systems-level approaches to computational optimization. Therefore, it does not seek to explain computational efficiency through model architectures, hardware infrastructure, inference optimization, or energy-aware computing techniques. Instead, the framework focuses on how human interaction patterns influence organizational consumption, coordination, and reuse of computational resources during software engineering work.

The framework focuses on collective computational outcomes rather than isolated individual productivity measures. Although individual attitudes, mental models, and computational behaviors are included as antecedents, the framework primarily seeks to explain how computational efficiency and computational waste emerge within groups. It is also noteworthy that computational efficiency in our framework is analytically distinct from productivity or task-completion speed. Interventions that reduce computational waste may, in some cases, slow individual task completion or reduce learning opportunities. The framework does not assume these outcomes are always aligned. Conversely, computationally inefficient behaviors may improve learning outcomes, code quality, or long-term team velocity even where they increase immediate computational cost.

Notably, the framework is developed around human-directed interactions. The use of autonomous or semi-autonomous agents that execute multi-step tasks with limited human oversight at each step is an important boundary requiring further extensions. The constructs of computational behavior, waste, and rationality extend naturally to how developers configure, delegate to, and supervise such agents, but the framework does not yet fully address computational dynamics that emerge from agent-to-agent interaction absent a direct human decision point.

Finally, while the framework is developed in the context of AI-assisted software engineering, several of the propositions may generalize to other forms of AI-assisted knowledge work characterized by collaborative workflows and coordinated actions.

# 4 Proposed Research Agenda

In this section, we outline future research directions on computational efficiency.

## 4.1 Understanding Individual Human-AI Interaction Behaviors and Computational Outcomes

**Industrial relevance.** Organizations increasingly recognize that the cost of AI-assisted software engineering depends not only on model pricing but also on developers' everyday interaction behaviors. In one partner organization, developers expressed uncertainty regarding which models were appropriate for different tasks, with some defaulting to expensive models while others experimented with cheaper alternatives. In their case, the difference in cost between high-end and low-end models is noticeable (the former having a 15x request multiplier with usage around 90% of the total AI-related cost compared to 3x for the latter). Practices such as iterative sparring, repeated generation, and autonomous debugging loops can have substantial economic consequences. This becomes especially critical in light of transition from request-based to token-based pricing, where existing interaction patterns are estimated to triple monthly AI-related costs (from around USD 20,000 to USD 65,000). For industry, this makes individual AI literacy, task-model fit, and interaction discipline central concerns for balancing productivity, learning and computational cost.

**Research questions.** Based on these considerations, we suggest the following directions.

*What constitutes wasteful computation?* As a starting point, wasteful computation can be operationalized as AI interactions whose outputs are discarded, duplicated, unnecessarily regene rated, or replaceable by cheaper deterministic or specialized alternatives. Empirical work is needed to validate and refine such an operationalization across different software engineering tasks and contexts.

*How do self-efficacy beliefs, attitudes, and mental models of AI in general, and agent autonomy in particular, influence computational behavior and delegation decisions?* TPB and SCT suggest that developers' attitudes, perceived behavioral control, outcome expectations, and self-efficacy beliefs shape how they interact with AI systems. Future work should investigate which beliefs and mental models contribute to exploratory, coordinated, wasteful, or overly cautious computational behaviors.

## 4.2 Understanding Collective Human-AI Interaction Behaviors and Collective Computational Outcomes

**Industrial relevance.** Computational outcomes increasingly emerge from collective patterns of AI use rather than isolated individual interactions. In a partner company, teams organically negotiate model choices, develop informal heuristics of task-model fit taking into account reliability, speed, and cost, and collectively evaluate when expensive models are worthwhile. For example, some developers argued that more capable models may be cheaper in practice because they avoid costly error loops, while others report cases where expensive models still become trapped in unnecessary debugging and backtracking. These experiences suggest that computational efficiency is partly a collective learning and coordination problem: organizations need mechanisms for sharing knowledge about AI capabilities, failure modes, and task suitability, while preserving local autonomy and innovation.

**Research questions.** Based on these considerations, we suggest the following directions.

*Under what conditions does aggregation of individually rational AI use produce collective waste?* Individually rational AI interactions may accumulate into collective computational patterns such as duplicated inference, repeated experimentation, fragmented workflows, or computational reuse. Future work should investigate how aggregation mechanisms influence collective computational efficiency.

*How can productive redundancy be distinguished from wasteful redundancy in practice?* Not all repeated computation is undesirable. Redundancy may support learning, independent verification, resilience, creativity, or exploration. Future work should investigate how organizations can practically distinguish computational redundancy that contributes to collective value from redundancy that merely reproduces already available computational effort.

*Which coordination mechanisms reshape these dynamics?* Shared shared AI artefacts (prompts, contexts), collaborative AI workflows and multi-agent orchestration, organizational memory systems, and coordinated AI-assisted development practices may improve computational reuse and reduce duplicated effort. However, tightly coupled AI-assisted collaboration may also amplify coordination overhead, recursive generation, and collective computational waste. Future work shall focus on understanding the costs and benefits of different coordination mechanisms.

## 4.3 Understanding Organizational Computational Visibility, Alignment and Governance

**Industrial relevance.** As AI-assisted software engineering scales, organizations increasingly require computational visibility, alignment, and governance. Partner organizations report a transition from exploratory AI adoption toward governed AI operations, including usage dashboards, model cost overviews, and internal adoption metrics. However, visibility into computational behaviors often remains incomplete, particularly regarding duplicated effort,

repeated inference, and interaction patterns across teams. Organizations therefore need governance mechanisms that reduce avoidable computational waste and costs, without suppressing experimentation, learning, and innovation.

**Research questions.** Based on these considerations, we suggest the following directions.

*How can organizations improve visibility into and control over collective computational behaviors on an organizational scale?* As AI-assisted work becomes increasingly distributed across individuals, teams, and autonomous agents, organizations require mechanisms for observing, coordinating, reusing, and controlling computational resources across workflows. Future work should investigate how computational visibility systems can support learning, reuse, and computational coordination, and what corporate AI governance practices help control the AI expenditure adherence to budgets.

*How do organizational narratives and leadership attitudes toward AI shape computational behaviors?* Leadership expectations, AI strategies, and symbolic pressures to demonstrate AI adoption may influence how employees interact with AI systems. Future work should investigate how top-down narratives regarding AI productivity, innovation, or competitiveness shape computational behaviors such as excessive model usage, or performative AI interaction.

*How can organizations reduce avoidable computational waste without suppressing learning, exploration, resilience, and innovation?* Governance mechanisms aimed at reducing computational expenditure may unintentionally discourage experimentation, independent verification, or exploratory learning. Future work should investigate how organizations can balance computational efficiency with developer autonomy, creativity, resilience, and collective learning.

## 5 Conclusion

Interest in teams composed of multiple human and AI engineers seamlessly coordinating and combining their work is already high on the research agenda [7]. This is easier said than done. Yet, stakes are concrete: companies like Uber reportedly exhaust its entire yearly AI-coding budget within months of deployment, partially driven by internal tokenmaxxing invitations [14], and single engineer's fleets of 100 autonomous coding agents are capable of generating over a million of dollars in API spent within a single month. The instinctive response, simply curbing AI usage, is itself a trade-off: reducing computational expenditure can just as easily suppress the exploration, verification, and learning that make AI-assisted work valuable in the first place. So, what organizations need is governance that manages computational efficiency rather than blindly minimizes it.

In this vision paper, we argue that computational efficiency in AI-assisted software engineering should be understood not only as a technical property of AI models and infrastructure, but also as an emergent socio-technical dynamics shaped by patterns of human-AI interaction, collective coordination, and organizational governance. As such, our vision extends current discussions of AI efficiency beyond systems-level optimization toward the organizational coordination of AI-assisted work. In particular, we highlight the importance of understanding how computational behaviors aggregate, amplify, and become socially reinforced across teams and workflows, and how organizational structures shape computational visibility, reuse, and governance.

This tension is sharpest where AI participants are no longer simply tools invoked by software engineers but autonomous or semi-autonomous agents that plan, delegate, and act with limited human oversight at each step: autonomy that is locally efficient for a single agent or team can generate hidden computational costs that only surface once agentic behaviors are aggregated and observed at the organizational level.

Our targeted outcomes include terminology, measurement programs, and recommendations for *organizational computational governance*. We plan to collect empirical experiences and derive requirements for computational policies, collective AI resources, collaborative infrastructures, workflow-level AI governance, reasoning budgets, and organizational AI observability. More broadly, we hope our vision will encourage software engineering research to move beyond studying isolated individual AI interactions toward understanding the collective socio-technical dynamics through which computational efficiency and waste can be managed in industrial settings. Ultimately, we do not suggest eliminating computational cost, but distinguishing the redundancy, exploration, and autonomy that generate long-term value from the waste that does not, at both the human and agentic level.

## Data Availability Statement

This is a vision paper and reports no empirical data.

## Abstract

**Background.** Large language models (LLMs) have become increasingly capable of understanding and generating source code, leading to their widespread adoption in software engineering tasks such as code completion, repair, and vulnerability detection. However, despite their strong empirical performance, the internal mechanisms through which LLMs recognize malicious or vulnerable code patterns remain poorly understood.

**Aim.** We investigated where the malware detection behavior is encoded inside LLMs Feed Forward Network (FFN) neurons and verified the attribution with causal interventions on the neurons identified. This aims to identify the most important neurons in detecting malicious code.

**Methods.** We applied mechanistic interpretability methods to locate the neurons being responsible for malware-detection behavior in three instruction-tuned LLMs: `Llama3.1-8B-Instruct`, `Mistral-v0.3-7B-Instruct`, and `Qwen2.5-7B-Instruct`. Using 1,500 malicious and 1,500 benign PyPI packages from the PyPI Malregistry, we attribute the behavior to a set of neurons.

**Results.** The experimental results reveal that amplifying facilitating neurons for malware detection while suppressing inhibiting ones can boost accuracy, while the reverse collapses predictions toward a single class, although the magnitude and consistency is heavily model-dependent. We demonstrated that the guardrail detection mechanism varies across models, each represents its malware detection behavior differently within its FFN layers.

**Conclusions.** Probing the neurons associated with security-relevant knowledge helps us gain insights into how LLMs encode malicious programming concepts, identify potentially harmful memorized behaviors, paving the way toward more reliable defense mechanisms, such as neuron-level editing, selective unlearning, and security-aware alignment for code-focused LLMs.

## 1 Introduction

Large Language Models (LLMs) have transformed software engineering (SE) by powering advanced code-generation tools such as GitHub Copilot, or DeepSeek-Coder [5, 18]. While these models significantly boost developer productivity, they also introduce serious security risks [28, 29]. Despite their strong empirical performance, the internal mechanisms through which LLMs recognize malicious or vulnerable code patterns remain poorly understood. This lack of interpretability raises important concerns regarding trustworthiness, robustness, and security, particularly in safety-critical software development scenarios where incorrect or manipulated predictions may introduce severe risks [19, 32]. Such vulnerabilities stem from the models' tendency to memorize and reproduce harmful patterns present in their pre-training or fine-tuning data, especially from public repositories and security-related datasets [2, 16]. To mitigate this, current defense strategies primarily rely on prompt engineering, safety fine-tuning, or post-hoc filtering. However, these approaches treat the model as a black box and often fail in adaptive or adversarial prompts [20, 25].

**Motivation.** Recent studies have shown that safety mechanisms and refusal behaviors are not uniformly distributed across the model but are encoded in specific internal representations [9]. There has been evidence showing that LLMs can memorize insecure coding patterns, generate vulnerable code, and remain susceptible to adversarial manipulation [1, 23]. Despite this insight, there is limited understanding of which layers are primarily responsible for detecting and blocking malicious code. Thus, studying which neurons and representations contribute to malicious code detection is crucial for improving transparency and enabling fine-grained control over model behavior.

**Objectives.** Our work aims to bridge such a gap by systematically probing the internal neurons of code LLMs to identify those that most effectively detect malicious code. Using benign and malicious PyPI packages [12], we attribute malware-detection behavior to individual feed-forward neurons and verify the attribution through causal interventions. Having pinpointed where and how LLMs recognize malicious code is a prerequisite for both future safeguards and halting the malware generation of such requests.

**Methods and Findings.** Experiments on `Llama3.1-8B-Instruct`, `Qwen2.5-7B-Instruct`, and `Mistralv0.3-7B-Instruct` reveal that guardrail activation is highly layer-dependent, i.e., middle layers for `Llama3.1-8B-Instruct` and `Mistralv0.3-7B-Instruct`, late layers for `Qwen2.5-7B-Instruct`. By localizing guardrail mechanisms, our work provides practical benefits: *(1)* enabling lightweight, early-exit safety checks that significantly reduce inference cost while maintaining high detection accuracy; *(2)* supporting targeted model editing and layer-specific unlearning to strengthen defenses without degrading general code-generation capability; and *(3)* laying the foundation for self-monitoring defenses that let a model recognize and reject malicious generation at its source.

**Contributions.** Through this preliminary study as a NIER paper, we advocate for fundamentally new research directions in probing and understanding LLMs for software engineering tasks. Our work represents an initial step toward systematically investigating the behaviors of LLMs in the detection of malicious code, making the following contributions.

- A practical approach to understand LLMs' behaviors in recognizing malicious code.
- An empirical study with three LLMs on real-world datasets to validate the performance.
- A replication package including code and data to foster open science [7].

**Structure.** Section 2 presents the background and motivate related to our work. Afterward, Section 3 describes our methodology, covering dataset construction, neuron attribution methods, and intervention conditions. Section 4 details the experimental setup. Section 5 reports and discusses the results addressing our research questions. Finally, Section 6 concludes the paper and outlines directions for future work.

## 2 Motivation and Background

Recent work suggests that high-level behaviors are not evenly distributed across an LLM but rather concentrate in specific layers or sets of neurons. Di Palma et al. [9] have analyzed sentiment encoding across layers and scales using probe classifiers, identifying layers and pooling methods that best capture sentiment signals. The work showed that sentiment information is most concentrated in the mid-layers for the binary polarity task, although the analysis stops at the layer level.

Integrated Gradients (IG), proposed by Sundararajan et al. [24], provides a way to measure how much each input contributes to a prediction by accumulating gradients along a path from a baseline. Neuron Conductance (NC) [8] extends further, tracking how much of that contribution flows through a single neuron. Both apply naturally to FFN blocks, which act as key-value memories in which each neuron responds to a pattern in input and writes to the output distribution as stated by Geva et al. [11]. Dai et al. [6] used IG on those activations to trace individual facts to single neurons; Chen et al. [4] extended the idea to gated FFNs, using multiple-choice prompting as a proxy task; and Li et al. [14] applied it at the task level in NeuronLLM, a framework inspired by biological functional antagonism, identifying *good* and *bad* FFN neurons that jointly govern task performance in LLMs and confirm their roles by amplifying one group while suppressing the other, reporting the neurons it finds sit predominantly in the middle and the top layers.

However, current interpretability-based safety research has focused predominantly on natural language jailbreaks [31, 3], often treating safety as a monolithic "refusal." The application of these mechanistic techniques to security-relevant tasks-and to the detection of subtle, cross-file malicious logic in code-specialized LLMs in particular-remains largely unexplored [26, 13]. This leaves a critical gap in understanding whether malicious code is encoded in distinct *"toxic neurons"* or emerges from a fragile, distributed representation that current defense-in-depth layers fail to capture.

To our knowledge, this work is the first one to tackle the issue of probing LLMs for malicious code detection.

## 3 Methodology

We employed various mechanistic interpretability methods [8, 14] to pinpoint the neurons that support and hinder the model's ability to detect malicious code. Both malware and benign samples were collected to perform contrastive analysis of the models' internal representations when detecting malware versus benign code. As whown in Fig. 1, our pipeline consists of four main stages, i.e., *(1)* Dataset Construction & Proxy Prompting; *(2)* Neuron Attribution; *(3)* Scoring & Neuron Selection; and *(4)* Causal Intervention & Evaluation, explained as follows.

We use the terms "good" and "bad" neurons to refer to neurons that help or hinder the model in the malware-benign code classification task. For each example, we use attribution methods to assign a score to each neuron based on its contribution to the model's answer. A positive score means the neuron supports the correct answer, while a negative score means

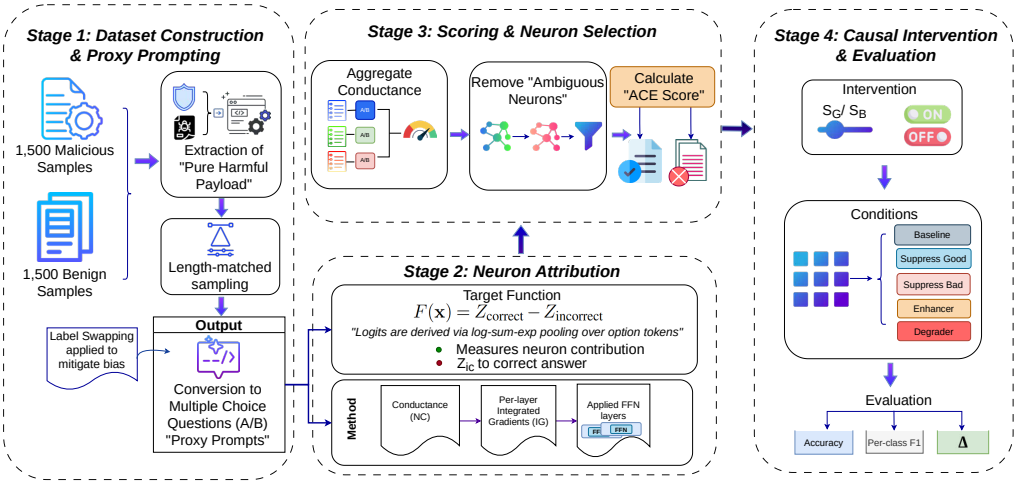

**Figure 1** Framework overview: Neuron-level detection of malicious code patterns.

it opposes it. After filtering and selection, the neurons that most strongly supports correct answers across both malware and benign samples form the good set, while those that most strongly work against form a bad set. These two sets of neurons are treated as task-level neurons for binary malware-benign code classification.

## 3.1 Dataset Construction and Proxy Prompting

Malicious PyPI packages leverage Python automation mechanisms at two key stages: install-time and import-time [12]. We developed a heuristic to collect the pure harmful payload, avoiding unwanted benign implementation in those malware packages. In particular, instead of throwing all package files into the malware samples, which may lead to false positives due to the cloning implementation, we scan for the setup file (`setup.py`), which is run during installation. For runtime attacks, we look for the initial file (often named `__init__.py`) that is suspiciously long, which may indicate it contains the malicious payload. For benign samples, to create a suitable contrastive set with the malware, we develop a heuristic to prioritize collecting package setup code files with a similar structure and length.

From the collected dataset (cf. Table 1), we ask LLMs if a code snippet is malware or benign in the form of multiple choice question A/B. To avoid the tendency of LLMs to pick the first answer or default to specific tokens [21, 30], we designed the proxy question to swap the label of A/B and change the prompt for the proxy questions.

**Table 1** Dataset distribution by line-count bucket.

| Bucket (lines) | Malware | Benign | Total |
|---|---|---|---|
| $\leq 20$ | 98 | 98 | 196 |
| 21 – 50 | 1,107 | 1,107 | 2,214 |
| 51 – 100 | 110 | 110 | 220 |
| 101 – 200 | 139 | 139 | 278 |
| $> 200$ | 46 | 46 | 92 |
| **Total** | **1,500** | **1,500** | **3,000** |

## 3.2 Neuron Attribution

Integrated gradients (IG) [24] is an axiomatic attribution method that assigns contributions to inputs by accumulating the gradients along an interpolation path from the baseline input $x'$ to the actual input $x$ as expressed in the following formula. Let $F : \mathbb{R}^n \to [0, 1]$ be the function representing a deep neural network, $\mathbf{x} \in \mathbb{R}^n$ be the input, $\mathbf{x}' \in \mathbb{R}^n$ be the baseline input. The integrated gradients calculate the attribution of each input entry by integrating the gradients along the interpolation path from $x'$ to $x$.

$$\text{IntegratedGrads}_i(x) := (x_i - x_i') \times \int_{\alpha=0}^{1} \frac{\partial F(x' + \alpha \times (x - x'))}{\partial x_i} d\alpha$$

The target function F is defined as: $F(x) = Z_{correct} - Z_{incorrect}$, in which $Z_{correct}$ is the raw logit at the output layer corresponding to the correct answer's token prior to the softmax activation; and $Z_{incorrect}$ is the raw logit value corresponding to the incorrect answer. By applying the target function $F(x)$ as given, we can equally reward a neuron for amplifying the correct answer, i.e., increasing $Z_{correct}$ and penaltying the wrong answer $Z_{incorrect}$.

Two methods [8, 14] are applied to identify neurons responsible for malware detection.

- **Per-layer IG on FFN neurons (IG).** Our second attribution method builds on the framework proposed by Li et al. [14]. Particularly, for $w_i^l$ is the i-th neuron in a l-th layer in an FFN, $\hat{w}_i^l$ is the neuron activation value. The integrated gradient for neuron i in layer l is:

$$\text{IG}(\hat{w}_i^l) = \frac{\hat{w}_i^l}{m} \sum_{k=1}^{m} \frac{\partial F(\frac{k}{m} \cdot \hat{w}_i^l)}{\partial \hat{w}_i^l}$$

- **Neuron Conductance (NC).** The Neuron Conductance method [8] extends Integrated Gradients to attribute a model's output to individual hidden neurons by measuring how much signal that neuron conducts from the input to the output:

$$\text{Cond}_i^y(x) = (x_i - x_i') \cdot \int_{\alpha=0}^{1} \frac{\partial F(x' + \alpha(x - x'))}{\partial y} \cdot \frac{\partial y}{\partial x_i} d\alpha$$

## 3.3 Scoring and Neuron Selection

From the given methods and framework, we adopted them to our malware detection task. We calculate the Example Score by summing the conductance on all 3 questions:

$$\text{ES}_{e_j} = \sum_{t=1}^{3} \text{Cond}(w, p_t^{(j)})$$

in which, the $p_t^{(j)}$ is the t-th prompt for the j-th sample. From the Example Scores values, we picked 2 sets of neurons for each sample: *(i)* $G_j$: z neurons with the highest ES; *(ii)* $B_j$: z neurons with the lowest ES. After that, we filter out the ambiguous neurons, i.e., those that are considered a Facilitator in one sample but an Inhibitor in another. Formally, a neuron $(l, i)$, the i-th neuron in the l-th layer, is considered as ambiguous if

$$(l, i) \in \bigcup_j G_j \text{ and } (l, i) \in \bigcup_j B_j$$

Finally, we calculate the aggregated conductance score by aggregating per-example example scores, with the ambiguous neurons masked out.

$$\text{ACE}(w) = \frac{1}{N}\sum_{j=1}^{N} 1[w \in G_j \cup B_j] \cdot 1[w \notin \mathit{Ambiguous}] \cdot ES_{e_j}(w)$$

The final set of neurons is selected: *(i)* $G_T$: top K neurons with the highest ACE score; and *(ii)* $B_T$: top K neurons with the lowest ACE score, K was set to 100.

### 3.4 Causal Intervention

After selecting the good and bad neurons using both methods, we intervened the neurons' values to test whether they were functional and had effects on the models' performance. We evaluated five intervention conditions on each model. Writing $s_G$ and $s_B$ for the multiplicative scales applied to good and bad neurons respectively, there are the following configurations: **Baseline** ($s_G$=$s_B$=1, no modification), **Suppress Good** ($s_G$=0, $s_B$=1), **Suppress Bad** ($s_G$=1, $s_B$=0), **Enhancer** ($s_G$=2, $s_B$=0), and **Degrader** ($s_G$=0, $s_B$=2) [14].

## 4 Experimental Setup

### 4.1 Evaluation Metrics

We evaluate model performance on a held-out balanced test set under five intervention conditions. Let $TP$, $FP$, $TN$, and $FN$ denote true positives, false positives, true negatives, and false negatives, respectively, where the positive class is *malware*, then the metrics are defined as follows.

- **Per-class Precision, Recall, and F1-score.** For each class $c \in \{\text{benign, malware}\}$:

$$\text{Precision}_c = \frac{TP_c}{TP_c + FP_c} \qquad \text{Recall}_c = \frac{TP_c}{TP_c + FN_c} \qquad F1_c = \frac{2 \cdot \text{Precision}_c \cdot \text{Recall}_c}{\text{Precision}_c + \text{Recall}_c}$$

- **Overall Accuracy.** Accuracy and its 95% Wilson confidence interval [17, 22, 27] are:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \qquad \text{CI}_{95} = \frac{\hat{p} + \frac{z^2}{2n} \pm z\sqrt{\frac{\hat{p}(1-\hat{p})}{n} + \frac{z^2}{4n^2}}}{1 + \frac{z^2}{n}}$$

  where $\hat{p}$ is the observed accuracy, $n$ is the test-set size, and $z = 1.96$.
- **McNemar's Test.** To assess whether two intervention conditions produce significantly different error patterns, we apply McNemar's test with Edwards' continuity correction [10, 15] (paired, $\alpha = 0.05$). Let $b$ and $c$ denote the number of samples where condition 1 is correct and condition 2 is wrong, and vice versa. The test statistic is:

$$\chi^2 = \frac{(|b - c| - 1)^2}{b + c}$$

  which is asymptotically distributed as $\chi^2$ with one degree of freedom under the null hypothesis that both conditions have equal error rates.
- **Effectiveness Gap.** To summarize the overall utility of the identified neuron sets in a single scalar, we define the effectiveness gap as: $\Delta = \text{Accuracy}_{\text{Enhancer}} - \text{Accuracy}_{\text{Degrader}}$. A large positive $\Delta$ indicates that the identified neurons are both sufficient to boost correct predictions (Enhancer) and necessary to maintain them (Degrader), providing strong causal evidence for their role in malware detection.

## 4.2 Model Settings

- **Model Configuration and Infrastructure.** All models are loaded in full `bfloat16` precision *without* quantization–a hard requirement, as quantization introduces numerical noise that corrupts the gradient signals needed for both IG and Conductance attribution. Models are deployed with automatic device mapping across available GPUs. `Llama3.1-8-B-Instruct` consists of 8B parameters with 32 layers, while `Mistralv0.3-7B-Instruct` and `Qwen2.5-7B-Instruct` both have 7B parameters, with 32 and 28 layers, respectively.
- **Attribution Hyperparameters.** For IG, the $m = 16$ integration steps are approximated via a right Riemann sum (excluding $\alpha = 0$); since IG patches one layer at a time, the total forward-pass cost per sample is $m \times L$ (e.g., $16 \times 32 = 512$ for 32-layer models). Conductance interpolates input embeddings with the same step budget but runs all layers freely, requiring only $m$ forward-backward passes total - substantially cheaper than per-layer IG. The attribution sample count $|\mathcal{D}_{\text{attrib}}|$ is swept over $\{10, 20, 50, 100, 200\}$ to assess sensitivity; 20 is the default used in all primary results.
- **Prompting and Truncation.** Source code samples are truncated to a maximum of 2,000 characters; samples exceeding this limit receive a `\n...[truncated]` suffix. The truncated code is embedded in a structured binary-choice prompt (Section 3). Model predictions are derived from logit argmax over the space-prefixed token sets {`" A"`, `" B"`}, aggregated via log-sum-exp pooling to handle multiple tokenization variants of each option letter. This strategy is applied identically at both attribution and evaluation time, ensuring that the target function $F$ optimized during attribution matches the criterion used to measure accuracy.
- **Data Split.** The length-matched dataset was partitioned by both class label and line-count bucket, yielding a held out test set of 2,890 samples (1,445 benign, 1,445 malware) that is used exclusively for intervention evaluation and is separated from the 110 samples used for neuron attribution and ACE scoring.

# 5 Results and Discussion

## 5.1 RQ$_1$: *Are the probing mechanisms able to identify the most defensive neurons?*

Causal interventions on the identified neurons produce measurable shifts in accuracy and per-class F1, with effect sizes differing substantially by model and method.

**Table 2** Intervention accuracy and Effectiveness Gap Δ. 95% Wilson CIs are within ±0.019 of every point estimate (tightest, ±0.009, at the near-ceiling rows). "n.s." = not significant at $\alpha = 0.05$; bold $p$-values are significant.

| Model | Method | Base | Sup-G | Sup-B | Enh | Deg | Δ | McNemar |
|---|---|---|---|---|---|---|---|---|
| `Llama3.1-8B-Instruct` | IG | 0.939 | 0.513 | 0.939 | 0.941 | 0.500 | 0.441 | 0.386 n.s. |
| `Llama3.1-8B-Instruct` | NC | 0.939 | 0.901 | 0.932 | 0.941 | 0.500 | 0.441 | 0.359 n.s. |
| `Mistralv0.3-7B-Instruct` | IG | 0.665 | 0.625 | 0.920 | 0.941 | 0.616 | 0.325 | **<0.001** |
| `Mistralv0.3-7B-Instruct` | NC | 0.665 | 0.652 | 0.696 | 0.800 | 0.645 | 0.154 | **<0.001** |
| `Qwen2.5-7B-Instruct` | IG | 0.939 | 0.939 | 0.940 | 0.941 | 0.832 | 0.109 | 0.181 n.s. |
| `Qwen2.5-7B-Instruct` | NC | 0.939 | 0.941 | 0.939 | 0.939 | 0.932 | 0.007 | 0.617 n.s. |

▷ **Intervention effects on accuracy.** Effect sizes varied across models, i.e., the high-baseline models `Llama3.1-8B-Instruct` and `Qwen2.5-7B-Instruct` (93.9%) show little response to corrective interventions (Suppress Bad, Enhancer), whereas `Mistralv0.3-7B-Instruct`

improves from 66.5% to 94.1% under the IG Enhancer. IG Suppress Bad alone raises it to 92.0%, suggesting that these inhibitory neurons drive `Mistralv0.3-7B-Instruct`'s low baseline. NC shows the same direction but weaker, with its Enhancer reaching only 80%.

Under destructive interventions (Suppress Good, Degrader), `Llama3.1-8B-Instruct` and `Qwen2.5-7B-Instruct` diverge: the former collapses to 50.0% under the Degrader (both methods) and 51.3% under IG Suppress Good, proving its identified neurons are causally necessary. The latter resists with only the IG Degrader has a mild effect (83.2%). `Mistralv0.3-7B-Instruct` degrades slightly, bounded by its already-low baseline.

IG and NC agreed on direction but not on magnitude: identical on `Llama3.1-8-B-Instruct`'s Degrader ($\Delta = 0.441$ for both) but divergent sharply on Suppress Good (IG: 51.3% and NC: 90.1%). The effectiveness gap $\Delta_{IG}/\Delta_{NC}$ is roughly 2 times on `Mistral-v0.3-7B-Instruct` (0.325 vs 0.154) and over 10 times on `Qwen2.5-7B-Instruct` (0.109 vs 0.007). IG produces a gap of equal size or larger in every row of the table.

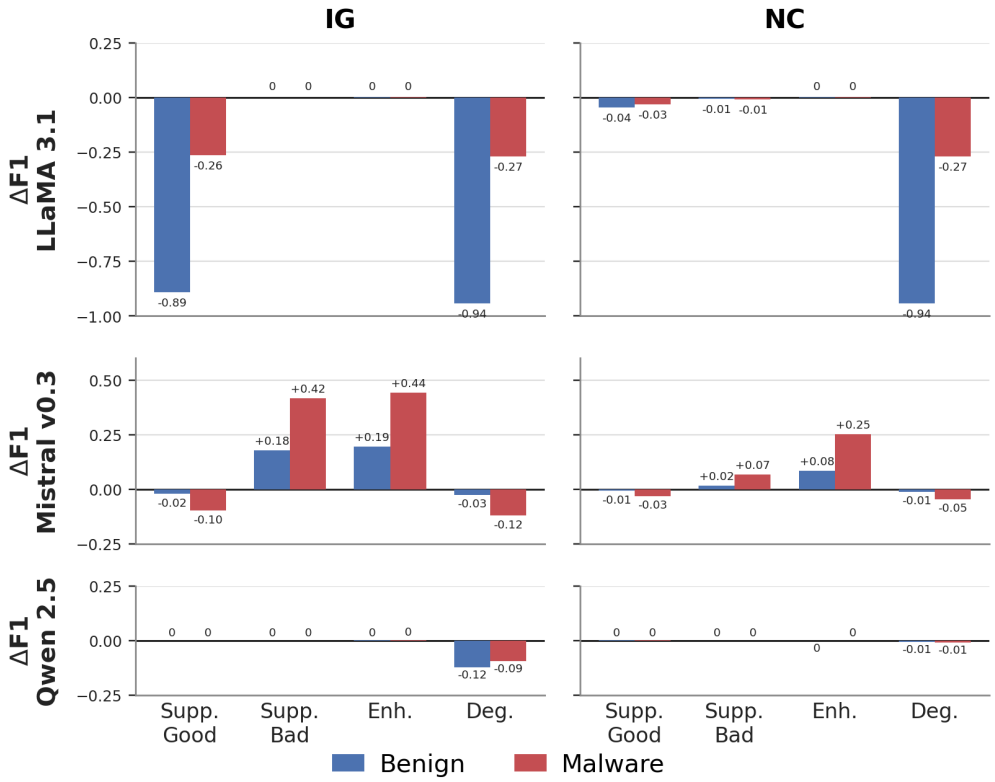

**Figure 2** Per-class ΔF1 relative to baseline for each combination. Blue bars = benign class; red bars = malware class. Positive values = improvement; negative values = degradation.

▷ **Intervention effects on Per-class F1.** As shown in Fig. 2, the models behave differently to the interventions. Those with strong initial baselines, such as `Llama3.1-8B-Instruct` and `Qwen2.5-7B-Instruct`, respond minimally to Suppress Bad and Enhancer, both yield $\Delta F1 \approx 0$. `Mistralv0.3-7B-Instruct`, whose baseline was asymmetric (benign 0.99, malware recall 0.33), responds more clearly: IG Suppress Bad and the Enhancer raise malware recall to 0.84–0.89 while holding benign recall at 0.99.

The destructive interventions, such as Suppress Good and Degrader, separate `Llama3.1-8B-Instruct` and `Qwen2.5-7B-Instruct`, both of which were low responders to the corrective interventions. `Llama3.1-8B-Instruct` collapses under both IG and NC Degrader ($\Delta F1_{benign} = -0.94$, $\Delta F1_{malware} = -0.27$) and IG Suppress Good ($\Delta F1_{benign} = -0.89$, $\Delta F1_{malware} = -0.26$), whereas `Qwen2.5-7B-Instruct` stays stable with only slight degradation under IG Degrader. `Mistralv0.3-7B-Instruct` also degrades slightly with its $\Delta F1_{benign} = -0.03$, $\Delta F1_{malware} = -0.12$ under the IG Degrader. NC showed less visible effects than IG overall: dramatic only on `Llama3.1-8B-Instruct`'s Degrader, and weaker across other models and intervention types.

**Answer to $RQ_1$.** Both IG and NC identify neurons that causally encode malware-detection behavior, though effect sizes are strongly model-dependent. `Mistralv0.3-7B-Instruct` suppresses inhibiting neurons alone increases the accuracy. For `Llama3.1-8B-Instruct` and `Qwen2.5-7B-Instruct`, the Enhancer yields negligible gains, yet the Degrader collapses `Llama3.1-8B-Instruct` to 50.0%. Meanwhile, `Qwen2.5-7B-Instruct` is relatively robust and stable to these intervention effects. Overall, IG achieves larger or equal effectiveness gaps compared to NC.

## 5.2 $RQ_2$: *How are the defensive neurons distributed across the layers and how stable is their selection across runs?*

We investigate where in the network these neurons reside and whether attribution consistently points to the same regions across different data subsets.

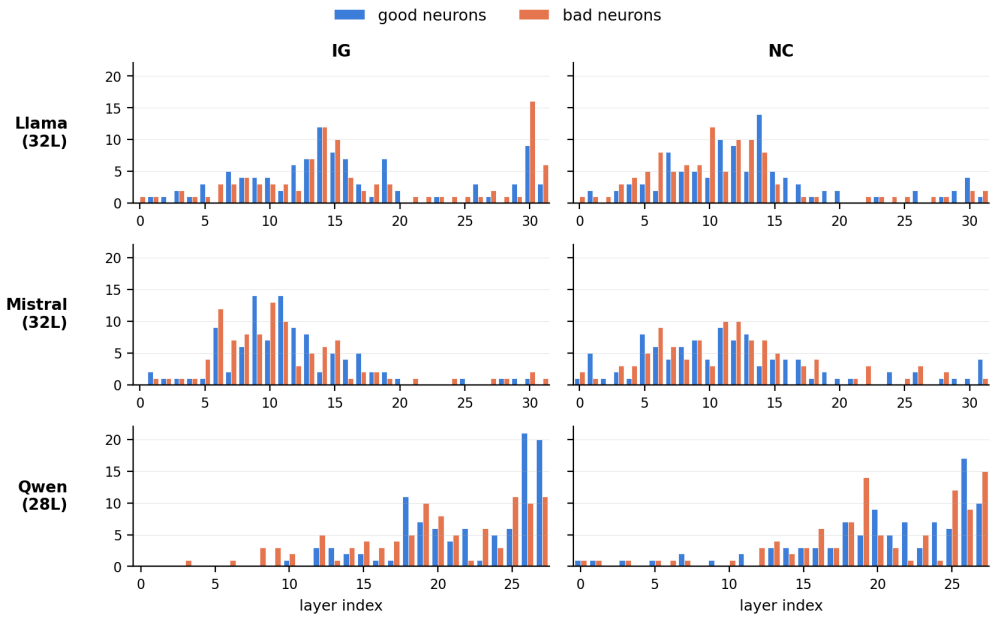

**Figure 3** Per-layer distribution of top-100 good (blue) and bad (orange) neurons.

▷ **Distribution.** The results are shown in Fig. 3. `Llama3.1-8B-Instruct` (32 layers): Both IG and NC place the primary concentration in the middle layers. Under IG, good neurons peak in Layer 13, and bad neurons peak in Layers 14-15, with an additional spike in Layer 30. NC shows a similar mid-layer peak at Layer 14 with good and bad neurons co-located throughout Layers 6-18, plus a modest late spike at Layer 30.

`Mistralv0.3-7B-Instruct` (32 layers): The concentration is the tightest among all three models. Both IG and Conductance place good and bad neurons almost exclusively in layers 5-14, with IG peaking at layer 10 and Conductance still within the same band. After layer 15, both methods select almost no neurons, and the IG and Conductance distributions are most similar across all three models.

`Qwen2.5-7B-Instruct` (28 layers): The dominant signal is in the late layers. Using IG, the distribution shows a secondary cluster around layer 12, followed by a sharp spike at layers 25-26, peaking at layer 26, the highest single-layer count across all models. Under NC, the signal is more spread across layers 10-27, with the same peak at layer 26 but less abrupt than IG. The first ten layers carry almost no signal under either method.

Each model exhibits a clear preferred layer region: middle layers for `Llama3.1-8-B-Instruct` and `Mistralv0.3-7B-Instruct`, late layers for `Qwen2.5-7B-Instruct`. *A consistent pattern across all three models is that good and bad neurons co-localize in the same layer bands rather than being separated into different regions of the network.*

▷ **Stability.** We test whether the neuron selection is consistent by repeating attribution five times on different random subsets of the data (K = 100 neurons per run, seeds 0-4). We compute two complementary similarities over the 10 pairs of runs: Jaccard similarity of the selected neuron sets, capturing whether the same individual neurons are picked; and cosine similarity of the per-layer neuron-count histograms.

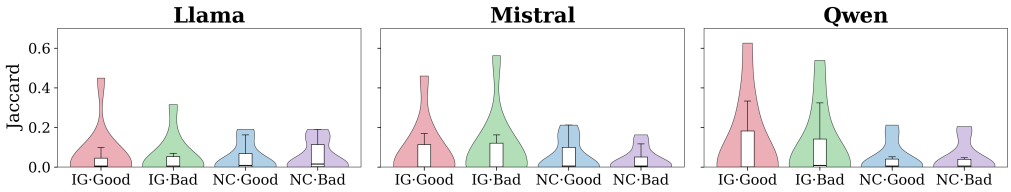

**Figure 4** Pairwise Jaccard similarity of the top-100 neuron sets across 5 stability runs.

As shown in Fig. 4, Jaccard values are low across all models and methods (all medians below 0.20), showing that the specific neurons identified do not reliably repeat across attribution subsets. `Llama3.1-8B-Instruct` IG is the least consistent (medians ≈0.03-0.04 for both classes, upper tails to ≈0.45), with NC slightly more stable (≈0.10). `Mistral-v0.3-7B-Instruct` IG has higher medians (≈0.10 good, ≈0.12 bad) and a wide upper tail for bad neurons (≈0.57). `Qwen2.5-7B-Instruct` IG-Good has the highest median of all conditions (≈0.17, tail to 0.62), reflecting the sharp single-layer concentration in Fig. 3, whereas `Qwen2.5-7B-Instruct` NC collapses to near-zero (≈0.03).

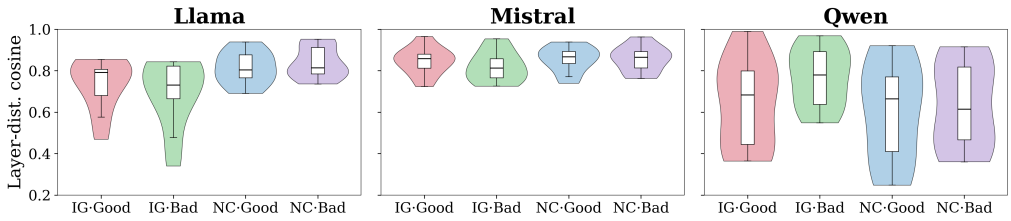

**Figure 5** Pairwise cosine similarity of the per-layer neuron-count histograms across the same 5 runs. Medians span between 0.6 and 0.9, an order of magnitude above the corresponding Jaccards.

As shown in Fig. 5, despite low Jaccard values, the layer-level shape of the selection is substantially more stable: cosine values across all conditions range from 0.61 to 0.86, an order of magnitude above the corresponding Jaccard. `Mistralv0.3-7B-Instruct` is the most stable at the layer level. All four conditions (IG/NC × Good/Bad) have medians of 0.82-0.86 with narrow IQRs (≈0.78-0.90), so the early-to-middle band (layers 5-14) is consistently identified regardless of which neurons within it are selected. `Llama3.1-8-B-Instruct` is intermediate, with NC more stable than IG: NC-Good ($0.813 \pm 0.076$) and NC-Bad ($0.840 \pm 0.073$) are tighter than IG-Good ($0.732 \pm 0.120$) and IG-Bad ($0.694 \pm 0.159$). IG-Bad shows the widest spread (outliers to ≈0.45) because the late layer-30 spike is not always selected. `Qwen2.5-7B-Instruct` is the least stable, having the widest IQRs of all three models (especially NC-Good, $0.606 \pm 0.231$, run pairs ranging cosine ≈0.4-0.8): IG concentrates sharply at layers 25-26 while NC spreads across the final third.

**Answer to $RQ_2$.** Each model concentrates its malware-detection signal in a unique layer band: middle layers for `Llama3.1-8B-Instruct` and `Mistralv0.3-7B-Instruct`, late layers for `Qwen2.5-7B-Instruct`. The selected neurons are not stable across runs. However, stability resides at the layer level. `Llama3.1-8B-Instruct` and `Mistralv0.3-7B-Instruct`, which exhibit this layer stability behavior, also respond most clearly to causal intervention effects in RQ1, whereas `Qwen2.5-7B-Instruct`, whose layer distribution is the most dispersed, responds the least, a co-occurrence suggesting that stable layer-level localization may be a prerequisite for effective causal interventions.

## 5.3 Discussion

- **Implications.** By probing the neurons associated with security-relevant knowledge, we can gain deeper insights into how LLMs internally encode malicious programming concepts and insecure coding patterns. Such understanding enables the identification of potentially harmful memorized behaviors and paves the way toward more reliable defense mechanisms, including neuron-level editing, selective machine unlearning, and security-aware alignment for code-focused LLMs. Moreover, this line of research opens opportunities for fine-grained security interventions at the neuron and layer levels, such as targeted suppression of harmful behaviors, activation steering, and layer-specific hardening strategies. For instance, understanding which layers are more strongly associated with malicious code recognition may help explain why certain adversarial attacks succeed, e.g., by bypassing safety-relevant intermediate representations, and may inspire the integration of dedicated safety adapters.

- **Limitations.** Due to limited computational resources, we were able to conduct experiments with relatively small LLMs, i.e., less than 8B parameters. Being a NIER contribution, *the primary objective of our work is to introduce and demonstrate the feasibility of a novel probing-based approach for understanding malicious code detection in LLMs, rather than to provide a large-scale or exhaustive evaluation.* Essentially, since the proposed probing methodology does not require expensive retraining or architecture modifications, it can be scaled to larger and more capable code-generation models with a lot more layers in a relatively lightweight and model-agnostic manner. We believe that the encouraging preliminary results motivate further investigation and broader empirical validation in future work.

## 5.4 Threats to Validity

- **Internal Validity.** Attribution identifies a layer-level signal that is stable across seeds, but the specific neurons selected are not: pairwise Jaccard similarity remains below 0.20 (Fig. 4). Our conclusions, therefore, hold at the granularity of layer bands rather than at the level of individual neurons. Attribution hyperparameters ($m$=16, $K$=100, $|\mathcal{D}_{\text{attrib}}|$=20) are also fixed. Hence, a sensitivity analysis is left to future work.
- **External Validity.** Our findings are derived exclusively from three 7-8B LLMs and Python/PyPI packages, focusing on install-time and import-time payloads. They may not transfer to larger or differently aligned models, to other ecosystems (e.g., npm, Maven) or attack vectors (e.g., typosquatting), or to malware more recent than the PyPI Malregistry [12].

# 6 Conclusion and Future Work

This paper proposes a practical approach to locate the FFN neurons responsible for distinguishing malicious from benign code inside three instruction-tuned LLMs, i.e., `Llama3.1-8-B-Instruct`, `Mistralv0.3-7B-Instruct`, `Qwen2.5-7B-Instruct`. Using two attribution methods, we attributed the detection behavior to a specific set of neurons and verified the attribution using causal interventions. Furthermore, we found that each model concentrates its signal in a distinct layer band, and that neuron localization is stable at the layer level rather than at the individual neuron level. This work provides a foundation for LLM safety behavior in recognizing malicious code, offers open avenues for early-exit safety checks, and enables targeted model editing. For future work, we plan to bridge code recognition and generative refusal, disentangle surface-level cues from semantic intent, and extend the analysis to larger models and other software ecosystems.

## Data Availability Statement

The replication package of our work is available in a public repository [7]. It includes the source code, data, and instructions in the form of a detailed README.MD file for reproducing the results obtained in this paper.

# Prompts Blend Requirements and Solutions: From Intent to Implementation

## Abstract

AI coding assistants are fundamentally reshaping software development by shifting developers' effort from writing code toward specifying intent through natural language prompts. In emerging chat-based development practices such as *vibe coding*, prompts mediate the transformation of human intent into executable software. While Requirements Engineering (RE) emphasizes capturing, validating, and evolving requirements, current prompting practices remain informal and ad hoc. In this vision paper, we argue that prompts represent lightweight, evolving requirements artifacts that combine expressions of user needs with varying degrees of solution guidance. We use an existing conceptual model that decomposes prompts into three interrelated dimensions: *Functionality and Quality* (capturing intended system requirements), *General Solutions* (capturing architectural strategies and technology choices), and *Specific Solutions* (capturing implementation-level constraints and directives). Building on this conceptualization, we formulate four research hypotheses concerning (i) the evolution of prompts over time, (ii) the influence of user characteristics on prompt evolution, (iii) the relationship between prompt content and requirements validation and verification activities, and (iv) the impact of prompt characteristics on requirements and resulting software quality. We envision an empirical research agenda combining real-world AI-assisted development data, corpus analysis, and controlled experimentation to investigate these hypotheses and derive evidence-based practices for requirements-aware prompt engineering. By reframing prompts through the lens of RE, we position prompting not merely as an interaction mechanism with AI systems, but as a central software engineering concern requiring systematic study.

## 1 Introduction

Software engineering has been reshaped by AI-assisted chat-based coding systems. Tools like GitHub Copilot[1], Tabnine[2], and Codex[3] enable developers to describe desired functionality, constraints, or behavior in natural language rather than writing code; the AI the responds with implementations, design suggestions, or complete components. The quality of these prompts – their clarity, completeness, and structure – often determines whether the resulting code meets expectations. Consequently, prompt engineering and requirements engineering now overlap more than in traditional workflows: developers must think both about *what* must be built (requirements) and *how* to communicate it to the model (prompt). In emerging paradigms like vibe coding [23] and agentic coding [35, 25], natural language prompts become the primary artifact bridging human intent and executable software. Unlike traditional workflows that maintain clear divisions between requirements, design, and implementation, chat-based development collapses these boundaries: a single prompt encapsulates requirements, architectural strategy, and implementation constraints simultaneously.

Yet prompts remain informal, ephemeral, and ad hoc. They lack the rigor traditionally associated with Requirements Engineering (RE). We argue that prompts should be understood as lightweight, evolving requirement artifacts that blend requirements with solution guidance, and that systematic prompt engineering represents a new frontier for RE in the age of generative AI.

This paper builds on the existing prompt triangle [6] as an emerging result, a conceptual model decomposing prompts into three interrelated dimensions: (1) Functionality and Quality (the requirement), (2) General Solutions (architectural strategy and technology choices), and (3) Specific Solutions (implementation-level constraints). We validate this model using the DevGPT dataset [37], position it relative to existing prompt patterns and RE validation techniques, and formulate four testable hypotheses about prompt evolution, user characteristics, requirements verification in iterative prompting, and the relationship between prompt refinement and code quality. Our vision is to establish empirically-informed best practices for requirements-aware prompt engineering, rejuvenating RE for AI-assisted development.

## 2 Chat-based Coding Assistants

AI coding assistants operate in two distinct modes that shape developer interaction fundamentally differently. *Code completion interfaces* work within existing code structures, assisting with boilerplate, method bodies, and idiomatic patterns where developers provide the architectural skeleton. *Chat-based interfaces* enable developers to describe functionality, constraints, and solution strategies in natural language, potentially revamping entire codebases from a single prompt. There is a rapidly growing body of literature on AI coding assistants, with new papers posted to arXiv and other repositories without peer review daily. The peer-reviewed sources are still few and far between and often make no distinctions between chat-based interfaces to the AI and code completions. However, it is crucial to make this distinction since they differ significantly in terms of user experience: while code completion interfaces work within existing code and help the developer implement certain

[1] https://azure.microsoft.com/en-us/products/github/copilot
[2] https://www.tabnine.com/?utm_source=chatgpt.com
[3] https://openai.com/codex/?utm_source=chatgpt.com

boilerplate code, smaller features, or tests, chat interfaces have a much bigger scope and give the developer the chance to revamp entire code bases with a single prompt. We are interested in the former setting. Sergeyuk et al. [29], for instance, conducted a study with 481 respondents in which they asked about tasks such as "Implementing new features", "Writing tests", or "Bug triaging". Depending on whether a code completion interface or a chat interface is used, the user experience will be quite different. For a code completion interface, the developer will create a structure for the feature with functions etc. that might have small pieces of documentation that describes the desired functionality. For a chat interface, the developer might write a single prompt and include elements of the requirements and the solution approach as we argue above. This distinction is methodologically critical [2, 32, 29]: code completion preserves traditional incremental programming, while chat-based prompting externalizes problem-solving into conversational exchanges where a single prompt conflates requirements specification, design rationale, validation-verification criteria, and implementation intent.These are a methodically and cognivitely distinct approaches that should not be treated the same when asking developers how much they "enjoy" these activities. Conflating the two modes risks masking key differences in cognitive effort, developer mental models, and the role of requirements [36]. This paper focuses on **chat-based interfaces** and their implications for requirements engineering.

## 3 Prompts and Requirements

Prompt engineering refers to the practice of carefully crafting and refining prompts to guide large language models (LLMs) toward producing desired outputs [24, 8]. In the context of software development, prompt engineering is increasingly seen as a crucial skill for effectively leveraging chat-based coding assistants. However, while prompts may contain elements of system requirements or design intent, they are often ad hoc and lack the structure of formal requirements [2]. Many developers struggle to provide the right level of detail and to translate requirements into prompts consistently [33]. This raises an important question for RE: **How can the rigor of RE be infused into prompting practices?** Viewing prompts as lightweight but evolving requirement artifacts offers a way to bridge the gap between informal developer intentions and structured requirements specification [34]. Such an integration will enhance the reliability of AI-generated solutions and redefine RE practices in the era of AI-assisted chat-based development.

### 3.1 A Conceptual Model of Prompts

Recent work has begun to examine the role of prompts in software development and RE [27, 14]. However, understanding prompts as artifacts within AI-assisted development remains an open challenge. This is particularly relevant in emerging practices such as *vibe coding*, where software is iteratively developed through conversational interactions with AI [20], and *agentic coding*, where autonomous AI agents reason about and execute development tasks, guided by the developer and a large language model (LLM). In such settings, prompts become the primary medium through which developer intent is communicated and translated into executable systems. Consequently, prompts increasingly occupy a role that extends beyond simple instructions and intersects with core concerns of RE, such as requirements elicitation, specification, and evolution.

To better understand this role, we draw on an existing conceptual model that decomposes prompts into three interrelated components. The *Prompt Triangle* (Figure 1) provides a practical and conceptual lens for structuring prompts and assessing their completeness from an RE perspective. We posit that most prompts used in chat-based coding contain these three dimensions implicitly.

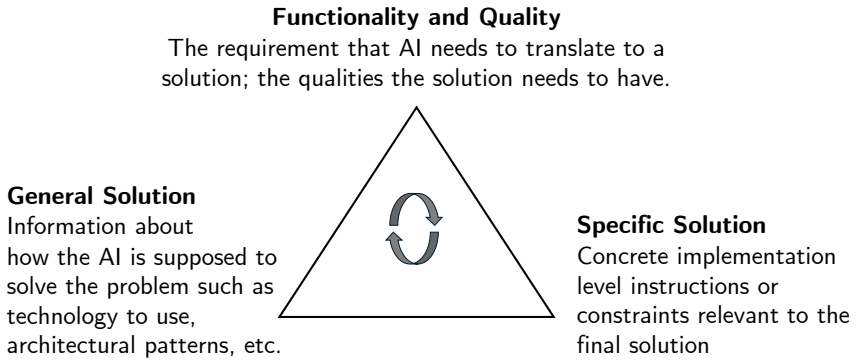

**Figure 1** Prompt Triangle: prompts consist of three interrelated dimensions: Functionality and Quality, General Solutions, and Specific Solutions. The circular relationship indicates iterative refinement across development interactions.

The *Prompt Triangle* consists of three interrelated dimensions. *Functionality and Quality* captures intended system behavior and desired quality characteristics, i.e., what the system should do and how well it should perform, encompassing both functional requirements and quality requirements such as performance, security, accessibility, reliability, and usability. *General Solutions* capture higher-level guidance on how functionality should be realized, including architectural decisions, preferred technologies, design paradigms, and development strategies. *Specific Solutions* represent detailed implementation instructions and constraints that further narrow the solution space and guide concrete realization. Embedding quality attributes directly within the functionality description ensures that prompts capture not only *what* a system should achieve, but also *how well* it should achieve it. Whenever possible, these requirements should be expressed in a measurable way, while guidance on realization mechanisms remains within the General and Specific Solutions dimensions. Co-locating quality requirements with functionality stabilizes developer intent and creates a clearer foundation for validation and verification activities.

Unlike traditional requirements artifacts, which often separate requirements from implementation concerns, prompts frequently blend these dimensions within a single interaction. During iterative development, prompts evolve by expressing intent, refining solution strategies, and constraining implementation details. The circular relationship within the Prompt Triangle represents this continuous refinement process, where movement across components occurs as developers and AI systems progressively converge toward a desired solution.

As an **illustrative example** of the Prompt Triangle, consider the following prompt:

Build a React web app that shows the current weather for a given city, and make it fast, reliable, safe, and accessible. Use server-side rendering; fetch data from OpenWeather. Style the page cleanly and show city, condition, humidity, wind, and Celsius temperature with an icon. It should load quickly on a typical phone, show a loading state, retry if the network fails, and display clear errors. Keep the API key on the server, avoid logging personal details, and ensure people can use the app with a keyboard and screen readers with readable colors.

Although the prompt appears as a single instruction, it combines multiple concerns that can be mapped to the dimensions of the Prompt Triangle. *Functionality and Quality* includes the requirement to build a weather application, together with quality characteristics such as performance, reliability, security, and accessibility (e.g., fast loading, robust error handling, privacy-preserving logging, and support for keyboard and screen-reader interactions). *General Solutions* guide broader implementation decisions, including the use of React, server-

side rendering, and integration with the OpenWeather API. Finally, *Specific Solutions* further constrain implementation through concrete design choices such as displaying weather attributes (city, humidity, wind, temperature, icons), applying a clean visual style, and ensuring that API keys remain securely stored on the server.

We believe that this triangular model provides a lens through which we can examine prompts not just as one-off commands, but as **evolving artifacts of requirements expression, negotiation, and realization** which capture the main intentions of the developer [17]. As prompts are iteratively refined, attention may oscillate between specifying what is needed (Functionality and Quality), how it should be approached (General Solutions), and how exactly it should be executed (Specific Solutions). The developer thus incrementally reshapes the solution space. In this sense, even prompts focused on implementation remain grounded in a shifting understanding of *Functionality and Quality*.

**Model Validation.** Before devising an empirical research agenda around this model, we conducted an initial assessment of its applicability using a diverse set of prompt examples drawn from sources on the web and from the DevGPT dataset [37]. Selected examples are presented in Table 2. In addition, we analyzed a sample of 359 prompts extracted from DevGPT (~2% of the prompts in DevGPT) and examined the extent to which prompt content could be mapped to the dimensions of the Prompt Triangle.

To obtain the sample, we randomly extracted initial prompts from conversations contained in `20230803_095317_commit_sharings.json` and `20231012_233628_pr_sharings.json`. We focused exclusively on initial prompts, as the objective at this stage was not to investigate prompt evolution during interactions, but rather to assess whether the Prompt Triangle dimensions are observable in standalone prompt formulations. Prompt content was categorized using Claude Sonnet 4.6 and subsequently reviewed manually to verify consistency. All prompts and analysis artifacts are available in the replication package [5].

Our analysis shown in Table 1 demonstrates a strong tendency toward structured, multi-component prompts. Requirements (i.e., *Functionality and Quality*) appeared in 80.8% of prompts, establishing them as the foundational element of prompt construction. The predominant pattern ($n = 247$, 68.8%) incorporated all three components, indicating that users frequently provide comprehensive specifications of the solution. *General Solutions* (79.7%) are more commonly included than *Specific Solutions* (69.4%), suggesting that users prefer constraining the solution while preserving implementation flexibility. Co-occurrence analysis shows that requirements with at least one solution component accounted for all but two prompts. This asymmetry supports a way of thinking where specifying intent precedes the prescription of a solution. The secondary pattern of requirement-plus-general-solution prompts ($n = 39$, 10.9%) further supports a two-stage refinement process from "what" to "how" that may optionally extend to specific implementation details. Around 20% of prompts were not applicable as they did not relate to coding (e.g., "translate to Spanish").

## 3.2 Prompting as a Tool for Requirements Validation and Verification

Requirements Engineering traditionally distinguishes between *validation* (ensuring we are building the right thing) and *verification* (ensuring we are building it right). In the context of AI-assisted chat-based development, structured prompts offer a novel mechanism to support both activities. By explicitly articulating *Functionality and Quality*, *General Solutions*, and *Specific Solutions*, prompts act as evolving artifacts of stakeholder intent and technical interpretation. Requirement *validation* occurs as the functionality component is refined in light of feedback and gradually reconciled with specific solutions, ultimately aligning the

**Table 1** Prompt Component Analysis (N=359).

| **(%)** | **(80.8)** | **(79.7)** | **(69.4)** | | | |

prompt with stakeholder needs. Meanwhile, requirement *verification* is observable in the iterative interactions and adjustments between the three prompt components, which mirror the ongoing process of checking that the system is being built correctly. Thus, prompts not only guide the AI in code generation, they serve as dynamic roadmaps for both validating what should be built and verifying how it is implemented.

This bears similarities to classical requirement validation and verification techniques. Atoum et al.'s recent systematic review [1] categorizes these into six approaches. Our method resembles prototyping, inspection, and testing-oriented techniques.

In terms of validation by *inspection*, the *Functionality and Quality* part of the Prompt Triangle serves a similar role to traditional requirements documents subjected to inspection. However, there are two distinctions: First of all, rather than discrete review meetings, the approach enables continuous, AI-mediated inspection through the iterative refinement between *Functionality and Quality* and *Specific Solutions*. The AI acts as an automated consistency analyzer that surfaces conflicts when it cannot reconcile high-level intent with implementation details, though the effectiveness of this detection depends on the AI's interpretive capabilities and how explicit the formulation in the prompt is. Second of all, we expect the *Functionality and Quality* part of a prompt to be much more limited than a requirements document. An important part of inspections is the relationships between requirements [21]. We do not expect such relationships to become visible in individual prompts, but potentially as part of longer conversations.

*Prototyping* as a requirement validation technique was introduced by Boehm in 1984 [3]. In prototyping, working models of the software are created to validate that requirements meet stakeholder needs. One of the strengths of the Prompt Triangle is that it separates the solution components from the *Functionality and Quality* parts, thus enabling rapid iteration between *Functionality and Quality* and multiple solution formulations. Unlike traditional prototyping, which requires substantial development effort to explore alternative designs, the Prompt Triangle allows developers to experiment with different approaches in the *General Solutions* and *Specific Solutions* components while holding Functionality constant, generating executable prototypes within seconds rather than days [4]. When the AI fails to generate satisfactory code when a *Specific Solution* is provided, this failure signals either requirement ambiguity or an incorrect solution approach. Notably, this mechanism also works in reverse: when the AI successfully generates code that nonetheless fails to meet stakeholder needs upon review, this reveals gaps in the *Functionality and Quality* rather than implementation errors – a form of validation through executable prototyping.

**Table 2** Example prompts with classification of the information contained in them to the components of the prompt triangle. More examples can be found in the supplementary material [5].

| Prompt | Functionality and Quality | General Solutions | Specific Solutions |
|---|---|---|---|
| Write a Python implementation of merge sort optimized for memory efficiency with time complexity analysis and error handling for edge cases including empty arrays.[1)] | Sort input values; Provide time complexity analysis; Handle error/edge cases; Optimized for memory efficiency | Use merge sort algorithm; Implement in Python | |
| Create a TypeScript function that validates email addresses with the following requirements: Must be RFC 5322 compliant Rejects disposable email domains Returns detailed error messages. Example of expected function signature and usage: function validateEmail(email: string): { isValid: boolean; message: string }[1)] | Validate input; RFC 5322 compliance; Reject disposable email domains; Return detailed error messages | Use TypeScript | validateEmail(email: string) |
| I want to enable custom, unobtrusive update notifications and installs by customizing SPUUserDriver. Let's start by planning the custom UI we'll need. We'll ONLY work on UI. Create a plan for creating SwiftUI views that can show the various states that are required by SPUUserDriver. I think the best place for these to show up is in the macOS window titlebars on the top-right. Create a plan to put it there. Consult the oracle.[2)] | Enable custom update notifications; Only UI work | | Put UI in macOS window titlebars; Use SwiftUI views |
| Generate a Python function using pandas to: Read a CSV file. Drop null values. Convert a date column to datetime format. Group data by category and calculate average values.[3)] | Read CSV file; Drop null values; Convert date column; Group data by category; Calculate average values | Use pandas library; Implement in Python | Read with pandas.read_csv |
| Write a FastAPI endpoint that: Accepts a POST request with JSON data ({name: str, age: int}). Validates the input. Returns a success message with the received data.[3)] | Validate input; Return success message | Use FastAPI framework; Implement in Python | Define a POST endpoint; Accept JSON with {name: str, age: int} |
| Create a Python script using BeautifulSoup to: Fetch HTML from 'example.com/news'. Extract all headlines (h2 tags). Export results to a JSON file.[3)] | Fetch HTML; Extract data from HTML; Export results to JSON | Use BeautifulSoup library; Implement in Python | Extract all <h2> tags |

1) `https://margabagus.com/prompt-engineering-code-generation-practices/`
2) `https://mitchellh.com/writing/non-trivial-vibing`
3) `https://zencoder.ai/blog/vibe-coding-prompts`

In verification via *testing-oriented approaches*, prompts inherently produce testable artifacts. By maintaining explicit traceability between *Functionality and Quality* (what to test) and *Specific Solutions* (how it is implemented) within the same artifact, the Prompt Triangle enables test generation that simultaneously validates stakeholder intent and verifies implementation correctness. However, the quality of generated tests depends critically on whether the AI grasps the essential test scenarios implied by *Functionality and Quality* and the edge cases introduced by the *Specific Solutions*. This dual focus is difficult to achieve when requirements and code exist as separate artifacts. In many cases, developers instruct AIs to generate test cases for each new functionality automatically. Research on automated test case generation with LLMs is just emerging (see, e.g., [28]), but combining requirement and solution approaches in a prompt can help guide the generation towards more targeted tests of the technical solution.

## 3.3 Prompt Patterns and Prompt Iterations

Recent studies analyze prompt patterns, but none treat prompts as blends of requirements and solutions. DiCuffa et al. [11] identify seven patterns, such as *persona* ("you are", "pretend to be") or *recipe* ("step-by-step", "guide"), focusing on structural conventions rather than semantic content. Siddiq et al. [30] investigate quality issues with developer prompts, finding they often suffer from ambiguity and insufficient context for producing high-quality output. While these anti-patterns are complementary to our findings, we believe the Prompt Triangle can alleviate some of the issues Siddiq et al. identified by making the prompt components explicit and providing a way to reason about their balance. Della Porta et al. [10] analyze how prompt patterns affect code quality across three dimensions: meta-prompting (zero-shot and few-shot), chain-of-thought, and personas. They find no statistically significant differences between combinations, but like others, do not examine prompt content systematically. Huang et al. [14] specifically address prompt engineering for requirements engineering, exploring techniques including multimodal prompting (e.g., UI mockups) and self-reflection prompts where LLMs provide confidence values. They propose using generated code to validate requirements, yet do not distinguish between requirement and solution elements within prompts themselves. Beyond individual prompts, Robino [26] proposes "conversation routines" to structure extended human-LLM dialogues through system prompts, applicable to software development contexts. Our prompt triangle provides the first systematic model decomposing prompts into requirement (Functionality and Quality) and solution (General, Specific) dimensions, enabling analysis of how these elements evolve through iterative refinement and therefore significantly goes beyond the state of the art in terms of analytical powers and the ability to craft high-quality prompts.

# 4 Hypotheses

The Prompt Triangle decomposes prompts into three complementary dimensions that characterize the information developers communicate when interacting with AI coding assistants: *Functionality and Quality*, *General Solutions*, and *Specific Solutions*. While this decomposition helps explain *what* information is present in prompts, understanding prompts as requirements artifacts also requires explaining *how* these components are used throughout the development process.

As discussed in the previous sections, prompts increasingly resemble evolving software artifacts that support activities traditionally associated with Requirements Engineering (RE). Following established RE practice [22], we distinguish between three fundamental activities:

*validation*, concerned with ensuring that the right system is being built; *verification*, concerned with ensuring that the system is built correctly; and *solution generation*, concerned with exploring and realizing implementation alternatives. While the Prompt Triangle captures the semantic structure of prompt content, these RE activities characterize the role such content plays during development interactions.

Reflecting on the relationships between Prompt Triangle components and RE activities raises several questions concerning how prompts evolve, how developers compose them, and how prompt composition may influence resulting software quality. Based on the conceptual arguments developed throughout this paper and prior observations of iterative AI-assisted development [2, 6], we formulate the following hypotheses:

**H1 (Prompt Evolution)** During iterative AI-assisted development, prompt content gradually shifts from emphasizing **Functionality and Quality** toward increasingly detailed **General Solutions** and **Specific Solutions** information.

**H2 (Developer-specific Prompt Composition)** The composition of Prompt Triangle components differs according to developer characteristics, such as programming experience and domain familiarity. In particular, developers with greater experience are expected to provide proportionally more **Specific Solutions** information.

**H3 (Prompt Components and RE Activities)** Prompt Triangle components are associated with different RE activities. Specifically, **Functionality and Quality** information is expected to occur more frequently during validation-oriented interactions, whereas **Specific Solutions** information is expected to occur more frequently during verification-oriented interactions.

**H4 (Prompt Alignment and Development Outcomes)** AI-assisted development interactions exhibiting stronger alignment between Prompt Triangle components and their corresponding RE activities are expected to produce higher software quality outcomes.

Together, these hypotheses define an empirical research agenda for studying prompts as evolving requirements artifacts. H1 and H2 focus on understanding how prompt composition emerges and changes across interactions and users, whereas H3 and H4 investigate whether these structures influence development processes and software outcomes.

## 5 Discussion

The power of chat-based interfaces is most obvious in vibe coding. Meske et al. [20] define vibe coding as the culmination of a historical process of intent mediation: "the level of abstraction required to implement solutions has evolved from hardware manipulation through conceptual modeling to prompting, shifting the mediation of developer intent from deterministic instruction to probabilistic inference." To guide this inference, "goal-oriented intent expression" via prompts is necessary. Crucially, Meske et al. consider actual implementation details irrelevant. However, in the chat-based coding prompts we have studied, solution details as captured in the Prompt Triangle are almost always present.

This discrepancy suggests either that current practice remains anchored to solution-level control due to developer trust issues or LLM limitations, or that Meske et al.'s vision represents an idealized future state not yet achievable. Our Prompt Triangle embraces this reality by explicitly accommodating solution guidance alongside functional intent, rather than treating solution details as impurities to eliminate. As LLMs mature, we hypothesize the relative weight of Specific Solutions may decrease, but the tripartite structure will remain relevant as developers will always need some architectural control. Our work on H1 and H2 will identify how developers evolve prompts during their work, while H3 and H4 will reveal how requirements and solutions co-evolve and whether this strategy benefits code quality.

Taking this further, OpenAI's Sean Grove proposes that prompts become executable specifications, arguing future programmers will write elaborate specifications that generative AIs turn into complex programs[4]. Counter-arguments exist: executable specifications have long existed [13, 12] but have arguably failed to achieve large-scale adoption, and making specifications fully executable constitutes programming itself. Moreover, unlike formal programming languages, natural language is ambiguous. Jackson considers this ambiguity a strength rather than weakness for natural language reasoning in AI [15]. LLMs arguably realize his vision by connecting natural language to vector space concepts. However, Jackson envisioned reasoning AIs, not code generators: the ability to "understand the world" via natural language does not directly translate to reproducibly creating programs fulfilling user needs. Much requirements engineering work addresses disambiguating unclear requirements [16].

Our work addresses this conflict directly: we study how requirements are captured in prompts with all their ambiguity and how engineers constrain generation by providing solution approaches. We believe prompt requirements must evolve through disambiguation and scaffolding. H1 and H3 will illuminate this process, while H4 will reveal the impact on code quality when validation and disambiguation happen early.

The tool landscape further validates our premise that prompts are not merely transient instructions but increasingly function as software engineering artifacts. For example, Kiro[5] promises to turn "your prompt into clear requirements, system design, and discrete tasks." Here, prompts come first and requirements follow, suggesting that the requirements are already embedded within the prompt alongside implementation guidance, architectural decisions, and domain knowledge. Kiro's value proposition is therefore not creating requirements from scratch, but extracting, structuring, and disambiguating the information that already exists within the prompt. This pattern is not unique to Kiro. Modern AI-assisted development environments such as GitHub Copilot Chat, Claude Code, and OpenCode also preserve conversational context and support reusable prompt artifacts in the form of prompt files, skills, or similar templates. In these systems, prompts are often iteratively refined, versioned, and shared among team members, resembling traditional software artifacts such as design documents or user stories. For instance, developers frequently maintain prompt libraries that encode architectural constraints [19, 18] (e.g., "generate a REST API following hexagonal architecture with Spring Boot"), testing strategies (e.g., "write unit tests using Mockito with clear separation of concerns"), or organizational coding standards. This observation aligns with recent research that explicitly frames prompts as software engineering artifacts and argues that prompt engineering can be informed by requirements engineering principles [33]. In that view, a prompt is not just a query to a model; it is a specification vehicle that captures intent, constraints, quality expectations, and contextual assumptions.

Another compelling argument lies in the role of prompts as boundary objects between stakeholders. In collaborative settings, prompts often encode both user intent and technical constraints, effectively bridging the gap between domain experts and developers [31]. For example, a product manager might articulate a feature through a structured prompt that includes user goals, edge cases, and acceptance criteria, which is then directly consumed by an AI system to generate implementation scaffolding. In this sense, prompts blur the distinction between requirements specification and implementation, collapsing phases of the traditional software lifecycle.

**Table 3** Comparison of data collection methods.

| Method | Data Type | Strengths | Limitations |
|---|---|---|---|
| Controlled Experiments | Structured, curated | Complete metadata, ground truth requirements, comparable tasks | Limited scale, potential observer effects |
| Community Uploads | Real-world, diverse | Authentic usage, varied contexts, scalable | Incomplete metadata, self-selection bias |
| Public Mining | Opportunistic | No recruitment overhead, naturally shared | Sparse, variable quality |

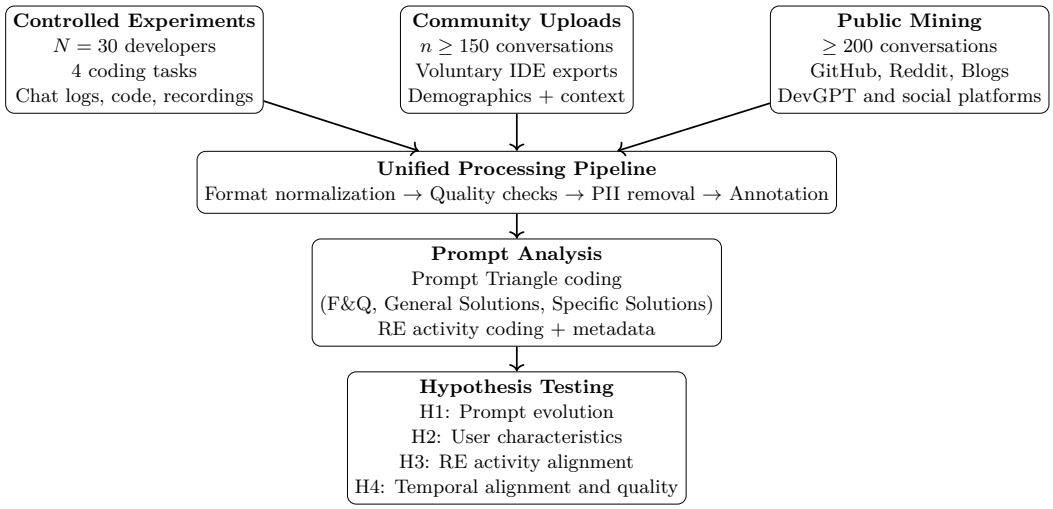

**Figure 2** Overview of the mixed-method study design. Three complementary data sources (controlled experiments, community-sourced uploads, and publicly mined conversations) are integrated through a unified processing and annotation pipeline to investigate the proposed hypotheses.

These observations support a reconceptualization of prompts as structured, information-rich artifacts that encapsulate requirements, design intent, and domain knowledge.

## 6 Plans for Empirical Validation

We intend to employ a *multi-method data collection strategy* to construct a comprehensive corpus of developer–AI interactions. Our approach combines three complementary sources of data: (i) controlled experiments, (ii) community-sourced prompt exports, and (iii) mining of publicly available datasets. Figure 2 shows the complete vision for this study. It is described in more detail in a registered report [7].

Our triangulated design balances internal and ecological validity through three complementary data sources. Following Colnet et al. [9], who review methods for combining randomized trials and observational studies, our controlled experiment ($n = 30$) provides unconfounded causal estimates with full quality measures, while community uploads (target $n \geq 150$) and mined public datasets assess generalizability through observational data. Confirmatory hypothesis testing (H1–H4) is based on controlled experiment data; community uploads serve as co-primary replication data for H2 and supplementary validation for H1 and H3; mined datasets serve an explicitly exploratory role for pattern characterization only. Table 3 summarizes the collection approaches and their contributions to the corpus.

## 7 Conclusion

With chat-based development becoming more common, the role of software developers is starting to change. Instead of spending most of their time writing code line by line, developers are increasingly focused on thinking about how to communicate with AI systems. In many cases, writing a good prompt has become just as important as writing good code. These prompts are no longer simple instructions, they combine high-level requirements, design decisions, implementation hints, and constraints into a single artifact. Because of this, prompts deserve to be treated as first-class software engineering artifacts rather than temporary inputs to an AI tool. The Prompt Triangle provides a structured lens to characterize prompt content, enabling the analysis of prompt composition, evolution, and its relationship to requirements engineering activities and software outcomes. Based on this perspective, we formulate hypotheses on prompt evolution, developer strategies, and software quality. Looking ahead, we see this work as only the beginning. The ideas presented here raise several interesting questions about how developers refine prompts, how prompting strategies change throughout a development task, and how prompt evolution compares to the evolution of traditional software artifacts such as requirements and design documents. Future work will investigate these hypotheses to derive evidence-based practices and tool support for requirements-aware prompt engineering. Ultimately, we hope this will lead to practical guidelines, evidence-based prompting strategies, and tools that help developers create prompts that better capture software requirements and support high-quality AI-assisted development.

## Data Availability Statement

The following materials are available in the supplementary material [5]: (1) a small set of prompts from sources on the web that were manually classified; (2) a set of 359 prompts randomly extracted from the DevGPT dataset and classified by Claude Sonnet 4.6; (3) a set of scripts to extract, classify, and visualize prompts from DevGPT.

## Abstract

Healthcare AI software systems raise ethical concerns that are often discussed as high-level principles but are difficult to translate into concrete software engineering requirements. This emerging-results paper reports preliminary findings from a multi-stakeholder interview study on how practitioners experience and prioritise ethical concerns in healthcare AI software systems. We conducted 17 semi-structured interviews with healthcare professionals (n=5), healthcare researchers (n=6), and software engineers (n=6). Using thematic synthesis, we identified three AI use contexts and four recurring challenge categories: model reliability and quality, data quality and processing, human oversight and skills gaps, and institutional and regulatory constraints. Privacy and safety emerged as baseline concerns across roles, while bias, accountability, and transparency varied depending on practitioners' responsibilities and use contexts. Based on these preliminary findings, we propose role-specific patterns as lightweight requirements artefacts to translate practitioner priorities into actionable software engineering practices across requirements elicitation, system design, testing, and auditing. We present these patterns as an initial artefact for community feedback and as a first step toward a broader approach to ethical requirements engineering (RE) for healthcare AI software systems. Future work will validate and refine the patterns using a larger, more balanced sample, evaluate their usefulness through practitioner workshops, and develop a reusable catalogue with guidance on traceability, verification, and auditing. Long-term, our goal is to support healthcare AI teams in moving from abstract ethical principles to testable requirements that can be integrated into existing development and governance workflows.

## 1 Introduction

Artificial intelligence is increasingly embedded into healthcare software systems, including predictive models, AI-assisted imaging, clinical documentation tools, patient-facing applications, robotic support systems, and newer large language model (LLM)-based applications [17, 19]. In *healthcare AI-based software systems* (henceforth, *HAISS*), the stakes are acute: software

© Yutan Huang, Chetan Arora, Tanjila Kanij, Anuradha Madugalla, and John Grundy;
licensed under Creative Commons License CC-BY 4.0

behaviour is tied to sensitive patient data, clinical decision-making, and organisational accountability. Failures can therefore cause harm rather than prevent it, including poor predictive accuracy, racial or demographic bias, unsafe recommendations, and increased clinician workload [4]. From a requirements engineering (RE) perspective, this turns ethics from a post hoc discussion into a concrete engineering problem: ethical concerns must be elicited, negotiated among stakeholders, specified as verifiable requirements, and checked throughout design, validation, deployment, and audit. Yet in practice, teams often do not treat ethics as requirements; privacy and safety concerns are identified late in development, as incidents or ad-hoc checks, rather than as elicited and verifiable non-functional requirements (NFRs) [22, 18]. Because these concerns arise at handoffs among engineers, clinicians, and researchers, we frame them as a cooperative RE problem. As AI systems become increasingly sophisticated, ethical dilemmas and RE challenges arise. Early work in AI ethics emphasised transparency, fairness, accountability, and privacy [14], prompting numerous ethical guidelines and frameworks [15]. In $HAISS$, AI is integrated into diagnostic imaging, digital health applications used by patients and staff, predictive analytics, and robotic surgery – settings where ethical concerns are acute due to patient sensitivity and direct impact on human lives [12]. Researchers have advocated multi-scale approaches to govern AI ethics in healthcare, operationalised through SE practices that span requirements to deployment [25]. Despite the growing number of ethical guidelines and frameworks, a significant gap remains as they rarely incorporate the perspectives of the software engineers who design and validate $HAISS$, nor those of the healthcare practitioners whose daily use shapes how principles are realised, and they seldom translate high-level principles into concrete SE activities [14, 5, 27]. Real-world, multi-stakeholder evidence is therefore needed to ground ethical principles in practice.

In this paper, we treat ethical priorities as ethical requirements spanning (i) quality requirements (NFRs), (ii) constraints (e.g., data residency, access controls), and (iii) assurance/process requirements (e.g., audits, monitoring, incident response), and we explore how to operationalise them via lightweight If-Then requirement patterns. To do so, we conducted 17 semi-structured interviews with software engineers, healthcare professionals, and healthcare researchers across three countries. Our study is guided by three research questions (RQs): **RQ1.** In what contexts and use cases is AI currently applied in healthcare? **RQ2.** What challenges and limitations do practitioners report when deploying AI in HAISS? **RQ3.** Which ethical considerations of HAISS do practitioners prioritise, and how?

**Contributions.** In this emerging results paper, we provide an initial empirically grounded artefact and make three contributions to industrial SE practice:

1. **Empirical analysis of role-specific AI use.** We characterise how software engineers, healthcare professionals and researchers incorporate AI in practice, and show how these distinct usage patterns imply different requirements, verification, and integration concerns.
2. **Role-specific challenges.** We identify four recurring challenge categories across three roles, and locate where each calls for new requirements, tests, or deployment safeguards.
3. **Ethical priorities → SE artefacts.** We map how practitioners prioritise five ethical dimensions and derive lightweight If-Then patterns that operationalise these priorities into actionable requirements.

**Paper Structure.** Section 2 reviews background on AI in healthcare and ethics. Section 3 describes our research methodology. Section 4 presents the results. Section 5 discusses our findings and implications. Section 6 reports threats to validity. Section 7 concludes with directions for future work.

## 2 Background / Related Work

**Ethics of AI use in Healthcare.** Prior work on healthcare AI ethics has identified recurring principles and risks, but it has also been less often explained how they should be operationalised as concrete SE requirements. Reviews of AI in healthcare highlight concerns around transparency, fairness, bias, privacy, patient safety, and accountability, while also noting that practitioner perspectives are underrepresented in the implementation of ethical principles [24, 13]. Karimian et al. identify key principles such as privacy, fairness, explicability, and human autonomy, but also show that tools and processes for testing and upholding ethical requirements remain under-specified [16]. Li et al. similarly map ethical issues and proposed strategies for healthcare AI, while emphasising the need to translate these strategies into practice in system development [20]. In our prior work, we organised ethical concerns of generative AI around five recurring dimensions: safety, privacy, transparency, bias/fairness, and accountability, and synthesised mitigation strategies including governance frameworks, human oversight, auditability, and privacy-preserving methods [14]. Building on this work, we use these five dimensions to elicit and compare practitioners' ethical priorities.

**Practitioner Perspectives on AI in Healthcare.** Practitioner studies show that healthcare professionals recognise both the opportunities and risks of AI adoption. Prior qualitative work has identified concerns about transparency, equity, accountability, data privacy, and the effect of AI on patient care and professional relationships [9, 23, 2]. These studies provide valuable insight into clinical and nursing perspectives, but the role of software engineers remains less visible. Existing work often treats software engineers as technical implementers rather than stakeholders who shape ethical outcomes through requirements, design, validation, deployment, and maintenance decisions [7]. Building on this gap, we incorporate the perspectives of healthcare professionals, healthcare researchers, and software engineers to examine how ethical concerns are discussed across roles in $HAISS$.

## 3 Methodology

We conducted a qualitative interview study across three stakeholder groups to investigate how practitioners experience, encounter, and prioritise ethical concerns in $HAISS$. We chose semistructured interviews because our goal was to surface reasoning specific to each role and varying with context, which structured surveys cannot capture. We analysed the resulting transcripts using the thematic synthesis process recommended for software engineering by Cruzes and Dybå, which proceeds in five steps [8].

**Research Questions.** The study is guided by three research questions (RQs).

**RQ1: In what contexts and use cases is AI currently applied in healthcare?** We examine real-world applications and the roles AI plays in patient care, diagnostics, and operations, including how AI is integrated into workflows, the motivations behind adoption, and the applications supported.

**RQ2: What challenges and limitations do practitioners report when deploying AI in $HAISS$?** We examine implementation and integration issues, ethical dilemmas, and operational constraints, comparing experiences across roles to understand factors that hinder adoption and areas for improvement.

**RQ3: Which ethical considerations of *HAISS* do practitioners prioritise, and how?** We aim to understand which of the five ethical dimensions carried over from our prior synthesis [14] (privacy, safety, bias, accountability, and transparency) practitioners consider most important.

**Participant recruitment and sampling.** In our study, we aimed to recruit a diverse sample of participants representing three key groups: healthcare professionals, healthcare researchers and software engineers, as mentioned above. We advertised the study through a multi-channel strategy across professional and social platforms (LinkedIn, WeChat, and X) and recruited from IT companies, clinics, hospitals, and universities across China, Australia, and India. The first author conducted all interviews between February and July 2025, both via video conference and in person. The final sample comprised 17 participants (8 female, 9 male) with 1 to 24 years of professional experience. We continued recruitment until we reached this sample and observed thematic recurrence across the three roles. The study was approved by our institutional human research ethics committee (Project ID [45523]).

**Interview Protocol.** Before the main study we conducted three pilot interviews, one per role, and made minor refinements to the wording and the order of sections based on the feedback. Each interview lasted approximately 30 minutes and followed a protocol with three phases aligned to the research questions, preceded by an introduction and demographics questions. The first phase, *Practical Use Scenarios*, asked participants to describe in detail how they use AI in their clinical practice, research, or development work, and the benefits they have experienced. The second phase, *Current Challenges and Limitations*, asked participants about the limitations of failures they had encountered, the specific incidents involved, and whether and how these had been resolved. The third phase, *Ethical Considerations*, asked participants to rank the five ethical dimensions from 1 (highest priority), to 5 (lowest), having first been given brief definitions and examples of each, and to justify they ranking and suggest any solutions.

**Analysis.** We analysed the transcripts following the five stpes of thematic synthesis recommended for software engineering by Cruzes and Dybå [8]: (1) reading all transcripts and noting recurring ideas; (2) segmenting each transcript into units aligned with the three research questions; (3) coding each segment with concise labels (for example, AIUseCase or TransparencyIssue); (4) merging overlapping codes into sub-themes; and (5) grouping sub-themes into the higher-level themes used to structure our results. For RQ3, we report the distribution of ranks assigned to each dimension and qualitatively analyse the accompanying justifications to explain how priorities differed across roles.

**Trustworthiness of the analysis.** The first author performed the primary coding of all 17 transcripts. Because a single coder introduces a risk of interpretation bias, we took two steps to make the analysis traceable. First, we maintained an audit trail: every code records the transcript identifier and the verbatim segment it was derived from, so each sub-theme and theme can be traced back to the utterances that produced it. Second, we attended explicitly to cases that diverged from the emerging pattern, most notably P12, who declined to produce a single ranking, and P16, whose account of accountability differed from that of every other software engineer.

**Table 1** Participant summary.

| Group | n | Countries | Experience | AI usage |
|---|---|---|---|---|
| Healthcare professionals | 5 | China, Australia | 3–24 yrs | Rarely–Always |
| Healthcare researchers | 6 | China, Australia | 1–10 yrs | Sometimes–Always |
| Software engineers | 6 | India, Australia | 2–10 yrs | Sometimes–Always |
| **Total** | **17** | China (8), Australia (8), India (1) | 1–24 yrs | Rarely–Always |

**From Findings to Artefacts.** To turn our findings into an actionable artefact, we derived role-specific If-Then patterns through a systematic mapping procedure. For each recurring challenge identified in RQ2, we identified the ethical dimension from RQ3 that it most directly threatens, and then formulated a concrete SE response that combines participants' suggestions with the corresponding regulatory or technical obligation. Each resulting pattern specifies a trigger condition drawn from our interview data, a response, the responsible role, and the applicable guideline. This mapping is the methodological bridge between our findings and the proposed artefact, and it can be repeated as new scenarios emerge.

# 4 Results

The following findings in this section are reported from the participants' perspective on the real-world RE challenges in *HAISS* development. Specifically, how role-specific contexts, recurring failure modes, and different ethical priorities create requirements that cannot be captured by generic, one-size-fits-all ethical frameworks.

**Demographics of Participants.** To achieve diversity, we recruited 17 participants (8 female, 9 male) across healthcare systems, institutional settings, and cultural backgrounds from China, Australia, and India. The participants worked in IT companies, clinics, hospitals, and universities, and reported 1–24 years of professional experience. Table 1 summarises roles, countries, experience and levels of AI usage; Healthcare professionals (P2–P4, P14–P15), researchers (P1, P5–P8, P12), and software engineers (P9–P11, P13, P16–P17).

## 4.1 RQ1 (Use cases of AI) Results

We used thematic analysis to identify application areas for each participant role.

### 4.1.1 Software Engineers' perspectives

**SE-Led Clinical Model Development.** Software engineers focused on designing and training domain-specific clinical models rather than deploying generic tools. P9 described augmenting minority-class skin cancer data to address dataset imbalance: *"In the medical domain, we required a balanced dataset, so I used generative AI to enhance the control subject data – we had around 400,000 images used to classify lesions from darker skin as malignant."* P10 also reported a high staging accuracy of their developed system in cancer detection, though it varied across cancer types.

**Leveraging AI Tools as "Hacks" for Quick Explanations.** Software engineers used LLMs to bridge knowledge gaps when working across unfamiliar clinical domains. P11 described using chatbots for explanation of multidisciplinary fields: *"When working with medical professionals from a field I am not familiar with, these tools can give you a "hack" or a basic explanation of a topic."* P17 similarly noted reliance on AI when going through fragmented medical data and ethics approvals.

**SE Practices for AI Adoption in Healthcare.** Software engineers consistently identified interoperability and data isolation as the primary deployment challenges of $HAISS$. P13 described the burden in the background: *"There is a lot of effort being done in the background to synchronise the data, to fit into every single system, to provide consistency so they get the data rather than manual digging."* P11 also described that regulatory constraints simultaneously restrict data access and reduce prototype quality: *"Even if you had to do a prototype, it has to be on minimal accuracy and minimal data."* The conflict between ethical safeguards and system quality is a distinctive challenge for $HAISS$.

### 4.1.2 Healthcare Professionals' perspectives

**Use of Medical Bots in Practice.** Healthcare professionals described AI as embedded across multiple clinical workflow modalities. P2 described two types of bots in Chinese hospitals: surgical support robots for min. invasive procedures and pharmacy dispensing bots that automatically collect and dispense medication based on prescriptions.

**Use of AI Assisted Imaging System.** P3 described a cloud-based CT diagnostic system: *"Our doctors from the CT department use this system to aid them with the diagnosis of patients' CT scans. The system detects anomalies and generates a report for the doctors."* This system draws on large reference databases to support diagnostic uses across orthopedic and radiology departments.

**Use of Online Medical Scribe Platforms.** P14 described using both Heidi[1] and i-scribe[2], which are online medical scribe platforms that help transcribe consultations and generate draft clinical letters, reducing administrative burden. P14 emphasised the benefit of these platforms: *"My clinical notes are a lot more accurate and rarely anything is missed"*, while also noting that AI sometimes adds clinical advice that was never given, requiring thorough review of every generated note.

### 4.1.3 Healthcare Researchers' perspectives

**Use of AI Models for Data Processing.** Healthcare researchers predominantly used AI for data-processing tasks, motivated by speed and the need to manage large, heterogeneous datasets. P5 described combining traditional Chinese medicine and Western medicine data using AI models for interpretation, while P6 used large models to process classical medical texts imported from classical sources. These tasks highlight AI as a tool for accelerating data interpretation that researchers had to frequently validate.

**Use of AI Models for Image Processing.** AI models were also widely used for automated image analysis. P7 described using AI algorithms for human skeletal structure segmentation, automatically generating images in various formats across large visual datasets. P1, specialising in biomechanics and gait motion, similarly used AI models for walking video classification and image processing. For these researchers, AI enabled the processing of large volumes of visual data that would be difficult to handle manually.

[1] https://www.heidihealth.com/
[2] https://i-scribe.com.au/

**Labelling Datasets Smartly.** Healthcare researchers also used AI to label datasets more efficiently, reducing manual annotation effort and improving consistency at scale. P8 stated: *"I use AI models to label my datasets smartly and generate them in various formats"* P12 confirmed good labelling accuracy on omic-based data: *"After I collect and organise my omic-based data, I use AI models to label them – they have a good accuracy in labelling."*

**RQ1 Findings:** Software engineers, healthcare professionals and researchers adopt AI for different objectives. Software engineers focus on building customised AI frameworks, solving interoperability problems, and bridging cross-disciplinary knowledge gaps. Healthcare professionals focus on practical clinical applications such as medical bots, AI-assisted imaging, and scribe platforms. Researchers devote most of their effort to data-centric tasks such as augmenting imbalanced datasets, interpreting complex texts, and automating image segmentation. Despite their varied approaches, all three groups share a common goal of improving healthcare outcomes and supporting medical staff.

## 4.2 RQ2 (Challenges and Limitations) Results

We further asked participants to describe the main challenges and limitations they encounter when applying AI in their clinical, research or *HAISS* development workflows.

**Model Reliability & Quality.** Healthcare professionals reported diagnostic inaccuracies from AI-assisted imaging systems (P3, P4). An illustrative example came from a clinician using AI scribe tools, where the system added clinical advice that had never been spoken, recommending lifestyle modifications based on the patient's BMI without the clinician having mentioned it (P14). Software Engineers also highlight hallucinations more broadly: P11 noted that output always requires sanity checking and P9 described persistent garbage outputs even after extensive model training. Across different roles, the unreliability of AI forces practitioner into time-consuming manual verification, reducing the efficiency gains AI was intended to provide.

**Data Quality & Processing.** Healthcare researchers reported the most acute data quality challenges. P7 described a model that filled gaps in incomplete records with fabricated data, increasing manual review complexity. A particularly striking example came from P9, who trained a skin cancer classifier on 400,000 images drawn predominantly from European and American populations: because the training data contained almost no darker-skinned samples, the model consistently classified benign lesions from Asian skin as malignant – a false positive with significant potential to cause patient distress. P5 reported domain mismatch errors where specialised medical terminology was misrecognised, yielding erroneous outputs. These failures demonstrate how data representativeness and completeness directly affect the reliability and fairness of *HAISS* outputs.

**Human Oversight & Skills Gaps.** Healthcare professionals consistently described mandatory manual validation as a basic operational necessity. P14 stated clearly: *"I never rely on the answer of AI to a specific scientific question. Rather, I ask AI to provide the evidence and articles. I make the final call."* The need for medical expert validation also created resource constraints for researchers: P9 noted that generating realistic clinical images still requires domain expert review, which is both costly and time-consuming given the burden already placed on healthcare systems. P16 highlighted that non-technical stakeholders, such

as medical practitioners and researchers, often adopt AI tools without fully understanding their limitations or the associated ethical risks. This places an additional responsibility on SE practitioners to account for gaps in stakeholder awareness during requirements elicitation.

**Institutional & Regulatory Constraints.** Data access red tape was a consistent barrier described. P13 described a structural paradox in ethics approval processes: *"You can't even request if you don't know what you're requesting for,"* meaning software engineers cannot specify required data fields in their ethics applications because they lack the data visibility to know what to ask for. P9 raised privacy concerns that aligned with reinforced institutional restrictions. P12 observed that commercial AI platforms often operate on tiered pricing models, where paid subscriptions offer stronger data privacy and security features than free access. In healthcare contexts, this means institutions with greater financial resources can provide stronger data protections for their patients, while under-resourced practitioners may inadvertently expose sensitive data to greater risk.

**RQ2 Findings:** Participant groups reported concerns shaped by their professional roles and goals. Software engineers highlighted technical obstacles, hallucinations, and institutional restrictions that limit AI deployment in healthcare. Healthcare professionals described diagnostic issues, the burden of mandatory manual validation, and AI-generated content that was inconsistent with clinical facts. Healthcare researchers identified fabricated outputs, demographic bias in the training data, and unreliable model behaviour, all of which compromised the validity of the research.

## 4.3 RQ3 (Ethical Considerations) Results

For RQ3, we asked participants to rank five ethical dimensions on a scale of 1 (highest priority) to 5 (lowest priority), and to explain their reasoning. Privacy received the highest priority (mean = 1.2), followed by safety (mean = 2.2). Bias ranked third (mean = 3.3), while accountability (mean = 3.7) and transparency (mean = 4.5) ranked lowest.

**Privacy.** emerged as the top priority across all roles. Participants consistently emphasised that patient data must remain tightly controlled, grounding this concern in both institutional policy and personal experience. P14 described stripping patient identifiers from all AI-assisted consultations, while P12 noted that even unpublished research data is strictly prohibited from being entered into AI tools in their institution. In Chinese hospitals, P2 described strict governance measures that prevent the export of patient data outside the hospital.

**Safety.** ranked second and was also closely linked to privacy from participants' perspectives. P4 stressed the importance of data containment: *"For imported machines and bots, the database should be based in China"*, which highlights how participants associate safety with physical and institutional control over sensitive data.

**Bias.** was ranked third. P9 described how datasets trained on different populations can cause patient distress and clinical harm. By contrast, practitioners whose systems undergo institutional validation prior to deployment (P11, P16) considered bias more manageable, since verification processes identify biased outputs before they reach patients.

**Accountability.** was ranked fourth, and divergent across roles. P17 argued that without clear attribution of responsibility for AI outputs, it is difficult to correct the errors: *"When a ML tool is made, we don't know who is making that model. If there is anything wrong with a patient's medication or history, there will be no one accountable."* P9 similarly argued that given the life-critical stakes, accountability must be the primary concern for developers. Healthcare professionals framed accountability within existing clinical responsibility structures, as doctors are already responsible for decisions made by *HAISS*, making additional accountability feel less urgent. P16 noted that, in their context, accountability was largely pre-empted by design: their application explicitly prepares patients for GP consultations rather than replacing clinical advice, removing ambiguity about who bears responsibility.

**Transparency.** was ranked the lowest overall. Healthcare professionals stated that clinicians lack the capacity to understand the logic behind *HAISS* outputs. P14 stated that *"can deal with not much transparency, I am 100% sure about the rest."* P9, a software engineer, stated that while explainability tools such as SHAP and LIME are promising, a significant gap remains in interpreting black-box AI in clinical contexts. P12, declined to provide a single ranking, noting that *"priority depends entirely on context and purpose: for patient care, privacy comes first; for teaching, transparency; for research, security."* This response illustrates that a single, unified ethical requirements ranking is insufficient, and that role/context-specific elicitation is required.

**RQ3 Findings:** Privacy and safety were ranked in the top two positions by a large majority of participants and with little spread, indicating that both function as a baseline expectation across all three roles rather than as a discriminating priority; privacy was nonetheless ranked ahead of safety more often than the reverse. Bias, accountability, and transparency were ranked lower on average but with substantially wider variation, and their placement was tied to whether a participant had encountered a concrete failure of that kind. Accountability was ranked lower by healthcare professionals, who described it as already absorbed by existing clinical responsibility structures, than by software engineers, who described it as unassigned. One participant declined to rank the dimensions at all, arguing that priority is determined by purpose rather than by role.

## 5 Discussion

Our findings suggest that ethical risks in *HAISS* are not uniform. Instead, they vary systematically with (i) practitioners' roles and responsibilities, (ii) the regulatory constraints they operate under, and (iii) the organisational settings in which *HAISS* are designed and used. This variation explains why "one-size-fits-all" ethical requirements often fail in practice, and why responsible *HAISS* development benefits from cooperative but role-specific RE.

**Lesson 1: Ethical requirements in *HAISS* are role-specific, not universal.** Across all groups, privacy (mean $\approx 1.2$) and safety (mean $\approx 2.2$) consistently appear as baseline NFRs; participants widely expect that sensitive data must be protected and that system behaviour should not introduce avoidable harm. The remaining dimensions, however, showed greater variance across roles, and their importance depended on how each role encountered ethical concerns in everyday work. Healthcare professionals concentrated on issues that directly affect clinical decision-making, researchers emphasised reproducibility, and software engineers

**Table 2** Role-specific If-Then patterns derived from practitioner perspectives.

| If (Scenario) | Then (Response) | Role | Guideline(s) |
|---|---|---|---|
| Building models for underrepresented populations with imbalanced data (P9). | Augment minority classes, document in model cards, validate with domain experts, and report metrics separately for synthetic and natural data. | SE | EU AI Act [11]; FDA GMLP [31] |
| SE teams lack medical knowledge and use LLMs for quick explanations (P11, P17). | Limit LLM use to preliminary understanding, maintain validated glossaries, and mandate clinical review before implementation. | SE | IEEE EAD [6]; ACM Ethics [1] |
| Deploying AI where data must stay within institutional boundaries (P13, P9). | Architect for on-premise or private cloud only, block public APIs, and log all access to verify no external transmission. | SE | HIPAA [28]; GDPR Art. 44–50 [10]; PIPL [26] |
| AI imaging systems produce occasional diagnostic errors (P3, P4). | Require radiologist double-read of AI-flagged findings, surface confidence scores, and maintain an audit trail. | HP | ACR [3]; FDA CDS [30] |
| Clinical staff lack the knowledge to operate AI tools (P2). | Provide mandatory role-specific training with certification and simplified interfaces, and collect usability feedback. | HP | WHO [33]; FDA HF [29] |
| AI fabricates data to fill gaps (P7). | Reject incomplete records, use statistical rather than generative imputation, mark synthetic values, and exclude them from primary analysis. | HR | FAIR [32]; CONSORT-AI [21] |

SE = Software Engineer; HP = Healthcare Professional; HR = Healthcare Researcher.

focused on implementable governance mechanisms and on how ethical requirements translate into testable constraints. For RE, this implies that eliciting ethics requirements in *HAISS* cannot rely on a single fixed checklist, but must be stratified by role. We state this as a hypothesis rather than a finding. Because role and country are confounded in our sample, the stratification we observe may be organised as much by regulatory setting as by professional role. What the data more securely support is the weaker claim that a single, fixed checklist did not match how any of our participant groups encountered ethical concerns.

**Lesson 2: Role boundaries are the primary hotspots for ethical risk.** Several severe issues reported were not confined to a single role; they appeared at the boundaries, where one group produces artefacts that another group relies on. Examples included hallucinated outputs that appear clinically plausible and are mistakenly trusted; demographic bias that increases false positives and forces clinicians to make rapid judgments under pressure; and fabricated or low-quality data propagating through research workflows. These failures often arise because validation expectations and accountability are not explicitly specified at handoffs, allowing errors or uncertainty to flow downstream. This suggests that handoffs themselves should be treated as requirements artefacts, with explicit validation criteria and accountability assigned at each role boundary.

**Lesson 3: Regulatory compliance and ethical requirements are related, but not interchangeable.** Compliance is essential, but it represents a minimum legal threshold rather than a complete account of ethical practice. A system may satisfy data residency rules while

still producing biased outcomes, or obtain consent in a legally correct way while operating as a "black box" that makes accountability difficult to assign when something goes wrong. For SE practitioners, this is why data governance and residency should be treated as core architectural requirements rather than background tasks, with provenance tracking and automated completeness checks built in, rather than relying on compliance sign-off alone.

Based on our findings, we propose role-specific If-Then patterns as lightweight SE artefacts that operationalise practitioner-identified ethical priorities into actionable requirements. Each pattern specifies a trigger condition (If) drawn from a recurring scenario in our interview data, a concrete SE response (Then) grounded in both participant suggestions and established regulatory guidance, the responsible role, and the applicable guideline. The patterns were derived by mapping each RQ2 challenge sub-theme to the ethical dimension it most directly threatens (RQ3), then formulating a response that combines participant suggestions with the corresponding regulatory obligation. Table 2 presents an initial set of six patterns spanning all three roles, intended as structured prompts during requirements elicitation. We did not attempt to operationalise every RQ2 challenge. A sub-theme was carried forward only if it was reported by at least two participants or by one participant describing a specific incident, if its trigger could be stated as a condition a development or clinical team can observe, and if a response could be formulated that maps onto an obligation in a publicly available instrument. Sub-themes excluded on these grounds were P13's ethics-approval paradox, whose trigger is organisational rather than a property of the software, and P5's terminology mismatch, for which we could not formulate a response that did not restate the problem. Guidelines were selected by matching each response to the narrowest instrument that covers the obligation and applies in at least one of the three jurisdictions in our sample; we do not claim that the cited instrument mandates the specific response, only that the response is intended to discharge the obligation it states. The responses combine participant suggestions with our own additions, most often a verification or logging step that makes a participant's suggestion checkable, so the patterns are our formulation rather than a direct transcription of participant views. Their triggers are grounded in observed practice, but the responses have not been applied to a real project, and evaluating them through practitioner workshops is the first item of our future work.

# 6 Threats to Validity

## 6.1 Construct Validity

The five ethical dimensions were not derived inductively from the interview data. We adopted them from our prior systematic mapping study of ethical concerns in generative AI [14], which synthesised 39 primary studies into five recurring dimensions. Because the same team produced the framework and applied it as an elicitation instrument, a concern absent from the mapping study is unlikely to have surfaced here. The ranking task compounds this. It captures relative priority only, so a low rank means a participant placed that dimension below the others, not that they judged it unimportant, and the low rank of transparency should be read in this way. It also records what participants say they prioritise rather than what their projects protect in practice, since we did not observe any participant's work. To limit these effects, each interview included open discussion in which participants could raise concerns outside the five labels, and we asked every participant to justify their ordering, which is how the qualitative account in Section 4.3 was built. In the planned practitioner workshops we will elicit priorities against concrete scenarios rather than in the abstract, and compare stated priorities against project artefacts such as requirements documents and ethics applications.

## 6.2 Internal Validity and Credibility

The primary coding was performed by a single researcher, which is the most significant threat to the credibility of our themes. Section 3 describes the steps we took to reduce it: an audit trail linking every code to the transcript segment it came from, and explicit attention to cases that diverged from the emerging pattern. We did not conduct a formal inter-coder reliability assessment, nor did we ask participants to validate the themes. Our themes should therefore be read as an interpretation that can be traced back to the data and justified, rather than as the only structure a coder could have derived from these transcripts. To make competing interpretations possible, we release the codebook with links from each code to its source segment, so that another researcher can trace how each theme was built and construct an alternative reading from the same material.

## 6.3 External validity and Transferability

Our sample of 17 participants is small and unevenly distributed, and the distribution is not independent of role. Healthcare professionals were recruited only in China and Australia; software engineers, only in India and Australia; and India is represented by a single participant. Role and country are therefore confounded: any pattern we attribute to the software engineering role is, on this sample, indistinguishable from one attributable to the regulatory or institutional context in which those engineers work. This affects RQ3 most directly, since data-protection regimes differ sharply across the three jurisdictions. Australia is the only country represented in all three role groups, so we checked whether the role-level ordering holds there as well. Privacy and safety retain their positions, but the placement of bias, accountability, and transparency differs from the overall pattern, so the role differences we report for these three dimensions may partly reflect jurisdictional differences. Recruitment through professional and social platforms further biases the sample toward practitioners already engaged with AI. We therefore make no claim of statistical generalisation and present the role-specific findings as hypotheses. To test them we are extending the study to a sample stratified by role within each jurisdiction, so that role and country can be varied independently, and we will re-examine the ordering reported here before generalising from it.

# 7 Conclusion

In this paper, we demonstrate that understanding multifaceted AI adoption in healthcare requires considering the perspectives of stakeholder groups with distinct roles. By examining RQ1, we found that healthcare researchers use AI for data-centric tasks, healthcare professionals focus on integrating AI into diagnostic workflows, and software engineers focus on building and maintaining AI systems. Each group has unique challenges they encounter (RQ2) and ethical considerations they prioritise (RQ3), which are shaped by their objectives.

Based on these findings, we suggest creating role-specific guidelines that ground high-level principles in everyday practices by formulating if-then patterns. While our sample captures diverse geographic and institutional contexts, it remained limited in size and scope. As future work, we plan to implement these if–then patterns within role-specific guidelines, drawing on existing regulatory frameworks and ethical standards, and to validate and refine them across a wider range of healthcare environments to ensure broader applicability and relevance. By incorporating continuous practitioner feedback, we aim to produce a set of actionable rules that can be streamlined and, ultimately, embedded into an adaptive, ethical healthcare AI framework capable of evolving with emerging technologies and practical scenarios.

# When Work Relations Matter: A Vision of Forgiveness in Software Testing

**Mary Sánchez-Gordón**[1]
Østfold University of Applied Sciences, Halden, Norway

**Ricardo Colomo-Palacios**
Universidad Politécnica de Madrid, Spain

**Rahul Mohanani**
University of Oulu, Finland

## Abstract

The software testing process is inherently adversarial, creating conditions for frequent and pervasive developer–tester conflicts. Although forgiveness has been studied as a tool for resolving conflicts and as a coping mechanism in the workplace context that promotes well-being and productivity, its role in software testing remains unexplored. This paper posits that cultivating forgiveness can help practitioners manage their emotional responses to conflict and therefore deserves further investigation in the context of software testing.

**Category** Emerging Results, Vision & Reflection Track Paper

## 1 Introduction

The nature of testing differs from other software development activities, such as design and building. Although the latter activities focus on the construction of software, testing is often perceived as destructive, as testers attempt to "break" the software built by developers [19, 12, 23]. Apart from the different work mindset (build vs break), previous research has identified other dimensions [23]: thinking focus (theory vs practice), project goal (efficiency vs effectiveness) and job knowledge (depth vs breadth). Testers and developers perceive the software development process differently [4]. From the testing perspective, those human beings who build the software make errors (mistakes), which produce defects (faults, bugs), which in turn may result in failures [19].

An interview study on the characteristics of good software found that testers believe that they often give bad news (defects or problems) and that it must be communicated in a way that does not blame anyone for it [5]. The idea of testers as "bearers of bad news" is widely spread and acknowledged by the International Software Testing Qualifications Board (ISTQB) [19]. Moreover, ISTQB point out that a common human tendency is to blame the bearer of bad news, and that test result communication is frequently perceived as criticism of both the software and its author [19]. Indeed, the testers interviewed in a study on conflict in software testing [4] reported the developer's reluctance to accept the existence of errors, as they tend to view their code as an extension of themselves and thus took it personally when defects and failures were communicated.

As illustrated, the software testing process is inherently adversarial, setting the stage for developer-tester conflict [4]. Previous research supports the notion that conflict between software testers and developers is inevitable [4, 18, 24]. In this sense, a study has proposed three basic conflict layers in software testing that include organization, process, and people [4], while another identified process, people, and communication [24]. The impact of interpersonal conflict has been perceived to be negative, regardless of how it was managed or resolved [2]. Their effect can be minimized through communication, mutual respect, and even social interaction [4]. However, communication during conflicts can be difficult and the way testers and developers feel about their work and workplace relationships matters. A more recent study [25] also supports that conflict in software testing arises from people.

Given that conflict involves emotions, perceptions, and behaviors [18], this vision paper argues that software testing involves actions that developers and testers perceive as disrespect and exploitation, violating values, rules, or norms in their relationship. In psychological research, such perceived violations are referred to as *interpersonal transgressions* [22]. In simple words, an act that goes against what is considered acceptable or proper. Recognizing this, it becomes necessary to bring emotionality to the fore. Although developers and testers could choose how to act in response to their emotions, they cannot choose the emotions themselves – whether anger, sadness, or happiness. From this perspective, forgiveness emerges as a recognized conflict management strategy within organizations that cannot only diminish the detrimental impact of interpersonal conflict, but can also promote well-being and productivity [3]. However, its role in software testing remains unexplored.

To address this gap, this paper presents a vision and research agenda for understanding forgiveness through the lens of emotion regulation. It conceptualizes forgiveness and outlines future research directions aimed at helping the software testing community foster healthier workplace relationships and better manage interpersonal conflict.

## 2 Forgiveness Conceptualization

The human aspects of software engineering have gained increasing attention due to their influence on interactions among software practitioners [10, 20]. One such aspect closely related to forgiveness is empathy, which has been investigated in the context of software requirements engineering [10]. However, forgiveness and empathy can remain independent: one may empathize with others without forgiving them, just as one may forgive without fully understanding the motives of the other persons. Social interactions also play a central role in the shaping of testing culture [20]. Thus, an affective dimension influences both the tester's experience (TX) [6, 20] and the developer's experience (DX) [8].

In this context, we need to choose the conceptualization of forgiveness that we use in the software testing context. To do this, we first review the forgiveness literature. Forgiveness has attracted scholarly attention across scientific disciplines, beginning with philosophy and psychology, e.g., [7]. More recently, forgiveness has gained attention within organizational and managerial science, e.g., [1]. Some reviews on measuring forgiveness highlight that forgiveness measures assess forgiveness differently [3, 9]. Although there is still no consensus on what fundamentally constitutes forgiveness or how it should be defined [3], the definitions of psychological research have focused on the intrapersonal aspects of forgiveness [13].

Some conceptual issues have emerged over time. To better understand the challenges for the study of forgiveness in organizational behavior, Brady et al. [3] conducted a critical review and analysis of the literature. Among the identified issues, they highlighted that many existing conceptualizations and operationalizations remain atheoretical, since they are

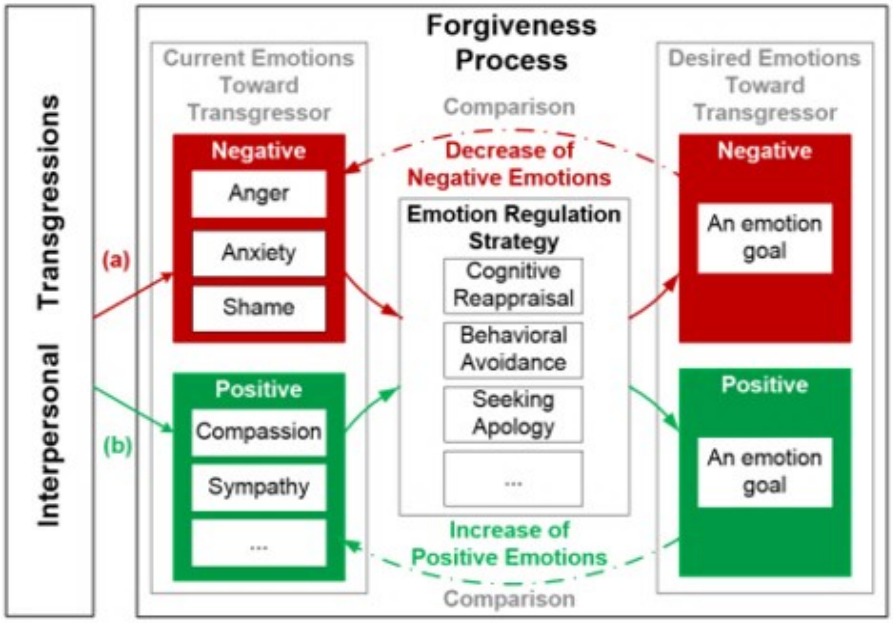

**Figure 1** Forgiveness process involving the decrease of negative emotions (a) and the increase of positive emotions (b) adapted from Brady et al. [3].

based on inductive research grounded in laypeople's understanding of forgiveness. This can lead to conceptual issues because this understanding is shaped by beliefs or ways of thinking about forgiveness, which in turn influence the experiences of laypeople [13]. Brady et al. [3] also proposed reconceptualizing forgiveness as a special case of emotion regulation, as shown in Figure 1.

Forgiveness as a form of emotion regulation occurs after an interpersonal transgression [3]. It involves an intraindividual change where individuals aim to improve their emotional response toward a transgressor by reducing negative emotions and/or increasing positive ones. This process is guided by a discrepancy between two emotional states: the current emotional state (how the person feels now) and the desired emotional state (how they want to feel). The current state reflects the emotional aspect of forgiveness, while the desired state represents a cognitive goal. When individuals recognize this emotional gap, they can consciously or unconsciously engage in forgiveness by using emotion regulation strategies – such as cognitive reappraisal – to align their current emotions with their emotional goals over time. For example, reinterpreting a transgression as unintentional can help decrease negative emotions and move the individual closer to emotional resolution. Common emotion regulation strategies identified in the psychological literature [16] include acceptance, avoidance, cognitive reappraisal, distraction, mindfulness, rumination, and suppression. These strategies are highly context-dependent and can take intraindividual, interpersonal, cognitive, or behavioral forms. Consequently, selecting an effective strategy can be complex and challenging, and people often struggle with emotion misregulation [3].

Finally, although the Eastern view of forgiveness as "compassion in action" [17] provides an example of a discrepancy, this concept is not examined in detail. In Eastern philosophy, pain is inevitable, but suffering arises from attachment to it. Consequently, forgiveness can be understood as the deliberate practice of employing emotion regulation strategies to release such attachment, transform emotional pain, and reduce unnecessary suffering that widens the emotional gap.

## 3 Forgiveness in Relation to Adjacent Constructs

This vision paper acknowledges that developer–tester relationships vary across organizational cultures and development approaches and argues that forgiveness should complement rather than replace adjacent constructs such as accountability, managerial responsibility, psychological safety, conflict resolution, or conflict management.

Unlike psychological safety and a blameless culture, which are team-level characteristics shaped by organizational culture, forgiveness is an intraindividual process of repairing emotional responses to perceived transgressions. Psychological safety does not mean the absence of blame. Blame may be appropriate when people intentionally cause or risk harm. Similarly, forgiveness is not appropriate in all situations, such as abuse, repeated misconduct, persistent disrespect, or unhealthy team cultures. These situations, as well as other conflicts rooted in structural issues such as process failures or power imbalances, can also require appropriate intervention rather than forgiveness alone.

In addition, psychological safety is improved by making explicit what types of behavior are acceptable and unacceptable within the organization [14] and by promoting practices such as blameless postmortems [21, 15] that focus on systems, processes and organizational learning rather than individual blame. However, neither psychological safety nor blameless postmortems eliminate conflict. Team members inevitably bring diverse experiences, perspectives, and past traumas into their interactions, and unresolved conflicts can persist. Forgiveness addresses this gap by helping individuals regulate emotions and gradually adopt more prosocial attitudes toward a transgressor. In this way, forgiveness can also complement conflict management and conflict resolution, which focus on reaching agreement between involved parties.

## 4 Research Agenda for Forgiveness in Software Testing

The research agenda is structured around three key themes: (i) Identifying conflicts and forgiveness in software testing, (ii) Understanding the role of forgiveness as a response to conflicts in testing practice, and (iii) Cultivating forgiveness within the testing culture.

**i) Identifying conflicts and forgiveness in software testing.** To the best of our knowledge, there is currently no empirical evidence on forgiveness in software testing. However, conflicts vary in severity and can arise from a wide range of testing-related issues. Future research should aim to:

- Identify the conflicts, including ethical and non-ethical workplace transgressions, that feel like interpersonal transgressions and trigger the forgiveness process.
- Map the (current and desired) emotions toward transgressors that are triggered by conflicts.
- Determine what emotion regulation strategies lead to a decrease or increase in emotions and how they affect working relationships over time.

Conceptual research approaches, such as thematic analysis and grounded theory, can help establish this theoretical foundation.

**ii) Understanding the role of forgiveness as a response to conflicts in testing practice.** Emotion regulation offers a path for navigating conflicts but the willingness to forgive is closely related to situational factors [11] that is a nonlinear and evolving journey. Thus,

researchers must investigate what motivates software practitioners involved in testing to demonstrate forgiveness. Potential contributions include:

- Identify the situational factors that shape forgiveness throughout the Software Testing LifeCycle (STLC).
- Identify perceived forgiveness-related challenges (e.g., cognitive distortion like black-and-white thinking) and benefits (e.g., restore motivation).
- Examine how practitioners employ emotion regulation strategies to repair damaged relationships and overcome debilitating thoughts and emotions.

Ethnographic fieldwork, team-based case studies, and situated interviews can uncover how forgiveness manifests in software testing practice. These studies are critical to building models of shared accountability and to inform governance policies.

**iii) Cultivating Forgiveness within the Testing Culture.** A key area of the agenda is the development of training programs to cultivate forgiveness. This includes:

- Identify skills to facilitate the forgiveness process and support a forgiveness testing culture within software projects.
- Understand how to build a common sense of the value of forgiveness in software culture.
- Define a set of actions that can be followed to increase awareness of forgiveness as a potential response to conflicts.
- Determine how to provide responsive managerial support during conflicts to improve practitioner well-being and strengthen software testing practices.

Collectively, these research directions define a path towards informing a set of actionable practices that ensure forgiveness is recognized, supported, and integrated into the software testing culture, allowing practitioners to continue working together in healthy and constructive ways despite interpersonal conflicts.

We acknowledge that conflict in software testing is inevitable and hope that this research agenda will bring attention to social interactions in software testing, especially the cultivation of forgiveness as a promising research direction.

## Abstract

Large-Scale Agile Frameworks (LSAFs) are widely used to coordinate agile transformation beyond individual teams. They are often associated with organisational adaptability, yet whether their formal guidance encodes the capabilities associated with socio-technical resilience (STR) is unclear. Drawing on Hollnagel's resilience potentials, this vision paper presents observations from an initial investigation of how resilience-relevant capabilities are represented in formal LSAF guidance. These observations indicate a potential resilience blind spot in LSAFs. The paper identifies opportunities for further empirical work on LSAFs and resilience, and on how organisations supplement LSAFs with resilience-oriented practices.

## 1 Introduction

In practitioner and academic discourse, agility and resilience are frequently treated implicitly as closely related or even equivalent organisational qualities [15]. The ability to respond quickly to change, learn from experience, and continuously improve are presented as hallmarks of both agile and resilient organisations [8, 13] but this assumed equivalence lacks systematic scrutiny. Is being agile sufficient to ensure resilience? Furthermore, what does "being resilient" mean in practice?

Our work aims to clarify these issues, and is informed by cases we have encountered in earlier research. For example, AgileCo [1] is a large video game developer with around 3000 employees. The company had been built on agile principles and used agile practices across

the organisation from the beginning. However, when they wanted to introduce new games, they recognised that a perspective that went beyond agile's "responding to change" mantra was required if they were to stay competitive. Taking this wider perspective led to some functions being centralised, which prompted changes in process and communication practices. In this case, being resilient required a wider perspective than team-based agility, and being agile was not sufficient to ensure resilience.

To understand resilience in this case, it is necessary to consider organisational capabilities that go beyond iterative delivery, continuous feedback, and team learning. Drawing upon Resilience Engineering (ResE), resilience in the organisation was achieved through dynamic adjustments that involved people, processes, and governance structures in combination [14].

This vision paper proposes that ResE can be combined with LSAFs, which aim to provide an organisation-wide perspective on agility. The ResE approach to identifying resilience presents a fruitful direction for future empirical software engineering research and the paper envisions an agenda for such research. To support our proposal, we present initial observations from a document-based analysis that applies a ResE framework to analyse LSAF guidance.

## 2 Background

Resilience matters to software teams and to individual developers because the social and technical processes that support software development impact team and individual wellbeing and productivity [17]. Large-scale agile frameworks shape the environment within which software is developed and hence they have the potential to influence whether or not socio-technical resilience can flourish.

### 2.1 Socio-Technical Resilience and Resilient Performance

Resilience refers to a system's capacity to absorb disturbances, adapt to change, and continue functioning or transform under stress [20]. In software engineering research, resilience has traditionally been associated with fault tolerance, redundancy, and continuity of service. The focus on technical capability cannot account for social and technical factors that contribute to performance outcomes [11]. ResE counters this view, treating resilience as a dynamic and ongoing aspect of socio-technical performance that involves operational tasks, organisational processes, and the design and production of technologies that are used in work [14].

Working within this approach, Hollnagel [7] developed a conceptual framework for examining resilience through four potentials (i.e. capabilities that enable resilience). The first, Anticipate, concerns a system's ability to foresee, prepare for, and respond to potential disruptions before they occur, including the capacity to reason about future operating conditions and emerging risks. The second, Monitor, concerns the ongoing observation of system performance, the detection of early warning signals, and the use of indicators to track changing conditions. The third, Respond, addresses the capability to act promptly and adaptively when disturbances arise, including the ability to identify triggers, verify readiness, and return to regular operation. The fourth, Learn, concerns the capacity to reflect on experience, collect and analyse operational data, and integrate understanding from successes and failures into future practice.

Within ResE, resilience is not a product of technical design, but is evident in the performance of individuals and teams as situated within organisational processes, technologies, and structures [6]. This perspective is especially relevant to software engineering organisations, where outcomes depend on complex interactions among development teams, delivery pipelines, governance structures, customer relationships, and technological ecosystems [20].

## 2.2 Large-Scale Agile Frameworks

LSAFs emerged as a response to the challenge of extending agile principles and practices beyond individual teams to address the coordination demands of organisations, including interdependent teams, multiple product streams, and alignment with strategic business goals [4]. LSAFs provide structured guidance across these multi-level settings, enabling improved collaboration, adaptability, and faster value delivery at scale [10]. As examples, five LSAFs that are widely recognised in practice and have been discussed in comparative LSAF research [5] are: the Scaled Agile Framework (SAFe), Large-Scale Scrum (LeSS), Scrum@Scale, Disciplined Agile (DA) and the Spotify Model.

SAFe provides a comprehensive, prescriptive model spanning team, programme, and portfolio levels, with strong emphasis on planning cadences, role definitions, and portfolio governance [18]. LeSS takes a contrasting approach, scaling Scrum with minimal additional structure while emphasising simplicity and empirical process control [12]. Scrum@Scale extends Scrum's core mechanisms to networks of teams through a lightweight coordination model [19]. DA provides a process decision framework that allows organisations to choose and tailor their ways of working from a toolkit of practices [16]. The Spotify Model, originally an internal engineering culture initiative, emphasises team autonomy, alignment through shared culture, and informal coordination through squads, tribes, chapters, and guilds [9].

However, no single framework covers all areas of organisational operations, and there is an absence of a unified basis for assessing frameworks against broader organisational goals [5]. Socio-technical resilience, as a distinct conceptual lens informed by ResE, has received limited attention in LSAF literature.

# 3 An initial investigation

This initial investigation used document analysis [3] to examine whether the formal guidance of five widely recognised LSAFs (SAFe, LeSS, Scrum@Scale, Disciplined Agile, and the Spotify Model) encodes capabilities associated with socio-technical resilience. The analysis considered the official framework guides and documentation referenced in Section 2.2, as these represent the primary sources through which each framework communicates its principles, practices, governance structures, and recommended ways of working. The unit of analysis was individual statements describing framework practices, roles, events, coordination mechanisms, metrics, and organisational guidance relevant to large-scale agile development.

The analysis adopted a deductive coding approach [2] using Hollnagel's four potentials [7] as the analytical framework. This provided a structured vocabulary for asking whether LSAF guidance makes resilience capabilities visible. Each statement was examined to determine whether its guidance supported any of the resilience potentials. The focus was on identifying evidence of resilience-related capabilities rather than measuring frequency or strength. The results were synthesised to identify areas of convergence, where LSAFs reflected resilience engineering concepts, and areas of divergence, where resilience capabilities appeared to be weakly represented or absent. This exploratory analysis resulted in an initial conceptual comparison between LSAFs and ResE rather than a quantitative evaluation.

## 3.1 Areas of convergence between LSAFs and ResE

From our analysis of the official LSAF documents, there are two areas where LSAF principles overlap with the capabilities associated with ResE.

Agile frameworks, including their large-scale variants, emphasise iterative delivery, retrospection, and continuous improvement as central practices. These principles align naturally with Hollnagel's Learn potential, which concerns the collection and analysis of operational data, learning from both success and failure, and embedding lessons into future practice. Retrospectives in Scrum-based frameworks, Improvement Kata in Lean-influenced approaches, and the culture of experimentation supported in the Spotify Model are mechanisms through which organisations can develop learning-oriented behaviour. The principle that learning is a shared organisational responsibility, rather than the province of management or specialist roles, is also consistent with how ResE frames learning as a distributed and ongoing capacity.

Similarly, the emphasis in LSAFs on metrics, feedback loops, and performance review creates a foundation for monitoring-related resilience capabilities. Frameworks that encourage regular inspection of performance indicators, the communication of results across teams and organisational levels, and the adjustment of practices in response to what indicators reveal are supporting the Monitor potential. The SAFe Lean metrics, LeSS's reliance on empirical process control, and DA's guidance on value stream measurement reflect this orientation. In this respect, the agile emphasis on transparency and inspection is meaningfully compatible with the concern of ResE for ongoing observation of system conditions.

### 3.2 Areas of divergence between LSAFs and ResE

The analysis identified resilience capabilities that were weakly represented or absent, divergences that reflect a difference in orientation between LSAF and ResE. ResE developed to counter the limitations of root cause analyses. Large-scale agile methods were designed to embrace uncertainty through iteration, feedback, and adaptation at an organisational scale.

The Respond potential goes beyond the agile notion of responsiveness to change. In ResE, this potential involves identifying in advance the classes of situations that may require action, defining triggering criteria for initiating a response, establishing readiness through systematic verification, and specifying when a response should stop. LSAFs, designed primarily to support continuous delivery and team coordination under conditions of manageable uncertainty, do not appear to provide this kind of guidance. Although SAFe includes risk management practices, and DA offers decision tools for process selection, these are oriented toward delivery risk rather than the broader organisational readiness that ResE addresses.

The Anticipate potential surfaces the most significant divergence. In ResE, anticipation goes beyond strategic vision or roadmap planning, and requires organisations to look beyond the next planning increment or programme interval and to reason systematically about conditions that have not yet arisen. LSAFs prefer near-term adaptation over long-range prediction, and are not naturally oriented toward anticipatory reasoning. The emphasis on strategic alignment in SAFe and DA, mainly concerns product and portfolio direction rather than anticipating systemic disruption or operating environment shifts.

These divergences suggest that LSAFs and ResE are compatible but not identical. Combining both requires attention to the capabilities that each one does not naturally emphasise.

## 4 Avenues for Further Research

### 4.1 A Potential Resilience Blind Spot

Our analysis suggests that LSAFs, as specified, provide useful foundations for some aspects of STR, particularly learning and monitoring, but other resilience capabilities, especially those associated with responding to disruption and anticipating future conditions, are less

explicitly addressed. This does not mean that organisations using LSAFs lack resilience. As Furniss et al. [6] argue, resilience is a product of ongoing adjustments made by people in practice, not solely of system design. It is possible, and indeed likely, that organisations supplement their use of LSAFs with additional risk management, incident response, and leadership practices that address the gaps identified here. Indeed, AgileCo, the example introduced earlier, illustrates this, and implicitly demonstrates the use of Anticipate and Respond capabilities: they anticipated the need to centralise functions in order to stay competitive, and they responded by creating new practices.

Nevertheless, framework documentation matters. It expresses the design logic of a framework and shapes what organisations and practitioners are encouraged to attend to, institutionalise, and measure. If resilience capabilities such as response readiness, risk threshold definition, and future-oriented modelling are weakly represented in the LSAF guidance, organisations may not recognise these as areas requiring deliberate attention. The connection between large-scale agile practices and STR, while frequently asserted in the practitioner and academic literature [8, 13], has not been examined in sufficient depth to determine whether adopting an LSAF is likely to produce the conditions required for resilient performance across all four potentials.

## 4.2 Implications for Research and Practice

For researchers, this analysis provides several avenues for future empirical work. First, longitudinal studies of organisations using LSAFs could examine how agile adoption and resilience capabilities manifest in practice, and the correlation between organisational agility and resilience. Second, comparative studies could examine how organisations combine elements from multiple LSAFs and supplementary practices to address the resilience gaps identified here. Third, the relationship between specific LSAF practices and the four potentials could be examined through case studies, providing finer-grained evidence about where the alignment and divergence identified here are most consequential.

For practitioners, the analysis suggests that organisations pursuing LSAFs may benefit from complementing their chosen framework with explicit guidance drawn from ResE or adjacent disciplines. The identification of situations that require readiness, the definition of response thresholds, and the development of anticipatory capacity, including systematic attention to weak signals and alternative futures, are areas where practices beyond standard LSAF guidance may be warranted.

Based on our reflection about the observed divergences, we envision a greater dialogue between ResE and large-scale agile communities. Both are concerned with how organisations sustain performance under uncertainty, but approach it from different theoretical traditions and with different assumptions about the nature and predictability of disruption. A more deliberate integration of these perspectives in research, in framework development, and in organisational practice could contribute to a richer and more complete understanding of what it means for a complex, software-intensive organisation to be both agile and resilient.

# AI-to-AI Code Reviews of GitHub Pull Requests

**Niruthiha Selvanayagam**

**Taher A. Ghaleb**
Department of Computer Science, Trent University, Peterborough, Canada

## Abstract

AI coding agents are increasingly integrated into software development workflows, operating on both sides of the pull request (PR) process: *AI authoring agents*, which create or modify PRs, and *AI reviewers*, which evaluate them. This creates a closed loop where one AI coding agent reviews contributions of another AI coding agent. In this paper, we construct an AI-to-AI code review dataset by linking AI-authored pull requests with AI-attributed review events from CodAGE, a public dataset of coding agent–generated GitHub events. Our dataset contains 248,641 PRs across 12 AI coding agents with at least one AI review, including 45,269 reviewed by a different AI product and 208,145 by the same product. We observe that cross-product AI-to-AI code review occurs in only about 1.6% of identified agent-authored PRs but is substantial in absolute terms: 45k PRs written by one identifiable AI product and reviewed by another. This activity grows by more than two orders of magnitude from 2025-Q1 to 2025-Q3. We measure reviewer behavior using CodeRabbit comment categories, per-PR comment volume, and time to first review, and find that it varies across author–reviewer pairs. For example, Claude-Code PRs receive more `refactor` comments from CodeRabbit than Copilot PRs (35.0% vs. 10.5%), a difference that may stem from PRs themselves rather than the reviewer. For three of four dual-role reviewers, mean comments per PR were 58–65% higher in the same-product group, though effect sizes were small or negligible and the difference was concentrated in the upper tail. Median time from PR creation to first AI review was 1.2 minutes for cross-product pairs and 4.7 minutes for same-product pairs, reflecting which reviewer bots are in each group rather than the product pairing. Overall, our large-scale characterization shows that closed-loop AI-to-AI code review is on the rise but remains a minority phenomenon, with review output varying across authoring-agent groups and author–reviewer configurations.

## 1 Introduction

Two types of AI coding agents now commonly appear in GitHub pull-request workflows. Some agents author code: systems such as Devin, OpenAI Codex, Copilot, Cursor, and Claude Code can open pull requests (PRs) on behalf of users, either autonomously or as assistive tools [12]. Others review code: tools such as CodeRabbit, Sourcery, and PR-Agent post line-level comments and review decisions. In addition, several authoring agents, including Copilot, Codex, Gemini Code Assist, and Amazon Q, also appear as reviewers in public GitHub data.

Together, these roles form what we call *closed-loop AI review*: an AI coding agent contributes to a GitHub repository, and one or more AI coding agents review it. We use "closed-loop" in this observable sense only. Our review stream is restricted to AI-attributed review events, so the term means that AI occupies both sides of the pull request, not that humans were absent: a PR in our datasets may also have received human review that we do not observe. This shift raises two research questions (RQs):

- **RQ1: How prevalent is closed-loop AI review on GitHub?**
  This RQ characterizes the prevalence and growth of closed-loop review. As AI-generated reviews become more common, an increasing share of public code may be evaluated without direct human review, affecting both downstream maintenance and studies that rely on GitHub review data as evidence of human decision making.
- **RQ2: How does reviewer behavior vary with the author–reviewer setup?**
  This RQ examines whether the authoring agent influences reviewer behavior. If reviewer behavior varies across authoring agents, then closed-loop review cannot be treated as a single process. Instead, both maintainers and researchers need to account for which agent wrote the code and which agent reviewed it.

Prior work has primarily studied AI coding tools and AI review systems in isolation, including productivity effects of code generation tools [16] and usability of AI-assisted suggestions [23]. Earlier studies of reviewer bots [26] were conducted before the current ecosystem of dual-role AI coding agents and do not analyze author–reviewer pairings. This paper addresses these questions by introducing a large-scale dataset and empirical study of AI-to-AI code reviews of GitHub PRs. We identify AI-authored and AI-reviewed PRs by applying our attribution method to CodAGE (CodAGE) events [7] from 2024–2026, enabling measurement of closed-loop interactions at scale. We find this phenomenon already substantial in absolute terms, if still a minority of all agent activity: in 2025, tens of thousands of PRs authored by AI coding agents are reviewed by other AI coding agents across multiple products.

**Contributions.** Overall, this paper makes the following contributions.

1. We introduce a large-scale dataset of AI-to-AI code reviews, covering 248,641 PRs that received at least one AI review: 45,269 cross-product and 208,145 same-product.
2. We characterize closed-loop AI code review patterns over time, tracking how PRs are reviewed by the same or different AI product.
3. We empirically analyze AI reviewer behavior under different author–reviewer setups, examining how reviewer output varies with authoring agent and setup using CodeRabbit comment-category labels, per-pull-request comment volume, and time to first review.

**Paper Organization.** The rest of this paper is organized as follows. Section 2 reviews related work. Section 3 describes our data and methodology. Sections 4 and 5 present our findings on closed-loop AI review prevalence and reviewer behavior. Section 6 discusses implications. Section 7 addresses threats to validity. Section 8 concludes the paper and outlines future directions.

## 2 Background and Related Work

**AI-authored pull requests on GitHub.** Prior work on AI code generation has largely focused on code-suggestion tools used by human developers, including studies of Copilot productivity [16], usability of LLM-based suggestions [23], and AI-assisted pair programming [10].

More recent autonomous or semi-autonomous agents open PRs with limited or no line-by-line human authorship [12]. Prior work characterizes these agent-authored PRs directly: in one study of Claude Code, 45.1 % of merged PRs required additional changes [24]; non-merged agent-authored PRs tend to involve larger changes, touch more files, and fail CI more often [6]; and merge outcomes turn on reviewer intervention and repository context more than on agent identity alone [18]. This work centers on whether agent-authored code is accepted; it says little about how AI reviewers behave when they are the ones doing the evaluating.

**Reviewer-side bots.** Wessel et al. [26] characterized the adoption of bots on GitHub and showed that bot introduction can affect human review volume and latency. Brown and Parnin [2] studied developer interaction with bots in code review workflows, and recent surveys chart how generative AI is now reshaping modern code review more broadly [27]. LLM-based review has since moved into practice, with systems evaluated or deployed at industrial scale [13, 4, 19, 22] and multi-agent review pipelines developed in research [20, 17], alongside a parallel line of work asking whether their output is trustworthy: developers accept only a minority of CodeRabbit suggestions [14], current systems remain weak at realistic review generation [28, 32], and review comments can be ungrounded in the code they describe [21]. A closer group of recent studies looks at reviewer bots specifically on agent-authored PRs [31, 30], reporting that AI suggestions are adopted far less often than human ones and that agent involvement can speed decisions without reliably improving review quality. This work establishes that AI now reviews AI-authored code; what remains open, and what we take up, is which agents review which others across the ecosystem, and whether observable reviewer behavior differs between same-product and cross-product configurations.

**Bot/Agent attribution.** Prior work identifies automated accounts using commit- and account-level heuristics, such as BIMAN [5], or comment-level classifiers, such as BoDeGHa [9]. Ghaleb et al. [8] recently used machine learning models to detect AI coding agents using behavioral fingerprints. While these studies distinguish automated contributions or infer the originating agent, they do not identify the corresponding AI product or vendor, which we address this gap using signature-based attribution of AI coding agents.

**Multi-agent LLM evaluation and this work.** Outside software engineering, "LLM-as-a-judge" [29] and constitutional AI [1] study settings in which models evaluate, critique, or revise model-generated outputs. However, the corresponding deployed software setting, AI reviewers commenting on AI-authored PRs in public repositories, is far less studied. To our knowledge, prior work has not characterized product-resolved AI-author–AI-reviewer pairings at this scale across GitHub. We address this gap by quantifying how often such closed-loop interactions occur, which agents participate, and how reviewer behavior varies with the authoring agent and the author–reviewer configuration.

## 3 Data and Methodology

This section describes the raw GitHub events data, the attribution of events to AI coding agents, the analysis dataset, and the CodeRabbit comment-category classifier.

## 3.1 Data source

Our data source is the CodAGE dataset (Coding Agent-generated GitHub Events) [7] collected from GHArchive.[1] We use the snapshot covering events from 2024-01-01 to 2026-04-15. CodAGE contains several event-type subsets. In this paper, we focus on CodAGE-PRs, CodAGE-Reviews, and CodAGE-ReviewComments from this period. These subsets capture PR authorship signatures and reviewer-side activity. Despite covering the relevant period, many autonomous AI coding agents emerged in early 2025. Candidate events were identified by a broad attribution pass over CodAGE-PRs, which includes branch-name evidence and yields 4,563,819 candidate PRs with a provisional agent label. The signature framework described in Section 3.2 is a stricter second pass over that pool: it requires body or vendor-login evidence and discards branch-only matches.

## 3.2 Identifying AI authorship and AI review

Attributing PRs to AI coding agents by actor login alone is unreliable: some use generic `[bot]` accounts, some use the human user's login with a machine-readable body signature, and some quote other agents' text, which can mislead body-only rules. We therefore use a two-tier signature framework. **S1 (high-confidence body signature)** is a regex or fixed substring the agent produces in the PR or comment body, such as the `Co-Authored-By: Claude <noreply@anthropic.com>` trailer from Claude Code, the `cursor.com/agents` URL from Cursor, or the `chatgpt.com/codex` URL from OpenAI Codex. **S2 (vendor-controlled account signature)** is an exact match or regex over a login unambiguously controlled by a vendor, such as `coderabbitai[bot]`, `devin-ai-integration[bot]`, or `gemini-code-assist[bot]`. `S1` agents require body-level evidence; `S2` agents accept body or login evidence. Branch-name prefixes (e.g. `codex/`, `cursor/`) are recorded but never sufficient alone, being user-controllable and prone to false positives.

We create one entry per matched (event, agent) pair. A few events match multiple agents, usually when one agent quotes another's body trailer: 98 of 4,141,107 review entries (0.002 %) and 111 of 8,560,237 review-comment entries (0.001 %). We retain all matches, report the duplicate rate in the coverage report, and deduplicate by event ID when event-grain analysis requires it. This attributes *review-side* events to 12 AI coding agents (CodeRabbit, Copilot, Gemini Code Assist, OpenAI Codex, Amazon Q, Devin, Claude Code, Sweep AI, PR-Agent, Kiro, Cursor, Aider). The *author-side* stream yields 2,830,284 unique agent-authored PRs and adds Google Jules, which authors PRs but has no reviewer activity.

## 3.3 Cleaning, deduplication, and quarantine

We apply three cleaning steps.

**(i) Quarantine.** Every candidate PR or review event is scored against each agent's signature set, and an entry is emitted only where the evidence meets that agent's *inclusion floor*: agents with an S1 floor require a body signature, whereas agents with an S2 floor accept either a body signature or a vendor-controlled login. A vendor-controlled login is therefore sufficient on its own for S2-floor agents. Any candidate meeting no agent's floor is quarantined, written to a separate file with a recorded reason. On the author side the reasons are `branch_only`, where only a branch-name prefix matched, and `no_evidence`; on the review side, they are

[1] `https://www.gharchive.org`

`empty_body` and `no_evidence`. Quarantine is negligible on the two review streams (590 of 4,141,598 review events and 793 of 8,560,919 review comments, 0.01 % of each) but substantial on the author stream, where 1,733,535 of 4,563,819 candidate PRs (38.0 %) are quarantined, 96.9 % of them as `branch_only`. This asymmetry underlies the coverage imbalance discussed in Section 7: our agent-authored population is the 62.0 % of candidates with a body or login signature, not all PRs a weaker rule would include.

**(ii) Relabeling.** We retain the provisional label from the first pass as `original_label` and report the two passes as a confusion matrix. Where they disagree, the signature attribution wins; the largest relabel consolidates `OpenAI_Codex_Cloud` and the CLI Codex trailer into `OpenAI_Codex`. Because both passes are ours, this is an internal consistency check rather than external validation.

**(iii) Thin agents.** Agents with fewer than 50 attributed PRs (Aider, Kiro, SWE-agent, Windsurf) are excluded from our per-agent quantitative claims.

## 3.4 Dataset construction

The unit of analysis is the *PR*, keyed by `(repo_name, pr_number)`. We aggregate per-event entries into one entry per (PR, Reviewer) pair, retaining review and review-comment counts and first/last review timestamps, then join with the agent-author PR set to yield three datasets (`A`: AI author; `B`: AI reviewer; `N`: no *detected* AI reviewer): **A×B-cross-product**, the closed-loop cross-product dataset with author and reviewer from different products (45,269 PRs, 47,259 pairs); **A×B-same-product**, same product, e.g. Copilot reviewing Copilot (208,145 PRs); and **A×N**, agent-authored PRs with no *detected* AI review (2,581,643 PRs, for context only); absence of an attributed reviewer signature is not evidence that no AI reviewed the PR. A×B PRs receiving both same- and cross-product review appear in both A×B datasets with an overlap flag, so the dataset counts are not mutually exclusive and do not sum to the unique agent-authored total. We do *not* analyze a matched human-authored control dataset.

These two closed-loop datasets are defined at the level of the identifiable agentic *product*, or agentic harness, rather than the parent company or the underlying foundation model: **A×B-same-product** contains PRs in which the same identifiable product appears as author and reviewer, and **A×B-cross-product** those in which the authoring and reviewing products differ. Products operated by the same corporate vendor, such as Google Jules and Gemini Code Assist, are therefore treated as distinct, because they are separately identifiable agentic systems with different product names and potentially different harnesses, configurations, and review workflows; 117 of the 45,269 A×B-cross-product PRs are of this kind. These categories consequently do not necessarily correspond to corporate vendor or foundation-model boundaries.

## 3.5 Severity classifier and released artifacts

**CodeRabbit comment categories.** To measure *review content* for RQ2, we use CodeRabbit's self-declared comment categories. CodeRabbit prefixes substantive comments with emoji-tagged headers: **Refactor suggestion**, **Potential issue**, and **Nitpick**, plus a fourth header, **Verification**, which appears in our historical data (9,525 comments) and which we treat as an observed comment prefix rather than a documented category. Because these headers appear explicitly in the comment text, we extract them deterministically using rule-based

matching without an LLM judge. We retain *severity* in artifact and column names for consistency with the released dataset, but do not interpret the categories as an ordered severity scale. In our dataset, CodeRabbit is the only dedicated reviewer-only bot with both substantial volume and machine-parsable category headers (Sourcery and PR-Agent together account for fewer than 250 review events).

**Classifier.** An ordered-regex pipeline strips boilerplate that would otherwise produce false matches, then applies the rules in order to the cleaned comment body; the first rule wins, and unmatched comments are `unlabeled`. It emits four substantive categories, `potential_issue` (suspected bug), `refactor` (working code whose structure could improve), `verification` (a request to verify a behavior or assumption), and `nitpick` (minor style), on which we impose no ordering, and three structural labels, `analysis_chain` (script-execution diagnostic), `conversational` (`@`-mention reply), and `rate_limited` (an operational rate-limit notice). The rule set and its ordering are provided in the replication package.

**Replication package.** Our replication package (data processing/analysis scripts, filtered data, signature registry, and detailed results) is available on GitHub.[2] The main source data used in this work is CodAGE (Coding Agent-generated GitHub Events), hosted on Hugging Face,[3] specifically CodAGE-PRs, CodAGE-Reviews, and CodAGE-ReviewComments.

# 4 RQ1: Prevalence and Composition of Closed-Loop AI-to-AI Code Reviews

We first establish the scale and growth of closed-loop review, then decompose it by author–reviewer pair and by same- versus cross-product composition.

## 4.1 Volume and growth

Of the 2,830,284 agent-authored PRs we identified, 248,641 (8.8 %) received at least one AI review: 45,269 cross-product and 208,145 same-product, with the counts read as lower bounds and the percentage as conditioned on signature attribution (Section 7). We focus on cross-product review because same-product review may be part of an integrated product workflow. Activity was negligible through 2025-Q1 (57 cross, 40 same) but increased by over two orders of magnitude by 2025-Q3, reaching 25,492 cross- and 57,080 same-product PRs (Figure 1). Because 2025-Q4 counts are incomplete due to GHArchive attribute lag, temporal comparisons use Q2 and Q3.

## 4.2 Who reviews whom?

Table 1 reports the A×B-cross-product author–reviewer crosstab ($N \geq 500$). OpenAI Codex dominates as author (31,601 cross-product PRs, 69.8 % of the 45,269). Its row in Table 1 sums to 32,379 rather than 31,601 because those cells count author–reviewer pairs, not unique PRs: a PR reviewed by agents from two different vendors counts once in Table 2 but contributes a pair to each reviewer column here (and the crosstab shows only cells with $N \geq 500$). Copilot dominates as reviewer (21,022 of the 47,259 author–reviewer pairs; modal pair *Codex authored, Copilot reviewed*, 18,114 pairs), and CodeRabbit, the only dedicated reviewer-only bot with usable volume, reviews PRs from at least six authoring agents.

[2] `https://github.com/Niruthiha/AI-AI-CodeReviews`
[3] `https://huggingface.co/datasets/taher-ghaleb/CodAGE`

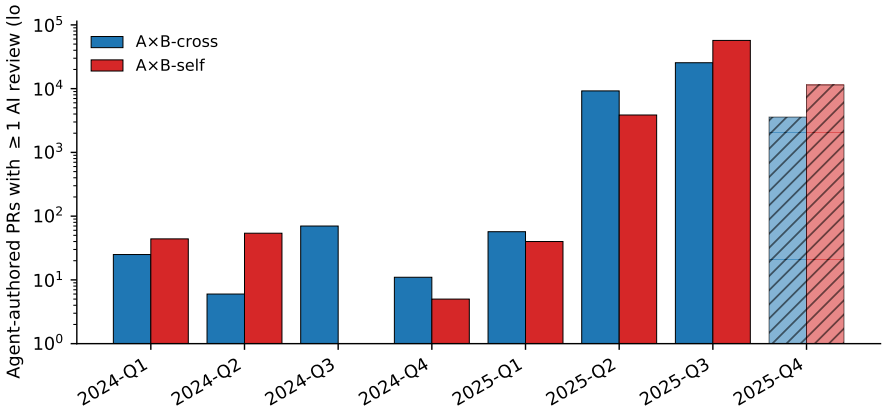

**Figure 1** Quarterly counts of agent-authored PRs receiving AI review, split into cross-product (A×B-cross-product) and same-product (A×B-same-product) groups. Both increased by over two orders of magnitude from 2025-Q1 to 2025-Q3. Hatched 2025-Q4 values are lower bounds because GHArchive attributes lag event data by about one quarter. The y-axis is log-scaled.

**Table 1** Closed-loop, cross-product author–reviewer pairs (A×B-cross-product), cells with $N \geq 500$. Cells report author–reviewer pairs. Because one PR may receive reviews from multiple agents, row totals may exceed the corresponding number of unique PRs.

| Author → Reviewer | Copilot | Codex | Gemini | CodeRabbit | Total (≥ 500) |
|---|---|---|---|---|---|
| OpenAI Codex | 18,114 | – | 8,995 | 5,270 | 32,379 |
| Copilot | – | 4,772 | 956 | 1,627 | 7,355 |
| Cursor | 1,000 | – | 593 | 516 | 2,109 |
| Claude Code | 956 | – | 501 | 716 | 2,173 |
| Devin | 656 | – | – | – | 656 |

## 4.3 Same- vs. cross-product composition

Table 2 reports the same- vs. cross-product split per authoring agent (≥ 200 A×B PRs). The pattern is sharply non-uniform, with three groups: *product-internal* authors reviewed mostly by their own product (Copilot 95.7 %, Amazon Q 91.8 %, Devin 76.5 % same-product); *balanced* (OpenAI Codex at 54.1 % self, the only author with substantial population in both datasets); and *cross-product* authors reviewed almost entirely by a different product (Cursor, Google Jules, Claude Code). This asymmetry motivates RQ2, in which we (i) hold the reviewer constant (CodeRabbit) and vary the author, (ii) contrast same- vs. cross-product review volume, and (iii) contrast time-to-first-review across reviewer bots and product pairings.

**RQ1 Summary:** AI review remains a minority of agent activity but is already substantial: 248,641 of the agent-authored PRs we identified (8.8 %) received at least one AI review, including 45,269 (1.6 %) across products, spanning 10,345 repositories. The counts are lower bounds; the percentages are conditioned on signature attribution. Activity grew by over two orders of magnitude in 2025. Copilot-authored PRs were reviewed mainly by Copilot, whereas Cursor-, Claude Code-, and Google Jules-authored PRs were reviewed almost entirely across products.

**Table 2** Same- vs. cross-product reviewer share, per authoring agent (A×B-cross-product + A×B-same-product, ≥ 200 PRs). Sorted by Total A×B descendingly.

| Authoring agent | Cross-product PRs | Same-product PRs | Total A×B | % Same-product |
|---|---|---|---|---|
| Copilot | 7,515 | 166,442 | 173,957 | 95.7 % |
| OpenAI Codex | 31,601 | 37,247 | 68,848 | 54.1 % |
| Devin | 1,171 | 3,811 | 4,982 | 76.5 % |
| Cursor | 2,309 | 0 | 2,309 | 0.0 % |
| Claude Code | 2,042 | 10 | 2,052 | 0.5 % |
| Amazon Q | 48 | 535 | 583 | 91.8 % |
| Google Jules | 478 | 0 | 478 | 0.0 % |
| Sweep AI | 100 | 100 | 200 | 50.0 % |

## 5 RQ2: Reviewer Behavior Across Authors and Vendor Pairings

We characterize reviewer behavior using three measures. First, we examine CodeRabbit's *comment-category mix* while holding the reviewer fixed and varying the authoring agent. Because these are self-declared labels rather than validated defects, we interpret them as reviewer output composition, not code quality [14, 21, 11]. Second, we compare per-PR comment *volume* between same- and cross-product pairs for Copilot, OpenAI Codex, Devin, and Amazon Q. Third, we measure *latency* from PR creation to the first AI review and examine whether aggregate differences reflect product pairing or reviewer composition.

### 5.1 CodeRabbit comment categories by authoring agent

We join the CodeRabbit classifier output against the union of the A×B-cross-product and A×B-same-product datasets on `(repo_name, pr_number)`, restricting to the five authoring agents with ≥ 200 classified comments (35,248 comments total; Figure 2 and Table 3). The comment-category distribution is visibly non-uniform: Copilot- and Devin-authored PRs receive far more `potential_issue` comments (49.0 %, 43.9 %) and far fewer `refactor` comments (10.5 %, 9.7 %) than Claude Code, Cursor, and OpenAI Codex (29.2 % to 35.0 % `refactor`), and the highest `unlabeled` shares (6.1 %, 12.3 %). Claude Code sits at the opposite end, with the highest `refactor` (35.0 %) and lowest `unlabeled` (0.3 %).

**Table 3** Normalized distribution of CodeRabbit comment categories (%) on agent-authored PRs, authors with $N \geq 200$ classified comments. Last column is the total number of entries ($N$).

| Author | p.issue | refactor | nitpick | a.chain | unlab. | conv. | verif. | N |
|---|---|---|---|---|---|---|---|---|
| OpenAI Codex | 29.9 | 29.2 | 20.5 | 12.8 | 2.4 | 4.7 | 0.5 | 16,292 |
| Claude Code | 42.0 | 35.0 | 7.8 | 10.6 | 0.3 | 3.7 | 0.6 | 8,757 |
| Cursor | 34.9 | 33.5 | 19.8 | 10.2 | 0.9 | 0.2 | 0.5 | 5,084 |
| Copilot | 49.0 | 10.5 | 12.9 | 18.9 | 6.1 | 2.5 | 0.1 | 4,260 |
| Devin | 43.9 | 9.7 | 11.6 | 20.0 | 12.3 | 2.2 | 0.4 | 855 |

The association between authoring agent and CodeRabbit comment category is statistically significant but small (Cramér's $V = 0.150$; Pearson $\chi^2 = 3177.5$, $df = 24$, $p < 10^{-300}$). We therefore focus on the largest category-level contrast. CodeRabbit labels 35.0 % of comments on Claude Code-authored PRs as `refactor`, compared with 10.5 % on Copilot-authored PRs, a difference of 24.5 percentage points (95% CI [23.1, 25.9]; Wald two-proportion test; $N = 8757$ and $N = 4260$ comments, respectively). We make no claim about code quality,

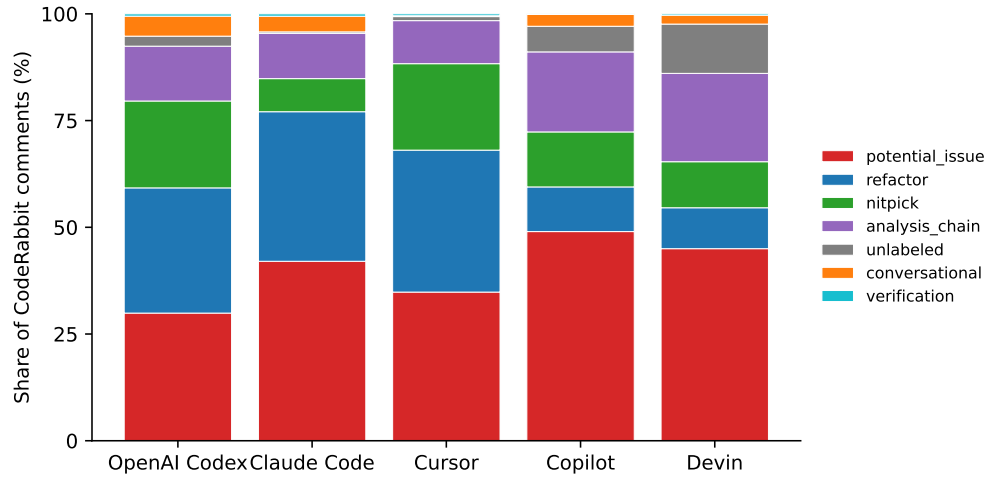

**Figure 2** Normalized distribution of CodeRabbit comment categories on agent-authored PRs, grouped by authoring agent (bars sum to 100%). The same reviewer bot produces visibly different mixes downstream of different authoring agents; the largest single difference is `refactor`, contrasting the Claude Code / Cursor / Codex cluster (29–35%) with the Copilot / Devin pair (10–11%).

as change size, language, repository, and configuration may influence the patterns observed. Our result is therefore observational and indicates that CodeRabbit produces different comment-category distributions for Claude Code- and Copilot-authored PRs.

## 5.2 Same- vs. cross-product review volume

We restrict to reviewer bots with $\geq 200$ PRs in *both* datasets (Copilot, OpenAI Codex, Devin, Amazon Q) and compare per-PR comment counts on same- vs. cross-product authored PRs (Table 4; means with Mann–Whitney $U$ tests, as counts are heavily right-skewed).

**Table 4** Mean review comments per PR by reviewer, split by same- and cross-product authors. Counts use the reviewer perspective: "Self PRs" match the same-product totals in Table 2, whereas "Cross PRs" do not. $p$ values are from two-sided Mann–Whitney $U$ tests; $|\delta|$ is Cliff's delta (self vs. cross; $< 0.147$ negligible, 0.147–0.33 small).

| Reviewer bot | Cross PRs | Mean cross | Self PRs | Mean self | $p$ | $\lvert\delta\rvert$ |
|---|---|---|---|---|---|---|
| Copilot | 21,022 | 1.49 | 166,442 | 2.35 | $< 10^{-292}$ | 0.15 |
| OpenAI Codex | 5,485 | 0.91 | 37,247 | 0.89 | $2.0 \times 10^{-3}$ | 0.02 |
| Devin | 392 | 1.09 | 3,811 | 1.80 | $3.0 \times 10^{-6}$ | 0.14 |
| Amazon Q | 522 | 4.94 | 535 | 8.08 | $2.2 \times 10^{-14}$ | 0.27 |

The per-PR distributions overlap heavily and Cliff's $\delta$ is small-to-negligible across all four bots (Devin and Copilot sit within 0.01 of the 0.147 boundary, so labels are indicative only). The mean-level gap is therefore not a population-wide shift but a long right tail of high-comment same-product PRs: three of four bots show same-product PRs receiving 58–65% more comments on average (Copilot 58 %, 1.49 to 2.35; Devin 65 %, 1.09 to 1.80; Amazon Q 64 %, 4.94 to 8.08), while OpenAI Codex is the lone exception (0.91 vs. 0.89, too small for a directional claim despite a sample-size-driven $p$). This gap is consistent across three otherwise dissimilar products, even though it is concentrated in the upper tail of the

distribution. Because same- and cross-product reviews differ in several key characteristics, including change size, language, repository, and reviewer composition, the observed differences should not be interpreted causally.

## 5.3 Latency from PR open to first AI review

We measure, for every qualifying PR-bot pair in both datasets, the elapsed time between PR creation and the bot's first recorded review event. After dropping pairs missing either timestamp and the small share with negative differences (clock-skew or backfill), 103,920 pairs remain; distributions are heavily right-skewed, so we report medians with IQRs (Table 5).

**Table 5** Median latency from PR open to first AI review, in minutes. Top: same- vs. cross-product pairs aggregated. Bottom: by reviewer bot (datasets pooled), reviewer bots with $\geq 100$ pairs.

| Split | N | p25 | median | p75 |
|---|---|---|---|---|
| Cross-product pairs | 37,420 | 0.4 | 1.2 | 4.4 |
| Same-product pairs | 66,500 | 2.4 | 4.7 | 38.2 |
| Gemini Code Assist (reviewer) | 9,873 | 0.3 | 0.5 | 1.8 |
| Amazon Q (reviewer) | 959 | 0.9 | 1.2 | 1.6 |
| OpenAI Codex (reviewer) | 34,765 | 1.9 | 2.6 | 3.7 |
| CodeRabbit (reviewer) | 6,709 | 3.7 | 7.0 | 31.6 |
| Copilot (reviewer) | 51,437 | 1.0 | 17.7 | 73.9 |

Two observations. First, median first-review latency in the aggregate is 1–5 minutes; AI review on these PRs commonly begins within minutes of PR creation. We do not compare this against a matched human baseline, which we do not have. Second, and counter-intuitively, cross-product pairs have a lower median latency than same-product pairs (1.2 vs. 4.7 minutes), the opposite of a "product rubber-stamps its own" reading. The reviewer-level results suggest that this aggregate difference is compositional: reviewers with shorter median latencies occur more frequently in the cross-product dataset, whereas Copilot, which has a longer median latency (17.7 minutes, p75 74 minutes), dominates the same-product dataset. Because the reviewer populations differ, the observed difference should be interpreted as reflecting reviewer composition rather than any inherent preference for same- or cross-product review.

**RQ2 Summary:** AI review typically starts within minutes, with cross-product reviews being faster than same-product ones (median 1.2 vs. 4.7 minutes). CodeRabbit's `refactor` share was 10 % to 35 % across all agents. Three reviewer bots produced 58 % to 65 % more comments on same-product PRs, though distributions were long-tailed and unmatched.

# 6 Discussion

**Closed-loop AI review is a fast-growing part of the development environment.** AI-authored and AI-reviewed pull requests, though still a minority of public GitHub activity, are already frequent enough in absolute terms that empirical software engineering can no longer assume a purely human-authored population. This complicates sampling assumptions: studies must explicitly account for AI-generated artifacts or risk mixing fundamentally different populations.

**Reviewer output differs across authoring-agent groups.** With CodeRabbit held constant, the observed comment-category distributions differ across authoring agents. These differences may reflect the types of PRs produced by each agent, repository context, or reviewer

behavior, which the present analysis cannot separate. Downstream tooling that summarizes or aggregates AI review output may therefore produce systematically different interpretations for different AI coders, even under the same reviewer.

**Same- and cross-product patterns may reflect product design.** The two groups differ in reviewer composition and may also differ in product integration and triggering, so the observed gaps need not reflect review strictness or reviewer preference. Product boundaries also need not match model boundaries, since different products may share a foundation model and one product may run several.

## 7 Threats to Validity

We organize the threats to validity into construct, internal, and external dimensions.

**Construct validity.** Our attribution uses signature-based identification, which can undercount agents whose signatures are missing, uncatalogued, or removed by vendors. The framework is designed to prioritize precision, but residual misclassification remains possible when signatures are copied, quoted, modified, or shared across product variants. Missing or removed signatures additionally produce under-attribution. The absence of a signature is not evidence that a PR was not AI-authored or AI-reviewed: such PRs are not quarantined but simply never enter our population. Under-attribution is also asymmetric, being far lower on the reviewer side, where the major reviewers post under vendor-controlled bot logins, than on the author side, which depends on body trailers that agents may not emit and that squash merges may strip. Absolute counts are therefore lower bounds, whereas rates expressed per agent-authored PR inherit the coverage of both sides and should be read as describing the attributable population rather than all AI-authored PRs. In addition, our RQ2 content measures rely on CodeRabbit's self-declared and observed comment categories. These labels describe the tool's own output and are not independently validated measures of issue type, severity, correctness, or code quality. External validation with human annotation or LLM-based judges is deferred to future work.

**Internal validity.** Our study reports observational associations rather than causal effects. Confounding factors such as pull request size, language composition, repository-level differences, and product-specific integration behavior may influence observed patterns. While we report several robustness checks in the main analysis, we do not claim causal identification.

**External validity.** Our dataset covers public GitHub events in CodAGE (CodAGE) [7] from 2024-01-01 to 2026-04-15, excluding private repositories, GitHub Enterprise deployments, and other version control platforms. AI reviewer activity is therefore conditioned on repositories that adopt specific integrations, and results may not generalize to non-adopting projects. Our "closed-loop" definition requires an AI coding agent on each side of the PR and does not require the absence of human review: the review stream we mine is restricted to AI-attributed events, so we cannot determine whether a human also reviewed a given PR, and some closed-loop PRs likely received human review as well. Finally, "cross-product" reflects product-level attribution rather than model-level identity.

## 8 Conclusion and Future Work

This paper presented a large-scale dataset and empirical study of AI reviews on AI-authored GitHub pull requests, defined as PRs authored by one identified AI coding agent and reviewed by one or more identified AI reviewers. Although still a minority of agent activity, such review grew rapidly over 2025 and already spans tens of thousands of cross-product interactions. Reviewer output differed across authoring-agent groups and author–reviewer configurations, in comment-category mix, per-PR comment volume, and latency. These findings describe observable reviewer behavior, not review correctness or software quality.

**Validating review content and usefulness.** Our content analysis relies on CodeRabbit's own categories, which describe its output but are not validated measures of correctness, severity, or usefulness, and prior work finds that AI review comments may be rejected, redundant, or poorly grounded in the code [14, 21, 28]. Future work should have human annotators rate a stratified sample of comments for correctness, localization, severity, and actionability, reporting inter-rater agreement, with LLM-based evaluation used only as a secondary check. Comment volume, latency, and category mix do not show whether a review improves the code, so annotation should be paired with outcome linkage to accepted suggestions, later commits, continuous-integration results, merges, and reverts, treating acceptance as a response signal rather than a measure of precision. Matched human- and AI-authored pull requests – aligned on repository, language, task type, and change size, would isolate AI authorship patterns from those of the review system or context.

**Separating product effects from model effects.** Attribution here operates at the product level because public records rarely reveal the underlying model, so same- and cross-product configurations are not same- and different-model configurations. Because LLM evaluators may favor outputs that resemble their own or appear more familiar [15, 25, 3], controlled experiments could review functionally equivalent pull requests from known models under fixed configurations, using source blinding and function-preserving transformations of naming, formatting, or structure. Outcomes should include defect detection, false-positive rates, severity calibration, comment volume, and review correctness.

**Testing correlated failures and security risks.** AI authors and reviewers may share failure modes when they rely on related models, training sources, prompts, or tools, which the current dataset cannot assess because model identity and ground-truth defects are unavailable. A controlled benchmark could inject known functional defects and security vulnerabilities into realistic pull requests and compare same-model, related-model, and independent-model reviewers on defect recall, false positives, localization, severity, and repair correctness, showing whether reviewer diversity reduces correlated blind spots.

**Provenance and longitudinal measurement.** Public records reveal little about how a contribution was produced and reviewed, so future tools should expose structured metadata on authoring and reviewing products, model versions, review triggers, configurations, and human involvement, distinguishing independent review from automatic same-product review. Because the ecosystem changes rapidly, the pairings and activity levels reported here describe one period; the broader contribution is a reproducible method for measuring AI participation in authorship and review, which, repeated over time with model-level provenance and outcome-based evaluation, will help assess whether these workflows improve software correctness, security, and maintainability.

## Data Availability Statement

The replication package, including the agent signature registry, data-processing scripts, classifier, and analysis code, is available at `https://github.com/Niruthiha/AI-AI-CodeReviews`. The source dataset, CodAGE(Coding Agent-generated GitHub Events), is available on Hugging Face at `https://huggingface.co/datasets/taher-ghaleb/CodAGE` under CC BY 4.0. These artifacts reproduce the counts, tables, and figures reported in this paper.

# Do LLMs Understand Validity? An Empirical Study of Machine-Generated Threats to Validity in Software Engineering

**Ryan Dang**
Department of Informatics, University of California, Irvine, USA

**Noshin Tahsin**
Department of Informatics, University of California, Irvine, USA

**Thomas Zimmermann**
Department of Informatics, University of California, Irvine, USA

## Abstract

**Background.** Threats to validity (TTV) are a core component of empirical research, yet software engineering studies fail to address them adequately. Published studies often omit validity discussions entirely, report generic concerns disconnected from the study's actual methodology, or treat validity analysis as a procedural formality rather than a purposeful part of the research process.

**Aim.** This study investigates whether large language models (LLMs) can generate threats to validity that are meaningful, study-specific, and novel, i.e., not reported by the original authors.

**Method.** We conducted an empirical experiment using Gemini 2.5 Flash across 375 papers from ICSE 2025, withholding each paper's TTV section prior to model input, ensuring the model reasoned from the study's content rather than reproducing author-reported concerns. Generated threats were evaluated against a four-dimension rubric covering *relevance, specificity, clarity,* and *mitigation quality*, and compared against the original threats to determine *novelty*. All threats were then grouped into a taxonomy of seven categories to characterize the distribution of generated validity concerns.

**Results.** The experiment produced 2,673 threats across the dataset, of which 97% were rated as relevant, specific, and clearly articulated, and 92% received high ratings for mitigation quality. Furthermore, 61% of the generated threats were absent from the original papers, suggesting that the model identified validity concerns beyond those reported by the original authors.

**Conclusions.** LLMs can generate technically sound and previously unreported threats to validity at scale, demonstrating their capacity to support researchers in identifying overlooked methodological risks and strengthening the completeness of validity discussions, while augmenting rather than replacing researcher judgment in the process.

## 1 Introduction

Empirical research is a significant area in software engineering, which offers a systematic basis for evaluating tools, methods, and practices in real-world contexts. The flexibility of empirical study design allows researchers to adapt their methodologies to their research

questions. However, this flexibility can lead to the validity of findings not being uniform across studies. The threats to validity (TTV) section in research papers exist to address this, providing documented concerns about what could have influenced a study's results and how those risks were mitigated [7]. The threats serve as the primary mechanism by which authors reason about the reliability of their conclusions across dimensions like internal, external, construct, and conclusion validity [24, 22, 30, 14].

Despite their importance, TTV sections are often poorly handled in practice. Prior studies show that validity discussions can be shallow or absent, rely on standardized categories that may not fit the study method, and treat validity reasoning as an afterthought rather than integrating it into research design [22, 9, 25]. So far, reporting guidelines have been proposed to address this gap, guiding researchers in identifying where validity reasoning is missing [23, 28, 2, 20]. However, inconsistencies in TTV identification and reporting remain. This motivates us to investigate whether LLMs can provide additional support for identifying study-specific validity concerns. We aim to move beyond manual threat identification toward the automated identification and generation of study-specific, meaningful threats using LLMs given their growing use for reasoning and scientific writing tasks [4, 13, 1, 18]. To empirically investigate this potential, we aim to answer the following research questions (RQs).

- **RQ1:** How effectively can LLMs generate study-specific, meaningful threats to validity?
- **RQ2:** To what extent can LLMs identify threats that are not documented in the original paper?
- **RQ3:** What taxonomy of threats emerges from LLM-generated output and how well are different categories of threats represented?

To answer these, we conducted an empirical experiment using Gemini 2.5 Flash on 375 papers collected from ICSE 2025. For each paper, we removed the original TTV section and provided the remaining content to the model as input, asking it to generate threats based on the study content. This ensured that the model derived threats from the study's goals, methodology, and findings rather than reproducing author-reported concerns. The resulting 2,673 threats were evaluated using a rubric covering relevance, specificity, clarity, and mitigation quality, and compared with the original threats to assess novelty. Followed by that, all threats were grouped into a taxonomy of seven thematic categories to characterize the distribution of LLM-generated validity concerns.

The results show that 97% of the generated threats were rated as relevant, specific and clearly articulated, and 92% received high ratings for mitigation quality. Moreover, 61% of generated threats were absent from the original papers, demonstrating that the model was able to identify concerns the authors had not reported. These findings position LLMs as practical assistive tools for validity reasoning, contributing both an empirical characterization of LLM capability in this domain and a reusable taxonomy of validity concerns for software engineering research.

## 2 Related Work

Threats to validity are a foundational concern in empirical research and have been studied extensively across software engineering literature. Classic methodology texts establish the need to distinguish internal, external, construct, and conclusion validity, and to reason about them throughout study design, execution, and reporting [24, 22, 30, 14]. In software engineering, these principles have been adapted to different empirical research methods, with validity considerations varying according to the research design, goals, data sources, and

context [20, 29, 2]. Despite the availability of these methodological frameworks, prior research has identified persistent problems in how threats to validity are addressed and reported in practice [9, 25].

For example, a literature review of 405 papers from major software engineering venues (ICSE, ESEC/FSE, EMSE) found that 46% of empirical studies did not discuss threats to validity at all, and just 23% differentiated between types of validity [22]. Another study that analyzed 91 Distinguished ICSE Papers published from 2014 to 2023 found that only 22% of ACM papers discussed study-specific threats in depth and another 22% omitted them entirely [9]. Besides, TTV sections in research papers are often superficial, treated as a checklist or afterthought, rather than as an essential part of research design and interpretation [9, 25]. Studies also report misuse of validity categorization, issues with community practice, confusion with limitations and neglected tradeoffs between threats [25]. Findings show that researchers often use a standardized TTV categorization approach without considering if it fits their study type or method. Both authors and reviewers enforce shallow, standardized TTV discussions, sometimes requiring irrelevant threats to be discussed. Authors also frequently conflate study limitations with genuine validity threats. Additionally, there is little discussion of trade-offs between different types of validity threats, even though some may be more important than others depending on the study's goals. To improve the identification of TTV in practice, a range of structured taxonomies and guidelines have been proposed across the literature. For example, there are case-study reporting guidelines that explicitly call for threat identification across construct, internal, external, and conclusion validity [20]. However, despite this guidance, inconsistency in how threats are classified and reported has persisted over time with no observed trend of improvement [9].

Followed by work on guidelines for authors, studies have taken a step ahead to investigate whether the empirical research process can be enhanced through automation. Existing studies explored LLM's ability to infer, deduce, or connect information, which are the core aspects of reasoning [13]. They showed that high-capacity language models can perform a wide range of natural language processing tasks including answering questions, reading comprehension, text summarization, translation, and commonsense reasoning. All these can be achieved in a zero-shot setting without explicit supervision or task-specific training while getting competitive results across many benchmarks [13]. Studies also investigated how chain-of-thought prompting makes reasoning better resulting in performance gains [27]. Prior work also shows how people's information practices are changing in academic settings regarding text summarization and citation generation in this age of LLM [5]. Studies in this area discuss how LLMs can accelerate the literature review process by speeding up traditional approaches including manual search and data synthesis [3, 15]. Studies also discuss the usefulness of LLM-generated data for prototyping and augmentation, and the risks associated with it (e.g., lack of consistency and representativeness) [19]. Besides, they mention how LLMs help in generating interview questions, structuring publications, and reviewing research papers, while also critically analyzing how humans and LLMs are different in their approach and the risks with relying entirely on LLMs [17, 31]. However, to the best of our knowledge, no study has explored how LLMs can guide the generation of threats to validity by producing meaningful, context-specific threats. In this study, we aim to fill this gap based on empirical evidence.

## 3 Methodology

To answer RQ1 and RQ2, we conducted an empirical experiment to evaluate the quality and novelty of LLM-generated threats by comparing them with the threats reported in the original papers. To answer RQ3, we conducted an iterative taxonomy development process

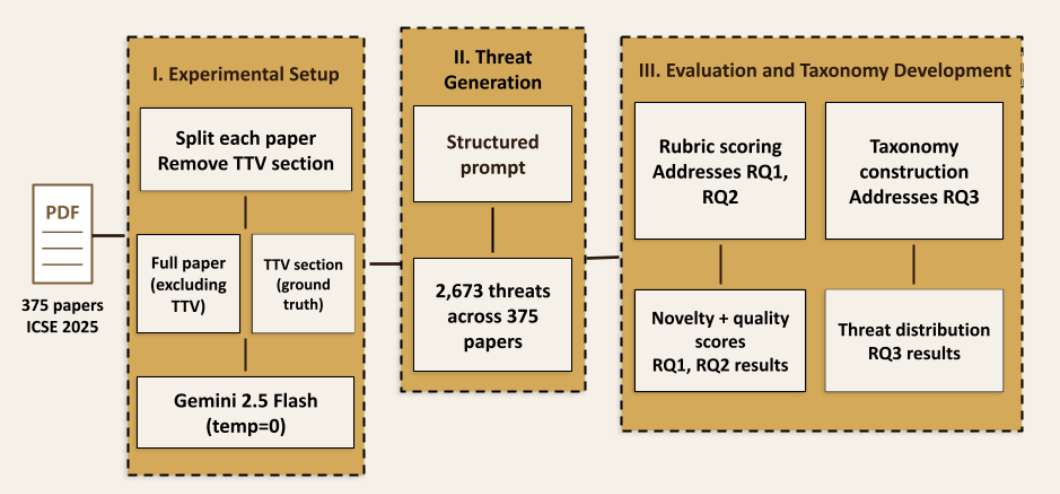

**Figure 1** Overview of the study design for the empirical experiment (RQ1-RQ2) and taxonomy development (RQ3).

to identify and categorize common patterns across the LLM-generated threats. The following subsections describe the experimental setup and threat generation, evaluation framework, and taxonomy development process in detail. Figure 1 presents an overview of the study design.

## 3.1 Experimental Setup and Threat Generation

To establish a reliable ground truth for evaluating the quality and novelty of the LLM generated threats, we collected 375 research papers from ICSE 2025 [10]. We selected ICSE papers because they represent the influential empirical work by the SE community and operate under consistent constraints. Although journal articles with larger page budgets may provide more comprehensive descriptions of threats to validity, the limited page budget of a conference like ICSE requires authors to prioritize the threats they consider most important, providing a clearer view of actual reporting practices under constraints.

Each paper $P$ was systematically split into two documents automatically: $D_M$ containing the full paper *excluding* the TTV section, and $D_{TTV}$ containing only the TTV section (so $P = D_M \cup D_{TTV}$). This splitting was done to prevent the LLM from directly using the TTV mentioned in the input document and ensure that it generates threats based on the research study's methodology, results and other information available that helps the model understand the study's procedure and purpose.

The separated TTV section also works as a reference point and enables us to compare the LLM generated threats against the original threats mentioned in the study and answer whether LLM generated threats overlap with the original threats or have been not reported in the original paper. We selected Gemini 2.5 Flash as the generation model based on its strong reasoning capabilities, its ability to process long documents within a single context window, and its throughput at the scale required to process 375 papers [8, 6]. The temperature was set to zero across all runs to ensure deterministic and reproducible outputs [16].

To investigate whether LLMs can generate study-specific, meaningful threats (RQ1) and identify previously undocumented risks (RQ2), each paper was passed to the model with a structured prompt instructing it to identify the research goal of the study, determine which

validity categories were most relevant to that goal, generate threats that could plausibly affect the study's conclusions, compare tradeoffs, and recommend appropriate mitigation strategies for each threat. This process produced 2,673 threats across the dataset.

Our approach is retrospective by design, as it generates threats from completed papers. The goal of this preliminary study is not to address validity concerns in already completed studies, but to use completed studies, where both the study methodology and reported TTV are available, to evaluate whether LLMs can identify additional meaningful threats. These findings provide a basis for future work investigating LLM-based threat generation earlier in the research process, when identified threats could inform study design and mitigation decisions.

## 3.2 Evaluation Framework

To assess the quality of generated threats (RQ1) and their novelty (RQ2), we developed an evaluation framework combining rubric-based scoring with comparison against the threats documented in the original TTV sections. Each of the 2,673 threats generated by the model was scored using a rubric across four dimensions: *relevance, specificity, clarity,* and *mitigation* where (a) *Relevance* assesses whether the threat meaningfully affects the study's conclusions, scored as either having impact or no impact, (b) *Specificity* measures how grounded the threat is in the study's design and context, (c) *Clarity* evaluates how well-articulated and understandable the threat is, and (d) *Mitigation* rates whether the proposed response is appropriate and actionable. The rubric was informed by prior work on empirical validity assessment [20, 7] and LLM output evaluation [26, 21]. To refine the rubric, Gemini was first prompted to generate rating criteria for relevance, specificity, clarity, and mitigation. Then two authors independently graded a subset of the generated threats, compared scores, and adjusted the rubric wherever disagreements revealed unclear or overlapping definitions. This process continued across different batches until consistent scores were achieved across reviewers.

Each generated threat was then automatically compared against the original TTV section of the corresponding paper and classified into one of three categories: (a) present in both the original paper and the model output, (b) present only in the original paper, and (c) generated only by the model. This comparison allowed us to determine how many of the generated threats were previously unreported, and how many were already reported by the authors in the original study.

See the Data Availability section to access all scripts, datasets, and prompts used in this study.

## 3.3 Taxonomy Development

To answer RQ3, we conducted an iterative taxonomy development process to identify patterns across the generated threats. We grouped the 2,673 threats produced by Gemini into thematic buckets based on semantic similarity. Threats were processed in batches of 100, with the model prompted to generate categories that best captured the similarities among threats within each batch. The resulting categories were compiled and manually reviewed, with overlapping and redundant categories merged for consistency. For example, categories such as "Researcher and Analysis Bias" and "Researcher and Observer Bias" were combined into a single category. This process produced seven final categories: (a) Measurement and Construct Definition Issues, (b) Sampling and Generalizability Issues, (c) Internal Validity and Confounding Factors, (d) Scope and Context Limitations, (e) LLM/AI-Specific

Challenges, (f) Statistical and Conclusion Validity, and (g) Researcher and Analysis Bias. This categorization allowed us to analyze the distribution of each threat category and identify which types of threats were frequently generated by the LLM but not documented in the original TTV sections, leading to a broader coverage of validity concerns.

# 4 Results

Our analysis of the 2,673 generated threats shows that LLMs are effective at generating relevant, specific, and clearly articulated threats with strong mitigation strategies in most cases, and contribute to novelty by identifying risks not present in the original papers. However, the model did not fully replicate all author-reported threats and occasionally produced generic outputs, positioning LLMs as assistive tools that augment rather than replace human reasoning. The following subsections elaborate on these findings.

## 4.1 Quality of Generated Threats (RQ1)

We evaluated the quality of generated threats using our rubric across four dimensions: relevance, specificity, clarity, and mitigation. We found that, the model produced high-quality threats across all dimensions. Of the 2,673 generated threats, 2,596 (97%) were classified as having meaningful impact and 77 (3%) had no impact. In terms of specificity, 2,597 threats (97%) were rated as highly specific, 75 ( 3%) had low specificity, while only 1 was categorized as having medium specificity. Similarly, 2,599 threats (97%) demonstrated high clarity and 74 (3%) showed low clarity. Mitigation quality was slightly lower but still strong: 2,464 threats (92%) received high ratings for concrete, study-specific, and actionable mitigation steps, 130 (5%) mentioned mitigation but lacked depth, and 79 (3%) had generic or boilerplate responses.

To illustrate what these scores mean in practice, we examine a threat generated for the paper "Designing Abandabot: When Does Open Source Dependency Abandonment Matter?"[12] in detail. The paper studies how developers perceive and manage the impact of abandoned dependencies in open source projects. The authors conducted semi-structured need-finding interviews with 22 open-source maintainers. During the interviews, participants discussed how the dependency's abandonment would impact their project, how the context of their usage of the dependency affects the impact of abandonment, and whether they would want to be made aware of its abandonment and why. The authors also used probing questions when participants had difficulty articulating their reasoning.

The LLM identified social desirability bias as a threat, where participants may provide responses they believe researchers expect rather than their genuine opinions because of feeling implicit pressure to present themselves as proactive or technically informed. This is relevant to the interview-based study design because the findings depend directly on participants' reported perceptions and reasoning. However, the generated threat did not connect this bias to specific aspects of the interview protocol, such as participants discussing their own dependencies or interacting with the prototype. The model nevertheless correctly identified this as a risk to the study's internal validity and proposed mitigation strategies including ensuring anonymity and confidentiality, using open-ended questions, and asking probing questions.

Scoring this threat against the rubric reveals an important pattern. While this threat is relevant and clearly articulated, it remains generic and is not strongly grounded in the specific design or findings of the study. Besides, the mitigation strategies, although valid, reflect standard interview practices rather than study-specific interventions. As a result, this

threat is characterized by high clarity but low specificity and low mitigation quality. This example illustrates how our rubric distinguishes lower-quality threats from more contextually grounded threats. Threats that identify valid risks but remain disconnected from the study's specific design, data, and findings tend to score high on relevance and clarity but low on specificity and mitigation, making them lower-quality threats. In contrast, threats that are contextually grounded, i.e., explicitly connected to the study's design, data, and findings, while also being clear and relevant, are considered higher-quality threats that are more specific, practically useful, and provide actionable mitigation.

## 4.2 Novelty and Coverage of Threats (RQ2)

To analyze the novelty of the generated threats, we compared each generated threat against the original TTV section of the corresponding paper. We found that 61% of the generated threats were new, i.e., they did not overlap with author-reported threats. This implies that the model is able to identify previously undocumented threats, providing an alternative perspective on potential validity concerns that researchers may overlook during the writing process. At the same time, the model did not fully reproduce all author-reported threats, which reflects an important limitation: certain study-specific concerns that authors identify through deep familiarity with their own work are not always recoverable from the paper text alone. This behavior demonstrates the role of LLMs as complementary tools for threat to validity identification. While the model is effective at expanding the space of possible threats, missing some study-specific concerns captured by the original authors indicates that it is not a replacement for human reasoning. The degree of novelty also varied across threat categories, with some categories showing higher rates of new generation than others, which we examine further in RQ3.

## 4.3 Taxonomy of Threats (RQ3)

We categorized all 2,673 generated threats into seven thematic groups to analyze their distribution across validity dimensions. The largest category was Measurement and Construct Definition Issues (802 threats), followed by Sampling and Generalizability Issues (642 threats) and Internal Validity and Confounding Factors (588 threats). Smaller categories included Scope and Context Limitations (187 threats), LLM/AI-Specific Challenges (160 threats), Statistical and Conclusion Validity (160 threats), and Researcher and Analysis Bias (134 threats). Newly generated threats were prevalent across all categories. Measurement and Construct Definition Issues contained 508 (out of 802) new threats, Internal Validity and Confounding Factors contained 401 (out of 588), and even smaller categories showed high novelty rates, with 107 (out of 134) Researcher and Analysis Bias threats being newly identified. These results show that LLMs generate a diverse set of threats spanning multiple validity dimensions rather than concentrating on a single type. The dominance of certain categories, particularly measurement and sampling concerns, may reflect biases in both model outputs and existing research practices, where these threat types are most commonly discussed and therefore most readily generated. Table 1 summarizes the full distribution of threats across categories and their corresponding novelty proportions.

# 5 Discussion

This section discusses the implications of our findings for the use of LLMs in validity reasoning and the broader research process. We discuss both the opportunities and limitations of LLM-generated threats, followed by the potential role of LLM in scientific writing, research artifacts, and human-AI research collaboration.

| Category | Total | New Threats | % of New |
|---|---|---|---|
| Measurement and Construct Definition | 802 | 508 | 63% |
| Sampling and Generalizability | 642 | 321 | 50% |
| Internal Validity and Confounding Factors | 588 | 401 | 68% |
| Scope and Context Limitations | 187 | 107 | 57% |
| LLM/AI-Specific Challenges | 160 | 107 | 67% |
| Statistical and Conclusion Validity | 160 | 107 | 67% |
| Researcher and Analysis Bias | 134 | 107 | 80% |

**Table 1** Distribution of Threats Across Thematic Categories (RQ3).

## 5.1 Expanding the Space of Validity Concerns

Our findings show the high relevance, clarity, and novelty of LLM generated threats which indicate that LLMs can expand the space of potential validity concerns beyond what authors typically report. This positions LLMs as supportive tools that help researchers identify overlooked risks and develop more comprehensive TTV sections. However, our findings also show that LLM-generated threats are not always perfect, as some were generic, insufficiently grounded in the specific study, or provided generic mitigation strategies, as illustrated by the "Designing Abandabot: When Does Open Source Dependency Abandonment Matter?" [12] example in Section 4.1. Therefore, LLMs do not replace the need for researchers to construct threats to validity, although they can significantly enhance this process. Automated generation also raises questions of responsibility, authorship, hallucinations, and bias, making human oversight essential to validate, refine, and contextualize the outputs. Researchers should verify generated threats instead of accepting them automatically. Rather than fully automating TTV construction, a more appropriate approach is human-in-the-loop collaboration, where researchers iteratively review and adapt LLM-generated suggestions. This can maintain correctness and accountability while benefiting from the model's breadth.

## 5.2 From Writing to Co-Writing: Rethinking Scientific Authoring

The ability of LLMs to generate structured and meaningful threats to validity reflects a broader opportunity to support scientific writing. By assisting in identifying gaps, refining arguments, and suggesting mitigations, LLMs can contribute to improving the overall quality and completeness of research papers. This aligns with emerging perspectives in the software engineering community that view AI as a co-authoring assistant capable of enhancing clarity and rigor. Beyond TTV, similar capabilities can support other stages of writing, such as designing methodologies, structuring literature reviews, and framing results. For example, an LLM can suggest missing experimental steps and alternative study designs, or organize prior work into coherent themes, helping researchers move from scattered ideas to a well-structured narrative. When framing results, it can assist in interpreting findings, identifying limitations, and connecting outcomes back to research questions.

An important distinction, however, lies in the type of input required. For generating threats to validity, the model benefits from access to the full context of the paper, including research goals, methodology, and findings, which allows it to reason about potential risks. In contrast, supporting other sections may require different forms of input. Methodology design may rely more on problem framing and prior work, literature review structuring depends on access to a corpus of related papers, and result interpretation requires detailed

experimental outputs. This suggests that effective use of LLMs in scientific writing is not one-size-fits-all, but depends on providing the right contextual grounding for each task. At the same time, reliance on AI-generated content must be carefully managed. Overuse of generic suggestions may reduce the specificity and originality of scientific writing. Over-reliance on automatic threat generation may also reduce researchers' active involvement in thinking about validity concerns and eventually lead to de-skilling. Therefore, the role of LLMs should be framed as augmentative rather than substitutive, supporting researchers in producing better-grounded and more thoughtful contributions. Future work should explore human-in-the-loop approaches that keep researchers actively involved in reviewing, validating, and refining LLM-generated suggestions.

## 5.3 From Consuming Static Papers to Interacting with Artifacts

LLMs can support not only the writing of research papers but also how they are consumed. While we focus on threats to validity, similar techniques can be extended to other components of a paper to make them more accessible and informative. For instance, LLMs could enable adaptive related work sections that evolve as new research emerges, helping readers stay up to date without manually tracking the literature. They could also suggest alternative analysis perspectives, generate clearer or more engaging visualizations, and provide personalized summaries tailored to different audiences, such as beginners, practitioners, or experts. This points toward a shift from static documents to more dynamic and **interactive research artifacts**. Instead of passively reading a paper, users could engage with it through conversational interfaces, ask follow-up questions, or explore specific sections in more depth. Concepts such as chatting with a paper, automatically generated summaries, or multimodal representations like audio explanations reflect this emerging direction.

However, these possibilities also introduce challenges. AI-generated interpretations may introduce inaccuracies or biases, and over-reliance on such summaries could reduce critical engagement with the original work. Additionally, there is growing pushback from the community regarding the use of AI in research dissemination, including concerns around AI-generated summaries and automated content (for example, see the release of AI summaries in the ACM Digital Library [11]). As a result, balancing accessibility with trust and fidelity remains an important consideration.

## 5.4 From Retrospective Evaluation to Research Collaboration

LLMs offer meaningful support to researchers well before the writing stage begins, acting as thinking partners across all the stages of the research process. In the earliest phases, they can help sharpen problem framing, surface promising research directions, and identify gaps in existing knowledge. They are especially valuable during literature review, where they can organize large bodies of prior work into coherent themes, reveal connections across studies, and surface relevant papers that a researcher might overlook, supporting more systematic and well-grounded research before it is translated into writing. They can flag missing steps in methodology, propose alternative approaches, and draw attention to assumptions or risks that might otherwise go unnoticed.

However, realizing this potential depends on how AI tools are designed. AI tools for research should be designed not as generic text generators, but as systems tailored to the needs of researchers. A key requirement is support for context-sensitive reasoning, where the quality of outputs depends heavily on the inputs provided. As seen in our study, generating meaningful threats to validity requires access to rich contextual information such

as research goals, methodology, and findings. This demonstrates the importance of designing AI systems that allow researchers to control and curate the context provided to the model. In practice, this implies giving researchers greater autonomy over prompt construction and context engineering. Rather than relying on fixed, opaque prompts, AI tools should expose mechanisms that allow users to iteratively refine inputs, select relevant sections of a paper, and guide the model toward more grounded outputs. Interface support becomes critical here, enabling users to structure inputs, compare outputs across variations, and trace how different contexts influence results. Such design shifts position AI not as a black-box assistant, but as an interactive collaborator which can improve transparency, reproducibility, and trust in AI-assisted research workflows, while also ensuring that researchers remain in control of the reasoning process.

## 6 Threats to Validity

We organized the threats to validity of our study around construct validity, internal validity, and external validity. We did not consider these threats only after completing the research. During the study design, we considered limitations associated with selecting only ICSE 2025 papers, using one LLM, evaluating generated threats using four dimensions and two raters, and constructing a common taxonomy across different study types. Given the exploratory nature of this study, we intentionally kept the initial scope limited and report these remaining threats transparently. Our findings provide a basis for future work using multiple LLMs, additional raters and repeated runs, journal papers, multiple venues and years, and method-specific validity frameworks. We discuss these threats in detail in the following subsections.

**Construct Validity.** First, we defined an "undocumented" threat as one generated by the LLM but not identified in the original TTV section of a paper. This does not necessarily mean that the authors overlooked the threat. Authors may have considered the threat and omitted it due to space constraints, mitigated the threat in the method section, or judged it as irrelevant for reporting. Therefore, our comparison measured whether a threat was explicitly documented in the TTV section rather than whether the original researchers were aware of it. Second, our evaluation measured the quality of LLM-generated threats using four dimensions: relevance, specificity, clarity, and mitigation. Although these dimensions provide a structured, checklist-like way to evaluate generated threats, they do not provide a deep assessment of the threats. The rubric was developed and refined by two authors and therefore may carry some subjectivity. Although we iterated until consistent scores were achieved, a larger and more diverse set of raters would strengthen the evaluation. However, the dimensions relevance and specificity in our evaluation rubric helped us to reduce the impact of hallucinated or biased outputs generated by the LLM. They helped assess whether each generated threat is actually relevant and grounded in the study's design and context. Finally, the taxonomy was also constructed iteratively using the same model that generated the threats, which introduces potential circularity. The resulting categories may reflect patterns in Gemini's output rather than an independent characterization of the validity threat space. Future work should validate the taxonomy against independently constructed frameworks and through expert review.

**Internal and External Validity.** Regarding threat to internal validity, the generated threats may depend on the prompt and model configuration used in the study. Although we used the same prompt and set the temperature to zero to reduce output variability, the prompts

used in this study may not be optimal. Alternative prompt formulations or more structured prompting strategies may produce different or higher-quality threats. Repeated runs and systematic evaluation of alternative prompts would provide stronger evidence that our findings are consistent across these design choices.

Regarding threat to external validity, our dataset is limited to ICSE 2025 papers, which may not represent TTV reporting practices across other publication settings. As justified in the Methodology, we selected a single conference and year to maintain consistent publication constraints and keep the scope manageable for this preliminary study. Future work should extend the study to journal papers and papers from multiple venues and years to assess the generalizability of our findings. In addition, papers published in 2025 may have been influenced by AI-assisted writing or proofreading, while older papers could provide a more independent baseline. Future work should therefore examine papers published before the widespread use of generative AI too.

Our evaluation also relies exclusively on Gemini 2.5 Flash. Whether the findings hold for other models (e.g., GPT-4, Claude, Llama) remains an open question. Different models are trained on different data, use different architectures, and undergo different optimization procedures, which can result in variation in their outputs. Therefore, the observed effectiveness, distribution of generated threat types, and degree of study-specific grounding may be specific to the model evaluated in this study. Future work should replicate our evaluation across multiple LLMs and repeated runs to assess the generalizability and consistency of the findings.

Finally, our study combines papers that use different empirical research methods, such as experiments, case studies, surveys, and mining software repositories, which may involve different validity concerns. We used a common taxonomy because, as an initial exploration, our goal was to examine the overall landscape of LLM-generated threats and understand how LLMs can support threat generation across empirical SE research. We do not claim that this taxonomy is universally applicable across all research methods. Future work should investigate method-specific threats and taxonomies based on existing validity guidelines for individual research methods.

## 7 Conclusion

This study investigated whether large language models can generate study-specific, meaningful, and novel threats to validity for empirical software engineering research. Across 375 papers from ICSE 2025, the pipeline produced 2,673 threats, of which 97% were rated as relevant, specific, and clearly articulated, 92% received high ratings for mitigation quality, and 61% were absent from the original papers, indicating the model consistently identified concerns the authors had not reported. The high novelty rates in categories such as Researcher and Analysis Bias (80%), Internal Validity and Confounding Factors (68%), and LLM/AI-Specific Challenges (67%) suggest these are the threat types most commonly missing from author-reported sections. The qualitative analysis further shows that threat quality depends directly on how well the model grounds its output in the study's specific design, data, and findings, with contextually grounded threats scoring higher across all four rubric dimensions.

The results suggest that LLMs are best understood as thinking partners for validity reasoning, capable of expanding the space of concerns a researcher considers without substituting the domain expertise and contextual familiarity that only the author can bring. Though the model does not fully reproduce all concerns that the authors identify through deep familiarity with their own work, the evidence suggests that it can meaningfully raise the quality and completeness of validity sections across the field.

Future work should extend our approach to other venues and model families, explore human-in-the-loop refinement workflows to improve specificity and actionability, and investigate whether LLMs can be applied proactively during study design rather than retrospectively applying them after writing, while shifting validity reasoning from a secondary concern and afterthought to a deliberately embedded activity throughout the research process.

## Data Availability Statement

All data and scripts supporting this study, including the 375 ICSE input papers, the threat generation prompt, the generated threats dataset, all evaluation scripts, and the scoring sample, are publicly available in our replication package on Zenodo at `https://doi.org/10.5281/zenodo.20453824` under a CC-BY 4.0 license.

# APCA in the Loop: An Empirical Study of In-Loop Patch Correctness Assessment for APR

**Sahand Moslemi Yengejeh**
Computer Engineering Department, Bilkent University, Ankara, Turkey

**Anil Koyuncu**
Computer Engineering Department, Bilkent University, Ankara, Turkey

## Abstract

Automated program repair (APR) tools generate candidate patches and accept those that pass a given test suite. A test-passing patch, called a plausible patch, is not necessarily correct: it may overfit the test suite without fixing the underlying bug. Automated patch correctness assessment (APCA) tools were developed to detect such overfitting patches, but they have been evaluated only as post-hoc classifiers on static datasets, never inside the repair loop they are intended to support. We investigate whether placing an APCA tool inside the generate-and-validate loop of an APR system, as a second validation gate, affects the APCA's classification effectiveness, the APR tool's repair capability, and the search cost it incurs. In this design, a candidate that passes all tests but is classified as overfitting by the APCA tool is discarded, and the repair tool continues generating candidates. We study it with three APR tools (TBar, ARJA, ChatRepair) crossed with three APCA tools (ODS, Quatrain, LLM4PatchCorrect), evaluated on 549 single-method bugs of Defects4J v3 with manual correctness assessment of 1,328 patches drawn from the in-loop candidate streams, and paired non-parametric tests (McNemar, Wilcoxon) per (APR, APCA) cell. Average in-loop $F_1$ on the correct class sits between 0.43 and 0.66 across the nine cells, with classification harder in-loop than post-hoc on every tool. The in-loop gate raises the share of correct outputs in 14 of 18 cells, but cuts the absolute correct-fix count whenever the APR baseline's first plausible patch is already correct at a high rate. The in-loop introduces a search-cost overhead that is statistically significant in 14 of 18 cells (Wilcoxon $p < .05$), with a geometric-mean per-bug multiplier of up to 17.46×. Placing an APCA inside the repair loop raises the output correctness rate in most (APR, APCA) cells, but at a search-cost overhead and, where the APR baseline already produces correct first plausibles at a high rate, a reduction in absolute correct fixes. The findings indicate that APCA tools should be trained and evaluated on the in-loop patch distribution they are deployed against, rather than on the curated, terminal patches of static post-hoc datasets.

## 1 Introduction

Automated program repair (APR) generates patches without direct human involvement under a generate-and-validate paradigm, where a candidate that passes all tests is called a plausible patch [11, 14, 24, 4, 12]. Plausible patches are frequently not correct [17, 9, 23], a problem known as patch overfitting [18, 17] that automated patch correctness assessment (APCA) tools address by predicting whether each plausible patch is correct or overfitting [30, 21, 27, 3].

Almost every published APCA tool operates after the generate-and-validate loop has terminated [22, 29, 2]: the repair tool runs to completion, and the APCA tool inspects its output. We refer to this arrangement as a *post-hoc* design: the APCA acts only after the repair tool has committed its output. Under such a design, APCA can reject an overfitting patch at the end, but it cannot extend the search. If the repair tool returned an overfitting patch, the opportunity to explore further candidates in the same APR run has already passed. Beyond this, we argue that evaluating APCA tools under the post-hoc design, as in most existing studies, does not reflect a real-world evaluation of these tools. APCA tools produce false labels, and human expert assessment is inevitable for both positive and negative cases. Whether the labels produced by an APCA tool enhance the repair process itself, rather than merely flagging an output the APR has already returned, has yet to be addressed.

To the best of our knowledge, no prior work has placed a general-purpose, standalone APCA classifier inside the generate-and-validate loop and studied the consequences. The closest, AdverIntent-Agent [7] and PRISM [19], either couple their filter to a single LLM repair agent or still apply after the APR has terminated.

To close this gap, we use APCA tools as *active filters* inside the generate-and-validate loop, placing them as a second validation gate. A candidate that passes all tests but is classified as overfitting by the APCA tool is treated as failed, and the repair tool continues to the next candidate. We call a patch that passes both gates an *approved patch*, a stricter notion of plausibility that requires both test-suite satisfaction and APCA approval. We investigate three research questions on this design:

**RQ1.** How effectively do APCA tools operate within the in-loop architecture?

**RQ2.** What is the impact of the in-loop architecture on the repair capability of APR tools?

**RQ3.** What is the impact of the in-loop architecture on the search cost of APR tools?

We instantiate the design with three APR tools (TBar [14], ARJA [32], ChatRepair [25]) and three APCA tools (ODS [30], Quatrain [21], LLM4PatchCorrect [35]) on Defects4J v3 [6], labelling 1,328 patches. The in-loop gate raises the share of correct outputs in 14 of 18 APR and APCA tool combinations but reduces the correct fix count where the baseline first plausible is already mostly correct, and adds a statistically significant search-cost overhead (Wilcoxon $p < .05$, geometric-mean per-bug multiplier up to 17.46×).

**Contributions.** We release an empirical study that evaluates APCA tools on the patch distribution the loop actually produces, a method that integrates any standalone APCA tool inside an APR loop as a second validation gate, and a labeled corpus of 1,328 in-loop plausible patches.

Sections 2–5 present background, setup, and results. Section 6 discusses implications, Section 7 addresses threats, and Section 8 concludes.

## 2 Background and Related Work

**Automated Program Repair.** Generate-and-validate APR produces candidate patches and halts at the first one that passes the test suite, called a plausible patch [4, 12]. Plausible patches are frequently not correct [17, 9, 23]. They satisfy the tests by exploiting coverage gaps rather than implementing the intended fix, a problem known as patch overfitting [18, 16]. Generation strategies range from template- and search-based tools (TBar [14], ARJA [32]) to learning- and LLM-based ones (ChatRepair [25]). In all of these families, the acceptance criterion is the test suite, leaving overfitting open.

The most recent line of APR work moves beyond this strict framework. Agent-based systems let an LLM autonomously invoke tools, inspect code, and reason about whether a candidate is correct before returning it. SWE-agent [28], AutoCodeRover [34], and RepairAgent [1] therefore embed a notion of in-loop correctness assessment, but that assessment is intertwined with the agent's own generation step and cannot be detached as a standalone classifier applied to patches from other APR systems. Whether placing an external, standalone APCA classifier inside the loop of an arbitrary APR tool changes its repair behaviour is a separate question and has not been studied.

**Automated Patch Correctness Assessment.** APCA tools take a plausible patch and predict whether it is correct or overfitting using signals such as execution traces [27], generated tests [26, 31], static features [30, 13, 5], learned code representations [33, 10], natural-language correlations [21], and pre-trained language models [35, 3]. Across all of them, the evaluation is the same: classify each patch in a labelled dataset collected after the APR has terminated [23, 29, 2]. Under this setting, the APCA acts as a passive annotator that can flag the patch the APR has already returned, but is never measured on the longer and noisier candidate stream it would face inside the loop.

Two recent works move closer to our setting. AdverIntent-Agent [7] embeds adversarial test generation inside a multi-agent LLM repair system to filter overfitting patches as they are generated. Its filter, however, is tightly coupled to artifacts produced by its own reasoning agent and cannot be detached as a standalone APCA classifier for other APR tools, so the design conflates the LLM repair agent and the APCA filter. PRISM [19] is a standalone APCA classifier that scores each APR tool's ranked plausible sequence and reports top-$k$ and review-effort metrics. It operates on the order in which plausibles arrive but still applies after the APR run, so it does not extend the search and study the effects of it. To the best of our knowledge, no prior work places a general-purpose, standalone APCA classifier inside the generate-and-validate loop of an arbitrary APR tool as a second validation gate.

## 3 Methodology

The fundamental difference between the prevailing post-hoc architecture and our proposed in-loop architecture lies in the feedback loop of the repair process (Figure 1).

Let $C = \{c_1, c_2, \dots\}$ be the ordered stream of candidate patches generated by an APR tool for a given bug. We define a validation test suite as a predicate $T : C \to \{0, 1\}$, where $T(c_i) = 1$ if $c_i$ passes all tests (making it a *plausible patch*), and 0 otherwise. We define an APCA classifier as a predicate $A : C \to \{0, 1\}$, where $A(c_i) = 1$ if the classifier predicts the patch is correct (making it an *approved patch*), and 0 if it predicts overfitting.

In the post-hoc automated assessment architecture, the automated assessment phase is decoupled from the search. The generation and validation phases run until they find the first candidate $c_{baseline}$ that satisfies $T$:

$$c_{baseline} = \arg\min_{c_i \in C} \{i \mid T(c_i) = 1\} \tag{1}$$

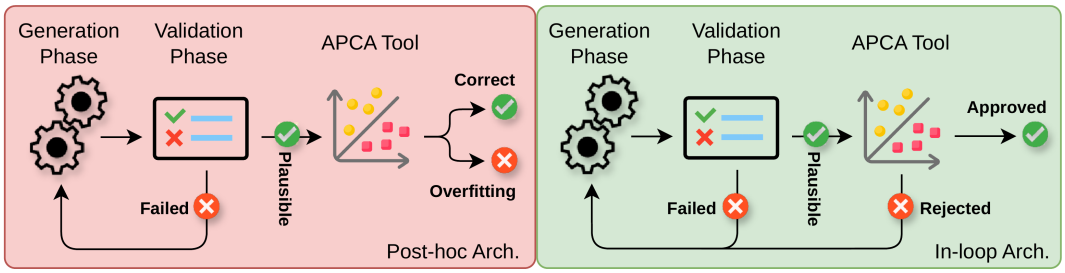

**Figure 1** The prevailing post-hoc architecture (left) versus the in-loop architecture we propose.

The search terminates immediately, returning $c_{baseline}$ as the final repair output. Then the APCA tool $A$, if applied to $c_{baseline}$, yields $A(c_{baseline})$. If $A(c_{baseline}) = 0$, the patch is flagged as overfitting, but the opportunity to explore alternative candidates has already passed.

In contrast, in-loop architecture integrates the APCA tool as a second validation gate. The search terminates only when it identifies an *approved patch* $c_{approved}$ that satisfies both the test suite and the APCA gate, defined as follows:

$$c_{approved} = \arg\min_{c_i \in C} \{i \mid T(c_i) = 1 \wedge A(c_i) = 1\} \tag{2}$$

If $T(c_i) = 1$ but $A(c_i) = 0$, the candidate is rejected, and the generator is triggered to produce the next candidate. To prevent infinite execution, we impose a search budget limit. If the APR tool exhausts this budget without achieving an approved patch, the repair is marked as a failure. This design forces the APR tool to explore deeper into the patch space. The APCA works as an in-loop filter, not as a generator: it does not change how the APR tool produces candidates or their order in the candidate stream. It only changes the stopping rule, from the first plausible patch to the first approved patch. Because the APR tools do not repeat a candidate in the same candidate stream, no duplicate patch enters the loop.

## 4 Experimental Setup

**APR Tools.** We use TBar (template-based), ARJA (genetic programming), and ChatRepair (LLM-based) with their published default configurations (ChatRepair: multi-turn conversational). All three use perfect fault localization to isolate the assessment gate from localization errors.

**APCA Tools.** We use ODS (202 AST features via the Coming framework), Quatrain (BERT encoding of bug-report and patch pairs), and LLM4PatchCorrect (GPT-based correctness reasoning, `gpt-4.1` via the OpenAI API). ODS and Quatrain use the authors' pre-trained models (on Defects4J 1 tool-generated patches [23, 21]) at their default threshold.

**Benchmark and Selection Criteria.** We evaluate on Defects4J v3 [6] (854 active bugs, 17 projects). Following ChatRepair [25], we scope to single-method developer fixes (the granularity at which ChatRepair's infill and TBar's fix patterns operate), giving 549 eligible bugs across the single-line, single-hunk, and single-function categories. Because ODS and Quatrain were trained on Defects4J 1 patches [30, 21], we report every result split into Defects4J 1 (282 bugs, 6 original projects) and Defects4J 2 and 3 (267 bugs, 11 added projects).

**Table 1** Has-plausible and has-approved bug counts per APR tool.

| APR tool | Has-plausible | Has-approved | | |
|---|---|---|---|---|
| | | ODS | Quatrain | LLM4PC |
| **Defects4J 1** | | | | |
| TBar | 62 | 52 | 47 | 52 |
| ARJA | 11 | 4 | 6 | 4 |
| ChatRepair | 90 | 56 | 51 | 87 |
| **Defects4J 2 and 3** | | | | |
| TBar | 49 | 31 | 23 | 27 |
| ARJA | 22 | 18 | 11 | 15 |
| ChatRepair | 176 | 133 | 123 | 174 |

**Execution Procedure.** We compare the baseline and in-loop configurations of Section 3. For each subject bug, the APR generates the candidate stream $C$ and every plausible candidate is forwarded in parallel to the three APCAs, so they inspect the same sequence in the same order (important for non-deterministic APR tools like ChatRepair). When the APCA rejects a plausible patch, we do not restart the APR tool. It continues along the same candidate stream and moves to the next candidate. We use each APR tool's own continue mode where it exists, and otherwise modify the tool's implementation to behave the same way. The APR tools drop candidates that fail to compile or fail the tests. For a bug, the search halts when all three APCAs have approved a patch or the 30-minute budget is exhausted.

An (APR, bug) attempt is *has-plausible* when the APR produced at least one plausible patch and *has-approved* for an APCA when that APCA approved one. The APR tools together produced a plausible patch for 125 of 282 Defects4J 1 bugs and 189 of 267 Defects4J 2 and 3 bugs. Table 1 shows the per-APR tool has-plausible and has-approved attempt counts.

**Metrics.** We quantify the impact of the architecture on the classification performance of each APCA, the repair capability of each APR tool, and the search cost of the repair process, each reported per APR and APCA combination within each Defects4J group. Every metric carries subscript B for the baseline (post-hoc) and L for the in-loop. The repair rate RR is the share of returned patches that are correct, the correct-fix count CF is the total number of correct patches returned, and the search cost is the number of candidates the APR tool examines before it halts. HP and HA are the number of has-plausible and has-approved attempts.

- **APCA Performance (RQ1):** accuracy, precision, recall, and $F_1$ on the *correct* class for each APCA, evaluated on the in-loop patch distribution rather than on pre-collected datasets.
- **Repair Capability (RQ2):** per has-plausible attempt, the baseline correct fixes $CF_B$ (has-plausible attempts whose $c_{baseline}$ is correct) and the in-loop correct fixes $CF_L$ (has-approved attempts whose $c_{approved}$ is correct). The repair rates $RR_B = CF_B/HP$ and $RR_L = CF_L/HA$ give the share of correct outputs under each architecture (HP, HA from Table 1). The filtering effects are $\Delta CF = CF_L - CF_B$ and $\Delta RR = RR_L - RR_B$, positive when the in-loop wins. We test the matched per-bug binary outcomes with **McNemar's test** (exact binomial for discordant counts $< 25$, Edwards' continuity correction otherwise) and report the continuity-corrected **odds ratio** OR , the number of bugs the baseline gets right but the in-loop misses divided by the number the in-loop gets right but the baseline misses. An OR above 1 means the in-loop drops more correct fixes than it recovers, and an OR below 1 means it recovers more.

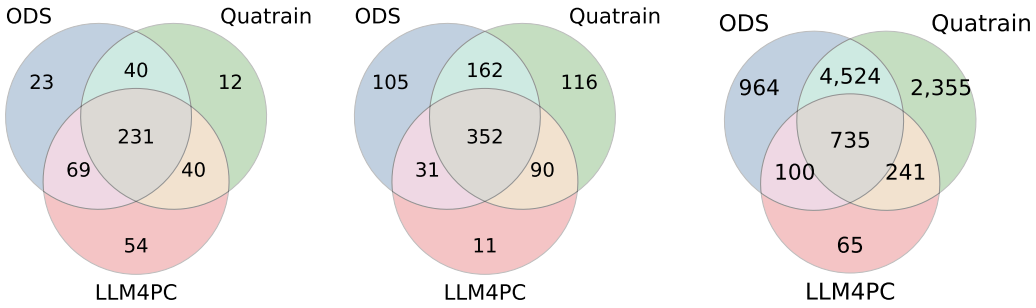

**Figure 2** Split of the 1,328 manually labelled patches across the three APCA tools by which tool inspected, for Defects4J 1 (left, 626 patches) and Defects4J 2 and 3 (right, 702 patches).

**Figure 3** Number of the 8,984 generated plausible patches each APCA tool inspected before approving, and how those subsets overlap.

- **Search Cost (RQ3):** per has-approved bug: the baseline candidate position $B_i = (k \mid c_k = c_{baseline})$ and the in-loop position $L_i = (k \mid c_k = c_{approved})$. Per cell we report $n$ (has-approved count), the medians $\widetilde{B}$ and $\widetilde{L}$, the median per-bug ratio $\widetilde{L/B}$, and the geometric mean $\mathrm{GM}(L/B)$. We test the paired values with the two-sided **Wilcoxon signed-rank test** (zeros dropped) and report the matched-pair **Cliff's $\delta$** (negligible $|\delta| < 0.147$, small $< 0.33$, medium $< 0.474$, large otherwise).

Every paired statistical test uses $\alpha = 0.05$. We choose these paired tests to match the data. In RQ2 each bug gives two yes/no outcomes, correct under the baseline and correct under the in-loop, so we use McNemar's test, which is built for paired binary outcomes. In RQ3 each bug gives two candidate positions, $B_i$ and $L_i$, whose per-bug ratios are skewed and far from normal, so we use the two-sided Wilcoxon signed-rank test, a paired test that does not assume a normal distribution.

**Manual Patch Correctness Assessment.** The APR tools generated 8,984 plausible patches in total. Figure 3 shows how many each APCA inspected. For the RQ1 and RQ2 ground truth, we label 1,328 patches (626 Defects4J 1, 702 Defects4J 2 and 3) in three stages, split across the APCAs as in Figure 2.

- **Stage 1:** every *first plausible* patch (410), establishing $\mathrm{CF_B}$.
- **Stage 2:** every *first approved* patch (485, of which 163 are new beyond Stage 1), establishing $\mathrm{CF_L}$.
- **Stage 3:** after excluding Stage 1 and 2 patches, we draw up to 60 Defects4J 1 and 60 Defects4J 2 and 3 patches uniformly at random from each of the seven Venn regions of Figure 3 (taking all when a region has fewer in a group). This yields 755 patches (414 Defects4J 1, 341 Defects4J 2 and 3), exceeding the Cochran sample size for a 95% confidence interval of $\pm 6\%$ at $p = 0.5$ in every per-APCA, per-group total.

We first reuse verdicts from prior studies [27, 15, 20, 30, 23] (1,469 correct, 64,939 overfitting) plus the developer patches: for each candidate we extract its target file and look for an *exact* match (identical bodies after stripping comments and whitespace) and, failing that, an *AST* match (identical `javalang` ASTs). A matched candidate inherits its reference's verdict. Exact matching resolves 103 Defects4J 1 and 111 Defects4J 2 and 3 patches, and AST matching resolves a further 62 and 13.

**Table 2** Performance of APCA tools under the post-hoc baseline and the in-loop architecture.

The remaining 461 Defects4J 1 and 578 Defects4J 2 and 3 patches are classified by two researchers using the semantic-equivalence rules of Liu et al. [15] (correct iff semantically equivalent to the developer fix or logically resolving the root cause without side effects). Disagreements are resolved through discussion, and labelling averaged six minutes per patch. Before the discussion step, the two researchers' independent labels agreed at a Cohen's $\kappa$ of 0.79. The final corpus has 600 correct (240 Defects4J 1, 360 Defects4J 2 and 3) and 728 overfitting (386 and 342), totalling 1,328.

# 5 Evaluation

## 5.1 RQ1: APCA Performance in the Loop

**Approach.** RQ1 checks whether each APCA keeps its classification effectiveness on the longer, noisier in-loop patch stream it is deployed on but is never tuned or reported on. To measure performance of these tools, we evaluate each APCA against the 1,328 manually labeled patches of Section 4, using the classification metrics of Section 4. Because each APCA stops at its first approval, the three inspection subsets differ. Figure 2 shows how the corpus splits across them. As a reference point, we also score each APCA on the 410 `plausible_1` patches (Stage 1) under a post-hoc baseline. We pool the labeled in-loop patches each APCA inspected without reweighting by Venn region. The first-plausible and first-approved patches are labeled in full, and the Stage 3 sample covers the remaining regions at the Cochran size for a 95% confidence interval of ±6%.

**Results.** Table 2 reports the per-cell metrics together with an Average row that gives each APCA's $n$-weighted mean across the three APR streams within a Defects4J group. The columns give $n$ (labeled patches scored), accuracy (Acc), precision (Pr), recall (Re), and $F_1$ on the correct class, under the post-hoc baseline and the in-loop gate. Several cells show high accuracy with low $F_1$ on the correct class (ARJA with ODS: accuracy 0.89 at $F_1$ 0.12 on Defects4J 1), so we read the table through the Average row's $F_1$ on the correct class.

- **Finding 1 (LLM4PC narrowly leads).** The average in-loop $F_1$ on the correct class ranges from 0.43 (ODS, Defects4J 1) to 0.66 (LLM4PC, Defects4J 2 and 3). LLM4PC leads on this average in both Defects4J groups, but the three APCAs sit close together rather than separating sharply.
- **Finding 2 (No training-distribution advantage).** ODS and Quatrain were both trained on patches generated for Defects4J 1 bugs [23, 21], so a higher in-loop $F_1$ on Defects4J 1 than on Defects4J 2 and 3 would be expected. Instead, the average in-loop $F_1$ on Defects4J 2 and 3 matches or exceeds the Defects4J 1 value for all three APCAs (ODS 0.43 $\rightarrow$ 0.57, Quatrain 0.58 $\rightarrow$ 0.60, LLM4PC 0.60 $\rightarrow$ 0.66). Because the tools do no better on their own training benchmark, their Defects4J 1 results are not inflated by training-data overlap, so we report them next to Defects4J 2 and 3 rather than dropping them.
- **Finding 3 (In-loop is harder than post-hoc).** Average $F_1$ drops on every tool when moving from post-hoc to in-loop on Defects4J 1 (LLM4PC 0.79 $\rightarrow$ 0.60, ODS 0.60 $\rightarrow$ 0.43, Quatrain 0.64 $\rightarrow$ 0.58). On Defects4J 2 and 3, LLM4PC drops 0.77 $\rightarrow$ 0.66 and the others stay flat. The longer in-loop stream contains overfitting near-duplicates the APCA must reject, lowering recall.

**RQ1 summary.** In-loop classification is harder than post-hoc for every APCA. The average in-loop $F_1$ on the correct class stays between 0.43 and 0.66, and LLM4PC leads by a small margin.

## 5.2 RQ2: Impact on Repair Capability

**Approach.** RQ2 checks whether the in-loop gate changes what an APR tool returns, both the rate of correct outputs and the absolute number of correct fixes, since a higher rate is only useful if it does not discard correct fixes the baseline would have returned. To answer it, we measure how the in-loop gate changes what each APR *returns*, using the repair-capability metrics of Section 4 on the paired baseline and in-loop outcomes per (APR, APCA) cell within each Defects4J group. Stage 3 patches are excluded from the ground truth: neither architecture returns them, since they are not first-plausible (the baseline output) and not first-approved by any APCA (the in-loop output).

**Results.** Table 1 shows LLM4PC the most permissive, approving at least one patch in 359 of 410 has-plausible attempts, and Quatrain the most restrictive at 261. Table 3 reports the per-cell metrics. Each row lists the baseline triple $HP/CF_B/RR_B$, the in-loop triple $HA/CF_L/RR_L$, the change in correct-fix count $\Delta CF$ with the change in rate $\Delta RR$ in brackets, and McNemar's $p$ with the odds ratio OR in brackets. The sign of $\Delta CF$ largely tracks the baseline repair rate $RR_B$. Where $RR_B$ is high (TBar and ChatRepair on Defects4J 1, and ChatRepair on Defects4J 2 and 3), the baseline's first plausible patch is already correct most of the time, so a conservative APCA that rejects the attempt or approves a later overfitting patch keeps $\Delta CF$ non-positive. On Defects4J 2 and 3, where $RR_B$ is low (TBar and ARJA, $RR_B = 0.29$ and 0.41), the longer search reaches correct patches the first-plausible halt would have missed, so $\Delta CF$ turns positive. ARJA on Defects4J 1 also stays non-positive, from a has-plausible set of 11 too small to gain from despite its low rate.

- **Finding 4 (In-loop raises output correctness rate in most cells).** $\Delta RR > 0$ in 14 of 18 cells, with the largest gains on the conservative APCAs over the low-$RR_B$ APR streams of Defects4J 2 and 3 (ARJA with Quatrain +0.59, TBar with Quatrain +0.54). The four cells with $\Delta RR \leq 0$ are all within 0.02 of zero, and ChatRepair with LLM4PC keeps $RR_L \approx RR_B$ in both groups by approving nearly every plausible patch.

**Table 3** Repair capability of different APR & APCA configurations.

| | | $HP/CF_B/RR_B$ | $HA/CF_L/RR_L$ | $\Delta CF$ ($\Delta RR$) | $p$ (OR) |

**Table 4** Patch-correctness transitions from the baseline first plausible patch to the in-loop output, summed over the nine (APR, APCA) cells in each Defects4J group.

| **Transition** | **Defects4J 1** | **Defects4J 2 and 3** |
|---|---|---|
| *From a correct first plausible patch* | | |
| to a correct approved patch (kept) | 275 | 388 |
| to an incorrect approved patch | 17 | 21 |
| to no output | 38 | 38 |
| *From an incorrect first plausible patch* | | |
| to a correct approved patch (recovery) | 6 | 44 |
| to no correct patch | 153 | 250 |
| Paired outcomes | 489 | 741 |

- **Finding 5 (The rate gain coexists with a count loss).** Despite the positive $\Delta RR$, $\Delta CF$ is negative or zero in every Defects4J 1 cell and in all three ChatRepair Defects4J 2 and 3 cells: the in-loop returns fewer correct fixes in absolute count because the APCA gate rejects many has-plausible attempts. Only the TBar and ARJA cells of Defects4J 2 and 3, where $RR_B$ is low, turn $\Delta CF$ positive.
- **Finding 6 (The count loss is statistically significant for conservative APCAs).** McNemar's test rejects equality of paired outcomes for ChatRepair with ODS and ChatRepair with Quatrain in both Defects4J groups ($p \leq .011$, OR up to 9) and for TBar with ODS ($p = .004$, OR $= 19$) and TBar with Quatrain ($p = .039$, OR $= 5.67$) on Defects4J 1. Other cells do not reach $\alpha = 0.05$ due to small discordant-pair counts.

To show where the count change in Table 3 comes from, we track each has-plausible bug from its baseline first plausible patch to the in-loop output, summed over the nine (APR, APCA) cells per group (Table 4). On Defects4J 1, where the baseline is already correct most of the time, the gate turns 55 correct first plausibles into an incorrect approved patch (17) or no output (38) and recovers only 6, which is the count loss of Finding 5. On Defects4J 2 and 3 the recoveries rise to 44, and 33 of them fall on the low-$RR_B$ TBar and ARJA streams, where the longer search reaches correct patches the first-plausible halt would have missed.

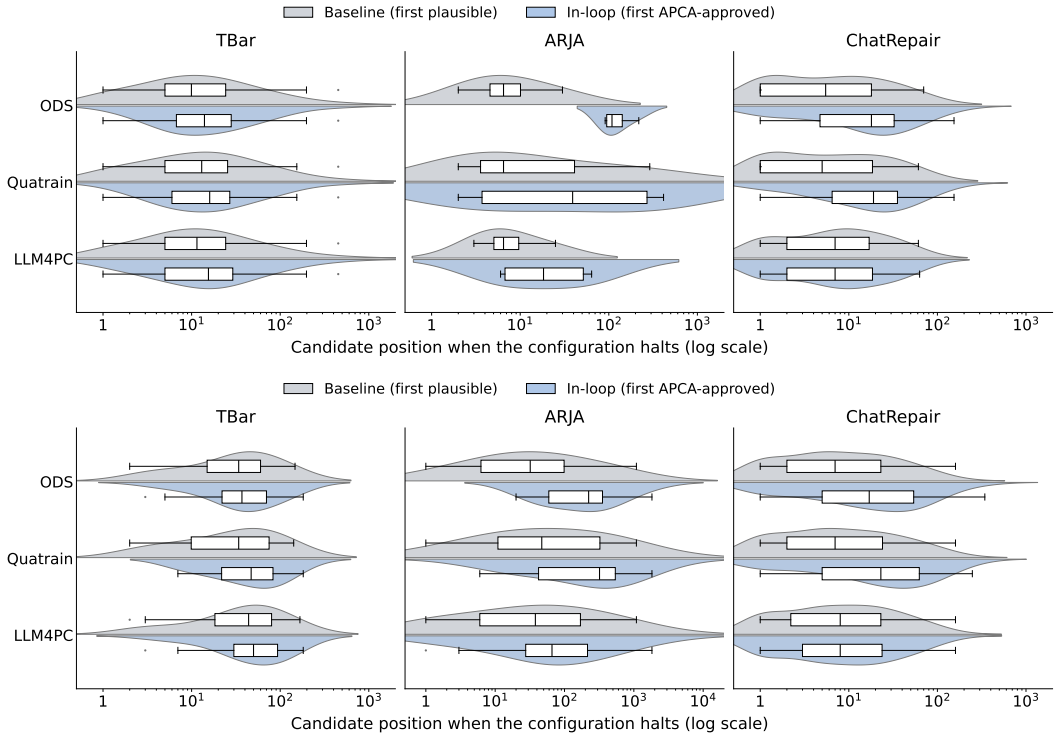

**Figure 4** Distribution of candidate positions at which the baseline (first plausible) and the in-loop (first approved) halt, over has-approved bugs, for Defects4J 1 (top) and Defects4J 2 and 3 (bottom).

**RQ2 summary.** The in-loop gate raises the correct-output rate ($\Delta\mathrm{RR} > 0$) in 14 of 18 cells, but it lowers the absolute correct-fix count wherever the baseline first plausible patch is already correct at a high rate.

## 5.3 RQ3: Impact on Search Cost

**Approach.** RQ3 checks how much extra search the in-loop gate costs by pushing the APR tool deeper into the candidate stream, since the rate gain from RQ2 is only worthwhile if the added cost stays acceptable. To answer it, we quantify the search-cost overhead from replacing the first-plausible halting rule of Section 3 with a first-approved halting rule, using the per-bug pairs $(B_i, L_i)$ and the cell-level summaries of Section 4. We restrict to has-approved bugs, where both halting points exist. Summed across the nine (APR, APCA) cells (each of the 549 eligible bugs contributes up to nine matched pairs), this yields 359 matched observations on Defects4J 1 and 555 on Defects4J 2 and 3.

**Results.** Table 5 shows $\widetilde{L} \geq \widetilde{B}$ in every cell of both Defects4J groups. The columns give $n$ (has-approved bugs), the median baseline position $\widetilde{B}$, the median in-loop position $\widetilde{L}$, the median per-bug ratio $\widetilde{L/B}$, the geometric mean $\mathrm{GM}(L/B)$, the Wilcoxon $p$, and Cliff's $\delta$. The split-violin shape in Figure 4 is consistent across cells: the in-loop distribution preserves the baseline shape and shifts right on the log axis by a tool-dependent factor. ARJA with ODS drives the upper end of the GM range ($\mathrm{GM} = 17.46$ on Defects4J 1, 5.21 on Defects4J 2 and 3), with median in-loop candidate positions of 110 and 224 against baseline medians of 6 and 32.

**Table 5** Search cost per APR and APCA combination.

| | Defects4J 1 | | | | | | | Defects4J 2 and 3 | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | $n$ | $\widetilde{B}$ | $\widetilde{L}$ | $\widetilde{L/B}$ | GM($L/B$) | $p$ | $\delta$ | $n$ | $\widetilde{B}$ | $\widetilde{L}$ | $\widetilde{L/B}$ | GM($L/B$) | $p$ | $\delta$ |
| TBar&ODS | 52 | 10 | 14 | 1 | 1.34 | $<.001$ | $+.29$ | 31 | 34 | 37 | 1.06 | 1.31 | $<.001$ | $+.52$ |
| TBar&Quatrain | 47 | 13 | 16 | 1 | 1.25 | .003 | $+.23$ | 23 | 34 | 47 | 1.18 | 1.59 | .001 | $+.57$ |
| TBar&LLM4PC | 52 | 12 | 16 | 1 | 1.25 | .005 | $+.19$ | 27 | 44 | 50 | 1 | 1.42 | .001 | $+.48$ |
| ARJA&ODS | 4 | 6 | 110 | 26.95 | 17.46 | .125 | $+1$ | 18 | 32 | 224 | 3.62 | 5.21 | .001 | $+.72$ |
| ARJA&Quatrain | 6 | 6 | 112 | 1 | 2.43 | .500 | $+.33$ | 11 | 47 | 320 | 1.52 | 3.47 | .031 | $+.55$ |
| ARJA&LLM4PC | 4 | 6 | 28 | 1.46 | 2.53 | .500 | $+.50$ | 15 | 38 | 66 | 1 | 1.98 | .018 | $+.47$ |
| ChatRep&ODS | 56 | 6 | 18 | 1.13 | 2.29 | $<.001$ | $+.54$ | 133 | 7 | 17 | 1.11 | 2.05 | $<.001$ | $+.54$ |
| ChatRep&Quatrain | 51 | 5 | 19 | 1.03 | 2.61 | $<.001$ | $+.51$ | 123 | 7 | 23 | 1.20 | 2.43 | $<.001$ | $+.58$ |
| ChatRep&LLM4PC | 87 | 7 | 7 | 1 | 1.07 | .068 | $+.05$ | 174 | 8 | 8 | 1 | 1.03 | $<.001$ | $+.08$ |

- **Finding 7 (Search-cost overhead).** GM($L/B$) ranges from 1.07 to 17.46 on Defects4J 1 and 1.03 to 5.21 on Defects4J 2 and 3. TBar pays the least (GM $\leq$ 1.59 everywhere, $\widetilde{L/B} = 1$ on every Defects4J 1 cell), ChatRepair a moderate amount (GM $\leq$ 2.61, LLM4PC near 1), and ARJA the most (driven by ARJA with ODS).
- **Finding 8 (The overhead is statistically significant in most cells).** Wilcoxon's signed-rank test rejects equality of $B_i$ and $L_i$ in 14 of 18 cells ($p < .05$, $p < .001$ in 7). Cliff's $\delta$ is positive throughout, with 11 cells in the large band. The four non-significant cells are the three small-$n$ ARJA Defects4J 1 cells ($n \leq 6$, masking $\delta$ between $+.33$ and $+1$) and ChatRepair with LLM4PC on Defects4J 1 ($\delta = +.05$, negligible, and the Defects4J 2 and 3 cell reaches $p < .001$ at $\delta = +.08$, large $n$ but small effect).

**RQ3 summary.** The in-loop gate adds a search-cost overhead that is significant in 14 of 18 cells (Wilcoxon $p < .05$), with a geometric-mean per-bug multiplier up to 17.46×.

## 6 Discussion

**In-loop changes the role of an APCA tool.** The in-loop architecture turns each APCA classification into a search step (RQ1): a rejected plausible patch returns the APR tool to generation, and an approved patch becomes the repair output. The cost of a false negative is therefore higher than in post-hoc use. For instance, in TBar with ODS on Chart_1, ODS rejected the correct first plausible patch (a single-token `!=` to `==` flip) and later approved an overfitting `instanceof` check, replacing a correct repair with an incorrect one. Static post-hoc evaluation does not surface this failure mode.

**When the gate helps and when it hurts.** RQ2 shows the gate raises the share of returned patches that are correct, but $\Delta$CF stays at most zero in every Defects4J 1 cell because the baseline already returns a correct first plausible patch for 27% to 81% of has-plausible attempts. The picture flips on TBar and ARJA Defects4J 2 and 3, where baseline correctness drops to 29% and 41% and the longer in-loop search reaches correct patches the baseline would have missed. RQ3 shows this rate gain comes at a search-cost overhead that is statistically significant in 14 of 18 cells, with a geometric-mean per-bug multiplier up to 17.46×, so the gate's practical use has to weigh $\Delta$RR against this multiplier.

**Implications for APCA design.** RQ1 shows that APCA classification, although evaluated until now on pre-collected terminal-patch datasets, also operates on the in-loop stream and generalises across Defects4J 1 and Defects4J 2 and 3. A natural methodological consequence

is that future APCA evaluations should report the repair-capability gain and the search-cost overhead the tool induces inside an APR loop (RQ2 and RQ3), not classification accuracy alone, so that the trade-off is visible. A triage policy that ranks plausibles by APCA score and lets the APR keep searching, instead of a binary approve-or-reject gate, would retain the $\Delta$RR gain of RQ2 without the count loss it currently causes.

## 7 Threats to Validity

**Internal Validity.** Manual correctness labels are inherently subjective: Le et al. [8] found significant disagreement among human evaluators. We mitigate this by having two authors independently assess each patch, resolving disagreements through discussion, and cross-referencing against prior published labels where available [14, 30, 23]. TBar's search is deterministic, so any in-loop deviation from the baseline output is attributable solely to the APCA gate. ARJA and ChatRepair are stochastic, which we mitigate by sharing the same generated candidate stream between the baseline and the in-loop configurations.

**Construct Validity.** Precision does not capture all aspects of practical utility: a configuration with higher precision but fewer correct fixes overall may not be preferable. We report both repair-rate metrics ($RR_B$, $RR_L$) and absolute correct-fix counts ($CF_B$, $CF_L$) to give a complete picture. The 30-minute per-bug wall-clock budget is a resource restriction. Some APR tools fail to produce any plausible patch within it on certain bugs, which trims the has-plausible set. Extending the budget is left to future work.

**External Validity.** We deliberately control two parts of the setup, and these controls limit external validity. First, we evaluate only on Defects4J v3, a Java benchmark, so the findings may not carry over to other tools, programming languages, or bug benchmarks. Second, all APR tools use perfect fault localization, isolating the APCA gate as the only difference between the in-loop and baseline runs. Under imperfect fault localization the absolute numbers would differ. We chose APR tools from three paradigms (template-based, genetic-programming-based, LLM-based) to diversify within the benchmark, but the space of possible combinations is large. ODS and Quatrain are used as their authors released them, trained on patches from earlier APR tools. Retraining on tool-specific patches could change results. ODS and Quatrain were trained on Defects4J 1 patches, so their Defects4J 1 numbers could gain from training overlap. We keep these rows for completeness but do not lean on them, since Finding 2 shows their in-loop $F_1$ on Defects4J 2 and 3 matches or exceeds Defects4J 1.

## 8 Conclusion

We presented the first systematic study of an APCA tool placed inside the generate-and-validate loop of an APR tool as a second validation gate, since every prior APCA evaluation operates post-hoc on the patches an APR has already returned. We ran three APR tools (TBar, ARJA, ChatRepair) crossed with three APCA tools (ODS, Quatrain, LLM4PatchCorrect) on the 549 single-method bugs of Defects4J v3, manually labelling the 1,328 patches that the evaluation relies on. APCA classification effectiveness in the loop is at most comparable to and usually below post-hoc. The gate raises the share of returned patches that are correct in 14 of 18 cells, but cuts the absolute correct-fix count whenever the APR baseline already produces correct patches at a high rate. The in-loop also incurs a search-cost overhead, statistically significant in 14 of 18 cells, of up to a 17.46× geometric-mean increase. Closing this gap therefore requires APCA tools trained or calibrated for the in-loop patch distribution rather than the post-hoc one. That is the direction we leave to future work.

## Data Availability Statement

The replication package, including tool configurations, patch logs, and manual correctness labels, is publicly available on Zenodo: https://doi.org/10.5281/zenodo.20456574.

# CWEFT: CWE-Aware Evaluation of Free-Text vs. Typed Prompts

**Lanaya A. Carbonell**
Department of Computer Engineering, Bilkent University, Ankara, Turkey

**Anıl Koyuncu**
Department of Computer Engineering, Bilkent University, Ankara, Turkey

## Abstract

Adding vulnerability context to a prompt is known to improve LLM repair quality, but the studies that establish this vary two things at once: the domain knowledge injected, such as a CWE label or a fix pattern, and the form that knowledge takes in the prompt. Prompt-engineering research treats format as a variable in its own right, yet in automated vulnerability repair it has never been isolated under a controlled ablation, leaving open whether the wording of guidance matters once its content is fixed. This paper presents CWEFT, a controlled ablation that holds injected repair knowledge constant across a free-text and a typed-schema rendering while decomposing the separate contributions of naming a vulnerability and supplying fix guidance. We construct four prompt conditions that differ by exactly one factor each, grounding all injected knowledge in APR4Vul's empirically mined fix patterns. Using this design, we generate 504 patches across 42 Java vulnerabilities from Vul4J spanning 15 CWE classes on three frontier models – Claude Sonnet 4.5, GPT-5, and Gemini 2.5 Pro – and score each patch on a Proof-of-Vulnerability-aware hierarchy that separates code that compiles from code that closes the vulnerability and from code that does so without regression. Our emerging results invert a common assumption: naming the CWE class alone achieves the highest correct-fix rate at 19.8%, ahead of the 12.7% unenriched baseline ($p = 0.049$, exact McNemar), while both richer conditions that add explicit repair guidance fall back to 16.7%. Crucially, the free-text and typed-schema conditions are indistinguishable at 16.7% with perfectly symmetric paired discordance, and with only eight discordant pairs the design cannot rule out a smaller format effect. Across all conditions, repair rate tracks how concrete the vulnerability class is, falling to 3.1% for improper input validation. These initial findings suggest that for frontier models on common vulnerability classes, what a prompt identifies matters more than how elaborately that information is formatted – a direction that warrants higher-powered replication before it is treated as a design principle.

## 1 Introduction

Software vulnerabilities are disclosed faster than developers can patch them by hand, sustaining research interest in automated vulnerability repair (AVR) and, more recently, in LLM-based repair. A growing body of work shows that adding vulnerability context to a model's prompt raises repair quality [14, 10, 7]. Yet these studies conflate two variables:

licensed under Creative Commons License CC-BY 4.0

*what* domain knowledge is added, such as a CWE label or a fix pattern, and *how* that knowledge is rendered into the prompt, whether as a sentence, a list, or a typed schema. The prompt-engineering literature treats format as an experimentally meaningful variable in other tasks [19, 8], but in AVR specifically the question has not been tested under a controlled ablation.

CWEFT treats representational format as a controlled variable. It holds injected fix knowledge identical across a free-text condition and a typed-schema condition, and adds two further conditions, an unenriched baseline and a CWE-named-only condition, that decompose the separate contributions of naming a vulnerability and supplying fix guidance. The injected knowledge is grounded in real repair behavior: we mine it directly from APR4Vul's empirical fix patterns [4]. Because adjacent conditions differ by exactly one factor, any outcome difference traces to that factor alone. We evaluate the ablation on 42 Java vulnerabilities from Vul4J across 15 CWE classes, generating 504 patches with three frontier models from three providers, and we score each patch on a Proof-of-Vulnerability-aware trustworthiness hierarchy that separates code that compiles from code that closes the vulnerability and from code that does so without breaking other tests.

We organize the study around four research questions:

**RQ1** To what extent does enriching prompts with vulnerability-type-specific fix knowledge improve patch quality over an unenriched baseline?

**RQ2** To what extent does the representational format (free-text vs. typed schema) of that knowledge affect patch quality when content is held constant? *(central question)*

**RQ3** How does single-shot LLM repair compare across three frontier models?

**RQ4** Under a multi-level trustworthiness hierarchy, how does repair rate vary by vulnerability class?

This paper makes three contributions:

1. A controlled ablation that separates the *content* of injected vulnerability knowledge from its *representational format*, holding source content fixed across a free-text and a typed-schema condition so that the two factors can be attributed separately.
2. An empirical finding that runs against common prompt-engineering practice: naming the CWE class alone outperforms both richer conditions built from the same repair knowledge, and it is also the cheapest enrichment to run.
3. A fully open replication artifact covering prompt construction, patch generation, and Proof-of-Vulnerability-aware evaluation, with all 504 per-cell outcomes released.

## 2 Related Work

**AVR and LLM-based repair.** AVR sits inside a broader APR landscape that recent surveys taxonomize as template-guided, search-based, constraint-based, and learning-driven [9]. The most directly relevant prior work is APR4Vul, which evaluated traditional APR techniques on Vul4J and found testable patches for only 20% of bugs with correctness rates under 50%, while also mining the recurring fix patterns behind real human patches [4]. Those mined patterns, among them input sanitization, canonical-path verification, and secure parser configuration, are the direct source of the repair knowledge we inject in our C3a and C3b conditions. A parallel line of LLM-based work has established that prompt content affects repair quality [7, 11, 14, 6, 17]. PromptFix is closest in framing, since it augments prompts with CWE and CVE context, yet it delivers all of that context as unstructured prose [14]. Most pointedly, Khan et al. showed that progressively injecting domain knowledge about a vulnerability lifted GitHub Copilot's buffer-overflow repair rate from 15% to 63% [10]. Their

result establishes that content can help a great deal; what stays open is whether returns continue as the guidance grows more elaborate, and whether its *form* matters once content is fixed. Recent systems such as APPATCH and chain-based repair pursue stronger results through agentic or multi-step pipelines [16, 15, 12], a direction orthogonal to ours: we hold the pipeline fixed and vary only how knowledge is represented. Separately, prior work found that pre-trained model choice and tokenization substantially affect AVR performance [23], which is why we evaluate three frontier models from different providers rather than rely on one.

**Prompt format as a variable.** The prompt-engineering literature treats format as an experimentally meaningful variable independent of content. Brown et al. introduced few-shot in-context learning and showed that how examples are framed within a prompt changes task performance [3]. Wei et al. showed that chain-of-thought structure, which inserts intermediate reasoning steps, improves reasoning-heavy tasks even when no new information is added [22]. More recent work quantifies sensitivity to surface features: Sclar et al. found that separator choice and field ordering swing LLM performance as much as switching models [19], and He et al. replicated the effect on a separate task suite [8]. Framing effects extend to security-specific tasks: Bosnak et al. found that persona and phrasing choices substantially change how reliably open-source models produce a requested CWE, and read this as evidence that models rely on pattern recall over semantic reasoning about vulnerability classes [2]. The evidence is not one-sided in security tasks, however. A recent survey notes that structured strategies such as chain-of-thought improve some vulnerability-detection metrics but show inconsistent effects across settings rather than a uniform gain [20]. This mixed prior evidence is exactly what motivates testing format as a controlled variable in repair, instead of assuming structure helps.

**Evaluation of LLM repairs.** Measuring repair quality is itself contested, and the choice of metric shapes what a study can claim. Qi et al. analyzed plausible-but-incorrect patches across several APR systems and found that most reported patches amounted to functionality deletion rather than correct repair [18]. The same concern carries into the LLM era: recent evaluations report that models often misidentify or fail to genuinely fix vulnerabilities even when their output looks plausible [21, 1]. We take this seriously in our scoring rather than treating a passing test suite as success. Our trustworthiness hierarchy is Proof-of-Vulnerability-aware: it separates patches that merely compile from those that close the vulnerability, and from those that close it without regressing the rest of the suite, which guards against the functionality-deletion failure mode Qi et al. identified. We return to the limits of this scoring in Section 6.

## 3 Methodology

The pipeline has four stages: dataset selection, prompt construction, patch generation, and automated evaluation in a reproducible environment. Figure 1 gives a visual overview, and the subsections below describe each stage.

**Dataset.** We draw our subjects from Vul4J [5], a benchmark of real Java CVEs that ships reproducible build and test environments. We selected Vul4J over other Java vulnerability datasets because it pairs every entry with both a CVE and a CWE label and provides an executable build-and-test harness; alternatives such as CWE-Bench-Java [13] supply

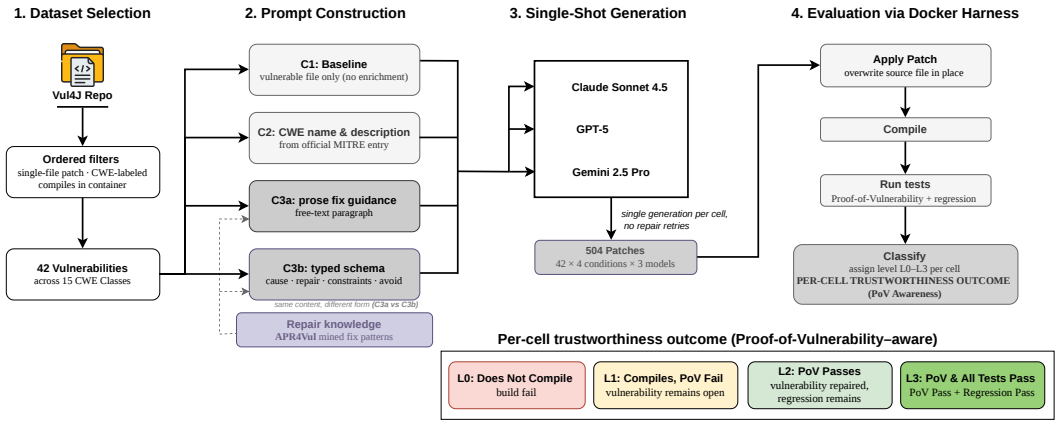

**Figure 1** The CWEFT pipeline. Each of 42 vulnerabilities is processed under all four prompt conditions with three frontier models, producing 504 patches. Each model returns a complete repaired source file, which is compiled and tested in a reproducible Docker harness; outcomes are classified into the four levels of our Proof-of-Vulnerability-aware trustworthiness hierarchy.

**Table 1** CWE distribution across the 42 selected Vul4J vulnerabilities, sorted by frequency. Classes with two or more vulnerabilities anchor per-class observation; the remainder appear as singletons and probe the long tail.

| CWE | Description | Count |
|---|---|---|
| CWE-20 | Improper Input Validation | 8 |
| CWE-835 | Infinite Loop | 7 |
| CWE-22 | Path Traversal | 5 |
| CWE-79 | Cross-Site Scripting | 5 |
| CWE-611 | XML External Entity (XXE) | 4 |
| CWE-264 | Permissions and Access Controls | 2 |
| CWE-287 | Improper Authentication | 2 |
| CWE-502 | Deserialization of Untrusted Data | 2 |
| 7 additional CWE classes (one each) | | 7 |
| *Total* | | 42 |

CWE labels and build scripts but no per-project test harness, since they target vulnerability detection rather than test-based repair validation; our evaluation requires executable Proof-of-Vulnerability and regression tests. From Vul4J we derive a working set through an ordered chain of filters, each demanded by a requirement of our design. First, we keep only vulnerabilities whose reference human patch modifies a single file, because our task asks a model to return one repaired file. Second, we keep only entries carrying a CWE label, since the C2, C3a, and C3b conditions cannot be built without one. Third, we require that the vulnerable revision compile cleanly in our container before any patch is applied; this step removes VUL4J-15, -23, -35, and -39, the first three of which the Vul4J maintainers themselves flag as non-compilable or needing manual modification, and the fourth of which fails to build in our environment despite its upstream status. Applying the first two filters yields 46 candidates; the buildability filter removes four of these, leaving the 42 vulnerabilities we study, spanning the 15 CWE classes shown in Table 1. Selection was performed once, ahead of generation, and the resulting subset is released as an explicit list rather than as a re-runnable script, together with the buildability record behind the final four exclusions.

**Listing 1** Example C3a (free-text) and C3b (schema) for CWE-22 Path Traversal. Both encode identical repair knowledge drawn from APR4Vul's mined fix patterns; only the form differs.

```
# C3a (free-text):
Path traversal vulnerabilities are typically fixed by
canonicalizing user-supplied paths with
File.getCanonicalPath() and verifying the result
remains within an allowed base directory before any
file operation.

# C3b (schema):
Root Cause      : Untrusted path fragment used in
                  file resolution without
                  normalization.
Canonical Repair: Canonicalize via
                  getCanonicalPath() and verify
                  startsWith(base).
Constraints     : Preserve original method signature;
                  do not alter exception types.
What to Avoid   : String.contains("..") checks; these
                  bypass via encoded variants.
```

**Prompt construction.** The four conditions form a controlled ablation in which each condition adds exactly one factor over the previous one. This is what licenses the study's central claim: a difference between two adjacent conditions can be attributed to the single factor that separates them. Every condition shares the same input and the same output instruction. The input is the complete vulnerable source file together with its path; the instruction asks the model to return the complete modified file as code only.

**C1 (Baseline)** provides the vulnerable file with a generic repair instruction and no vulnerability-specific information. It measures the model's intrinsic ability to recognize and fix the flaw from the code alone, and serves as the floor against which enrichment is measured.

**C2 (CWE-Named)** adds the CWE identifier and a short description of the class, taken from the official MITRE CWE entry for that identifier. Comparing C2 with C1 isolates the effect of *naming the vulnerability type*, independent of any repair guidance.

**C3a (Free-Text Fix Guidance)** adds a short prose paragraph describing how the class is typically fixed in practice. We wrote this guidance by hand for each class, drawing its content from APR4Vul's empirical fix-pattern tables so that it reflects real human repair behavior rather than invented instructions [4]. Comparing C3a with C2 isolates the effect of *fix-pattern knowledge delivered as prose*.

**C3b (Typed Schema)** carries the same underlying knowledge as C3a, reorganized into four labeled fields: *Root Cause*, *Canonical Repair*, *Constraints*, and *What to Avoid*. The fields map onto APR4Vul's findings: root cause from its fault taxonomy, canonical repair from its fix-pattern tables, and the two constraint fields from its failure analysis. Comparing C3a with C3b is the study's critical contrast: source content and surrounding instruction are matched and only the form changes, although the field labels themselves are part of C3b's form and convey a kind of structural cue that C3a does not. Listing 1 shows the two renderings for one class.

**Patch generation.** Three frontier models from different providers generate the patches: Anthropic Claude Sonnet 4.5, OpenAI GPT-5, and Google Gemini 2.5 Pro, each accessed through its public API. Drawing from three providers lets us check whether any format effect generalizes across model families rather than reflecting one provider's training or inference behavior. Each model receives the complete vulnerable file and returns a complete candidate

file in a single call. We use single-shot prompting with no repair-retry loops, self-consistency sampling, or tool-use feedback. This is a deliberate constraint: retry and voting strategies produce gains of their own, and admitting them would confound the format comparison this study exists to make. The absolute correct-fix rates we report are therefore a floor on what these models can reach, not a ceiling.

**Experimental configuration.** We report the generation configuration in full so that the run can be reproduced. The three models were accessed through their providers' public APIs under the identifiers `claude-sonnet-4-5-20250929`, `gpt-5`, and `gemini-2.5-pro`, which were the frontier offerings of their respective providers at the time of collection. All 504 cells were generated over 27–28 May 2026, strictly sequentially, one call at a time, with no concurrency and no client-side rate cap. The system prompt is identical across the three providers. We passed neither a temperature nor a `top_p` value to any provider, so each model sampled at its own default; we fixed no random seed and enabled no provider-side prompt caching, so generation is not deterministic across re-runs. Output budgets were not matched: Claude and GPT-5 were capped at 8192 output tokens, while Gemini was allowed 32768 output tokens together with a 512-token thinking budget. Transport failures were retried up to three times with exponential backoff (4 s, then 8 s); these retries respond to API exceptions alone and never resample a response that returned successfully, so the single-shot repair design is preserved. One provider-specific exception applies: our Gemini client raises on an empty response body, so an empty or blocked Gemini return is regenerated where the equivalent Claude or GPT-5 return would not be. Before a returned file is written to disk we strip Markdown code fences from the response; no other post-processing is applied. Every call is logged with its prompt, raw response, model identifier, input and output token counts, and condition.

**Patch application.** Because every condition asks the model for a complete file, application is direct: we take the returned file and write it in place of the original, with no method-level extraction and no import reconstruction. This whole-file design keeps the application step identical across all four conditions, so no condition is advantaged by how its output is reassembled. The only exception is the Markdown fence stripping noted above, which is applied identically to every response.

**Compilation and testing.** We compile and test each patched project through the Vul4J CLI inside a Docker container, which standardizes per-project build configuration. Every build and test action is issued through the Vul4J wrapper (`vul4j compile` and `vul4j test`); we never invoke Maven or Gradle directly, so no project receives special build handling. A 900-second bound guards each compile-and-test cycle against runaway dependency resolution; because each patch is generated in a single shot rather than by an iterative repair tool, we do not need the multi-hour repair-process budgets that search-based APR requires [4]. For every patch we record whether compilation succeeded, whether the Proof-of-Vulnerability test passed, and the names of any regression tests that failed; these three fields drive the classification below.

**Trustworthiness hierarchy.** We score each patch on a four-level hierarchy adapted from APR4Vul and made Proof-of-Vulnerability-aware, so that closing the vulnerability is scored separately from merely passing tests. **L0** marks a patch that does not compile. **L1** compiles but fails the Proof-of-Vulnerability (PoV) test, so the vulnerability remains open. **L2** passes

the PoV test, closing the vulnerability, but leaves one or more regression tests failing. **L3** passes the PoV test and the full regression suite, and is our definition of a correct fix. For each vulnerability we obtain the PoV test selector from Vul4J's own metadata, using the explicit `failing_tests` field when present and otherwise parsing the `-Dtest` clause of the recorded test command. These are the tests the benchmark maintainers certify as failing on the vulnerable revision and passing on the human patch, which makes them the vulnerability-witnessing tests for each entry. Executing the PoV explicitly is what separates a patch that genuinely closes the hole from one that merely keeps tests green, the failure mode that inflates plain test-passing rates [18]. APR4Vul's two highest levels require manual judgement of exploit removal and intent preservation; we hold those out of scope and revisit the limitation in Section 6.

## 4 Results

The experiment produced 504 patches: 42 vulnerabilities under four conditions across three models. Every cell generated, compiled, tested, and classified without pipeline error, so all 504 enter the analysis. Because the hierarchy is Proof-of-Vulnerability-aware, each patch is scored not only on whether it compiles but on whether it closes the vulnerability and whether it does so without regressing the rest of the suite. Throughout, "correct" means L3: the PoV test passes and the full regression suite passes.

**Overall outcomes.** Table 2 gives the distribution across all 504 cells. Compilation is not the dominant obstacle: 77.2% of patches compile. The harder wall is semantic. Only 22.6% of patches make the PoV test pass, and 16.5% are fully correct. The distance between a 77.2% compile rate and a 16.5% correct-fix rate locates the real difficulty of LLM-based repair past the point of producing code that builds.

**Table 2** Overall trustworthiness distribution across all 504 cells.

| Level | Meaning | Count (%) |
|---|---|---|
| L0 | Does not compile | 115 (22.8) |
| L1 | Compiles, PoV fails | 275 (54.6) |
| L2 | PoV passes, regressions remain | 31 (6.2) |
| L3 | PoV passes, all tests pass | 83 (16.5) |
| Compile rate (L1+L2+L3) | | 77.2% |
| PoV-pass rate (L2+L3) | | 22.6% |
| Correct-fix rate (L3) | | 16.5% |

**RQ1: How much enrichment improves patch quality.** Enrichment does not improve correctness in proportion to its detail. Table 3 reports outcomes by condition. The baseline (C1) reaches 12.7% L3. Naming the CWE class (C2) is the single best condition at 19.8%, yet the two richer conditions that add explicit fix guidance, free-text (C3a) and schema (C3b), both fall back to 16.7%. The largest gain therefore comes from simply telling the model which vulnerability class it faces; layering on detailed repair guidance adds nothing further and, on this sample, slightly reduces the rate. The two contrasts behind this paragraph deserve different treatment. For C1 vs. C2, a paired McNemar test on the 126 (vuln, model) pairs gives 13 cases where only C2 succeeded against 4 where only C1 succeeded (with 12 pairs correct under both, reconciling the 16 and 25 marginal totals in Table 3), for an exact two-sided $p = 0.049$. In magnitude, naming the CWE class raises the correct-fix rate by 7.1

**Table 3** Outcomes by condition ($n = 126$ each). L3% is the correct-fix rate; PoV% is L2+L3; Compile% is L1+L2+L3. Bold marks the best value in each column.

| Condition | L0 | L1 | L2 | L3 | L3% | PoV% | Comp% |
|---|---|---|---|---|---|---|---|
| C1 (baseline) | 31 | 72 | 7 | 16 | 12.7 | 18.3 | 75.4 |
| C2 (CWE name) | 24 | 68 | 9 | 25 | **19.8** | 27.0 | 81.0 |
| C3a (prose) | 25 | 71 | 9 | 21 | 16.7 | 23.8 | 80.2 |
| C3b (schema) | 35 | 64 | 6 | 21 | 16.7 | 21.4 | 72.2 |

percentage points, from 12.7% to 19.8%. The margin is narrow – one reclassified pair would push the test above the conventional threshold – so we treat the direction as reliable and the size as suggestive. The C2-vs-C3a/C3b margin is too small to test at this scale, as the C3a-vs-C3b McNemar in RQ2 already shows; we report it as suggestive only and return to both in Section 5.

**RQ2: How much representational format matters.** The central contrast is C3a against C3b: identical repair knowledge rendered in two different forms. Both conditions achieve a 16.7% correct-fix rate (21 of 126), showing that the injected knowledge remains robust to representational choice at the scale of our experiment. The paired outcomes reinforce this parity: among the eight discordant pairs pooled across the three models, four favor prose and four favor schema, and this even split holds even though the three models respond to enrichment along visibly different curves (RQ3). The observed difference is therefore 0.0 percentage points, and a paired McNemar test detects no directional advantage for either representation ($p = 1.000$, two-sided exact). Across standard interval methods for paired proportions, a 95% bound on that difference is approximately ±4.5 percentage points. At this sample size the design therefore excludes a format effect larger than roughly four and a half points in either direction, and says nothing about smaller ones.

**Table 4** McNemar test, C3a vs. C3b, success = L3. $b$: only C3b correct; $c$: only C3a correct. Two-sided exact $p$.

| Group | $a$ | $b$ | $c$ | $d$ | disc. | $p$ |
|---|---|---|---|---|---|---|
| Claude | 5 | 0 | 2 | 35 | 2 | 0.500 |
| Gemini | 6 | 3 | 2 | 31 | 5 | 1.000 |
| GPT | 6 | 1 | 0 | 35 | 1 | 1.000 |
| Pooled | 17 | 4 | 4 | 101 | 8 | 1.000 |

**RQ3: Comparison across models.** The three models differ both in overall success and in how they respond to enrichment. Table 5 reports outcomes per model. Gemini 2.5 Pro is the strongest single model on this benchmark at 22.0% correct, with the highest compile rate at 84.5%, ahead of Claude Sonnet 4.5 at 14.3% and GPT-5 at 13.1%. Their enrichment profiles also diverge: GPT-5 improves close to monotonically as context is added, Gemini spikes sharply at C2 and then declines, and Claude peaks at C2 and C3a before dropping at C3b. These are three distinct response shapes, yet, as RQ2 showed, the prose and schema conditions still converge to the same pooled correct-fix rate. The format result is therefore not an artifact of one model's behavior.

**RQ4: Repair rate by vulnerability class.** Correct-fix rate varies sharply across CWE classes (Table 6), and the variation tracks how concrete the class is. Classes that name a specific, recognizable repair pattern are repaired often: improper authentication (CWE-287) at 37.5%,

**Table 5** Outcomes by model ($n = 168$ each). Bold marks the best value in each column.

| Model | L0 | L1 | L2 | L3 | L3% | PoV% | Comp% |
|---|---|---|---|---|---|---|---|
| Claude Sonnet 4.5 | 44 | 89 | 11 | 24 | 14.3 | 20.8 | 73.8 |
| GPT-5 | 45 | 89 | 12 | 22 | 13.1 | 20.2 | 73.2 |
| Gemini 2.5 Pro | 26 | 97 | 8 | 37 | **22.0** | 26.8 | **84.5** |

XXE (CWE-611) at 25.0%, deserialization (CWE-502) at 25.0%, infinite loop (CWE-835) at 21.4% across its 84 cells, the largest of the well-repaired classes, and path traversal (CWE-22) at 20.0%. Broad, abstract classes are repaired rarely or never: improper input validation (CWE-20) at 3.1%, and the access-control, cryptographic, privilege-management, and data-processing classes at 0%. CWE-20 is both the largest class, at 96 cells, and one of the lowest-scoring, which drags the overall average down. The high end of the table rests on individual vulnerabilities: the 91.7% for CWE-74, for instance, comes from a single injection bug seen across all conditions and models. We therefore read this as a gradient over *classes* rather than a precise per-class rate, and treat the singleton-backed entries as suggestive. The pattern fits RQ1: enrichment helps when the class points the model at a concrete repair, and stops helping when the class is too generic to act on.

**Table 6** Correct-fix (L3) rate by CWE class. Multi-instance classes anchor the gradient; single-vulnerability classes ($n_{\text{cells}} = 12$) are suggestive only and listed separately.

| CWE | Description | $n$ | L3% |
|---|---|---|---|
| *Multi-instance classes ($\geq 2$ vulnerabilities)* | | | |
| CWE-287 | Improper authentication | 24 | 37.5 |
| CWE-611 | XML external entity (XXE) | 48 | 25.0 |
| CWE-502 | Deserialization | 24 | 25.0 |
| CWE-835 | Infinite loop | 84 | 21.4 |
| CWE-22 | Path traversal | 60 | 20.0 |
| CWE-79 | Cross-site scripting | 60 | 15.0 |
| CWE-20 | Improper input validation | 96 | 3.1 |
| CWE-264 | Permissions / access control | 24 | 0.0 |
| *Single-vulnerability classes ($n = 12$, suggestive only)* | | | |
| CWE-74 | Injection | 12 | 91.7 |
| CWE-532 | Sensitive info in log | 12 | 16.7 |
| CWE-77 | Command injection | 12 | 8.3 |
| CWE-284 | Improper access control | 12 | 0.0 |
| CWE-310 | Cryptographic issues | 12 | 0.0 |
| CWE-269 | Improper privilege management | 12 | 0.0 |
| CWE-19 | Data processing errors | 12 | 0.0 |

**Cost of enrichment.** Because an approach that is accurate but unaffordable is of limited practical use, we report what this study cost to run. Generating all 504 patches cost approximately $70 in API charges at the prices in force during collection: roughly $30 for GPT-5, $30 for Claude Sonnet 4.5, and $10 for Gemini 2.5 Pro, or about $0.14 per patch. Evaluation adds only local compute. The four conditions are nested by construction: every prompt carries the complete vulnerable source file, C2 adds a CWE identifier and its MITRE description, C3a adds a prose paragraph, and C3b adds a four-field block. Prompt length therefore rises monotonically from C1 to C3b, making C3b the most expensive condition to run. Correct-fix rate does not follow that ordering: it peaks at C2, the cheapest of the three enriched conditions, and is flat across C3a and C3b (Table 3). The cheapest enrichment we tested is also the best-performing one. Two qualifications keep this in proportion. The

vulnerable file dominates every prompt, so the absolute cost difference between conditions is small; the point is which enrichment earns its place, not that a large saving is available. And we report cost for the run as a whole rather than per condition, since per-cell token counts are not part of the released artifact.

**Classifier validation.** Because the L0–L3 verdicts drive every result above, we manually audited cells spanning the riskiest classification boundaries. For one XXE patch scored L3, the model disabled external-entity expansion on the input factory, matching the root-cause fix of the human patch. For one deserialization patch scored L3, the model enabled secure processing and disabled external DTD and stylesheet loading, a broader hardening than the human patch, with all tests still passing. For one authentication patch scored L2, the model closed the authentication hole, so the PoV test passed, but dropped a containment check and regressed more than thirty tests; the classifier correctly recorded L2 rather than L3. The audit supports treating the automated verdicts as faithful.

## 5 Discussion

**A bare label beat elaborate guidance.** The clearest result of the study is also its most useful: naming the vulnerability class outperformed every richer condition. C2 reached 19.8% correct against 16.7% for both fix-guidance conditions, so a single line of classification did more than a paragraph of repair instructions or a four-field schema built from the same knowledge. This inverts the working assumption of much prompt-engineering practice, where more context is presumed to help. Two mechanisms fit. First, frontier models already hold CWE-level repair knowledge from training, having seen many path-traversal or XXE fixes, so a label is enough to retrieve the right pattern while added guidance is redundant. Second, the extra text lengthens the prompt and pushes the code further from the instruction, which can dilute attention on the file being repaired. We hold the size of the effect loosely, since the C2 lead is 25 versus 21 correct fixes out of 126, but the direction is consistent and runs against the field's default, which is what makes it worth reporting. We stress what this does not license: the result is a direction worth testing, not a design principle, and it should not be read as showing that naming the CWE class is sufficient. Adopting it as practice would require a higher-powered replication than an emerging-results study can provide.

**Repair tracks how concrete a class is.** The by-class results sharpen the same point on the full 504 cells: correct-fix rate forms a clear gradient from concrete classes (authentication, XXE, deserialization, path traversal) down to broad ones (CWE-20 at 3.1%, the access-control and cryptographic classes at zero). A concrete class points the model at a canonical fix; a broad class such as CWE-20 names a symptom with no single repair shape to retrieve.

**Equivalent knowledge was robust to representational choice.** Within the enrichment story sits the question we set out to isolate: does the form of the guidance matter when its content is fixed? In our experiment, equivalent repair knowledge proved robust to two distinct representations. Free-text guidance and a typed schema each produced a 16.7% correct-fix rate, while the paired outcomes were symmetric: four discordant cases favored prose and four favored schema. This parity is practically useful. A structured schema can be easier to generate consistently, validate automatically, and integrate into a repair pipeline, yet it matched the correctness of hand-written prose without an observed penalty. We remain careful about the scope of the claim: with only eight pooled discordant pairs, our interval

excludes a format effect larger than about 4.5 percentage points but leaves anything smaller open, and says nothing about other settings. The supported conclusion is narrower: for the frontier models, vulnerability classes, and schema design tested here, repair guidance transferred cleanly across representations.

**Next steps.** Five follow-ups would extend these findings. First, a higher-powered replication on more vulnerabilities would resolve whether the prose-schema null holds once the discordant sample is large enough to detect a small effect, and would re-establish the ordering on whatever models are current at the time; the full design costs roughly $70 to run end to end, so it is cheap to repeat as models advance. Second, extending the enrichment comparison to rarer, domain-specific CWE classes would test whether guidance pays off where a model's prior knowledge is thinner, since our set leans toward common classes. Third, promoting our automatic L0–L3 hierarchy toward APR4Vul's security-verified levels through manual exploit-replay on a sample of L3 patches would test whether passing the PoV test corresponds to genuinely removing the exploit, the construct-validity limit we note in Section 6. Fourth, richer structural context – architecture summaries or code property graphs – would vary the content axis this study deliberately holds fixed, and is complementary to the format question rather than a substitute for it. Finally, extending the comparison to open-weight models would test whether these patterns hold outside proprietary APIs, since pre-trained model choice is known to affect AVR performance [23].

## 6 Threats to Validity

**Internal validity.** We generate one patch per cell with no repeated sampling, and we passed no temperature to any provider, so each model sampled at its own default rather than at a common fixed value (Section 3). Because those defaults differ across providers, the three models were not sampled under matched decoding settings, which limits exact replication and weakens the cross-model comparison in RQ3; a higher-powered replication should fix a single common temperature across all three. Because model output is stochastic, an individual cell could land differently on another run, though pooled rates over 504 cells should be far more stable than any single cell; we chose a single trial per cell to keep the design tractable for an emerging-results study, and we treat per-cell verdicts as evidence in aggregate rather than individually. Two further asymmetries qualify RQ3 in the same direction. Our output-token budget was four times larger for Gemini than for Claude and GPT-5, so a long repaired file could be truncated under the smaller budget and recorded as non-compiling. And because our Gemini client treats an empty response body as an exception, empty Gemini returns were regenerated while equivalent Claude and GPT-5 returns were not. Both asymmetries favour Gemini, the strongest model in our results, so the per-model ordering in Table 5 warrants more caution than the per-condition comparisons, which are unaffected: within any one model, all four conditions ran under identical settings. Our L0–L3 verdicts also rest on Vul4J's own metadata correctly identifying the vulnerability-witnessing test for each entry; we rely on the maintainers' curation and do not independently re-derive each Proof-of-Vulnerability test from the CVE. Finally, the classifier that assigns trust levels was checked by a manual audit of cells at the riskiest boundaries rather than an exhaustive review of all 504, so the audit supports the verdicts without certifying every one.

**External validity.** The study covers a single language (Java), a single benchmark (Vul4J), and three specific frontier models, so generalization to other languages, to smaller or open-weight models [23], or to vulnerability classes outside our set is not established. The three

models were the frontier offerings of their respective providers when the data was collected in May 2026, and more capable models have since been released. What the study reports is the relative ordering of prompt conditions under a controlled ablation, not absolute repair rates, and that ordering is the object of interest rather than any particular model's ceiling. The buildability filter also removed four entries (VUL4J-15, -23, -35, -39); the maintainers themselves flag the first three as non-buildable, while the fourth builds upstream but not in our container, an environmental quirk that bounds the working set. Within the 42 vulnerabilities we study, the class distribution is uneven: a few classes such as CWE-20, CWE-835, CWE-22, and CWE-79 supply most cases, while several classes rest on a single vulnerability seen across twelve cells, so the per-class rates for those small classes are suggestive rather than firm. The format comparison is similarly limited in power: with only eight discordant pairs pooled, the null McNemar result means no effect was detectable at this scale, not that no effect exists.

**Construct validity.** We operationalize a correct fix as passing the Proof-of-Vulnerability test and the full regression suite. Qi et al. have shown that test-based correctness can overstate true repair quality [18]: a patch may pass the available tests yet leave some exploitable behavior open or regress an untested path. We do not perform manual security verification, so APR4Vul's two highest levels, which judge exploit removal and intent preservation by hand, remain out of scope and are listed in Section 5 as future work. A further construct assumption is specific to our central comparison. We operationalize C3a and C3b as matched-source encodings drawn from the same APR4Vul fix patterns, written by one author rather than generated automatically and without an inter-rater check on prose quality. Variance across the 15 classes is bounded by construction, since both renderings for a class derive from the same source rows, but we cannot rule out that some classes received sharper guidance than others; a sensitivity analysis on prose quality is left to future work. Strict informational equivalence is not measured: C3b's field labels (Root Cause, Canonical Repair, Constraints, What to Avoid) are themselves a structural cue that C3a does not contain. A reviewer could therefore read our null result as evidence that this label-level asymmetry is also not detectable at scale, rather than as evidence that form is irrelevant in general.

## 7 Conclusion

Across 504 patches spanning 42 Java vulnerabilities, 15 CWE classes, and three frontier models, three findings emerge. First, naming the CWE class improves repair performance over an unenriched baseline and achieves the highest observed correct-fix rate among the four conditions. Adding more elaborate prose or schema guidance does not produce a further observed improvement. Second, repair success varies sharply across vulnerability classes. The descriptive pattern suggests that specific classes with recognizable repair templates are easier to repair than broader classes. Third, the free-text and typed-schema conditions reach an identical 16.7% correct-fix rate with symmetric McNemar discordance. We interpret this as no detectable format effect at the scale of our experiment, not as proof that representation never matters. For frontier models on common vulnerability classes, what a prompt identifies may matter more than how elaborately that information is formatted, a direction that warrants higher-powered replication before it is treated as a design principle.

# Toward Entanglement Dependence Metrics for Quantum Software Complexity

**Haibo Yu**
Kyushu Sangyo University, Fukuoka, Japan

**Jianjun Zhao**
Kyushu University, Fukuoka, Japan

## Abstract

Quantum software is often described using circuit-level metrics, including the number of qubits, the number of gates, circuit depth, the number of two-qubit gates, and the number of measurement operations. These metrics are useful for estimating program size and execution cost, but they do not directly describe whether and to what extent qubits become structurally related through possible entanglement during program execution. This paper argues that entanglement dependence provides a basis for measuring a quantum-specific form of software complexity. The proposed metrics capture possible entanglement-related structural dependence, not physical entanglement observed in a particular execution. Based on this notion, we define a focused set of six metrics that characterize the amount, density, local connectivity, global scope, program span, and modular crossing of entanglement-related dependencies. We also analyze these metrics using Weyuker's properties for evaluating software complexity measures. The paper presents the metrics as a measurement framework and research direction for empirical quantum software engineering. It discusses how future studies can validate the metrics and examine their usefulness for testing, debugging, maintenance, and program comprehension of quantum software.

## 1 Introduction

Software complexity metrics have long been used to support program comprehension, testing, debugging, maintenance, and empirical analysis [6, 22]. For classical software, many metrics have been proposed to measure different aspects of complexity, such as program size, control-flow structure, data-flow relations, coupling, and cohesion [3, 8, 9, 11]. Although no single metric can fully explain software complexity, these metrics provide useful evidence for comparing programs and studying software engineering tasks. Quantum software also needs suitable complexity metrics. Current metrics for quantum programs are often defined at the circuit level, including the number of qubits, the number of gates, circuit depth, the number of two-qubit gates, and the number of measurement operations [4, 5, 21]. These metrics are useful because they are related to program size, hardware requirements, and execution cost on current quantum devices. However, they mainly describe circuit size and gate structure, and do not directly describe whether and to what extent qubits become structurally related through possible entanglement during program execution.

Entanglement is one of the main sources of such relations [12]. When qubits become entangled, the state of one qubit cannot be understood independently from the state of the others. This has direct implications for software engineering. A developer may not be able to reason about one qubit locally after it has become entangled with other qubits [14, 19]. A fault in an operation that creates or propagates entanglement may affect several qubits and may only be observed later through a measurement operation. These cases suggest that entanglement can introduce a form of structural complexity that is not well captured by simple size-based or circuit-level metrics.

In this paper, we use entanglement dependence as a structural notion. The proposed metrics do not measure physical entanglement observed in a particular execution. Instead, they measure possible entanglement-related dependence induced by program operations and represented in a program dependence structure. This distinction is important because the goal is to support software engineering tasks, such as program comprehension, testing, and debugging, rather than to characterize the exact quantum state produced in one run.

Recent work on quantum program dependence analysis has introduced entanglement dependence as a quantum-specific form of program dependence [20]. Entanglement dependence captures possible state influence among qubits caused by operations that may create or propagate entanglement. This notion provides a possible bridge between quantum state relations and software structure. If entanglement dependencies can be represented in a program dependence graph, they can also be counted, compared, grouped, and related to software engineering tasks. This paper explores this idea from a measurement perspective. We argue that entanglement dependence can serve as a basis for defining metrics for quantum-specific software complexity. The proposed metrics are intended to complement existing circuit-level metrics, not to replace them. While circuit-level metrics describe size and gate structure, entanglement dependence metrics aim to describe whether, where, and to what extent possible entanglement-related dependencies appear in a quantum program, including their amount, density, local connectivity, global scope, program span, and modular crossing.

This paper does not report an empirical validation study. We do not claim that the proposed metrics are already validated. Instead, we make a first step toward a measurement framework for entanglement-related complexity. To make the proposal precise, we define a focused set of six metrics over a dependence-graph representation of quantum programs. We also analyze these metrics using Weyuker's properties for evaluating software complexity measures [18]. This analysis helps clarify what the metrics can capture and what still needs empirical validation.

This paper makes the following contributions.

- It identifies entanglement dependence as a basis for measuring a quantum-specific form of software complexity.
- It defines a focused set of six metrics for characterizing entanglement-related dependencies in terms of their amount, density, local connectivity, global scope, program span, and modular crossing.
- It analyzes these metrics using Weyuker's properties for software complexity measures and outlines a research agenda for their empirical validation and use in quantum software engineering activities.

The rest of this paper is organized as follows. Section 2 reviews background and related work. Section 3 motivates the problem and introduces entanglement dependence. Section 4 defines the metrics and illustrates their use. Section 5 presents the theoretical analysis. Section 6 discusses the research agenda and limitations. Section 7 concludes the paper.

## 2 Background and Related Work

Quantum programs are usually represented as quantum circuits [12]. A quantum circuit operates on qubits, which are the basic units of quantum information. A qubit can be transformed by quantum gates and later read by a measurement operation. Single-qubit gates act on one qubit, while two-qubit gates, such as controlled gates, act on two qubits and may create or propagate entanglement. When qubits are entangled, the state of one qubit cannot be fully described independently of the state of the others [12]. This property is important for quantum computing, but it also makes program comprehension, testing, and debugging different from those for classical programs.

Software complexity metrics have been studied for several decades [6, 22]. Classical metrics capture different aspects of software complexity, such as program size, control-flow structure, information flow, coupling, and cohesion. For example, McCabe's cyclomatic complexity measures control-flow complexity [11], Halstead's software science metrics characterize program size and vocabulary [8], Henry and Kafura's metrics consider information flow between modules [9], and object-oriented metrics capture design properties such as coupling and cohesion [1, 3]. Weyuker proposed a set of properties for evaluating software complexity measures [18]. These properties provide a way to reason about whether a metric can distinguish programs, react to composition, and capture structural differences. This paper uses these properties as a theoretical lens for analyzing the proposed metrics.

Quantum software metrics have also begun to receive attention. Sicilia *et al.* discussed quantum software measurement as part of quantum software engineering [16]. Prior work has proposed size and structure metrics for quantum software at different abstraction levels [21]. Other studies have considered metrics for quantum circuit understandability [4] and quantum software quality [5]. Functional size measurement has also been adapted to quantum software through Q-COSMIC [17]. Together, these studies show that quantum software can be measured from several useful perspectives, including size, structure, understandability, quality, and functional size. However, these perspectives do not directly characterize whether entanglement-related dependencies are localized, dense, widely connected, long-ranged, or crossing modular boundaries. This paper focuses on this missing measurement perspective by studying complexity from the viewpoint of entanglement dependence.

Program dependence analysis provides another structural view of software [7]. In classical software engineering, dependence relations have been used for slicing, testing, debugging, optimization, maintenance, complexity measurement, and program comprehension [2, 10, 13, 15]. For quantum programs, dependence analysis needs to consider quantum-specific features, including state evolution, measurement operations, and entanglement. Recent work has introduced quantum program dependence graphs and identified entanglement dependence as a quantum-specific dependence relation [20]. This paper builds on that idea and studies how entanglement dependence can be used as a basis for measuring an entanglement-related aspect of quantum software complexity.

## 3 Motivation and Entanglement Dependence

We use a small example to illustrate why circuit-level metrics may be insufficient for measuring quantum software complexity. Figure 1 shows two quantum programs that both use four qubits and a small number of gates. Program $A$ prepares two independent Bell pairs, while program $B$ uses the same four qubits in a simple entangling chain, creating a connected entanglement-dependence structure. At the circuit level, both programs are small and have similar values for common metrics such as qubit count, controlled gates, and circuit depth. However, their entanglement-dependence structures are different.

```
Program A:                    Program B:
h  q[0]                       h  q[0]
cx q[0], q[1]                 cx q[0], q[1]
h  q[2]                       cx q[1], q[2]
cx q[2], q[3]                 cx q[2], q[3]
```

**Figure 1** Two small quantum programs with different entanglement-dependence structures.

In Program $A$, the entanglement-dependence structure is local. The first two operations create a possible entanglement relation between $q[0]$ and $q[1]$, while the last two operations create another possible relation between $q[2]$ and $q[3]$. These two pairs are independent. Reasoning about one pair does not require reasoning about all four qubits together. In Program $B$, the entanglement-dependence structure is more connected. The first controlled operation may create an entanglement relation between $q[0]$ and $q[1]$. The following controlled operations may propagate this relation to $q[2]$ and $q[3]$. As a result, the program may require reasoning about a larger connected group of qubits. A fault in an earlier operation may also influence later qubits through the propagated entanglement-related dependence.

This example shows a gap between circuit-level metrics and entanglement-related structure. The number of qubits and the number of controlled gates provide useful information, but they do not directly tell whether entanglement is separated into small local groups or spread across a larger part of the program. A program with localized entanglement dependence may be easier to understand, test, and debug than a program where entanglement dependencies form a large connected structure. Entanglement dependence captures this kind of possible state influence at the program level. It is a form of program dependence that arises from possible entanglement among qubits. In a quantum program, operations such as controlled gates may create or propagate entanglement. After such operations, the state of one qubit may no longer be reasoned about independently from the state of other qubits. The dependence described here is structural and conservative: it indicates that program operations may create or propagate entanglement-related influence, not that physical entanglement is necessarily observed in every execution.

Entanglement dependence is different from classical data dependence. Classical data dependence usually describes how the value of one variable is computed from, or affected by, the value of another variable. Entanglement dependence does not mean that one qubit stores or copies the value of another qubit. Instead, it means that the quantum states of the involved qubits may become structurally related through quantum operations. Such a relation can influence later computation and measurement results, even when there is no classical value flow between program variables.

Entanglement dependence is also different from simply counting two-qubit gates. A two-qubit gate is an operation in a circuit, while an entanglement dependence is a relation induced by the possible state influence of that operation. The same number of two-qubit gates may lead to different dependence structures. Several two-qubit gates may create independent local relations, or they may connect many qubits into a larger entanglement-dependence structure. Therefore, measuring entanglement dependence can provide information that is not directly available from gate counts alone.

For measurement purposes, entanglement dependence is useful because it connects quantum state relations with program structure. Once such dependencies are represented as edges in a dependence graph, they can be measured in terms of their amount, density, connectivity, scope, and span, and then studied in relation to software engineering tasks.

A program where these dependencies form a large connected component may be harder to understand or test than a program where they are separated into small local components. Similarly, dependencies that persist across many statements or circuit layers may make debugging and fault localization more difficult.

This view treats entanglement dependence as a structural element of quantum software. It does not replace existing circuit-level metrics. Instead, it provides an additional layer of measurement. Circuit-level metrics describe properties such as circuit size, depth, and gate structure, while entanglement dependence metrics describe how qubits and program elements are connected through possible entanglement-related dependencies.

## 4 Entanglement Dependence Metrics

This section defines six metrics based on entanglement dependence. The goal is not to provide a complete metric suite, but to define a focused set of metrics that are precise enough for theoretical analysis and future empirical validation. For ease of presentation, we label the proposed metrics as $M_1, \ldots, M_6$.

Let $P$ be a quantum program and let $Q(P)$ be the set of qubits used in $P$. We assume that a dependence analysis produces a dependence graph $G_P = (V, E)$, where $V$ is a set of analysis nodes and $E$ is a set of dependence edges. Depending on the level of analysis, a node may represent a quantum operation, a program statement, a subroutine element, or a qubit-level abstraction. Let $E_{ent} \subseteq E$ denote the set of entanglement-dependence edges. Each edge $(u, v) \in E_{ent}$ indicates that node $v$ may be affected by a possible entanglement-related state influence created or propagated through node $u$.

### Assumptions for constructing the dependence graph

The proposed metrics depend on the entanglement-dependence graph used as input. This paper does not prescribe one fixed construction algorithm, because such a graph may be built at different abstraction levels and for different quantum programming languages. In general, the graph can be obtained from a quantum program dependence analysis that tracks operations capable of creating or propagating possible entanglement-related state influence. For a simple circuit without measurement operations, classical control, or subroutine boundaries, the resulting entanglement-dependence edges may be close to the topology induced by two-qubit gates. However, entanglement dependence is not intended to be only a count of such gates. In more general quantum programs, the dependence graph may also reflect propagation through later operations, interaction with measurement operations and classical control, and dependencies that cross modular boundaries. A conservative analysis may include possible dependencies that do not occur in every execution, while a more precise analysis may compute fewer edges but may be more expensive or language-specific. Therefore, metric values should always be interpreted together with the dependence model and analysis assumptions used to construct $G_P$ and $E_{ent}$.

The metrics defined below are independent of a particular implementation of the analysis. They assume that $G_P$ and $E_{ent}$ have already been constructed, and then measure different structural aspects of the resulting entanglement-dependence information.

We use several auxiliary functions when the corresponding information is available. Let $pos(v)$ denote the position of node $v$ in the program or circuit, such as its statement index or circuit layer. If the program is organized into subroutines, let $sub(v)$ denote the subroutine that contains node $v$.

### Metric $M_1$ (entanglement dependence count)

Metric $M_1$ counts the number of entanglement-dependence edges:

$$M_1(P) = |E_{ent}|.$$

It measures the amount of entanglement-dependence structure in a program. A larger value means that more program elements may be connected through possible entanglement-related dependencies.

### Metric $M_2$ (entanglement dependence density)

Metric $M_2$ normalizes the number of entanglement-dependence edges by the total number of dependence edges:

$$M_2(P) = \frac{|E_{ent}|}{|E|}.$$

When $E$ is empty, we define $M_2(P) = 0$. This metric describes how much of the dependence structure is related to entanglement. It complements $M_1$ by reducing the direct effect of program size.

### Metric $M_3$ (maximum entanglement degree)

For a node $v \in V$, let its entanglement degree be

$$edeg(v) = |\{u \in V \mid (u, v) \in E_{ent} \vee (v, u) \in E_{ent}\}|.$$

Metric $M_3$ is the maximum entanglement degree:

$$M_3(P) = \max_{v \in V} edeg(v).$$

It identifies the node that is most highly connected through entanglement dependence. Such a node may be a potential hotspot for testing, debugging, or program comprehension.

### Metric $M_4$ (maximum entanglement cluster size)

Let $G_{ent} = (V, E_{ent})$ be the subgraph induced by entanglement-dependence edges. We ignore edge directions when computing connected components. Let $C_1, C_2, \ldots, C_k$ be the connected components of $G_{ent}$ that contain at least one entanglement-dependence edge. Metric $M_4$ is the maximum entanglement cluster size:

$$M_4(P) = \max_{1 \le i \le k} |C_i|.$$

If $E_{ent}$ is empty, we define $M_4(P) = 0$. This metric describes the largest connected region of entanglement dependence in the program. It helps distinguish localized entanglement-dependence structure from a structure that connects many nodes.

### Metric $M_5$ (maximum entanglement span)

For an entanglement-dependence edge $(u, v) \in E_{ent}$, its span is defined as

$$span(u, v) = |pos(v) - pos(u)|.$$

Metric $M_5$ is the maximum entanglement span:

$$M_5(P) = \max_{(u,v)\in E_{ent}} span(u, v).$$

If $E_{ent}$ is empty, we define $M_5(P) = 0$. This metric describes the longest program range of entanglement-related state influence. Long spans may make reasoning and fault localization more difficult because the effect of an earlier operation may appear much later.

### Metric $M_6$ (cross-subroutine entanglement dependence)

For programs organized into subroutines, Metric $M_6$ counts entanglement-dependence edges that connect nodes in different subroutines:

$$M_6(P) = |\{(u, v) \in E_{ent} \mid sub(u) \neq sub(v)\}|.$$

This metric measures the amount of entanglement dependence that crosses modular boundaries. It may be useful for studying modular reasoning, integration testing, and maintenance of quantum software.

Table 1 summarizes the proposed metrics.

**Table 1** Proposed entanglement dependence metrics.

| Metric | Intended meaning |
|---|---|
| $M_1$ | Amount of entanglement-dependence structure |
| $M_2$ | Relative density of entanglement dependence in the dependence graph |
| $M_3$ | Highest local connectivity through entanglement dependence |
| $M_4$ | Largest connected region of entanglement dependence |
| $M_5$ | Longest program range of entanglement-related state influence |
| $M_6$ | Entanglement dependence across subroutine boundaries |

These metrics should be interpreted together rather than in isolation. Metric $M_1$ measures the amount of entanglement-dependence structure, but a high value may simply reflect a large program. Metric $M_2$ provides a normalized view of how much of the dependence graph is related to entanglement. Metric $M_3$ identifies locally central nodes, while $M_4$ captures the largest connected entanglement-dependence structure. Metric $M_5$ describes how far entanglement-related influence may extend in the program, and $M_6$ captures whether such influence crosses subroutine boundaries. Together, these metrics provide a focused view of entanglement-related complexity.

### Applying the Metrics to the Example

We use the example in Section 3 to illustrate how the proposed metrics can expose differences that are not fully captured by circuit-level metrics. This analysis is not an empirical evaluation. It only shows how the metrics can be applied once entanglement-dependence relations are identified.

For simplicity, we analyze the example at the qubit-relation level. This is a simplified view of the dependence graph that keeps only the qubit-level entanglement-dependence relations needed to illustrate $M_1$, $M_3$, and $M_4$. We treat each possible entanglement dependence relation between two qubits as an undirected edge. For readability, we write $q_i$ for $q[i]$ in the graph notation. Program $A$ creates two independent Bell pairs, while Program $B$ uses the same four qubits in a simple entangling chain, creating a connected entanglement-dependence structure. The simplified qubit-level entanglement-dependence graphs are:

$$G^A_{ent} = (\{q_0, q_1, q_2, q_3\}, \{(q_0, q_1), (q_2, q_3)\}), G^B_{ent} = (\{q_0, q_1, q_2, q_3\}, \{(q_0, q_1), (q_1, q_2), (q_2, q_3)\}).$$

In each graph, the first component is the set of qubit nodes, and the second component is the set of undirected entanglement-dependence edges. Thus, $G^A_{ent}$ contains two separate connected components, one consisting of $q_0$ and $q_1$ and the other consisting of $q_2$ and $q_3$, while $G^B_{ent}$ contains one connected component over all four qubits, formed by the chain $(q_0, q_1)$, $(q_1, q_2)$, and $(q_2, q_3)$.

Table 2 shows the values of three metrics that can be directly illustrated by this example. Program A has two entanglement-dependence edges, two connected components, and each qubit is connected to only one other qubit. Program B has three entanglement-dependence edges, one connected component containing all four qubits, and two middle qubits with degree two.

**Table 2** Illustrative metric values for the motivating example.

| Metric | Program A | Program B |
|---|---|---|
| $M_1$ | 2 | 3 |
| $M_3$ | 1 | 2 |
| $M_4$ | 2 | 4 |

The example shows that the two programs have different entanglement-dependence structures. Program $A$ has localized entanglement dependence, while Program $B$ has a connected entanglement-dependence structure that spans all four qubits. Thus, even when programs are small and have similar circuit-level metric values, their entanglement-dependence structures may differ.

This example does not compute all metrics. Metric $M_2$ requires the full dependence graph, not only the entanglement-dependence edges. Metric $M_5$ requires positional information such as statement indices or circuit layers. Metric $M_6$ is relevant only when the program is organized into subroutines. These metrics can be applied in the same way once the corresponding information is available.

The main point is that entanglement-dependence metrics make structural differences explicit. A simple count, such as $M_1$, shows that Program B has more entanglement-dependence edges. Metrics $M_3$ and $M_4$ further show that Program B has higher local connectivity and a larger connected entanglement-dependence structure. Such differences may matter for program comprehension, test design, debugging, and fault localization.

## 5 Theoretical Analysis of the Metrics

We analyze the proposed metrics using Weyuker's properties for evaluating software complexity measures [18]. These properties were originally proposed for software complexity metrics in general. In this paper, we apply them to metrics over quantum programs. The goal is not to prove empirical usefulness, but to clarify the formal behavior of the metrics before empirical validation.

Let $\mathcal{P}$ be the set of quantum programs under consideration. A complexity metric is a function

$$\mu : \mathcal{P} \to \mathbb{R}_{\geq 0},$$

where $\mathbb{R}_{\geq 0}$ denotes the set of non-negative real numbers. In this section, $\mu$ denotes an arbitrary metric, while $M_1, \ldots, M_6$ denote the concrete metrics defined in Section 4. We write $P; Q$ for sequential composition, $P \equiv Q$ for semantic equivalence, and $\rho(P)$ for a program obtained from $P$ only by consistent renaming of qubits, variables, or statement labels.

Tables 3 and 4 summarize the Weyuker properties used in this paper and the satisfaction results, respectively. Here, "Y" means that the property holds under the metric definitions used in this paper, and "N" means that it does not hold in general. For properties stated using "there exist", such as $W_1$, $W_3$, $W_4$, $W_6$, $W_7$, and $W_9$, a "Y" means that suitable programs or contexts can be constructed under the metric definitions. It does not mean that every program pair or every composition has that behavior.

**Table 3** Weyuker properties used in this paper [18].

| Property | Name | Form used in this paper |
|---|---|---|
| $W_1$ | Non-coarseness | There exist programs $P, Q$ such that $\mu(P) \neq \mu(Q)$. |
| $W_2$ | Finiteness | For every value $c$, only finitely many programs $P$ satisfy $\mu(P) = c$. |
| $W_3$ | Non-uniqueness | There exist different programs $P, Q$ such that $\mu(P) = \mu(Q)$. |
| $W_4$ | Design sensitivity | There exist semantically equivalent programs $P, Q$ such that $P \equiv Q$ and $\mu(P) \neq \mu(Q)$. |
| $W_5$ | Monotonicity under composition | For all $P, Q$, $\mu(P) \leq \mu(P; Q)$ and $\mu(Q) \leq \mu(P; Q)$. |
| $W_6$ | Interaction sensitivity | There exist programs $P, Q, R_a, R_b$ such that $\mu(P) = \mu(Q)$, $\mu(P; R_a) \neq \mu(Q; R_a)$, and $\mu(R_b; P) \neq \mu(R_b; Q)$. |
| $W_7$ | Order sensitivity | There exist programs $P, Q$ such that $Q$ is obtained by permuting the order of parts of $P$ and $\mu(P) \neq \mu(Q)$. |
| $W_8$ | Renaming invariance | For every consistent renaming $\rho$, $\mu(P) = \mu(\rho(P))$. |
| $W_9$ | Non-additive composition | There exist $P, Q$ such that $\mu(P; Q) > \mu(P) + \mu(Q)$. |

**Table 4** Satisfaction of Weyuker properties.

| Metric | $W_1$ | $W_2$ | $W_3$ | $W_4$ | $W_5$ | $W_6$ | $W_7$ | $W_8$ | $W_9$ |
|---|---|---|---|---|---|---|---|---|---|
| $M_1$ | Y | N | Y | Y | Y | Y | Y | Y | Y |
| $M_2$ | Y | N | Y | Y | N | Y | Y | Y | Y |
| $M_3$ | Y | N | Y | Y | Y | Y | Y | Y | Y |
| $M_4$ | Y | N | Y | Y | Y | Y | Y | Y | Y |
| $M_5$ | Y | N | Y | Y | Y | Y | Y | Y | Y |
| $M_6$ | Y | N | Y | Y | Y | Y | Y | Y | Y |

All six metrics satisfy $W_1$, $W_3$, $W_4$, $W_6$, $W_7$, $W_8$, and $W_9$. They satisfy $W_1$ because programs with and without entanglement dependence can have different values. They satisfy $W_3$ because different programs may have the same metric value. For example, two different circuits may both contain two independent entanglement-dependence edges, and therefore have the same value for $M_1$. They satisfy $W_4$ because semantically equivalent programs may use different decompositions and induce different entanglement-dependence structures. They satisfy $W_6$ because two programs with the same metric value may interact differently with suitable contexts on either side of a composition. For example, a context may connect

to qubits that are structurally independent in one program but already connected through entanglement dependence in another program. They satisfy $W_7$ when reordering parts of a program changes the dependence structure or the span of dependencies, and they satisfy $W_8$ because consistent renaming does not change the dependence graph up to isomorphism.

None of the metrics satisfies $W_2$ over an unrestricted program set. This is expected because the proposed metrics measure only entanglement-related structure. Many programs can differ in parts unrelated to entanglement dependence, such as additional single-qubit gates or classical computations, while keeping the same metric value.

For $W_5$, only $M_2$ does not satisfy the property in general. Metric $M_2$ is a density metric. When a program is composed with another program containing many non-entanglement dependencies, the ratio of entanglement dependencies may decrease. In contrast, $M_1$, $M_3$, $M_4$, $M_5$, and $M_6$ are absolute or maximum-based metrics, and their values do not decrease under composition that preserves existing dependence edges.

All six metrics satisfy $W_9$ because composition can introduce new entanglement dependencies across the composition boundary. Because $W_9$ is stated using "there exist", it does not require every composition to have a value greater than the sum of the values of its parts. For example, composing two independent Bell-pair programs without any cross-boundary entangling operation may not increase $M_4$ beyond the values of the parts. This does not contradict $W_9$. Thus, the metric value of the composed program can be greater than the sum of the values of the two parts. There exist compositions in which later operations connect previously separated entanglement-dependence components, introduce additional cross-boundary edges, or create longer dependence spans. In such cases, count-based metrics such as $M_1$ and $M_6$ may increase beyond the sum of the separate values, density-based metric $M_2$ may become larger after composition, and maximum-based metrics such as $M_3$, $M_4$, and $M_5$ may also exceed the sum of the corresponding values of the parts. This reflects the non-local and context-dependent nature of entanglement dependence.

This analysis does not replace empirical validation. It only clarifies the formal behavior of the proposed metrics.

## 6 Research Agenda and Limitations

The proposed metrics need empirical validation before they can be used as evidence in quantum software engineering. The theoretical analysis in Section 5 clarifies their formal behavior, but it does not show whether they are useful for explaining or predicting the difficulty of software engineering tasks such as testing, debugging, maintenance, and program comprehension. We outline several directions for future validation.

- **Comparison with Circuit-Level Metrics.** Future studies should compare $M_1$–$M_6$ with circuit-level metrics, including the number of qubits, the number of gates, circuit depth, the number of two-qubit gates, and the number of measurement operations. If they capture different properties, they can complement existing metrics and provide a more detailed view of quantum software complexity.
- **Testing Difficulty.** Programs with high entanglement-dependence density, high local connectivity, large connected entanglement-dependence components, or long entanglement-dependence spans may require more careful test design, test input preparation, or oracle construction. Future studies can examine whether $M_2$, $M_3$, $M_4$, and $M_5$ are associated with fault detection, mutation score, coverage achievement, or test generation cost.
- **Debugging and Fault Localization.** When a failure is observed in a measurement result, the cause may come from an earlier operation that created or propagated entanglement. Empirical studies can examine whether $M_3$, $M_4$, and $M_5$ are related to fault-localization accuracy or debugging effort.

- **Program Comprehension.** Entanglement-related complexity may also affect program comprehension. Controlled experiments or user studies can examine whether the proposed metrics are related to the time needed to understand a program, the accuracy of answers to comprehension questions, or the difficulty perceived by developers.
- **Design and Maintenance.** The metrics can be used to compare different implementations of the same quantum algorithm, different circuit decompositions, or different modular designs. Metric $M_6$ is especially relevant for studying whether entanglement dependence crosses subroutine boundaries.
- **Tool Support and Datasets.** Future work also needs tools for extracting entanglement dependence and computing the proposed metrics. Benchmark datasets should include small educational programs, standard quantum algorithms, and real quantum software projects.
- **Metric Correlation and Redundancy.** Future studies should also examine the relationships among the proposed metrics. Some metrics may be correlated on certain classes of programs because they are computed from the same entanglement-dependence subgraph. For example, programs with many entanglement-dependence edges may also tend to have higher local connectivity or larger connected components. However, this need not always be the case: a program with many small independent components may have a high value of $M_1$ but a small value of $M_4$, while a program with fewer edges may still contain one large connected component. Empirical studies are needed to determine when the metrics provide complementary information and when some of them are redundant.

Overall, the next step is to move from metric definition to empirical evidence. The main questions are whether the metrics can be computed reliably, whether they provide information different from existing metrics, whether they provide complementary information to each other, and whether they help explain software engineering effort or difficulty. These directions should be interpreted alongside the limitations of the current study, as outlined below.

- **Lack of empirical validation.** The proposed metrics have not yet been empirically validated. Future studies are needed to examine whether they are related to testing effort, debugging difficulty, fault-localization accuracy, program comprehension, or maintenance cost.
- **Dependence on the underlying analysis.** The metrics depend on how entanglement dependence is defined and extracted. Different dependence models may produce different entanglement-dependence edges. This issue is central because all metric values are computed from the dependence graph and its entanglement-dependence edges. For example, a conservative analysis may include possible dependencies that do not occur in every execution, while a more precise analysis may be harder to compute. Therefore, any use of the proposed metrics should clearly state the underlying dependence model and analysis assumptions.
- **Structural dependence rather than physical entanglement.** The metrics describe structural dependence rather than physical entanglement observed in a particular execution. An entanglement-dependence edge means that one program element may be affected by a possible entanglement-related state influence created or propagated through another program element. It does not by itself prove that a specific run produces entanglement between the corresponding qubits. This distinction is important for programs with conditional behavior, measurement operations, input states, or classical control.

- **Abstract definitions.** The current definitions are still abstract. They are defined over a dependence-graph representation of quantum programs, but this paper does not provide a complete algorithm for constructing such graphs for all quantum programming languages. In practice, the construction may depend on the language, the intermediate representation, the circuit model, and the treatment of measurement and classical computation.
- **Limited scope.** The proposed metrics focus only on entanglement-related complexity. Quantum software complexity also includes other aspects, such as control structure, measurement behavior, classical–quantum interaction, noise sensitivity, resource usage, and maintainability. We also define only an initial set of six metrics in this paper. Other useful variants, such as average degree, average span, or normalized cross-subroutine dependence, are left for future work. The proposed metrics should therefore be used as a complement to existing circuit-level and software engineering metrics.

## 7 Conclusion

This paper presented an initial measurement framework for quantum software complexity based on entanglement dependence. Existing circuit-level metrics, including the number of qubits, the number of gates, circuit depth, the number of two-qubit gates, and the number of measurement operations, are useful for describing program size and execution cost. However, they do not directly describe whether and to what extent qubits become structurally related through possible entanglement dependence during program execution. To address this gap, we defined a focused set of six entanglement dependence metrics that characterize different aspects of entanglement-related complexity, including amount, density, local connectivity, global scope, program span, and modular crossing of entanglement-related dependencies. We also analyzed the metrics using Weyuker's properties for software complexity measures. The analysis shows that these metrics can capture structural information not directly captured by existing circuit-level metrics. The proposed metrics are not yet empirically validated and should be viewed as a starting point for empirical quantum software engineering. Future work should develop tool support, apply the metrics to real quantum programs, and study their relationship with testing, debugging, maintenance, and program comprehension.

## Data Availability Statement

This paper does not report an empirical study and does not produce a new dataset or software artifact. All examples used in the paper are fully described in the text.

## Abstract

Industrial LLM compliance-auditing systems are maintained through both expert policy and executable support chains. After deployment, changing standards, user appeals, expert reviews, and report variants expose failures in rule interpretation, parsing, evidence binding, context assembly, output contracts, and regression checks. We propose CoEvolve, a feedback-driven policy-harness maintenance workflow in which an LLM maintenance agent proposes coordinated updates, an independent verifier checks target repair, regression, stability, and semantic risks, and experts confirm releasable changes. We report a five-month industrial experience in a Chinese compliance-auditing service, covering 33 production feedback instances, 128 audited systems, 384 reports, and 24,192 checklist items. The evaluation compares four frozen workflow states formed by different maintenance organizations; it is not a controlled comparison of methods on identical maintenance inputs. On a 979-item monthly holdout benchmark, the CoEvolve replay state reached 93.5% accuracy, 4.1 percentage points above prompt/SOP maintenance at 89.4%. Manual co-maintenance reached 93.6% (916/979), while CoEvolve reached 915/979; their Wilson intervals overlap and the five-system effective sample is small. Because the replay input included visible historical manual artifacts, this result shows that CoEvolve reconstructed a comparable release state from those artifacts, not that it substituted for manual co-maintenance. Across replay tasks, CoEvolve externalized 4.97 candidate attempts per feedback instance on average. The experience supports governed policy-harness maintenance without retraining and highlights verifier-gate predicates and blocked-candidate records as transferable release-governance mechanisms.

## 1 Introduction

Industrial compliance auditing is adopting LLMs to extract evidence, interpret rules, and produce structured checklist-level judgments across multiple reports, standards, and checklist items. Unlike general question answering, the output must remain tied to inspectable

evidence, applicable standards, and explicit audit items. After deployment, user appeals, expert findings, runtime failures, and changing standards expose boundary cases. Many feedback signals appear to concern prompts, while the actual repair surface may involve rule interpretation, report parsing, evidence binding, context extraction, output contracts, or verification.

Model-external failures cannot be repaired by changing model weights alone. Industrial teams therefore also maintain assets around a fixed model without retraining. Domain experts revise SOPs, rules, and prompt criteria. Developers maintain parsers, extractors, evidence routing, context schemas, and structured output contracts. This split helps initial delivery, but it also reflects a long-standing property of expert work: experts often know more than they can fully articulate at system cold start [17]. Production feedback turns some of these tacit boundaries into versioned rules, cases, and release records. A disputed judgment may require fixing field extraction before revising a rule boundary, while a local text repair may create regressions in previously confirmed behavior.

CoEvolve reframes the maintenance object as a *policy-harness bundle*. Policy denotes domain knowledge maintained by experts: standard interpretation, rule boundaries, audit criteria, SOPs, and prompt criteria. Harness denotes the executable support chain that makes policy usable: parser, extractor, reference retrieval, evidence binding, context assembly, and output contract. In CoEvolve, experts first adjudicate feedback and fix the expected audit semantics. An LLM maintenance agent proposes owner hypotheses and coordinated policy-harness candidates. The independent verifier derives target and regression cases from feedback records, candidate changes, and historically confirmed behavior, then checks target repair, regression, contract stability, and semantic-governance risks. Experts confirm release or scoped release after verification.

We study CoEvolve in a production Chinese safety/compliance auditing service. From December 2025 to April 2026, the service covered 128 audited target systems, 384 reports, and 24,192 checklist items, and accumulated 33 production feedback instances. One feedback instance may contain multiple disputed records or related issues; we count feedback by production maintenance triggers.

To observe the frozen states formed by different maintenance organizations, we score four completed workflow states on the same 979-item monthly holdout benchmark. This is a workflow-state comparison, not a controlled comparison of methods on identical maintenance inputs: the workflows share final scoring controls but differ in work organization, intermediate records, and human-effort profiles. The primary empirical contrast is CoEvolve at 93.5% versus prompt/SOP maintenance at 89.4%, a 4.1-percentage-point difference on the same holdout. Intensive manual co-maintenance reaches 93.6%, one checklist item above CoEvolve; the two estimates have overlapping Wilson intervals and only five system-level clusters. CoEvolve was introduced in April 2026 and evaluated retrospectively. Its replay input included visible historical manual artifacts, so the replay reconstructs a comparable release state rather than demonstrating substitution for manual co-maintenance. Section 4 details the replay boundary and scoring controls. The all-industry author team combines system development, release governance, and domain-expert adjudication roles.

This paper makes four contributions:

1. It frames post-deployment maintenance of industrial LLM auditing systems as policy-harness co-evolution.
2. It presents CoEvolve, a feedback-to-release workflow involving expert adjudication, owner hypotheses, policy-harness candidates, independent verification, expert confirmation, and release records.

3. It reports a five-month industrial trajectory and a 979-item monthly holdout comparison of frozen workflow states, leading with the 4.1-percentage-point contrast between CoEvolve and prompt/SOP maintenance and bounding the manual comparison as a historical reconstruction result.
4. It distills SEIP practice lessons: owner-before-patch, denominator-before-score, gate-before-release, and negative candidates as governance evidence.

# 2 Industrial Context and Problem

## 2.1 Runtime Audit Path

Figure 1 summarizes the runtime path. An audited target system typically provides three reports and related materials. These reports may include tables, screenshots, scanned pages, and cross-report references. Before the LLM auditor is called, the system parses multimodal reports, maps sections and checklist items, synchronizes cross-report references, checks system attributes and dates, selects applicable standard versions, binds evidence, assembles audit context and prompt criteria, and enforces a structured output contract.

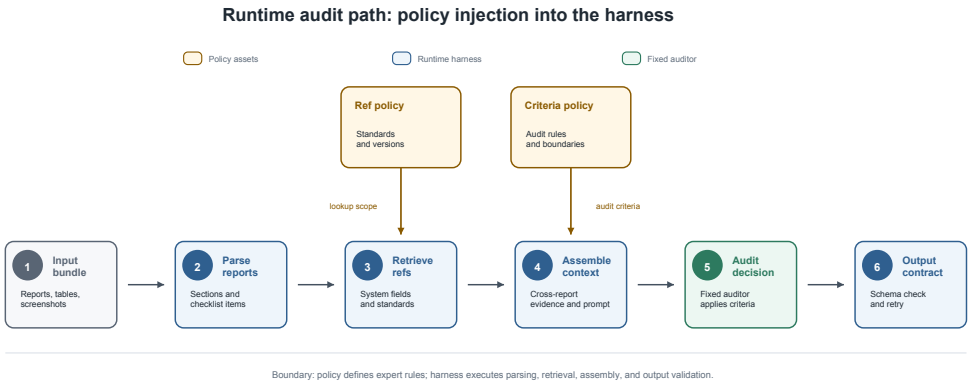

**Figure 1** Runtime audit path and responsibility surfaces. Policy is expert-maintained domain knowledge; harness components make that knowledge executable and usable by the fixed auditor.

The key point of Figure 1 is responsibility separation. Policy includes expert-provided standards, SOPs, audit criteria, responsibility boundaries, and prompt criteria. Harness includes executable components for multimodal parsing, cross-file retrieval, external-standard selection, evidence binding, context assembly, output contracts, and replay tests. Release gates are executed by the independent verifier. In the historical workflow, experts mainly owned policy while developers owned harness. CoEvolve addresses feedback that forces these assets to evolve together.

## 2.2 Why Prompt-Only Maintenance Is Insufficient

Production feedback comes from user appeals, expert findings, runtime failures, regression failures, and release audits. Several recurring signals require harness maintenance beyond prompt/SOP text: report-format changes can make stable fields disappear from the parsed input; evidence may exist but bind to the wrong checklist item; report-level context may be missing even when the prompt asks for it; structured outputs may violate the required schema;

and a local prompt repair may break historically confirmed behavior. These failures explain the policy-harness framing. Prompt text remains important, while production reliability also depends on the executable path that delivers facts, standards, and evidence to the fixed auditor.

# 3 CoEvolve Method

## 3.1 Maintained Object

Figure 1 motivates the maintained object. A reliable released state depends on whether expert policy can be delivered, assembled, checked, and invoked through executable harness components. We model a releasable state as a maintained runtime bundle plus an independent verification layer:

$$B = \langle P, H_{in}, H_{ref}, H_{ctx}, H_{out} \rangle, \quad V = \langle V_{target}, V_{replay}, V_{static}, V_{release} \rangle.$$

Here $B$ is the runtime bundle maintained by CoEvolve. $P$ represents expert policy; $H_{in}$, $H_{ref}$, $H_{ctx}$, and $H_{out}$ represent harness slots that make policy executable. The maintenance agent can propose changes to $B$, together with an owner hypothesis, affected surfaces, and expected impact. $V$ is held by the independent verification agent; in this paper, gates are the checks and blocking rules executed by that verifier. The verifier derives target and regression cases from feedback records, candidate changes, historically confirmed behavior, and sampled non-holdout items. Verification has two families. Hard checks cover target repair, historical replay, rerun stability, output-contract validity, parse-ok status, evidence/context validity, and release scope. Semantic-governance checks cover sample memorization, metric chasing, policy consistency, rule overreach, and denominator integrity. Validation rules, scoring manifests, target/regression denominators, and verifier gates remain in the verification layer.

**Table 1** Policy-harness bundle slots and their runtime roles.

| Layer | Runtime role | Typical content |
|---|---|---|
| $P$ | Domain policy and prompt criteria | Standard interpretation, rule boundaries, responsibility criteria |
| $H_{in}$ | Input parsing | Multimodal parsing, chunking, section mapping, checklist-item location |
| $H_{ref}$ | Reference retrieval | Official standard versioning, knowledge-base lookup, external field extraction |
| $H_{ctx}$ | Context assembly | Cross-report evidence binding, checklist context, prompt assembly |
| $H_{out}$ | Structured output | Output schema, parse-ok checks, retry contract |
| $V$ | Independent verification | Target repair, historical replay, rerun stability, semantic governance, release record |

## 3.2 Feedback-Driven Maintenance Loop

Figure 2 shows the maintenance loop. Production feedback first receives expert adjudication. The LLM maintenance agent then proposes failure-owner hypotheses and candidate policy-harness patches. Each candidate must declare the hypothesized owner, policy delta, harness delta, expected impact, and release risk. The independent verification agent derives target and regression cases from feedback records, candidate changes, and historical behavior, then

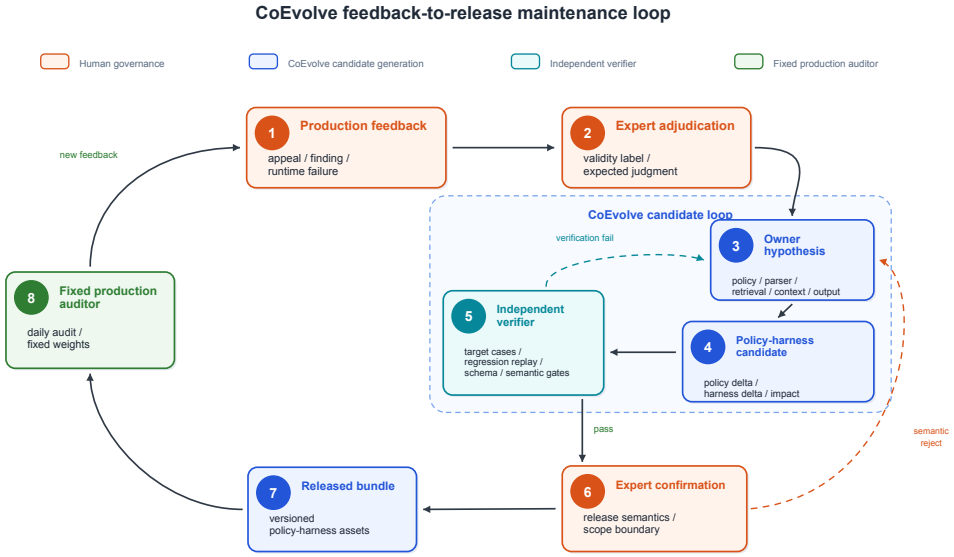

**Figure 2** CoEvolve maintenance loop. The LLM maintenance agent expands candidate repairs; the independent verifier and experts select releasable updates.

produces a verification summary. Gate failures and expert semantic rejection return to owner-hypothesis search. Released or scoped updates become the bundle used by the fixed production auditor.

The fixed production auditor handles daily audit checks. It is distinct from the offline candidate-generation endpoint used to propose maintenance candidates. Model weights remain fixed during the study; learning happens through versioned policy-harness assets and release records.

## 3.3 Maintenance-Agent and Verification-Agent Contract

The maintenance agent can access redacted feedback summaries, expert adjudication, current policy-harness assets, historical patches, and verification summaries. It cannot access production credentials, public copies of raw customer materials, benchmark labels, verification rules, scoring manifests, or production-release authority. It outputs candidate patch bundles to the independent verifier and expert-confirmation process.

The independent verifier holds validation logic outside the writable scope of the maintenance agent. It produces verification summaries, block reasons, residual owners, and release recommendations. Gate implementation is mixed. Programmatic checks cover parsing, schema and output-contract validity, denominator integrity, target-case scoring, historical replay, and repeated-run comparisons; these checks execute the fixed auditor where an LLM judgment must be rerun. Semantic consistency, rule scope, ambiguous target judgments, and final release scope require expert review. The maintenance agent does not approve its own candidates. Its hard checks ask whether the target issue is repaired, historical regression cases remain stable, repeated runs are consistent, output contracts remain parseable, evidence/context bindings are valid, and a candidate needs scoped release. Its semantic-governance checks look for memorization, metric chasing, policy inconsistency, rule overreach, and denominator changes. This separation matters in practice: the maintenance agent can suggest repairs, while release validation remains governed by an independent gate and expert confirmation. Here, independence means separation of role, permission, and writable assets:

**Table 2** Maintenance-agent contract and verification boundary.

| Boundary | Maintenance agent | Verifier / expert governance |
|---|---|---|
| Visible inputs | Redacted feedback, expert judgment, current bundle, historical patches, run summaries | Candidate bundle, feedback records, confirmed behavior, sampled non-holdout items |
| Writable records | Owner hypothesis, policy/harness deltas, expected impact, release risk | Verification summary, block reason, residual owner, release recommendation |
| Held outside | Raw customer materials, credentials, benchmark labels, scoring manifests, release authority | Gate rules, regression denominator, semantic-governance criteria |
| Decision role | Generates candidate repairs and revision options | Selects releasable updates through verifier gates and expert confirmation |

the candidate generator does not also hold verifier-gate authority, and verification rules, semantic-governance criteria, and scoring manifests are not edited by the maintenance agent. We report check families, redacted traces, and record schemas, while the full production gate rules remain internal control assets.

Three verifier-gate predicates illustrate the mechanism. A parse-ok gate blocks a candidate when required fields are missing or the structured output is malformed. A rerun-stability gate requests retry or rollback when repeated runs change the target judgment, parse state, or key context binding. A semantic-governance gate blocks release when a candidate copies feedback-specific answers into SOP or prompt text, which indicates metric chasing.

Operationally, the fixed production auditor is used for daily audit decisions. The offline candidate-generation endpoint is organization-approved and used only for maintenance candidates. Its exact vendor and model version are redacted for procurement and security reasons, while the replay uses a fixed endpoint configuration. The verification agent is a separate role: it consumes candidates and gate inputs, then produces verification summaries; bundle edits stay with candidate generation. A candidate attempt is one owner hypothesis plus a proposed policy delta, harness delta, or both, submitted to gate or expert judgment. Retries count as new attempts when they re-enter verification with a changed owner, delta, or target/regression set.

# 4 Study Design

## 4.1 Research Questions

We ask four research questions. RQ1 asks to what extent production feedback crosses the policy-harness boundary. RQ2 examines how a production feedback instance moves through owner hypotheses, policy-harness deltas, verification summaries, and release decisions. RQ3 compares the frozen CoEvolve replay state with initial, prompt/SOP, and manual co-maintenance workflow states under shared offline scoring controls. RQ4 measures candidate exploration and verification workload.

## 4.2 Data and Labels

The study window is December 2025 to April 2026. The production trajectory covers 128 audited target systems, 384 reports, and 24,192 checklist items. It contains 33 production feedback instances from user appeals, expert findings, and runtime issues. Feedback instances are not deduplicated, because they are the maintenance triggers observed in production; one instance may contain multiple disputed records.

For counting, a *feedback instance* is a production maintenance trigger, such as a user appeal, expert finding, or runtime failure report. A *disputed record* is a checklist/report-level disagreement inside an instance. A *candidate attempt* is a concrete maintenance proposal that enters verification or expert judgment. These levels are reported separately because one feedback instance can create several disputed records and several candidate attempts.

The monthly holdout benchmark samples one audited target system per month from December 2025 to April 2026. Each target system contains three reports, yielding five target systems, fifteen reports, and 979 checklist items. Benchmark labels were produced through two-person independent labeling and the organization's audit-adjudication process. The two annotators labeled the benchmark items without seeing each other's labels; disagreements were discussed and final labels followed the organization's adjudication rule. The expert group included four business experts, two with more than five years of relevant audit experience, and semantic disputes followed the senior-expert adjudication process. Benchmark labels were finalized before workflow scoring.

The holdout benchmark is within-setting: it shares the production domain, report families, and audit standards with the maintenance trajectory. The five holdout target systems and their fifteen reports were reserved as final scoring materials. Their raw report content, checklist outputs, labels, scoring manifest, and aggregate scores were not available during maintenance-state construction, and they did not enter replay as feedback, target, or regression material. The 33 feedback instances served as maintenance triggers, target cases checked whether feedback-triggered issues were repaired, and regression cases protected historically confirmed behavior. Final benchmark scoring was performed only after each workflow state was frozen. Thus, the holdout is deliberately close to the industrial stream in domain and standards; the isolation boundary is the system/report scoring materials, labels, outputs, manifest, and aggregate scores, rather than an external benchmark.

## 4.3 Baseline Construction and Fairness Controls

The study compares frozen maintenance states constructed from the same ordered stream of audited target systems. From December 2025 to April 2026, production maintenance was mainly conducted through expert-developer co-maintenance. We reconstruct additional workflow states along that trajectory. Because the workflows differ in organization, intermediate signals, editable assets, and human-effort profiles, this design compares completed workflow states; it does not estimate method effects under identical maintenance inputs.

We align workflows by the ordered system-input stream rather than by identical feedback text. Each workflow follows the same chronological sequence of audited target systems and submitted reports, with the same available external materials, feedback-raising channel, and expert-adjudication group. The concrete feedback records entering each workflow are workflow-specific. Domain experts owned the prompt/SOP baseline and could revise only SOP, rule, and prompt text; they had access to the same adjudication group and stopped at the workflow's normal release or no-change endpoint before the assets were frozen. Harness and regression-logic edits were not allowed in that state. Comparable total human-hours were not recorded for prompt/SOP maintenance, manual co-maintenance, and CoEvolve expert confirmation, so the study does not make an effort or cost comparison. Facing the same system, expert-developer co-maintenance may surface a parser or rule issue through human debugging, prompt/SOP maintenance may surface a text-maintenance problem or an escalation, and CoEvolve may surface a context-owner hypothesis, a verifier block, and a later candidate retry. These differences are part of the workflow behavior under study.

Except for the initial snapshot, each maintenance state completes one maintenance pass over the aligned system stream and freezes the resulting assets before offline scoring. All states then run on the same 979-item monthly holdout benchmark, using the same auditor interface, output schema, denominator, labels, and scoring manifest. The monthly holdout is not used as the target or regression denominator during maintenance. Target cases come from feedback-triggered disputed items, while regression cases come from historically confirmed behavior and sampled non-holdout items. Before final scoring, no item from the 979-item monthly holdout was used for candidate generation, target-repair checks, dynamic regression construction, prompt/SOP tuning, manual debugging, verifier-gate tuning, or release decisions. In the historical manual workflow, regression records were maintained by experts and developers; in CoEvolve replay, the verifier maintains and expands the regression denominator. Benchmark labels, benchmark outputs, scoring manifests, production credentials, and raw customer materials are outside maintenance-state construction.

**Table 3** Baseline construction, validation boundary, and scoring boundary.

| State | Maintenance surface | Feedback signal | Validation boundary | Scoring boundary |
|---|---|---|---|---|
| Initial | Initial policy and harness | Initial requirements and delivery materials | No post-deployment feedback maintenance | Frozen first release; same holdout |
| Prompt/SOP tuning | Policy text only | Text-maintenance signals surfaced from the aligned stream | Experts confirm feedback resolution; no harness or regression-logic edits | Frozen text assets; same holdout |
| Manual co-maintenance | Policy and harness | Historical system stream and human debugging signals | Experts and developers maintain target, regression, and release records | Frozen human release; same holdout |
| CoEvolve replay state | Candidate policy-harness bundle | Replay feedback signals from the aligned stream | Verifier maintains target/regression cases and checks repair, regression, rerun, semantic risk | Expert-confirmed replay state; same holdout |

The four states use different maintenance organizations, so the comparison is a workflow-state comparison. The scoring step is shared: after each state reaches its normal release or no-change endpoint, assets are frozen and evaluated offline on the same benchmark. The prompt/SOP state uses its workflow-specific feedback records and adjudication to update text assets only. Manual co-maintenance uses the historical expert-developer release record, including human-maintained policy, harness, and regression records. The CoEvolve replay is not a clean-room run from the initial release. Its input boundary includes the historically maintained asset state, the same system-input stream, redacted run summaries, verification summaries, and structured historical maintenance records. Those records include versioned manual release assets, repair records, and verification summaries. CoEvolve therefore reconstructs a comparable release state from visible historical manual artifacts through candidate search, independent verification, and expert confirmation. Raw expert communications, private root-cause rationales, and item-level holdout answers stay outside the replay input boundary. They do not contain benchmark outputs, labels, or scoring manifests. CoEvolve has no direct production-release authority.

The replay protocol has four steps. First, the target-system order, the three submitted reports, external materials, and the expert-adjudication entry point are fixed in production-time order. Second, each workflow forms its own feedback signals and maintenance records on that aligned input stream; CoEvolve generates owner hypotheses and candidate bundles at this step. Third, candidates enter independent verification, where the verifier actively maintains target/regression cases and records target repair, historical replay, rerun stability, parse/schema, semantic-governance, and release/block outcomes. Finally, after each workflow reaches a release, scoped release, block, or no-change endpoint, its assets are frozen and scored offline on the same monthly holdout benchmark.

### 4.4 Process Metrics

RQ4 measures the CoEvolve replay process directly. Active maintenance time is an internal replay-loop interval: it starts when the maintenance agent begins candidate processing and ends when the release decision record is formed. It includes candidate generation, verifier-gate execution, and the recorded confirmation step when present. It excludes user-waiting time, cross-team queueing, handoff delay, release windows, long-term gate maintenance, and organizational communication cost. Candidate count measures candidate patch / maintenance attempts that enter verifier or expert judgment. These metrics describe only replay-loop workload and are not an end-to-end efficiency comparison.

## 5 Results

### 5.1 RQ1: Feedback Crosses Policy and Harness

In 33 feedback-owner audits, 18 instances were policy-only, 6 were harness-only, 7 involved both policy and harness, and 2 were unclear or review-needed. The counts represent maintenance signals rather than mutually exclusive defect classes, and they are not a prevalence estimate for all production defects. They show that among feedback instances that triggered maintenance in our setting, a subset required harness or policy-harness repair. Overall, 13/33 feedback instances touched harness surfaces, and 7/33 required policy-harness co-maintenance.

At the candidate level, the same 33 feedback instances generated 164 candidate attempts: 31 were accepted, released, or scoped; 131 were blocked by verifier gates; and 2 required maintenance-guidance intervention. We report candidate outcomes separately from feedback-owner counts because one feedback instance can trigger several owner hypotheses and candidate revisions. Owner categories were consolidated from feedback adjudication, candidate owner hypotheses, verifier residual owners, and release records. We keep the coarse production categories to show whether feedback touched policy, harness, or both; we do not expand them into a mutually exclusive defect taxonomy.

### 5.2 RQ2: From Feedback to Candidate, Verification, and Release

The evidence-extraction trace in Figure 4 shows how CoEvolve advances one feedback instance through the loop. The feedback signal showed that the system did not consistently use a key field. The first candidate treated this as an evidence-supply and harness failure, then updated extractor, binding, and context logic. The result stabilized the evidence interface: raw `report_selection` reached 117/124, gated extraction reached 122/124, and downstream parse-ok reached 124/124. Downstream accuracy remained 0.8387, indicating residual judgment failure.

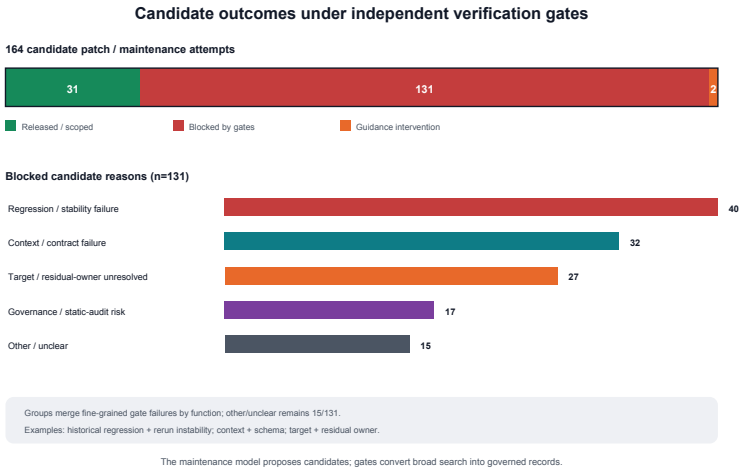

**Figure 3** Candidate attempts and blocking reasons. Verifier gates blocked 131 of 164 candidate attempts. Fine-grained failures are grouped by verifier-gate function; 15/131 blocked candidates remained other/unclear after coding.

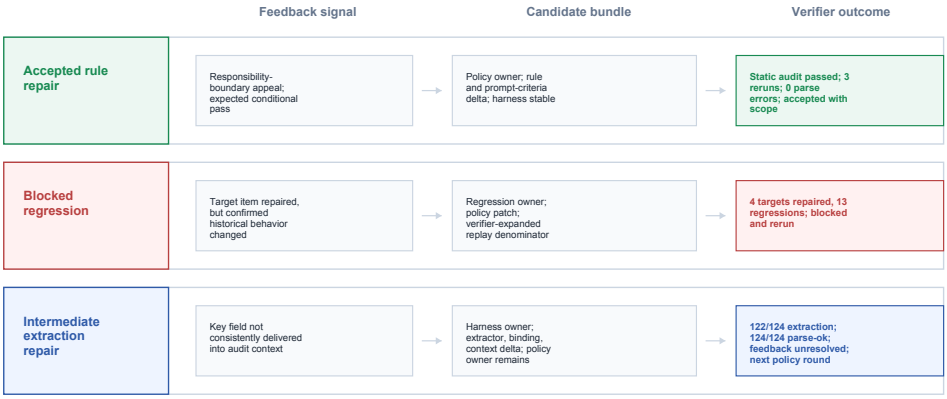

**Figure 4** Redacted end-to-end release traces used as in-paper governance evidence.

The next candidate shifted the remaining problem to a judgment-policy hypothesis, added a policy/prompt delta, passed runtime gates, and entered scoped release. The trace illustrates the loop: a local harness repair can be a necessary intermediate step; subsequent owner search handles remaining judgment errors.

Across replay, each CoEvolve candidate declared an owner hypothesis, policy/harness delta, expected impact, and release risk; target and regression cases were maintained by the verifier from feedback records, historically confirmed behavior, and sampled non-holdout items. Figures 3 and 4 show how candidate search is converted into governance evidence: release decisions, block records, residual owners, and scoped repairs.

Block categories were coded from verifier summaries and release records. Each candidate retains its original fine-grained block reason; Figure 3 merges related verifier-gate functions only for reporting, so recurring release risks do not appear as many small buckets.

Before release decisions, the verifier checks two evidence families. Hard checks cover target repair, historical replay, rerun stability, output contracts, parse-ok status, evidence/context validity, and release scope. Semantic-governance checks cover sample memorization, metric chasing, policy consistency, rule overreach, and denominator integrity. Failures return a residual owner, block the candidate, narrow release scope, or escalate to expert confirmation.

The traces cover three release outcomes: scoped acceptance, regression block, and intermediate harness repair. The first shows how a policy-oriented repair enters scoped release; the second shows target repair blocked by historical regression; the third is intentionally unfinished: the harness repair stabilizes evidence delivery, but the original feedback remains unresolved and moves to a later policy round. They are included to make the release logic inspectable from the PDF: a candidate is useful when it clarifies an owner and produces stable evidence, even when it is not itself the final accuracy-improving patch. The fields also instantiate the minimum maintenance record: feedback signal, disputed record, owner hypothesis, policy delta, harness delta, target/regression evidence, verifier output, and release decision. Practitioners can reuse these trace fields as a template for candidate bundles, verifier summaries, and release decisions while replacing confidential materials with local identifiers.

## 5.3 RQ3: Audit Accuracy

On the same 979 checklist items, the CoEvolve replay state reached 93.5% accuracy (915/979), 4.1 percentage points above prompt/SOP maintenance at 89.4%. This is the primary quantitative contrast: both states follow the same ordered system-input stream and offline scoring controls, while the maintained surface expands from text policy to a verifiable policy-harness bundle. The initial state reached 85.1%. Manual co-maintenance reached 93.6% (916/979), one item more than CoEvolve. Given the overlapping Wilson intervals and only five system-level clusters, the manual and CoEvolve results are statistically indistinguishable and within sampling noise. Moreover, because visible manual artifacts entered replay, this similarity reflects reconstruction of a comparable release state and must not be interpreted as a method effect or evidence of substitution.

Item-level Wilson 95% intervals are 82.7–87.2% for the initial state, 87.3–91.2% for prompt/SOP tuning, 91.9–94.9% for manual co-maintenance, and 91.7–94.8% for CoEvolve. Across the five audited target systems, CoEvolve remains between 93.2% and 93.7% and is higher than prompt/SOP maintenance on all five; its system-level gap from manual co-maintenance is at most about 0.5 percentage points. With five target systems and fifteen reports, these estimates remain descriptive and do not support a cluster-robust ranking of CoEvolve and manual maintenance.

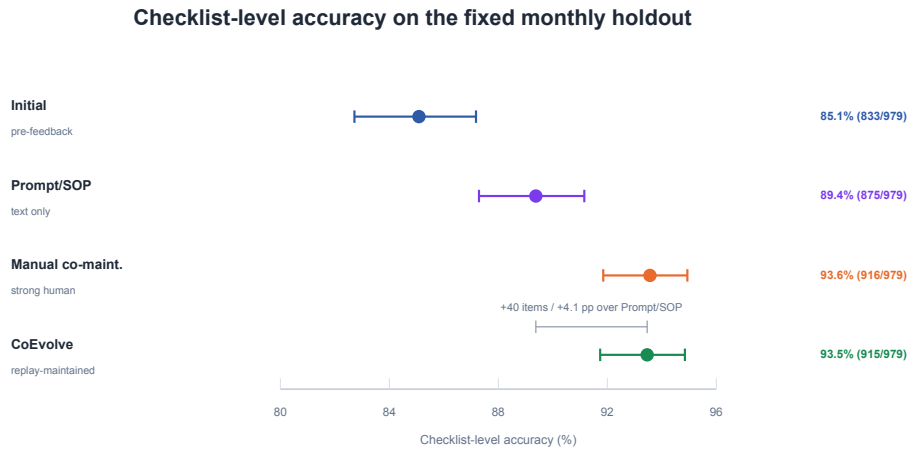

**Figure 5** Accuracy on the same 979-item monthly holdout benchmark. Error bars show item-level Wilson 95% intervals. The CoEvolve and manual states differ by one item and have overlapping intervals; the primary contrast is CoEvolve versus prompt/SOP maintenance (+4.1 percentage points).

**Table 4** Accuracy by audited target system.

| System/month | Items | Initial | Prompt/SOP | Manual co-maint. | CoEvolve |
|---|---|---|---|---|---|
| A / 2025-12 | 201 | 94.1% | 90.1% | 93.6% | 93.4% |
| B / 2026-01 | 190 | 89.5% | 89.7% | 93.5% | 93.7% |
| C / 2026-02 | 204 | 87.0% | 88.7% | 93.7% | 93.2% |
| D / 2026-03 | 191 | 80.5% | 89.1% | 93.6% | 93.5% |
| E / 2026-04 | 193 | 77.9% | 89.6% | 93.6% | 93.6% |
| **Total** | **979** | **85.1%** | **89.4%** | **93.6%** | **93.5%** |

The monthly holdout also shows a descriptive decline in the initial state, from 94.1% in December 2025 to 77.9% in April 2026, while the maintained states are flatter across the five samples. With one system per month, the study cannot distinguish distribution shift, sampling variation, and maintenance tracking of drift; the pattern should not be read as a causal drift result.

**Table 5** Decision-error directions on the 979-item benchmark.

| State | False pass | False fail | Other wrong | Wrong total |
|---|---|---|---|---|
| Initial system | 66 | 52 | 28 | 146 |
| Prompt/SOP tuning | 42 | 43 | 19 | 104 |
| Manual co-maintenance | 28 | 31 | 4 | 63 |
| CoEvolve replay-maintained state | 27 | 32 | 5 | 64 |

False pass means the expert label is fail while the system passes the item, a high-risk direction in compliance auditing. False fail means the expert label is pass while the system fails the item, increasing review and appeal workload. Other wrong covers evidence, rationale, category, structured-field, or output-parsing errors. Using the 979 checklist items as denominator, CoEvolve's false-pass item share is 2.8% (27/979), and its false-fail item share is 3.3% (32/979); prompt/SOP tuning is 4.3% and 4.4%, respectively. These are descriptive risk-direction metrics. We do not report business-loss weights, severity strata, or conditional error rates by true pass/fail base.

### 5.4 RQ4: Candidate Exploration and Verification Workload

Historical expert-developer end-to-end turnaround includes waiting, queueing, cross-role handoff, and release windows. We therefore report CoEvolve's directly measured replay-loop workload and do not interpret it as end-to-end speedup over manual co-maintenance. Across 33 matched replay tasks, active maintenance time averaged 0.37 hours, with a median of 0.34 hours, an interquartile range of 0.25–0.44 hours, and a range of 0.16–1.30 hours. This time includes candidate generation, verification execution, and the recorded expert-confirmation step when present; it excludes waiting, queueing, release windows, long-term gate maintenance, and organizational communication cost. Each task generated 4.97 candidate attempts on average, with a median of 5, an interquartile range of 4–6, and a range of 1–11. These figures describe the exploration and verification load inside the maintenance loop.

These metrics show that CoEvolve operates as candidate search under gate verification. A single feedback task usually explores several owner hypotheses and policy-harness candidates. Every candidate entering gate or expert judgment creates a verification summary, block record, or release record.

## 6 Release Governance and Negative Evidence

Production release is governed by more than target-case repair. Candidates must also pass historical replay, parse-ok checks, context validity, static audit, semantic audit, rerun stability, and expert release decisions. In the 164 candidate attempts, most candidates did not ship directly. They became block records, residual-owner labels, scoped-release evidence, or revised candidates. Two attempts required maintenance-guidance interventions: restructuring a long scattered SOP into a tree form and stopping metric chasing in which feedback samples were being memorized into SOP text.

Blocked candidates included target repairs that broke historical cases, high-scoring candidates that were unstable across reruns, parse/schema/context failures, shortcut-risk traces, and harness repairs that needed later policy/prompt updates. Negative evidence is therefore part of the contribution: it shows how LLM-generated candidates are converted into governed maintenance records. CoEvolve extends release engineering by using the maintenance agent to externalize multiple owner hypotheses and policy-harness repair options, then relying on verification and expert governance to select releasable updates. The 131 blocked candidates, residual-owner labels, and scoped repairs show that candidate generation expands the inspectable maintenance space, while release governance decides which candidates enter released assets. The familiar software-engineering principles become a concrete feedback-to-release record flow for LLM auditing systems.

## 7 Related Work

Expert systems and knowledge engineering provide the conceptual base for this work: professional systems depend on maintained domain knowledge, expert explanation, and case boundaries [17, 7, 6, 24]. CoEvolve revisits that maintenance problem in LLM-based auditing, where part of the expert system is textual policy and part is executable harness.

Prompt engineering and automatic prompt optimization improve fixed-model systems through textual feedback, prompt search, or program-like prompt structures [20, 1, 13, 27]. DSPy and related programming frameworks compile LM pipelines against demos and metrics [10]. These lines of work usually optimize model calls with examples, metrics, or textual feedback. CoEvolve treats the release object as a production asset: policy, parser, retrieval, binding, context, output contract, regression denominator, and release record evolve together, while benchmark labels and scoring manifests remain outside maintenance.

Meta-Harness is the closest technical neighbor: it studies how to search better harnesses around model calls [12]. CoEvolve studies a complementary production-maintenance problem: how feedback is organized into releasable, blockable, and traceable policy-harness records under independent verification and expert release authority. The distinction is not only the maintained surface, but also optimizer visibility and release authority: the maintenance agent does not see benchmark labels or scoring manifests, and release is controlled by the verifier and expert confirmation. Its output is a governed maintenance record rather than a single optimized harness. Reflective adaptation work also explores feedback loops without retraining [2, 25].

Production ML and LLM systems require testing, monitoring, reproducibility controls, and release governance [21, 5, 19, 11, 18, 15, 23]. Recent SE work on benchmarks, regression tests, integration defects, and user-feedback issue detection motivates the use of fixed denominators, replay, and feedback-derived cases as maintained assets [8, 4, 14, 22, 9]. Automated compliance checking and document intelligence further show why policy and harness evolve together: professional audit often requires extracting obligations, fields, layouts, and evidence before a decision can be made [28, 3, 26, 16].

Here, "LLM auditing systems" refers to systems that use LLMs to perform compliance auditing; the audited objects are compliance materials processed by an LLM-enabled workflow. Foundation-model auditing is adjacent literature. Table 6 summarizes the nearest-neighbor boundary.

**Table 6** Positioning against nearest neighboring work.

| Line of work | Maintained object | Feedback / metric visibility | Release authority |
|---|---|---|---|
| Prompt optimization | Prompt or instruction text | Task examples, scores, textual feedback | Optimizer or developer applies prompt |
| DSPy-style pipelines | LM modules and pipeline parameters | Demos and metrics used for compilation | Developer-controlled pipeline release |
| Meta-Harness-style search | Harness around model calls | Harness-level metrics for search | Search result selected by developer/evaluator |
| Production ML / LLMOps | Models, data, tests, monitors, deployment process | Monitoring, test suites, operational signals | Release engineering and governance process |
| CoEvolve | Policy-harness bundle plus verification record | Redacted production feedback; benchmark labels and scoring manifest withheld from maintenance | Independent verifier and expert release confirmation |

# 8 Discussion

## 8.1 From Prompt Tuning to Expert-Gated Maintenance

Prompt and SOP maintenance matter: prompt/SOP maintenance reaches 89.4% accuracy. The 4.1-percentage-point gap to the CoEvolve replay state is consistent with the practical value of allowing parsing, extraction, binding, context, output, and regression maintenance in addition to text edits. Because the workflow states differ in organization and intermediate inputs, the gap is not an isolated method effect. The evidence-extraction trace in Figure 4 illustrates the broader repair surface: unstable field extraction and binding prevented the auditor from reliably using the right evidence, and only after that interface was stabilized could remaining policy judgment be addressed.

## 8.2 Transfer Hypotheses

Table 7 separates the elements we expect to transfer from those that require local re-instantiation. These are design hypotheses derived from the observed workflow, not cross-domain validation claims.

**Table 7** Transfer hypotheses from the single-site experience.

| Design element | Hypothesized portable core | Setting-specific instantiation |
|---|---|---|
| Maintenance record | Feedback, owner, deltas, checks, decision | Local identifiers, work-item system, confidentiality rules |
| Verifier gates | Target repair, replay, stability, contract checks | Audit semantics, risk thresholds, regression denominator |
| Policy-harness split | Separate domain meaning from executable delivery | Standards, report families, parsers, context fields |
| Expert release authority | Independent semantic and scope confirmation | Expert roles, escalation rules, release windows |

## 8.3 Practitioner Playbook

**Minimum adoption protocol.** Record the feedback signal and affected item before repair; fix the expected audit judgment and rationale through domain-expert adjudication; assign an owner hypothesis before selecting a patch surface; version the candidate bundle with policy delta, harness delta, expected impact, and release risk; let an independent verifier maintain target cases, regression cases, and sampled non-holdout checks; run target repair, replay, parse-ok, schema/context, stability, and semantic-governance gates; record release, block, rerun, or scoped-release decisions together with residual owners.

Two operating rules were important. Accepted-with-scope is useful when target repair is valid, historical replay shows no high-risk regression, and residual owners are explicitly recorded. A high-risk false pass, a new report family, a weak regression set, or a new audit standard moves the workflow back to expert-led initialization before routine CoEvolve maintenance resumes. The minimum adoption protocol is to record feedback and expected judgment, form a candidate bundle, run independent verifier gates, preserve the verifier summary, obtain expert confirmation of release semantics, and record release/block/scope decisions in a work-item or versioning system. A team adopting the pattern also needs at least a stable output schema, a maintainable regression denominator, domain experts who can adjudicate audit semantics, and a verifier role separated from candidate generation.

## 8.4 Inference Cost and Deployment

CoEvolve runs outside the online audit path. The fixed production auditor handles production requests. The offline candidate-generation endpoint runs only when feedback, expert findings, runtime failures, or release audits trigger maintenance. This adds maintenance-time inference and regression-validation cost, with limited effect on user-facing audit latency.

# 9 Threats to Validity

**Setting and evidence scope.** This is a single-site industrial study in Chinese safety/compliance auditing. Language, report templates, standards, and organizational workflow may shape the result. Raw reports, feedback text, expert communications, credentials, and private deployment configuration remain inside the industrial project.

**Benchmark, labels, and attribution.** The 979-item benchmark covers five target systems and fifteen reports from the same production sample pool. It supports within-setting workflow-state behavior. Checklist labels were produced through two-person independent labeling and the organization's audit-adjudication path. The two annotators worked without seeing each other's labels; disagreements were discussed and final labels followed the organization's adjudication rule before workflow scoring. The 33 feedback instances are not deduplicated, so owner audit counts maintenance signals rather than defect classes.

**Workflow-state interpretation.** The comparison uses completed maintenance states with different work organizations, intermediate signals, and human-effort profiles. Manual co-maintenance is the strongest historical human state in the deployment. CoEvolve is a retrospective replay state constructed from a matched system-input stream and visible historical manual artifacts, including versioned release assets, repair records, and verification summaries. It therefore shows reconstruction of a comparable release state, not independent reproduction of manual quality, substitution for manual co-maintenance, or a causal method effect. Comparable total human-hours were not collected. A prospective window in which no parallel manual release artifacts are visible is required to evaluate independent effectiveness and end-to-end maintenance cost.

**Agent contribution.** CoEvolve combines candidate generation, independent verification, historical replay, and expert confirmation. The study measures the governed workflow as a whole. The candidate counts and block records show how the offline candidate-generation endpoint externalized repair options that were then filtered by verification and expert governance. We do not isolate the maintenance agent's net causal contribution; the better reading is that the LLM agent externalizes the maintenance space, while the verifier and experts decide which candidates enter released assets. Aggregate error totals also do not reveal which checklist items the manual and CoEvolve states disagree on; item-level disagreement analysis remains future work.

## 10 Conclusion

We presented CoEvolve, a feedback-driven policy-harness maintenance workflow for industrial LLM auditing systems operating without retraining. Across five months, the CoEvolve replay state reached 93.5%, 4.1 percentage points above prompt/SOP maintenance on the monthly holdout. Its 915/979 result is statistically indistinguishable from manual co-maintenance at 916/979; because replay used visible historical manual artifacts, the evidence supports reconstruction of a comparable release state, not substitution or a method effect. The workflow externalized multiple candidates per feedback task and used independent verification and expert confirmation to select releasable updates. The transferable lesson is to co-maintain policy and harness, keep denominator and regression as release conditions, and treat verifier blocks as governance evidence.

## Data Availability Statement

Raw industrial materials cannot be released. To support review, the paper provides the runtime and loop mechanisms, agent contract, feedback and candidate counts, verifier-gate outcomes, redacted release traces, accuracy and risk-error results, replay workload, and practitioner record fields. The label recheck and verifier-gate rubric are reported

at aggregate and schema level. Unavailable materials include raw reports and feedback, expert communications and internal labels, production configurations and credentials, and scoring manifests or gate rules used as operational control assets. Their review substitutes are aggregate counts, redacted traces, the label/adjudication protocol, role-level model boundaries, gate-rubric fields, and maintenance-record templates; these substitutes contain no customer reports, internal labels, or production configuration.

## Generative AI Declaration

Generative-AI tools assisted the camera-ready revision of the manuscript and the redrawing of figures. The authors directed and verified all revisions. No experimental data, labels, or new empirical evidence were generated using these tools, and the authors take full responsibility for the final content.

## Abstract

Software quality control in industry often relies on expensive analyses that run continuously in the Continuous Integration (CI) pipeline. Those analyses, such as static analysis for rule-based compliance, can provide important quality signals and often serve as strict gating points in the CI pipeline to ensure strict quality standards. However, strict continuous gating can slow the pipeline especially in the shared development environment. This study investigates the adoption of different software quality control strategies in safety-critical domain. By changing when the analyses take place and how the information can be delivered, we aim to identify a strategy that improves CI throughput while maintaining high standards of software quality. We conducted action research at a large safety-critical software organization for autonomous driving. Through this process, we investigated existing quality strategies and designed a new strategy that combine nightly analysis with feedback mechanism. We evaluate this strategy using both longitudinal data on static analysis issues and development activities, together with interview data with practitioners. The evaluation shows that nightly CI runs together with feedback mechanism helped keep selected quality issues under control during daily development and reduced reliance on clean-up in later stages. It can also improve the teams' follow-up responsibility and development efficiency. This study contributes an empirically grounded quality control strategy that mitigates the tradeoff between strict quality gate and CI pipeline throughput in safety-critical software development. It also identifies the organizational preconditions, implementation instructions and possible social effects for applying similar mechanisms in other environments that rely on expensive quality analyses.

## 1 Introduction

Software quality control in industrial practice is assured through a combination of development activities, such as testing, code review, and automated analyses. These mechanisms help organizations detect defects, enforce standard compliance, and monitor the health of the codebase throughout development. Among them, static analysis is a common approach for product quality control [31] since it can automatically and repeatedly examine large codebases for coding-rule violations, bug-prone constructs, and other quality-related issues without executing the software. As a result, static analysis provides a mechanism for enforcing development discipline and applying quality control at scale.

In automotive software development, however, applying these controls efficiently is challenging. Modern vehicles have become more software-intensive and safety-critical, and development environments often include resource-intensive and time-consuming analyses such as compliance checks against MISRA[1] and AUTOSAR [2] rules, as well as memory-related bugs captured by tools such as Valgrind or AddressSanitizer. Although these analyses provide valuable quality signals, many of them are too costly to execute continuously on the Continuous Integration/Continuous Deployment (CI/CD) pipeline. This creates a recurring industrial trade-off: strict enforcement keeps the codebase close to release-ready, but slows development feedback cycles; deferring checks improves short-term throughput, but allows quality debt to accumulate and shifts stabilization effort to later phases.

This trade-off is especially pronounced in monorepo-based development environments, where delays in shared pipelines affect many teams and post-merge quality regressions propagate broadly. In practice, organizations often rely on one of three strategies: continuously gated CI/CD, deferred clean-up during hardening, or nightly execution outside the main integration path. Nightly execution can reduce pressure on the main CI/CD pipeline by moving expensive analyses outside the critical development flow. However, it alone does not solve the problem of follow-up. When quality results are produced outside the normal integration path, they may become less visible, less attributable, and less actionable for the teams responsible for resolving them.

Recent works [1, 6, 29] have suggested that improving CI/CD efficiency is not only a matter of relocating analyses earlier in the pipeline, but also of improving what and how information flows back to developers. Sun et al. [26] argue that traditional shift-left strategies are limited when pre-merge stages are already heavily loaded. They also propose the complementary feedback-left to improve the observability in CI/CD pipeline, arguing that increasing the amount of diagnostic information passed from the later stages of the CI/CD back to developers can improve observability. This perspective suggests that pipeline effectiveness depends not only on where checks are placed, but also on whether their results are clearly analyzed and presented for the developers who need to respond. Building on this view, the central question of this study is whether expensive quality analysis can be relocated from gating CI/CD pipeline to non-gating nightly, supported by a feedback-left mechanism, in order to improve the pipeline throughput while preserving developers' awareness and maintaining software quality.

To answer the question, we conducted an action research study at a large company developing advanced driver assistance and autonomous driving systems. This study investigates how feedback-left mechanisms can support the relocation of expensive static analysis from gated CI/CD to nightly non-gating execution in a safety-critical software organization.

[1] https://misra.org.uk/

In collaboration with practitioners, we designed and evaluated a strategy that combines nightly QAC analysis, dashboard-based visibility, Slack-integrated notifications, and code ownership-based responsibility mapping. The study is guided by the following research questions (RQs):

**RQ1:** How can computationally expensive static analysis be reorganized from gated CI/CD to nightly non-gating execution in a safety-critical software organization?

**RQ2:** What benefits do developers perceive from adopting a nightly feedback strategy for software quality control?

**RQ3:** What limitations and risks do developers perceive from adopting a nightly feedback strategy for software quality control?

The paper makes two main contributions. First, it provides an industrial action research investigation on adopting different software quality control strategies in a safety-critical software organization, including the perceived benefits and limitations of moving expensive analysis from gated CI/CD execution to nightly non-gating execution. Second, it presents and evaluates the complementary feedback mechanism that transforms nightly static-analysis results into visible, attributable, and actionable feedback through dashboards, internal communication channels, and code guardianship-based responsibility mapping.

## 2 Background and Related Work

### 2.1 Software Quality Control Techniques

In industrial software development, software quality management depends on a set of coordinated activities, including quality planning, quality assurance, quality control, and process improvement [31].

In real projects, software quality characteristics can be examined using techniques such as testing, inspections, defect tracking, root cause analysis, and static analysis [31]. Among these techniques, static analysis is particularly popular and useful because it examines source code or other software artifacts without executing the program. This makes static analysis suitable for early, repeated and automated use during development, since it does not require the real execution.

Compared to manual inspection, static analysis tools can automate code inspections and help to find bugs, or defects, faster and cheaper, but their usages and adoptions are limited by issues such as result understandability and integration of the development workflow [13]. There are many popular commercial and open source tools for this purpose, including Cppcheck, FindBugs, SonarQube, PMD [25]. Lenarduzzi et al. [15] compared six static analysis tools in detection, agreement and precision. In industrial settings, tool choice may also be influenced by factors, such as safety standards, compliance requirements, and support for large-scale development workflows. For example, Emanuelsson and Nilsson [7] compared PolySpace Verifier, Coverity Prevent, and Klocwork K7, while QAC has frequently been discussed in relation to MISRA compliance for C and C++ systems [4, 12].

In modern development environments, static analysis is often integrated into Continuous Integration and Continuous Deployment (CI/CD) pipelines. This integration allows quality checks to be triggered automatically when code changes are submitted. However, not all analyses are equally suitable for continuous execution in the critical integration path. Some checks are computationally expensive, require scarce resources such as licenses, or produce feedback too slowly to be practical as always-on gates. This creates a placement problem: organizations must decide whether expensive analyses should block integration, run after integration, or be deferred to scheduled jobs such as nightly pipelines.

## 2.2 Quality Control Strategies in CI/CD

In this study, we distinguish three quality control strategies that reflect different ways of managing the trade-off between strict quality control and development throughput. These strategies differ in when quality checks are executed, whether they block development, and how feedback reaches developers.

The first is *Build-up & Clean-up (Strategy 1)*. This was historically more common in traditional automotive development, before the era of contemporary DevOps-driven practices. It emphasizes long development cycles in which feature growth may proceed quickly for months, followed by a lengthy hardening phase needed to remove accumulated violations. This method decouples fixes from the time when the original code was designed, which risks diluting the intent of the guidelines being enforced.

The second is *Always Gated CI/CD (Strategy 2)*, where quality checks are enforced continuously, often before changes are merged. This can keep the codebase close to a release-ready state at all time, but it may also reduce developer efficiency when checks are expensive, unstable, or too frequent. Strategy 2 can be optimized to some extent, for example by dividing the analyses and placing some of them in pre-merge and deferring the rest parts to post-merge, but the overall throughput remains low. Prior work shows that CI jobs and failures create productivity costs, such as long build durations and frequent breakages, hindering developer work [11, 10]. Similarly, pre-merge gating focuses on early failure preventions but can introduce risks such as longer build time and bottlenecks in the development pipeline [26, 21]. Together, these studies highlight the need to balance quality assurance with development efficiency in CI/CD environments and motivate the third strategy.

In *Nightly Non-gating Analysis (Strategy 3)*, instead of running all expensive checks in the critical integration path, selected analyses are scheduled during off-peak periods when CI/CD demand is lower. This can reduce the immediate burden on developers and improve the throughput of the main CI/CD pipeline [26, 5]. More generally, monitoring CI practices can support software quality and project communication [18]. However, nightly jobs also introduce a feedback challenge. Because results arrive outside the normal integration flow, they may be less visible and less urgent. In addition, nightly jobs often analyze the accumulated changes of many developers rather than a single commit, which can make accountability more difficult. As a result, issues detected by nightly jobs may remain unresolved and contribute to later quality debt.

Figure 1 illustrates the structural dilemma among the three strategies.

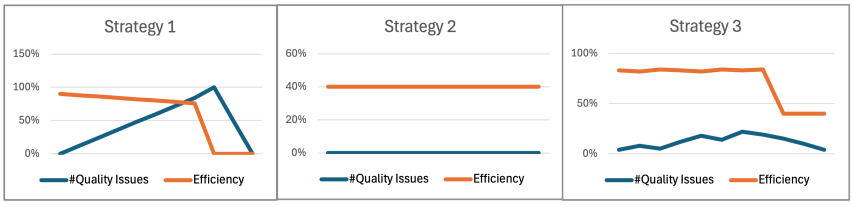

**Figure 1** Structural dilemma between quality-related issues and efficiency under three strategies. In Strategy 1, developer efficiency starts high but gradually decreases as quality-related issues accumulate. In Strategy 2, developer efficiency remains low, while quality-related issues stay at zero throughout the process. In Strategy 3, developer efficiency initially remains high while quality-related issues slowly accumulate, but both decline upon entering the hardening phase.

## 2.3 Feedback and Accountability

When quality control analyses are moved from gated CI/CD execution to nightly non-gating jobs, the main challenge shifts from execution cost to follow-up. In gated CI/CD, feedback is naturally visible because developers receive it as part of the integration process, and unresolved issues directly block progress. In nightly non-gating analysis, however, results are produced outside the normal development flow. As a result, developers may not notice the findings, may not know whether the findings concern their code, or may not treat them as urgent. This makes feedback mechanisms and accountability practices central to the effectiveness of non-gating quality control.

Prior studies show that developers value CI monitoring for build failures, code quality, and related metrics, but that native CI services often lack sufficiently comprehensive monitoring support [30, 19]. To address this limitation, dashboards that continuously monitor and visualize few indicators during software development can be a solution [23]. Dashboards can support awareness by making project status, quality indicators, and bottlenecks continuously available to development teams [28, 14]. Staron et al. [24] provide a dashboard selection model for choosing the right visualization and maximizing the impacts. However, dashboards are often passive mechanisms because developers must remember to visit them, interpret the information, and decide whether action is needed.

The other choice is notification bots, which provide a more active form of feedback by pushing selected information into developers' existing communication channels. Code review bots and CI bots can automate tasks such as reporting CI failures, checking code quality, and tracking code coverage [32]. Such bots can reduce manual effort and provide timely feedback. At the same time, prior work shows that developers may resist bots when they generate excessive notifications or create communication noise [16]. Therefore, effective bot-based feedback must balance visibility with relevance.

Making feedback visible is not sufficient if responsibility for follow-up remains unclear. Prior work on code ownership has shown that modules with clear ownership tend to have fewer defects than modules with shared or weak ownership [9, 3, 8]. In settings with weak or collective ownership, multiple developers contribute to the same components, making accountability less clear and increasing the risk of technical debt [20]. At the same time, strong ownership is not a universal solution, especially at the beginning of the adoption. Sundelin et al. [27] argue that compared with strict ownership models, self-selected ownership can actually contribute to fewer code clones.

Taken together, those studies suggests that nightly non-gating analysis requires more than scheduled execution. To support follow-up, results must be made visible through appropriate feedback channels, attributable through ownership information.

# 3 Research Methodology

We employed action research because the goal of the study was not only to observe existing quality-control practices, but also to intervene in an industrial setting and learn from the effects of that intervention. Action research is suitable for our study because it has been developed to combine learning, researching and making actions [22]. It is especially useful in industry-academia collaboration where the researchers and practitioners working together for a shared goal [17]. An action research cycle normally includes five steps, starting with diagnosing, action planning, action taking, evaluating and end with learning [17, 22].

For this study, we collaborated with a team from Zenseact for one year. The timeline for this project is listed as Table 1.

**Table 1** Overview of the action research timeline.

| Cycle | Diagnosis | Action planning | Action taking | Evaluation | Learning |
|---|---|---|---|---|---|
| 1 | The existing strategy used quality-related signals as gating mechanisms in the CI pipeline, which reduced pipeline throughput. | Adopt Strategy 3 in practice. | Move quality-related from gated CI/CD execution to non-gating nightly execution. | The throughput rate of CI increases as well as the number of issues during the development. | The nightly job lacks output illustration and makes it less obvious for developers to follow up. |
| 2 | Moving quality-related signals from gated CI pipeline to non-gating nightly execution improved throughput, but decrease the visibility of results. | Introduce a dashboard to present the nightly analysis results. | Develop a dashboard for viewing the results of nightly analysis. | The dashboard provides access but the usage is low among developers. | The dashboard lacks proactive features to engage developers. |
| 3 | The dashboard provides access to analysis results, but its passive nature did not prompt immediate developer follow-up. | Introduce active notifications to increase developer awareness. | Introduce Slack-integrated notification bot based on code guardianship. | The bot leads to increased visit traffic with the dashboard and quick responses. | The current approach improves the CI throughput while preserving developers' quality awareness. |

## 3.1 Diagnosis

The collaborating company, Zenseact, is a Swedish company develops advanced driver assistance and autonomous driving software in a safety-critical setting. The main programming language for product development is C++, and the organization uses a monorepo-based development environment with shared CI pipelines and nightly quality-analysis jobs. Static analysis is performed using Perforce Helix QAC (QAC), to check compliance with internal coding rules and industry standards (e.g., ISO 26262).

The company manages the code responsibility through code guardianship instead of the strict code ownership to create a collaborative rather than hierarchical culture [27]. Zenseact utilizes the concept of code guardianship to create a shared responsibility across components, this is a more relaxed form of code ownership with a coarser granularity and self-selected responsibility. In this setting, a team instead of a single developer is self-reported to be the main owner of a part of the code.

During the diagnosis phase, practitioners described a recurring tension between strict quality control and development throughput. To maintain high software quality in a safety-critical setting, the company used several automated checks in the integration pipeline, including compliance and code-quality checks. However, some of these checks were expensive to run and could reduce the throughput of the shared CI pipeline, especially in the monorepo setting where delays affect many teams. The central problem identified in the diagnosis was therefore how to maintain strict quality standards while reducing the cost of expensive analyses in the critical CI/CD path.

The action research team in this study consisted of three researchers and five practitioners. The practitioners contributed domain knowledge, access to development practices, and feedback on the intervention, while the researchers supported problem formulation, data collection, analysis, and reflection.

## 3.2 Action Planning

After identifying the problem during the diagnosis phase, we plan actions to address it. The planning was guided by three requirements. First, the non-negotiable requirement from the company is the "zero-defeat" threshold, meaning that selected quality issues could not remain unresolved before release. Second, the organization wanted to reduce the accumulation of quality issues during daily development, rather than relying mainly on late-stage clean-up. Third, the intervention should reduce the burden of expensive analyses on the critical CI/CD path and thereby support higher development throughput.

To meet those requirements, different software quality control strategies (as mentioned in Section 2) have been studied. Strategy 1, build-up and clean-up, was considered unsuitable because it conflicts with the company's need for strict high quality threshold and continuous awareness of safety-related quality issues. Strategy 2, always gated CI/CD, provided strict enforcement but imposed high costs on the shared CI/CD pipeline. Strategy 3, nightly non-gating analysis, could reduce the burden on the critical CI/CD path, but risked making results less visible and weakening follow-up.

Based on this analysis, the team planned a fourth strategy: *Nightly Analysis with Feedback-left*. The strategy combines nightly non-gating execution of expensive analyses with feedback mechanisms that make results visible, attributable, and actionable. In contrast to passive nightly reporting, the planned intervention would connect QAC findings to dashboard views, team communication channels, and code guardianship mappings. The goal was to preserve the development-efficiency benefits of non-gating analysis while supporting timely follow-up by responsible teams.

## 3.3 Action Taking

The action-taking phase implemented the planned Strategy 4. The intervention consisted of three main components: moving QAC to nightly non-gating execution, providing dashboard-based visibility, and introducing Slack-integrated notifications based on code guardianship.

First, QAC was moved from the normal gated CI/CD pipeline to a nightly non-gating pipeline. This change removed the expensive analysis from the critical integration path while preserving regular execution of the check. The nightly job produced analysis results that could be used to monitor coding-rule compliance and other selected quality issues.

Second, a central code-health dashboard was developed to make the nightly results accessible. The dashboard transformed raw QAC output into a navigable representation of the codebase. Developers could inspect quality findings at both team level and file level, trace findings to affected files, and identify the guardian teams associated with those files. The dashboard therefore aimed to provide an information source comparable to the feedback previously available through gated CI/CD results, but without blocking the main pipeline.

Third, a Slack-integrated notification bot was introduced to make the feedback more active. While the dashboard made information available, it still required developers to visit it manually. The bot addressed this limitation by sending targeted notifications to internal team channels after nightly analysis results had been processed. These notifications focused on newly introduced QAC issues and linked them to the relevant guardian teams. The purpose was to increase awareness of non-gating findings and support timely follow-up without reintroducing expensive checks as blocking gates.

Figure 2 illustrates the implementation of Strategy 4. In this strategy, the feedback mechanism collects nightly analysis results together with runtime and metrics-related data from the nightly pipeline, processes the data on a central server, and maps the findings

to affected files and guardian teams. The processed results are then presented through a dashboard and a notification bot. In this way, the intervention transforms raw analysis outputs into summarized feedback that developers can act upon.

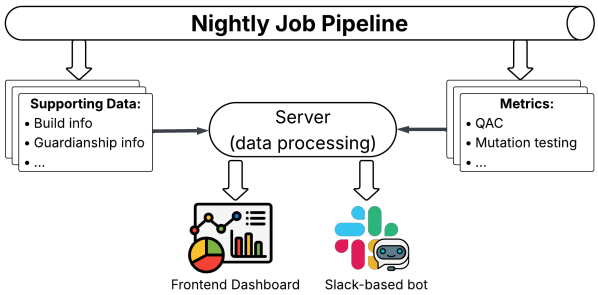

**Figure 2** Implementation of Strategy 4: Nightly Analysis with Feedback-Left. Runtime and metrics-related data are extracted from the pipeline, processed and analyzed on a central server. The resulting feedback is then published through the dashboard and internal communication channels.

## 3.4 Evaluation & Specifying Learning

To evaluate the impact of the action taken, we collected both quantitative and qualitative data to study how the nightly feedback mechanism functioned in practice and how it was perceived by developers.

The quantitative data were gathered from the software delivery environment over a longitudinal observation period of ten months (2025/06-2026/03). These data included repository activity, guardianship information, QAC analysis results, dashboard usage, and notification-related data. We used the number of successful merges to non-master branches as a proxy indicator of integration activity. We used the number of unresolved QAC issues to examine how selected quality findings evolved over time. The absolute number of merged commits and QAC issues will be normalized using z-scores (Equation 1) to preserve confidentiality.

$$z_i = \frac{x_i - \mu}{\sigma} \tag{1}$$

where: ( $x_i$ ) is the original value, ( $\mu$ ) is the mean of all values, ( $\sigma$ ) is the standard deviation of all values, ( $z_i$ ) is the normalized (z-score) value.

Dashboard traffic was used to assess whether developers actively accessed the passive feedback mechanism, and notification-response data were used to understand follow-up behavior after active feedback was introduced. Because the study was conducted in a real industrial environment, these quantitative measures were interpreted as indicators rather than controlled causal measurements.

To complement the quantitative data with qualitative data, we conducted semi-structured interviews with practitioners from teams affected by the nightly feedback process. Based on their team roles and their years of software development experience, ten participants were selected to represent a wide range of practitioner perspectives. The interviews focused on how participants experienced the new strategy in daily work, what benefits they perceived, what limitations or risks they experienced, and what kinds of quality-related signals they considered suitable for similar feedback mechanisms. The interview data were analyzed using thematic narrative analysis to capture participants' experiences, perceptions, and interpretations of the process.

**Table 2** Demographic information about participators.

| ID | Role | Years of experience |
|---|---|---|
| P1 | Software Developer | 28 |
| P2 | Software Developer | 14 |
| P3 | Software Developer | 19 |
| P4 | Software Developer | 10 |
| P5 | Technical Expert | 12 |
| P6 | Software Developer | 3 |
| P7 | Product Owner | 20 |
| P8 | Operational Flow Lead | 7 |
| P9 | Software Developer | 30 |
| P10 | Software Developer | 14 |

In this study, learning was specified through joint interpretation of quantitative trends, practitioner feedback, and interview results.

The evaluation results and lessons learned are presented in Section 4 as empirical findings and further discussed in Section 6.

# 4 Results

## 4.1 RQ1

RQ1 investigates how expensive static analysis can be reorganized from gated CI/CD to nightly non-gating execution in a safety-critical software organization. The action research process showed that nightly execution had to be combined with feedback mechanisms that preserved visibility, attribution, and follow-up. The resulting strategy consisted of three connected components: 1) moving from pre-merge gating to nightly non-gating, 2) providing dashboard-based visibility, and 3) introducing active notifications.

**1) Moving from pre-merge gating to nightly non-gating.** In December, QAC was moved from pre-merge gating to nightly, non-gating execution. The purpose of this change was to reduce the cost of expensive static analysis in the critical integration path while preserving regular analysis of the codebase.

To examine the effects of this change, we first analyzed the number of successful merges to non-master branches. As shown in Figure 3, the number of commits merged to non-master branches increased after QAC was moved to nightly execution. The observed increase suggests an improvement in CI/CD pipeline throughput. However, this improvement cannot be attributed solely to the removal of QAC from pre-merge gating, as participants noted that other concurrent factors may also have contributed. Nevertheless, many participants regarded the change as an important contributor to the improved throughput.

> *(**P3**)...type of commits made to the release branches. Some arbitrary category ideas: 1. New feature development 2. QAC fixes. 3. Test coverage fixes. 4. Bug fixes. 5. Documentation fixes.*

> *(**P4**) Removing QAC from premerge is definitely a contender/contributor here.*

These results suggest that moving expensive static analysis out of pre-merge gating can reduce pressure on shared CI/CD pipelines and support higher integration throughput. However, when we examined the number of unresolved QAC issues during the same period (the exact number of unresolved issues was normalized using z-scores), the data show that this change also introduced a follow-up challenge. As shown in Figure 4, unresolved QAC issues

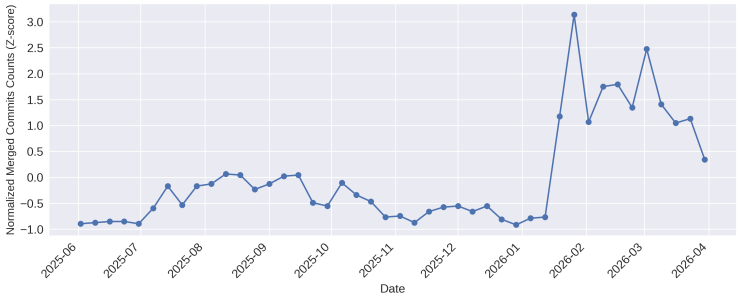

**Figure 3** Normalized number of commits that were merged to non-master branches.

increased after the move to nightly execution. This indicates a trade-off: moving QAC out of gating pre-merge was associated with higher integration throughput, but also with greater accumulation of unresolved quality issues. Interview data supported this interpretation:

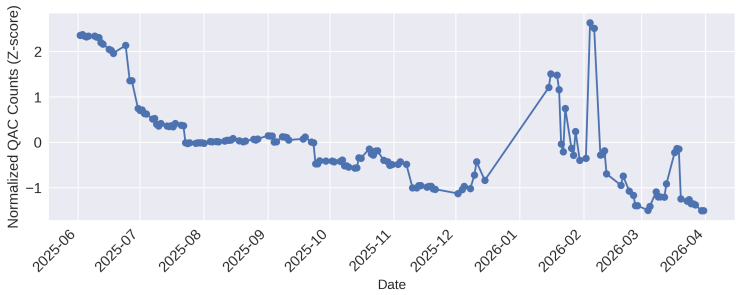

**Figure 4** Normalized number of QAC issues.

> *(**P8**) My anecdotal evidence is that we have had a lack of follow up on QAC and Code Coverage which has led to many patches having to be brought towards the release branches.*

This finding shows that nightly non-gating execution alone was insufficient in the studied safety-critical setting. Once QAC no longer blocked integration, additional mechanisms were needed to ensure that findings remained visible and were followed up by the responsible teams.

**2) Providing dashboard-based visibility.** To address the loss of immediate CI/CD feedback, the action research team developed a central code-health dashboard. The dashboard transformed nightly QAC results into a navigable view of the codebase. Developers could inspect findings at team and file level, trace issues to affected files, and identify the guardian teams associated with those files. An overview of the dashboard is shown in Figure 5.

The dashboard provided an equivalent information source outside the gated CI/CD path. In this sense, it restored access to information that had previously been exposed through pre-merge failures. However, dashboard usage data (Figure 6) showed that passive availability was not enough as developers did not frequently visit the dashboard after launching (2025/10–2025/12). It suggests that a dashboard can support transparency, but it cannot by itself guarantee timely follow-up.

Developers also expressed the need for more direct feedback through existing communication channels:

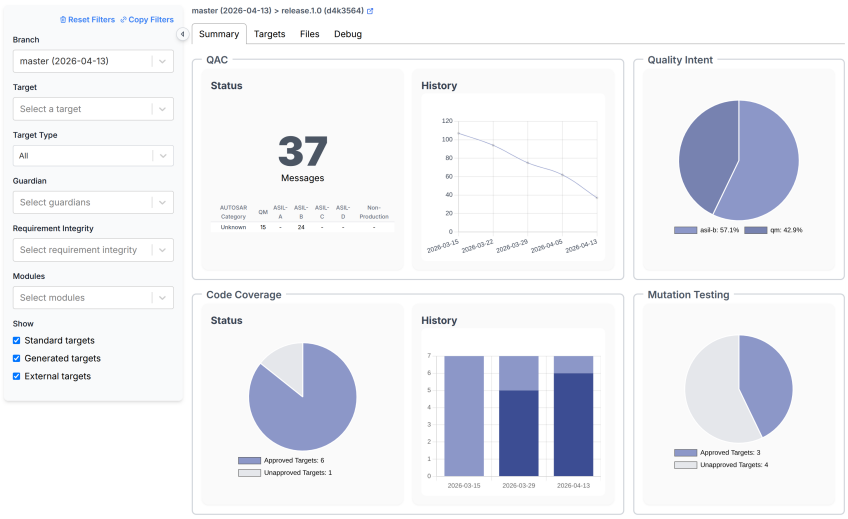

**Figure 5** Overview of the dashboard using mock data to preserve confidentiality. The homepage provides an overview of software metrics and analysis results, along with filtering options for branches, targets, guardians, and related attributes. The dashboard also offers multiple views for exploring affected targets and files, as well as supporting code inspection and debugging activities.

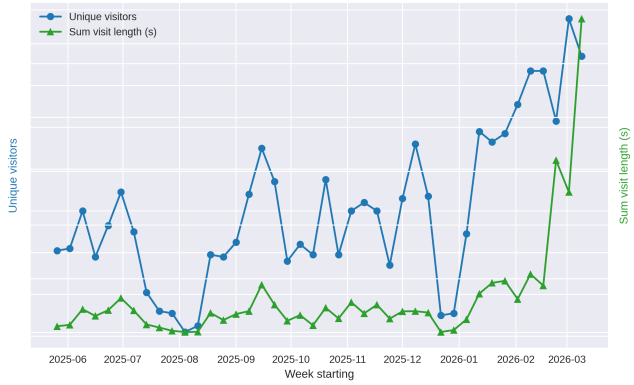

**Figure 6** Weekly traffic: unique visitors and total visit length.

*(**P1**) Can the system send slack notifications to a team's channel (if configured) for post-merge errors?*

This motivated the intervention in the next cycle: active notifications.

**3) Introducing active notifications.** On January 23, 2026, the organization introduced a Slack-integrated notification bot. The bot changed the feedback mechanism from passive access to active delivery. Instead of requiring developers to manually visit the dashboard, the bot sent targeted notifications to internal team channels after nightly analysis results had been processed. An example notification is shown in Figure 7.

The notifications focused on newly introduced QAC issues and used code guardianship information to route findings to the relevant teams. This made the nightly feedback more attributable because teams could see which findings were connected to the parts of the codebase they guarded. It also made the feedback more actionable because notifications linked developers to the relevant issue information.

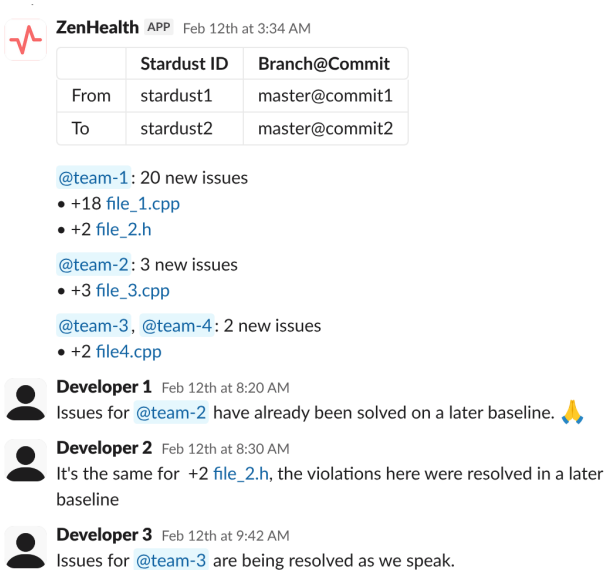

**Figure 7** A screenshot of the Slack notification.

After the bot was introduced, unresolved QAC issues fluctuated in the short term but then decreased and remained more stable in a saw-tooth pattern, as shown after January in Figure 4. This pattern is consistent with more regular follow-up on newly introduced issues rather than continued accumulation. Developers also described the bot as focused and accurate:

> *(**P1**) I think the bot does exactly what I envisioned, using the guardian system to get focused pings on new violations.*

In summary, the answer to RQ1 is that expensive static analysis can be reorganized from gated CI/CD to nightly non-gating execution, but complementary feedback mechanisms are required to preserve developer awareness and responsibility. In our study, the nightly results were made visible through a dashboard, actively delivered through Slack notifications, and attributed to responsible teams through code guardianship. They all have their own disadvantages, but the combination of all three enhances the immediate follow-up.

## 4.2 RQ2

RQ2 investigates what benefits developers perceived from adopting the nightly feedback strategy for software quality control. The interviews showed that developers perceived the strategy as beneficial mainly because it made non-gating QAC findings easier to notice, easier to assign to responsible teams, and easier to follow up without reintroducing expensive checks into the critical CI/CD path.

**Less manual checking.** A recurring benefit was that the strategy reduced the need for developers to manually inspect quality control results. Before the Slack-integrated feedback was introduced, developers had to actively visit the dashboard or rely on manual reminders to identify new QAC issues. Participants described this as inefficient because quality findings could remain unnoticed when they were only available through passive channels.

After the bot was introduced, developers received targeted messages in their existing team communication channels. This made follow-up more immediate and less dependent on developers remembering to check the dashboard:

> *(**P5**) Instead of relying on the somewhat inefficient manual process of "please check the dashboard daily for new debt", we now see teams engaging in fixing newly discovered debt ASAP, prompted by the bot's guardianship-directed messages.*

This suggests that developers perceived the active feedback mechanism as improving awareness of newly introduced quality issues. The benefit was not only that the information was available, but that it reached developers in a place where they already coordinated daily work.

**Focused and relevant feedback.** Developers also perceived the feedback as useful because it was focused on relevant issues rather than broad status reporting. The bot notified teams about newly introduced QAC violations and used guardianship information to direct these notifications to the teams associated with the affected files. This reduced the risk that developers would receive unrelated quality information.

Participants described the notifications as focused and aligned with the intended use of the guardianship system and the accuracy of the notifications:

> *(**P1**) I think the bot does exactly what I envisioned, using the guardian system to get focused pings on new violations.*

> *(**P4**) As for my experiences with the QAC bot in particular, it's very good. It's accurate, and when my team gets notified, it's always been a true positive.*

These perceptions indicate that developers valued the selectiveness of the feedback. Rather than treating nightly analysis as a general report that all developers had to inspect, the new strategy filtered and routed information so that notifications were more likely to be relevant to the receiving team.

**Quality awareness.** Finally, developers perceived the strategy as useful because it supported quality awareness while allowing expensive analysis to remain outside the critical CI/CD path. In the studied safety-critical setting, selected quality issues could not be ignored before release. At the same time, running expensive analyses as pre-merge gates created costs for development throughput. The nightly feedback strategy was perceived as a compromise between these concerns.

One participant described the importance of maintaining a complete view of non-negotiable quality metrics:

> *(**P5**) In safety-critical contexts, some software quality metrics are non-negotiable. We cannot ship to production with technical debt in these areas... the new strategy gives us a complete view of our delivery status against these metrics, providing a single source of truth.*

The answer to RQ2 is that developers perceived this strategy as useful not simply because QAC was no longer a pre-merge gate, but also the value in separating the execution of expensive analysis from the communication and follow-up of its results. This strategy allowed the organization to keep expensive checks outside the critical integration path while still maintaining issues' visibility and developers' awareness.

## 4.3 RQ3

RQ3 investigates what limitations developers perceived from adopting the nightly feedback strategy for software quality control. Although participants generally perceived the strategy as useful, they also identified limitations related to message scope, notification noise, and feedback latency.

**Message scope trade-off.** One limitation concerned the scope of information included in Slack notifications. The implemented bot focused on newly introduced QAC issues. This design was intended to make notifications concise and action-oriented by highlighting regressions that required follow-up. However, some developers wanted notifications to include the current overall state in addition to newly introduced issues:

> *(**P7**) The only specific feedback has been to have also the current state in the messages not only regressions.*

> *(**P10**) Would it be possible to have the existing issues be posted as well?*

These requests indicate that developers sometimes need more contextual information than regression-only notifications provide. Knowing only that new issues have appeared may not be sufficient for understanding the broader quality situation of a component or team. At the same time, including the full current state in every notification could make messages longer, more repetitive, and less focused. This created a design trade-off. Regression-focused notifications supported concise and actionable feedback, while full-state information supported broader situational awareness. In the studied strategy, this trade-off was handled by using Slack notifications for newly introduced issues and the dashboard for complete status information. This separation suggests that push-based channels are better suited for concise alerts, while dashboards are better suited for detailed exploration.

**Notification fatigue.** A second perceived risk was notification fatigue. Although active notifications improved visibility, participants were concerned that sending too much information could make the feedback channel noisy. This was especially relevant for repeated notifications about unchanged issues:

> *(**P6**) I wonder if it would become too noisy? Like the same 50 messages would be posted the last three analyses. Our idea was that this would notify when it has gotten worse, and you can open the UI to see all.*

This concern shows that increasing visibility does not automatically improve follow-up. If notifications are too frequent, too broad, or too repetitive, developers may start ignoring them. In that case, the mechanism intended to improve awareness could instead reduce attention to quality feedback.

The perceived risk of notification fatigue supports the design choice to notify mainly about regressions rather than all existing issues. It also suggests that similar feedback mechanisms should provide configurable notification policies, such as allowing teams to choose notification frequency, thresholds, channels, or types of quality signals. Such configuration could help preserve relevance while reducing unnecessary interruption.

**Feedback latency and stale notifications.** A third limitation concerns the delay between code changes and feedback. Because QAC execution is computationally expensive and depends on available resources, codebase size, and analysis scope, nightly analysis results may only become available several hours after the relevant code changes have been introduced.

*(**P9**) The running time of QAC can in the ballpark of 12 hrs.*

In some cases, this meant that developers received notifications about issues that had already been fixed. This delay can weaken the immediacy of feedback and may make it more difficult for developers to connect reported issues to specific changes.

*(**P4**) The only downside I can think of is the delay, which sometimes causes it to flag violations that have already been resolved.*

This latency reduces the immediacy of the feedback and can make notifications appear stale. The delay may come not only from analysis runtime, but also from practical constraints such as licensing issues, queueing, and the time needed to collect and process results before notifications are sent. As a result, the feedback may not always reflect the latest repository state.

This limitation is inherent to some extent in moving expensive analysis outside the critical CI/CD path. Nightly non-gating execution improves development throughput by avoiding immediate blocking, but it also weakens the temporal connection between a code change and the feedback produced by static analysis. Therefore, nightly feedback should be understood as a complement to faster checks rather than a complete replacement for all pre-merge quality control.

Overall, the answer to RQ3 is that developers perceived the nightly feedback strategy as useful but sensitive to feedback design. The main risks were that notifications could become either too narrow to provide sufficient context or too broad to remain useful, that repeated alerts could create notification fatigue, and that long analysis times could make feedback stale. These limitations indicate that nightly feedback mechanisms must balance visibility with relevance and timeliness.

## 5 Threats to Validity

A threat to **conclusion validity** arises from the extended study period of one year. During this time, multiple events occurred, including product releases, organizational restructuring, and holiday periods, all of which may have influenced the observed results. To mitigate this, we analyzed outliers together with team members and identified alternative factors that could explain variations beyond the studied variables. Nevertheless, it remains difficult to fully isolate the effects of the studied factors from these external influences.

The primary threat to **external validity** stems from the several preconditions of the proposed framework on several preconditions in the studied environment: (1) clear code ownership, (2) a mono-repository setup, (3) a mature CI/CD and nightly pipeline, and (4) established internal communication tools. These conditions tightly couple the framework to the specific industrial context, thereby limiting its generalizability to other settings. In addition, this is a single-company case study, which further constrains the applicability of the findings across organizations and domains. Due to confidentiality constraints, we are unable to replicate the exact setup in other environments within this study. As future work, we plan to conduct similar studies in additional companies to further validate the approach.

One threat to **construct validity** is the relatively short time span between moving QAC from the CI/CD pipeline and releasing the bot. Consequently, the observation period for assessing dashboard-related effects is limited, and delayed responses may not be fully captured. We mitigate this by focusing on trends rather than absolute values. Another threat concerns the measurement of perceived benefits through interviews with employees. The selected participants were primarily developers most affected by the strict threshold, which

may introduce bias in their responses. As a result, the measured perceived benefits may not fully represent the perspectives of other stakeholders. In addition, the responses primarily focused on bot notifications rather than the dashboard, making it difficult to distinguish the individual effects of each component. To address this, we evaluate the combined effect of both tools as a single unit when answering RQ3.

A key threat to **internal validity** is the potential influence of organizational and pipeline maturation over time, independent of the studied factors. To reduce this risk, we restricted the study period to twelve months, aiming to limit the impact of long-term evolutionary changes.

# 6 Discussion

## 6.1 Visible, Attributable, Actionable Feedback

The findings of this study suggest that the effectiveness of non-blocking feedback from nightly analyses depends on how those results are presented to developers. In the studied case, three key properties were especially important: visible, attributable, and actionable.

**Visible feedback.** must reach developers through channels that fit their daily work. Dashboards can provide a comprehensive overview, but they may not be effective when used alone as they require developers to actively check them. Notification bots increase the visibility by pushing relevant updates into existing communication channels, but their usefulness depends on the frequency and content of the notifications. We also hear requests from developers to create a CLI tool to support the visibility, which is also a good option to consider when designing the feedback mechanism. This suggests that effective visibility requires selective presentation of the most relevant information and tools that can cause developers' awareness.

**Attributable feedback.** make it clear who should be responsible for following up on the identified issues. In practice, this means we need to link the findings to responsible teams or developers. In the studied case, the concept of code guardianship provided a natural way to attribute the results to specific teams, which made the process much more efficient. If such mechanism or information is not available in the organization, this can also be done manually with a dedicated team or person, but it is more effective to automate this process and we recommend to adopt similar code ownership practices.

**Actionable feedback.** must support sufficient follow-up once the issues are identified and visible to the responsible team or developers. In practice, this means that the issues should be clear presented and their emergence should be easily assessed. What's more, it should also be easy to trace the original files and relevant information to support the diagnose of the issues. Actionality is reduced when findings are hard to interpret, disconnected from the related code, or when the results are aggregated in ways that make it difficult to identify specific problems.

Taken together, feedback-left is not simply about feeding back the results of nightly analyses to the developers faster, but also about what and how to feed the results back to the developers.

## 6.2 Other Metrics

There are many quality-related signals existing in CI pipeline and can be moved to nightly CI jobs to enhance the development efficiency. In this study, we focused on QAC as the example metric to study the effect of moving a metric from gating (daily CI) to non-gating (nightly CI), and the effect of the feedback mechanism. However, there are many other metrics that can be moved to nightly jobs, and the feedback mechanism can also be applied to other metrics. Code coverage is one of the most frequently mentioned metrics during the interviews, and there are discussions on whether it should be moved to non-gating as well.

> *(P2) I think we should move code coverage to non-gating. ... The code coverage files could be retired other than for justifying why we should actually have lower coverage than the limit.*

Their main motivation of code coverage should be moved is mentioned as follows, and we believe code coverage is not the only case, in general, metrics have those properties hinder the current pipeline should be considered for moving to non-gating.

> *(P2) First, it (code coverage) is slow to run. Second, it's prone to A+B errors. Third, it adds another build configuration creating cache churn. Fourth, it's overly sensitive to minor changes.*

## 6.3 Behavioral and Social Effects

Our findings also suggest that the effectiveness of the feedback mechanism is not only a technical issue, but also a behavioral and social one. One important factor is that the developers have clear understanding of organizational expectations of zero issue and the consequences of not meeting them. In the studied case, the concept of "zero defeat" provided a clear standard for code quality, which made it easier for developers to understand the importance of addressing issues promptly. This shared understanding of quality standards appears to have made the feedback easier to accept as part of daily work.

A second factor is the social visibility of the feedback. Because the selected results were communicated through shared internal channels and tagged to responsible teams. This social visibility may have created a "positive shame factor" that motivated teams to address issues more promptly. In our interpretation, this did not function primarily as blame, but rather as a form of social accountability that encouraged teams to maintain their reputation for quality. Therefore, when other organizations consider implementing similar feedback mechanisms, they should prompt the collaborative setting in which follow-up is socially encouraged without becoming individualized blame.

# 7 Conclusion

In this study, we adopted an action research approach to explore different software quality control strategies in safety-critical settings, along with their benefits and limitations. The main contribution of this paper is a new strategy that combines nightly analysis with a feedback-left approach to balance CI throughput and strict quality standards. By shifting selected quality related signals from gated CI pipelines to non-gating nightly analysis, the strategy improves developer efficiency during the development phase. In combination with targeted feedback notifications and supporting dashboards, the approach also maintains high quality awareness and preserves timely follow-up actions. For future work, we plan to evaluate this strategy using additional software quality metrics and apply it across different organizational contexts.

## Abstract

Business Requirements often fail to fully capture the complete set of system requirements they intend to describe, resulting in under-specification and measurable gaps between documented requirements and production-ready implementations. While experienced business analysts attempt to mitigate these gaps using domain expertise, the resulting artifacts often remain incomplete.

This study uses Cross-Pollination, a domain-agnostic methodology for transforming incomplete natural language Business Requirements into comprehensive, production-grade functional user stories. To evaluate the completeness of LLM-generated user stories, the study systematically benchmarks them against realistic production artifacts. It further investigates the capability of Large Language Models (LLMs) to bridge the coverage gap between human-authored backlogs and production systems. It identifies the requirements that are overlooked during human-driven elicitation but are recovered through an LLM-assisted approach.

The cross-pollination technique is a structured multi-phase methodology supported by a gap analysis taxonomy and a domain complexity calibration mechanism to establish a minimum baseline for production readiness. The methodology is applied across real-world domains, and a comparative evaluation of analyst-authored, LLM-generated, and production-derived user stories is conducted. Empirical results demonstrate that a substantial proportion of requirement gaps can be systematically identified and addressed through this approach.

The findings indicate that Cross-Pollination provides a reproducible and scalable methodology for translating natural-language requirements into more complete and production-aligned user stories. The results demonstrate that while analysts produce precise requirements, LLM-generated user stories achieve higher recall across all evaluated domains and are effective in uncovering implicit and non-obvious requirements. These findings indicate that an integrated approach, with LLM-assisted elicitation functioning as a complementary mechanism to human expertise, produces more comprehensive and reliable requirement backlogs than either method independently.

## 1 Introduction

Over the past decades, software engineering has evolved significantly, with recent advances in artificial intelligence, including machine learning, large language models (LLMs), generative AI, and emerging agentic systems, further accelerating this transformation. Despite these advances, successful software development continues to depend fundamentally on the clarity, completeness, and quality of requirements and user stories.

Requirements elicitation (RE) remains a critical activity in software development, as business requirements establish the connection between organisational intent and system behaviour, while user stories translate these requirements into actionable units for downstream activities such as design, development, testing, and maintenance. Although requirements are typically gathered from domain stakeholders, analysts play a key role in refining them into structured and complete user stories.

Over the years, RE practices have evolved through various techniques and governance mechanisms aimed at improving requirement quality and completeness [3]. However, software project failures continue to persist [27], with many failures originating from incomplete or inadequate requirements rather than implementation limitations. This highlights the enduring challenge of ensuring that initial requirements sufficiently capture the functionality required for successful system delivery.

The emergence of LLMs introduces new opportunities for supporting RE activities. Unlike traditional approaches that primarily depend on individual analyst expertise, LLMs can leverage broad domain knowledge to identify potential gaps, infer missing capabilities, and provide contextual insights beyond explicitly documented requirements.

Motivated by these challenges and recent advances in LLMs, this study collaborates with industry practitioners to empirically investigate the role of LLM-assisted approaches in identifying requirement gaps and improving completeness. Through evaluation against real-world production-derived artefacts, the research examines both the effectiveness and limitations of LLMs in supporting requirements engineering and reducing downstream software development risks.

Quality Function Deployment (QFD) [2] provides a structured top-down approach for assessing whether engineering specifications satisfy customer intent. However, this study addresses an earlier stage of requirements engineering determining whether initial business requirements are sufficiently complete before specification development. To address this challenge, Cross-Pollination adopts a complementary bottom-up approach that combines structured gap analysis with LLM-assisted contextual reasoning to enrich incomplete requirements.

To address this challenge, this study introduces Cross-Pollination, a domain-agnostic methodology that transforms incomplete natural language business requirements into production-grade functional user stories. Complementary to the top-down perspective of QFD, Cross-Pollination adopts a bottom-up approach that combines structured gap analysis with LLM-assisted contextual reasoning, leveraging both BRD context and domain knowledge embedded within pre-trained LLMs to identify missing capabilities and enrich requirements. The resulting user stories provide a more comprehensive foundation for downstream software development.

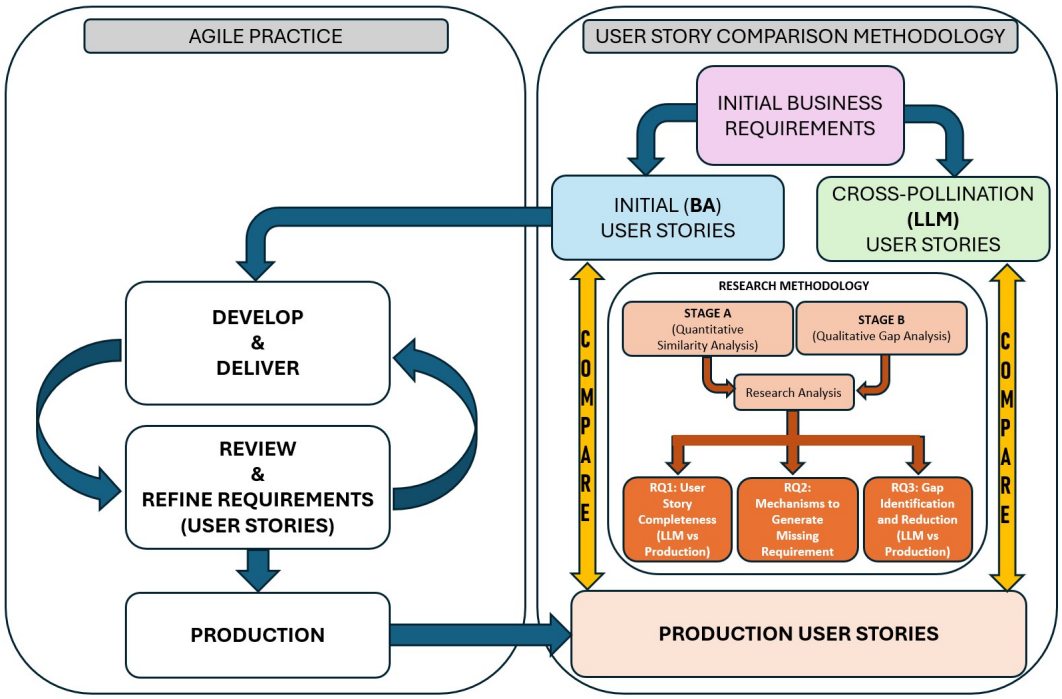

**Figure 1** User story comparison and comparative analysis methodology.

To evaluate the effectiveness of the proposed methodology, this study benchmarks LLM-generated user stories against realistic production artefacts. It investigates the ability of LLMs to bridge the gap between business analyst (BA) authored requirements and production-ready specifications by identifying functional requirements that may remain implicit or overlooked during human-driven elicitation.

We adopt a three-source comparative evaluation framework (see Figure 1), where analyst-authored and LLM-generated user stories are evaluated against production-derived user stories as the reference baseline. The same Business Requirements Document (BRD) provided to analysts during elicitation is supplied to the LLM, enabling a controlled comparison of human-driven and LLM-assisted generation. This design facilitates the assessment of requirement completeness, coverage, and alignment with functionality implemented in real-world production systems.

These observations motivated the development of a structured methodology in which the LLM first establishes domain understanding, identifies gaps across defined System Capability Dimensions, calibrates expected story coverage, and generates additional requirements to improve completeness. The methodology involves two stages: (1) Cross-Pollination and (2) Comparative Evaluation of User Stories.

- **Cross-Pollination Methodology:** A domain-agnostic, ten-stage framework that transforms incomplete business requirements into production-aligned functional user stories using structured gap analysis and LLM-assisted reasoning.
- **Comparative User Story Evaluation:** A production-derived benchmarking approach that quantitatively evaluates analyst-authored and LLM-generated user stories for completeness and requirement gaps.

To carry out an empirical investigation, we subsequently employed this methodology on three real-world software systems from distinct domains: an E-Commerce application, a Library Management Solution and a Cosmetics and Wellness Education Portal. To evaluate

the outcomes of these approaches, the study formulates a set of research questions. These questions guide the analysis by examining how effectively LLM-assisted techniques identify requirement gaps, improve completeness, and support decision-making during requirements elicitation. The study is structured around research questions:

- **RQ1:** To what extent are LLM-generated user stories complete when benchmarked against production user stories?
- **RQ2:** What qualitative mechanisms enable LLMs to generate comprehensive user stories from Business Requirements Documents (BRD)?
- **RQ3:** What gaps exist between analyst-authored and production user stories, and to what extent can LLMs reduce these gaps?

The findings demonstrate that requirements incompleteness follows structured patterns across domains and that LLM-assisted elicitation complements analyst expertise by improving requirement coverage while requiring human validation to maintain precision.

## 2 Background and Related Work

### Requirements engineering as a continuous and high-risk activity

Requirements engineering (RE), although often treated as a discrete initial phase in the software development lifecycle, is inherently a continuous and evolving stage. In practice, there is a strong desire to stabilise and freeze the requirements early to ensure consistency across subsequent stages of development; however, this objective is rarely achieved. Requirements evolve due to changing stakeholder needs, emerging business priorities and dynamic operational environments, extending RE beyond its initial phase to persist throughout the lifecycle and even post-deployment. Even in stable production systems, new features, enhancements, updates and modifications continue to emerge, reflecting the ongoing evolution of requirements. This continuous nature of RE introduces additional complexity, necessitating effective mechanisms to manage change while maintaining consistency and traceability.

The consequences of requirements deficiencies are considerable and are well documented. Synthesis across multiple empirical programmes indicates that approximately 31% of corporate software projects are cancelled before completion, and a further 53% exceed their original cost estimates by close to 200%. Broader failure rate estimates range from 67% to 85% across different organisational contexts, with 5%–15% of projects being abandoned either before or shortly after delivery due to severe inadequacies. Additional studies report that approximately 20% of projects fail outright, with another 46% experiencing high cost and schedule overruns [50]. For instance, Arianespace suffered from several specifications and design errors, and the failure has been attributed to specification and design errors, including issues related to requirements and requirement changes that propagated into system design. Similarly, a Sydney Water Board project incurred high costs and schedule overruns due to poorly defined requirements and inadequate planning, with rework costs exceeding the initial budget. These findings are further supported by industry analyses, including reports from the Standish Group [50].

More recent evidence from the CHAOS reports [14] indicates that these challenges persist, and the latest trends are not promising either, as only 31% of projects are classified as successful, 50% are challenged, and 19% fail, with large-scale projects exhibiting success rates below 10%. Historical case studies further reinforce these observations.

Fernández et al., [17] in one of the largest global empirical studies in RE have delivered a key insight that many of the most severe issues in software projects originate during early RE activities, particularly due to incomplete, hidden, or poorly elicited requirements. These

problems are not isolated; rather, they propagate throughout the software lifecycle, leading to rework, delays, increased costs, and, in many cases, project failure. The study further emphasises that deficiencies in communication and stakeholder knowledge during elicitation contribute to these issues, reinforcing the complexity of accurately capturing organisational intent. In this context, RE emerges as a foundational and high-risk activity, where early inaccuracies have long-term consequences that are difficult and costly to correct. Therefore, the effectiveness of requirements engineering, especially elicitation and validation, directly influences the alignment between stakeholder needs and system behaviour, making it a critical aspect of software engineering.

## Evolution from Traditional Practices to Advanced Approaches

Requirements elicitation has evolved from manual and expert-dependent techniques to AI-driven approaches capable of processing complex, large-scale artefacts. Early methods surveyed by Zowghi et al. [57] remain foundational: interviews [1, 24] enable rapid information gathering but depend heavily on interviewer skill [18], while structured variants such as Volere [41] offer consistency at the cost of flexibility. Complementary techniques including task analysis [13, 40], introspection [18], repertory grids [12], CRC cards [8], and laddering [23] support structured domain understanding. Collaborative brainstorming requirements workshops [19], and focus groups [28] facilitate group-driven exploration, while ethnographic methods [6], protocol analysis [18, 35], and apprenticing [42, 9] provide deeper contextual insight [34]. Goal-oriented and scenario-based approaches like CREWS, Inquiry Cycle [49] decompose objectives into refined requirements [43, 38, 21], while viewpoint-oriented methods [46, 36] capture multi-stakeholder perspectives for more comprehensive specifications.

The increasing complexity of modern systems has driven the adoption of computational techniques to augment these traditional methods [11]. As documented by Popoola et al. [37], NLP has emerged as a key enabler, automating the analysis of textual requirements artefacts [56] and addressing the inefficiency and error-proneness of manual approaches. NLP techniques parse unstructured text, extract entities, detect implicit requirements, and identify inconsistencies [54, 7]. ML (Machine Learning) models further extended these capabilities through historical data-driven prediction of requirement evolution, while HCI techniques enhance stakeholder engagement via interactive interfaces and prototyping [45, 15]. Together, these advances underscore the need for integrated models that improve requirement quality and completeness [39].

The House of Quality (HoQ), a core component of Quality Function Deployment (QFD) [2], captures the Voice of the Customer (VoC)[20] and maps customer requirements to engineering characteristics through weighted relationships. This mapping acts as a transfer function for evaluating specification coverage, with approaches such as the Convergence Gap [31] providing measures of completeness.

The emergence of large language models (LLMs) has further expanded the scope of requirements engineering beyond task-specific NLP. Trained on diverse, cross-domain data, LLMs can surface non-obvious patterns and functional expectations, yet remain inherently uncertain and difficult to control [25, 55], producing inconsistent outputs that raise trust concerns [44, 16]. This has driven focus on prompt engineering (PE), the systematic design of inputs to guide LLM behaviour [33] encompassing techniques such as few-shot prompting [10], chain-of-thought reasoning [51], retrieval-augmented generation (RAG) [29], constraint injection, and multi-role prompting. Despite their promise, these approaches remain fragmented in RE contexts, often lacking holistic evaluation frameworks [26]. Knowledge-

augmentation methods such as RAG [29], ReAct [52], and Chain-of-Knowledge prompting [30] offer further reliability by grounding outputs in external domain knowledge, improving both relevance and trustworthiness.

## 3 Research Gaps and Motivation

In practice, initial business requirements are captured at a high level, when stakeholders rarely possess a complete understanding of the required functionality. As development progresses, additional business rules, workflows, validations, and exception scenarios inevitably emerge. Consequently, the challenge is not solely whether engineering specifications satisfy customer intent, but whether the initial business requirements are sufficiently complete to derive a production-ready functional specification.

Recent literature identifies domain understanding, hallucination, and limited industry validation as persistent challenges in applying LLMs to Requirements Engineering. Hemmat et al. [22] highlight difficulties with domain-specific language, hallucinations, complex dependencies, and the lack of actionable guidance for LLM adoption in RE, while Arora et al. [4] identifies domain understanding as a critical factor influencing LLM effectiveness in SWOT analysis. Although LLMs can acquire broad domain knowledge, they may not capture the tacit expertise required for accurate requirements elicitation. Furthermore, Zadenoori et al. [53] report that 76% of LLM4RE studies rely on laboratory evaluations, with only 7% involving field studies, indicating limited industrial validation. Existing industry evaluations also largely depend on manual validation of individual stories against acceptance criteria rather than systematic completeness assessment [48]. The absence of realistic production-derived benchmarks and reproducible domain-agnostic evaluation methods remains a key limitation.

These gaps motivate the need for a methodology that can (i) evaluate requirement completeness against production-grounded references, (ii) support domain-aware yet domain-agnostic requirement discovery, and (iii) quantify the gap between documented requirements and implemented functionality. To address these needs, Cross-Pollination combines structured System Capability Dimension-based gap analysis with LLM assisted contextual reasoning to identify implicit and omitted functional requirements. Unlike QFD, which begins with a structured Voice of the Customer exercise, Cross-Pollination operates on an existing BRD the primary artefact available at the start of software development and serves as a complementary downstream approach for enriching requirements before specification development. The methodology further establishes a production derived evaluation framework to benchmark analyst-authored and LLM generated user stories, enabling objective assessment of completeness beyond subjective validation.

## 4 Methodology

The proposed methodology comprises two complementary components aligned with the research questions: (i) the Cross-Pollination methodology, which transforms incomplete BRD into production-grade functional user stories through structured gap analysis and LLM-assisted contextual reasoning (RQ2); and (ii) a comparative evaluation framework that benchmarks analyst-authored and LLM-generated user stories against production-derived user stories to quantify completeness and analyse requirement gaps (RQ1 and RQ3).

Preliminary experiments were conducted using a Ticket Booking System to examine LLM behaviour under different prompting strategies. Providing individual requirements produced detailed user stories but offered limited additional value, while providing the complete BRD

without structured guidance resulted in insufficient coverage. Multi-shot prompting improved coverage but introduced example-dependent bias. Therefore, a structured zero-shot approach was adopted to provide a consistent and domain-agnostic evaluation setting.

Hence, the methodology employs zero-shot prompting, whereby the LLM receives only the Cross-Pollination prompt and the BRD as input. This configuration isolates the effectiveness of the proposed methodology while providing a consistent basis for comparison across datasets. Cross-Pollination consists of ten sequential stages, each building upon the outputs of preceding stages. Consequently, isolating the contribution of individual stages through conventional ablation is challenging, as removing or modifying an earlier stage changes the contextual information available to subsequent stages and affects the behaviour of the complete pipeline. Therefore, Cross-Pollination is evaluated as an integrated methodology rather than through isolated component analysis.

To support reproducibility, the complete replication package, including the Cross-Pollination prompt suite, datasets, workflow documentation, and evaluation scripts, is publicly available through the accompanying GitHub repository[1]. Practitioners require only a Business Requirements Document (BRD) as input, while researchers reproducing the evaluation additionally require a production-derived user story reference set to compute the reported completeness and comparison metrics.

## 4.1 Cross-Pollination Methodology

The Cross-Pollination methodology is based on the observation that requirement incompleteness is structural rather than random, with high-level business requirements often under-specifying functional details that emerge during implementation. Our experiments demonstrate that directly prompting an LLM to generate user stories from a BRD frequently produces incomplete coverage and hallucinated requirements due to the absence of structured guidance.

To address this, Cross-Pollination adopts a structured ten-stage, zero-shot methodology that guides the LLM through domain understanding, gap identification, scope calibration, and user story generation. Rather than generating requirements directly, the methodology systematically analyses the BRD and cross-references documented requirements with LLM domain knowledge to identify implicit or omitted functionality. The analysis is organised using System Capability Dimensions comprising functional dimensions (Actors, Workflows, Data, Business Rules, States, Integrations, System Events, and Reporting) and regulatory dimensions (Compliance, Security and Privacy, and Governance). These dimensions provide a consistent framework for extracting documented requirements from the BRD and identifying domain standard capabilities from LLM to support systematic gap analysis.

The methodology incorporates complexity calibration to estimate the expected range of production-ready user stories and maintains end-to-end traceability by classifying each generated story according to its source: BRD-derived, gap-identified, or LLM-inferred. The first five stages focus on domain understanding and requirement discovery, while the remaining stages perform calibration, generation, validation, and output assembly.

The ten phases of the Cross-Pollination methodology are outlined below:

1. **Domain Reference Scan:** Reviews the Business Requirements Document (BRD) to establish the system context, purpose, stakeholders, operating environment, and scope. Using this understanding, the LLM leverages its domain knowledge to identify

[1] GitHub Repository: `https://github.com/VinayKabadi/Cross-Pollination`

representative production systems within the same domain and synthesises their common capabilities into a consolidated domain reference model. These capabilities are organised according to the System Capability Dimensions providing a structured baseline for subsequent comparison.

2. **Deep BRD Comprehension:** Systematically analyses the BRD by extracting all explicitly specified requirements and system elements across the System Capability Dimensions, establishing the baseline representation of documented requirements.
3. **Static Gap Analysis:** Compares the extracted BRD requirements against the domain reference model across the ten gap dimensions (see Table 1) to identify missing or under-specified requirements, producing a structured gap inventory for subsequent requirement discovery.
4. **Dynamic Cluster Analysis:** Groups the extracted requirements and identified gaps into logical functional clusters by analysing semantic relationships, dependencies, and interactions, establishing the contextual links required for Cross-Pollination.
5. **Cross-Pollination Matrix:** The core phase of the methodology, where BRD elements are systematically cross-referenced with identified gaps derived from the LLM's domain knowledge and functional reference model. This structured cross-pollination uncovers contextual relationships, dependencies, and missing capabilities, generating functional requirements that are not explicitly documented in the BRD.
6. **BRD Complexity Calibration:** Estimates the expected range of user stories for a production system by evaluating the BRD across eight functional and structural dimensions (see Table 2), producing a calibrated Floor, Ceiling, and overall Complexity Tier. This brings stability to the number of user stories.
7. **Gap Report:** Documents all identified gaps, supporting evidence, and their traceability to the generated requirements.
8. **Story Generation:** Generates production-ready functional user stories within the calibrated range by combining BRD-derived, gap-driven, and LLM-inferred requirements while maintaining full traceability. The generation process applies consistency checks to minimise hallucinations, redundancy, and duplicate user stories.
9. **Production Readiness Checklist:** Validates the generated user stories for completeness, consistency, coverage, and adherence to production standards.
10. **Output Assembly:** Compiles the final deliverable, including the generated user stories, traceability matrix, gap report, domain reference model, and coverage summary.

Cross-Pollination methodology employs two kinds of dimensions, i.) Gap analysis dimensions (see Table 1) and ii.) Calibration dimensions (see Table 2).

## Gap Analysis Dimensions

Business requirements typically describe systems in terms of intended operation defining actors, workflows, and data while omitting the elements required for reliable and complete production behaviour. The ten gap analysis dimensions in Cross-Pollination capture this boundary as a structured taxonomy of commonly missing requirement categories, including automated roles, exception paths, data integrity controls, configurable rules, lifecycle states, integration failures, validation constraints, notification triggers, background jobs, and data migration processes.

These ten dimensions are applied in Phase 3 of cross-pollination to form a closed, domain-agnostic framework that is used consistently across all business requirements. No dimension is added, removed, or adjusted for specific domains. The focus remains on functional aspects – to ensure that identified gaps can be expressed as testable user stories and compared uniformly across domains. Table 1 presents the complete taxonomy.

**Table 1** The Ten Gap Dimensions Used for Requirements Analysis.

| Code | Dimension | What It Measures |
|---|---|---|
| D01 | Actor Completeness | Named actors, all roles and personas explicitly identified |
| D02 | Workflow Completeness | End-to-end processes fully described including exception paths |
| D03 | Data Completeness | Data entities and integrity mechanisms what is captured and how |
| D04 | Business Rules | Configurable policies, thresholds, and constraints explicitly stated |
| D05 | State Machine | Object lifecycle states and all transitions named |
| D06 | Exception Handling | Failure modes, error paths, and fallbacks covered |
| D07 | Validation | Input constraints and format rules specified |
| D08 | Notification Events | All trigger conditions for notifications named |
| D09 | Background Jobs | Scheduled and automated execution mechanisms specified |
| D10 | Onboarding & Offboarding | Registration, activation, suspension, and deactivation flows |

### Complexity Calibration Dimensions

The calibration model addresses a key challenge in completeness assessment: without a complexity-based reference, it is difficult to determine whether a backlog is complete or simply large or small. The BRD is evaluated across eight weighted dimensions (six functional and two structural), informed by practitioner experience and observed production patterns. The aggregated score produces a midpoint, from which a Floor ($\times 0.78$) and Ceiling ($\times 1.28$) define the acceptable range of user stories, along with a Complexity Tier for cross-project comparison. Higher weights are assigned to dimensions such as actor count, state complexity, and integrations, as these increase interaction paths, lifecycle scenarios, and system dependencies. The bounds are grounded in the observation that approximately 20% of requirements typically emerge during later refinement; the lower bound accommodates under-specification, while the upper bound allows greater tolerance for over-specification, which is more prevalent once minimum coverage is achieved.

## 4.2 Comparative User Story Evaluation

Evaluating the quality of requirements artefacts presents a fundamental measurement challenge: unlike source code or test suites, user stories have no universally accepted ground truth against which correctness can be objectively assessed. Prior work has relied predominantly on expert inspection, structured walk-through and checklist-based heuristics, all of which are labour-intensive, subjective and difficult to reproduce across domains.

To address this limitation, we deployed a systematic, domain-agnostic evaluation framework that operationalises requirements quality as measurable functional coverage against a production-implemented reference set. The method comprises two sequential analytical stages: Stage A an automated similarity evaluation analysis that produces quantitative coverage metrics, and Stage B a structured gap analysis that diagnoses the nature and

**Table 2** Calibration Dimensions and Scaling Formulas.

| Code | Calibration Dimension | Formula |
|---|---|---|
| D-C01 | Actor Count | actors ×4 |
| D-C02 | Workflow Density | decision points ×1.8 |
| D-C03 | Business Rules | rules ×1.5 |
| D-C04 | State Machine Depth | states ×2 |
| D-C05 | Integration Count | integrations ×3 |
| D-C06 | Notification Surface | events ×1.2 |
| D-C07 | Reporting Depth | reports ×1.8 |
| D-C08 | Distributed Network | Single / Multi |

distribution of coverage gaps. Together the LLM answers both, in Stage A, it answers how much of the production system each candidate backlog predicts, and in Stage B it answers which requirements were missed, why they were missed, and what structural categories they belong to.

To evaluate we gather three data sets for each project: **PROD**, **INITIAL** and **LLM**. PROD serves as the reference set, comprising production-derived user stories reconstructed by industry professionals through multiple approaches, including recreating stories from the live production system, reverse engineering from source code and API routes, and consolidating artefacts from project boards across the entire development lifecycle. Unlike specification documents, which may describe intended rather than realised behaviour, production artefacts provide an unambiguous record of implemented functionality. INITIAL comprises user stories produced by a business analyst from a BRD, while LLM comprises stories generated by a Large Language Model from the same BRD. Comparing both candidate sets against the shared PROD reference isolates the effect of the elicitation method while controlling for input document, domain, and evaluation instrument.

## Stage A – Quantitative Similarity Analysis

The matching process is carried out in five steps. Each step prepares the stories, compares them, and evaluates how well they match production.

**Step 1: Text Normalisation.** All stories are normalised by applying three sequential stop-word layers to the story body text: (i) standard English function words; (ii) universal user story boilerplate (e.g., *as, want, so, that, can*); and (iii) domain-specific high-frequency vocabulary. The story title is excluded to avoid naming bias. The remaining tokens form the semantic representation used for matching.

**Step 2: TF-IDF Vectorisation.** Each normalised story is converted to a weighted term vector using Term Frequency–Inverse Document Frequency (TF-IDF) [47] which down-weights common terms while emphasising discriminative, domain-specific vocabulary. The inverse document frequency for term $\boldsymbol{t}$ is computed as:

$$\mathrm{IDF}(t) = \log\left(\frac{N+1}{df(t)+1}\right) + 1$$

where $\boldsymbol{N}$ is the total number of user stories in the corpus and $\boldsymbol{df(t)}$ is the number of stories containing term $\boldsymbol{t}$. The smoothing terms (+1) prevent division by zero and ensure stable weighting for infrequent terms.

**Step 3: Cosine Similarity.** Cosine similarity measures the semantic similarity between two TF-IDF vectors and is well suited to short-text comparison because it is invariant to document length [32]. Given two TF-IDF vectors A and B:

$$\text{cosine}(A, B) = \frac{A \cdot B}{\|A\| \cdot \|B\|}$$

where $A \cdot B$ denotes the dot product and $\|A\|$ and $\|B\|$ are the Euclidean norms of the corresponding vectors. Cosine similarity ranges from 0 (no shared semantic content) to 1 (identical vector representations). A supplementary functional-area boost of +0.03 is applied when two stories share the same epic code, rewarding domain alignment without overriding the primary semantic similarity signal. Average Match Score is reported as the mean similarity of all matched pairs.

**Step 4: Find the best one-to-one matches.** Greedy matching is applied by assigning each PROD user story to the highest-scoring unmatched candidate, provided the similarity score exceeds a configurable threshold of 0.10. The low threshold was selected heuristically because independently authored requirements often use different terminology to describe the same functionality [5], and was reviewed by industry practitioners to provide a reasonable balance between recall and valid semantic matching. Its impact can be further evaluated through sensitivity analysis in future work.

**Step 5: Metric Calculation.** Matching performance is evaluated using Precision, Recall, and F1-score. A True Positive (TP) represents a correctly matched user story, a False Positive (FP) is a generated story with no corresponding production match, and a False Negative (FN) is a production story with no corresponding generated match. Precision measures the proportion of generated stories that are correct, Recall measures the proportion of production stories identified, and the F1-score provides their harmonic of precision and recall. True Negatives (TN) are excluded, as their inclusion would artificially inflate performance in this retrieval-style evaluation.

$$\text{In-Scope (Precision)} = \frac{\text{TP}}{\text{TP} + \text{FP}} \qquad \text{Coverage (Recall)} = \frac{\text{TP}}{\text{TP} + \text{FN}}$$

$$\text{F1} = \frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}$$

## Stage B – Qualitative Gap analysis

This stage serves as the interpretive complement to Stage A's quantitative evaluation. While Stage A measures *how much* of the production system is captured by each source, Stage B focuses on understanding *which* requirements were missed, *why* they were missed, and *what structural categories* are systematically absent. It operates on the unmatched story sets produced in Step 4 of Stage A and analyses them through four independent steps, each addressing a progressively deeper diagnostic question about the nature of the gaps. These steps collectively provide a structured explanation of coverage deficiencies and are summarised below.

**Step 1: Blind Spot Analysis.** This step identifies where coverage gaps exist by examining production (PROD) stories that were not matched by candidate sets. These unmatched stories are grouped by functional area (epics) to distinguish between scattered gaps – where coverage exists but is incomplete – and concentrated gaps, where entire functional areas are missing. This helps separate minor omissions from fundamental misunderstandings of system scope.

**Step 2: FP Classification.** This step reassesses unmatched candidate stories (False Positives) to determine whether they are truly incorrect or simply outside current production scope. Stories are classified into three categories: Aspirational (valid but not yet implemented), Over-generated (irrelevant or unnecessary), and Future scope (plausible extensions). This classification refines the interpretation of precision by recognising that not all unmatched stories are noise.

**Step 3: BRD Cross-reference.** In this step, each section undergoes a review to identify missing or under-represented requirements. The analysis highlights role gaps (missing actors), requirement gaps (unstated functionality), and code-only features (implemented behaviour not documented in the BRD), providing a deeper understanding of specification completeness.

**Step 4: Gold Standard Synthesis.** In the final step, findings from all previous analyses are combined to construct a comprehensive "gold standard" backlog. This backlog includes production-derived users stories as a baseline reference set, supplemented with missing requirements identified in earlier steps and enriched descriptions where applicable. Each story is tagged based on its origin (e.g., PROD, BRD gap, inferred), ensuring full traceability and enabling a complete and validated representation of system requirements.

## 5 Experiments and Results

To evaluate the proposed methodology[2], three industry projects were selected in which the participating practitioners, who are also the authors, were directly involved: (i) an E-Commerce platform, (ii) a Library Management System (LMS), and (iii) a wellness and cosmetic beauty application developed by Trawelli Pty Ltd. For each project, three datasets were established: INITIAL, comprising analyst-authored user stories derived from the original Business Requirements Document (BRD); PROD, representing the final implemented functionality; and LLM, comprising user stories generated using the proposed methodology.

While the INITIAL dataset was obtained from project artefacts, the PROD dataset was reconstructed because no single consolidated source existed and requirements had evolved throughout development. Reconstruction was performed by industry practitioners using backlog artefacts, product documentation, domain knowledge, and, where necessary, reverse engineering from the implemented systems. The reconstructed user stories were subsequently validated to ensure consistency of functional intent.

The LLM dataset was generated using Claude Sonnet 4.6 (web) in a zero-shot configuration, relying solely on the initial BRD. Consequently, both the analyst-authored and LLM-generated user stories were derived from the same source requirements, enabling a controlled comparison. Overall, two-thirds of the evaluation dataset originated from industrial artefacts, while one-third was generated under controlled LLM conditions.

[2] GitHub Repository: `https://github.com/VinayKabadi/Cross-Pollination`

The study evaluates the completeness of business analyst (BA) authored and LLM-generated user stories by benchmarking them against the PROD dataset, which serves as the ground truth. The INITIAL user stories represent the business analyst's initial interpretation of the Business Requirements Document (BRD), while the LLM outputs provide an independent, model-driven perspective. Experiments are conducted across all three projects, evaluating user stories against the ten System Capability Dimensions to identify requirement gaps, followed by a comparative assessment of BA (Business Analyst) and LLM performance relative to the production baseline.

**RQ 1: To what extent are LLM-generated user stories complete when benchmarked against production user stories?**

**Table 3** E-Commerce: Comparison of BA and LLM user stories against PROD.

| Metric | INITIAL (BA) vs PROD | LLM vs PROD | LEADER |
|---|---|---|---|
| *User Stories* | 47 vs 122 | 258 vs 122 | – |
| In-Scope (Precision) | 97.9% | 46.5% | BA |
| Coverage (Recall) | 37.7% | 98.4% | LLM |
| F1 | 54.4% | 63.2% | LLM |

**Table 4** LMS (Library Mgmt System): Comparison of BA and LLM user stories against PROD.

| Metric | INITIAL (BA) vs PROD | LLM vs PROD | LEADER |
|---|---|---|---|
| *User Stories* | 47 vs 110 | 224 vs 110 | – |
| In-Scope (Precision) | 93.6% | 46.4% | BA |
| Coverage (Recall) | 40.0% | 94.5% | LLM |
| F1 | 56.1% | 62.3% | LLM |

**Table 5** Wellness app (Trawelli): Comparison of BA and LLM user stories against PROD.

| Metric | INITIAL (BA) vs PROD | LLM vs PROD | LEADER |
|---|---|---|---|
| *User Stories* | 160 vs 220 | 222 vs 220 | – |
| In-Scope (Precision) | 100.0% | 78.8% | BA |
| Coverage (Recall) | 72.7% | 79.5% | LLM |
| F1 | 84.2% | 79.2% | BA |

Across all three projects, BA-generated stories maintain very high rate for being in scope with a high precision range of 93.6%–100%, indicating that most of their stories are directly relevant to production. In contrast, LLM-generated user stories achieve lower precision scores, ranging from 46.4% to 78.8%, reflecting the generation of additional stories that do not map directly to implemented functionality. This suggests that while LLMs significantly expand coverage, they also introduce a higher proportion of exploratory requirements which, might be relevant, fall outside the scope of production and may be considered as noise.

But LLM-generated user stories consistently achieve significantly higher coverage (recall) compared to analyst-authored (BA) stories, indicating a stronger ability to capture the full scope of production functionality. In the E-Commerce (refer to Table 3), LLM recall reaches 98.4% compared to 37.7% for BA, while for LMS (refer to Table 4), it achieves 94.5% versus 40.0%. A similar pattern is observed for the Wellness App (Trawelli) (refer to Table 5), where LLM recall (79.5%) exceeds BA recall (72.7%). This demonstrates that LLMs are highly effective in identifying missing requirements and approximating production-level completeness.

When considering the F1 score, which captures the trade-off between precision and recall, LLMs outperform BA in two of the three domains (E-Commerce: 63.2% vs 54.4%, LMS: 62.3% vs 56.1%), indicating a better overall balance between completeness and relevance. In the dataset from Trawelli, BA achieves a slightly higher F1 score (84.2% vs 79.2%), primarily due to near-perfect precision, though at the cost of lower coverage. Trawelli results differ because the development scope was tightly controlled, with no changes accepted into the current release. Additional or emerging requirements were deferred to next development stages, resulting in BA outputs that closely align with the implemented scope (precision of 100%) but exclude future-stage requirements, leading to lower overall coverage (72.7%).

Overall, the results indicate that LLM-generated user stories provide substantially higher completeness relative to production systems, making them effective for uncovering missing requirements. However, this completeness is achieved by generating a broader set of stories, requiring further filtering or validation to ensure precision or to identify the noise.

**RQ 2: What qualitative mechanisms enable LLMs to generate comprehensive user stories from Business Requirements Documents (BRD)**

The results presented in Table 6 reveal that LLM-generated stories identify substantially more requirement gaps than analyst-authored stories across all ten dimensions and all three evaluation domains. In aggregate, the BA identified 40, 34 and 38 gaps across E-Commerce, LMS and Trawelli respectively, while the LLM contributed an additional (+) 84, 79 and 78 gaps beyond those identified by the BA, an aggregate gap discovery ratio of approximately 3:1 in favour of LLM generation across all domains. These results confirm the central hypothesis of this research: LLMs do not simply generate more requirements, they recover a class of requirements that were not identified during elicitation from the same BRD.

**Table 6** Comparison of gaps identified by BA and LLM across three domains.

| Dimension | E-COMMERCE | | LMS | | TRAWELLI | |
|---|---|---|---|---|---|---|
| | BA | LLM | BA | LLM | BA | LLM |
| D01: Actor Completeness | 5 | +2 | 4 | +3 | 4 | +1 |
| D02: Workflow Completeness | 14 | +9 | 12 | +7 | 14 | +8 |
| D03: Data Completeness | 9 | +4 | 7 | +5 | 8 | +5 |
| D04: Business Rules | 3 | +13 | 0 | +9 | 2 | +9 |
| D05: State Machine | 5 | +21 | 5 | +17 | 3 | +19 |
| D06: Exception Handling | 1 | +6 | 0 | +7 | 0 | +7 |
| D07: Validation | 0 | +8 | 0 | +6 | 0 | +5 |
| D08: Notification Events | 3 | +8 | 6 | +7 | 4 | +6 |
| D09: Background Jobs | 0 | +9 | 0 | +10 | 2 | +11 |
| D10: Onboarding/Offboarding | 0 | +4 | 0 | +8 | 1 | +7 |
| **TOTALS** | **40** | **+84** | **34** | **+79** | **38** | **+78** |

The results indicate that business analysts primarily capture requirements explicitly documented in the BRD, particularly Actors (D01), Workflows (D02), and Data (D03), which are typically articulated by stakeholders during elicitation. In contrast, the largest improvements achieved by Cross-Pollination occur in dimensions that are often implicit within Business Requirements, including business rules, state transitions, validation constraints, exception handling, background processes, and onboarding. These aspects are rarely documented as standalone requirements and instead emerge from the interactions between actors, workflows, and business context. The findings therefore suggest that LLM-assisted reasoning complements human elicitation by systematically inferring operational behaviours and constraints required for production-ready systems rather than simply generating additional user stories.

The results also suggest that Actors (D01) and Workflows (D02) function as foundational dimensions from which many other requirements emerge. Business rules, validations, exception paths, and background processes are typically associated with specific actors performing defined workflows. Consequently, omissions in these dimensions can propagate across multiple dependent capabilities, whereas more complete actor and workflow definitions provide a stronger foundation for identifying implicit requirements. Although this cascading relationship requires further empirical validation, it offers a plausible explanation for the consistently higher completeness achieved by Cross-Pollination.

Across all three industry projects, despite differences in domain and system complexity, the same structural pattern was observed. These findings suggest that business analysts and LLMs should be viewed as complementary rather than competing approaches. Analysts contribute stakeholder understanding and domain expertise, while LLMs systematically expand requirement coverage by identifying implicit functional requirements. Together, they suggest a more comprehensive foundation for production-ready functional specifications than either approach in isolation.

**RQ3: What gaps exist between analyst-authored and production user stories, and to what extent can LLMs reduce these gaps?**

The results reveal a consistent gap between analyst-authored (INITIAL) and production (PROD) user stories, primarily arising from missing requirements in structurally underspecified areas. While BA outputs provide strong coverage of explicit elements such as actors, primary workflows, and data entities, they consistently under-represent business rules, state transitions, validation, exception handling, background jobs, and onboarding processes, all of which are essential for production-ready systems.

LLM-generated user stories substantially reduce these gaps by identifying implicit functional requirements across all System Capability Dimensions. As demonstrated in RQ1, this leads to consistently higher recall, particularly in dimensions that are sparsely represented in BA outputs, indicating that LLMs are effective at uncovering missing functional capabilities beyond those explicitly documented in the BRD. However, this improvement is accompanied by lower precision as some generated requirements represent plausible but non-implemented functionality. Such user stories should be treated as candidates requiring validation by business analysts and stakeholders before incorporation into the product backlog.

Overall, the findings indicate that LLMs substantially reduce the gap between analyst-authored and production user stories by improving functional completeness, while human review remains essential to ensure alignment with stakeholder intent and production scope.

## Summary of Key Findings and Results

**RQ1 – Completeness of LLM-generated user stories.** LLM-generated user stories achieve higher completeness than analyst-authored stories, with recall ranging from 79.5%–98.4% compared with 37.7%–72.7% for BA. However, this increased coverage is accompanied by lower precision (46.4%–78.8% versus 93.6%–100%), due to additional plausible but non-production requirements.

**RQ2 – Mechanisms enabling comprehensive user story generation.** Cross-Pollination improves requirement discovery by combining structured gap analysis, contextual reasoning, and LLM domain knowledge to identify implicit requirements, particularly business rules, validations, exceptions, and operational workflows that are frequently under-represented in BA-authored user stories.

**RQ3 – Gap reduction between analyst-authored and production user stories.** Cross-Pollination reduces the gap between analyst-authored and production user stories by recovering systematically omitted functional requirements. However, human validation remains necessary to ensure alignment with stakeholder intent and production scope.

**Overall Finding.** LLMs complement rather than replace analysts by improving requirement completeness, while analysts provide the judgement required to maintain precision and relevance.

## 6 Threats to Validity

The study relied exclusively on the Claude Sonnet 4.6 web interface, selected based on the industry practitioners' experience at the time of the research, which may limit generalisability. For API-based replication, the closest equivalent configuration, based on Anthropic guidance, is a temperature of 0.2, a maximum output of 16,000 tokens, and a 200,000-token context window. The evaluation employed zero-shot prompting; however, evolving model versions may affect exact reproducibility. Furthermore, LLM non-determinism and hallucination may influence the generation of plausible but non-aligned requirements.Such behaviour may contribute to reduced precision and functionalities outside the intended scope.

The methodology assumes that the BRD reasonably reflects stakeholder intent. Similar to QFD, where outcomes depend on the quality of the Voice of the Customer (VoC), Cross-Pollination relies on the available requirements context while using domain knowledge to complement missing information. Ambiguous inputs may result in gaps being identified against an incorrect baseline or generate requirements beyond the intended scope. Furthermore, although designed as domain-agnostic, its applicability may vary across domains with different documentation practices, terminology, and regulatory contexts, and the curated datasets may not capture the full diversity of real-world requirements.

The evaluation involves human judgement in validating requirements, reviewing outputs, and constructing ground truth, which may introduce reviewer bias. Although structured validation procedures and source classification help mitigate this risk, expert review remains necessary before incorporating generated requirements into production backlogs.

Finally, the similarity threshold used for automated user story matching was selected heuristically and reviewed by industry practitioners rather than empirically optimised. Different thresholds may influence precision, recall, and overall evaluation outcomes; therefore, sensitivity analysis is required to further assess its impact.

## 7 Future Work

An open question is whether LLM outputs reflect genuine reasoning or statistical pattern matching, particularly in domains that are well represented in public training data. Evaluating the methodology across niche and proprietary domains with limited exposure would help assess its robustness and generalisation capability.

Further investigation should evaluate the Cross-Pollination methodology using multiple state-of-the-art LLMs (e.g., GPT, Gemini, Llama, and Mistral) and alternative prompting strategies (e.g., one-shot and few-shot) to assess its sensitivity to different models and prompting configurations. Exploring domain-specific fine-tuning, human-in-the-loop refinement, and structured requirement representations could further improve the robustness, accuracy, and broader applicability of the approach.

Additional evaluation should examine the sensitivity of user story matching thresholds by analysing their impact on precision, recall, and overall matching performance across diverse datasets. Standardised evaluation frameworks could further enhance reproducibility and facilitate comparison across different approaches.

A further research direction is to investigate the completeness–precision trade-off in practical settings by measuring practitioner validation effort, acceptance rates of LLM-generated requirements, and effective strategies for integrating LLM-assisted requirement generation into existing requirements engineering workflows.

## 8 Conclusion

This study aimed to improve the identification of incompleteness in Business Requirements Document (BRD) and support the derivation of more complete functional specifications through the proposed Cross-Pollination methodology. By benchmarking analyst-authored and LLM-generated user stories against production-derived ground truth, the study presents a reproducible, domain-agnostic framework for generating and evaluating user stories, enabling measurable assessment of requirement coverage.

While Cross-Pollination improves requirement completeness, generated requirements should be treated as candidate requirements rather than confirmed stakeholder needs. The methodology augments, rather than replaces, business analysts by combining human expertise with LLM-assisted discovery. Organisations can apply Cross-Pollination after establishing an initial BRD, where analysts validate, prioritise, and integrate relevant requirements into existing workflows.

Across all evaluated domains, analyst-authored stories demonstrate high precision but limited recall, capturing explicitly documented requirements while missing functionality implemented in production systems. In contrast, LLM-generated stories achieve higher recall by identifying implicit and omitted requirements, although with reduced precision due to plausible but non-implemented or out-of-scope scenarios. This completeness–precision trade-off positions LLMs as requirement discovery assistants rather than autonomous elicitation tools, requiring additional validation effort.

Overall, the findings demonstrate the value of a human–LLM collaborative approach to requirements engineering, where analysts provide contextual judgement and validation while LLMs support broader requirement exploration. Cross-Pollination operationalises this collaboration through structured gap analysis and traceable evaluation, supporting more complete and production-aligned functional specifications.

## Generative AI Declaration

Generative AI tools were used to improve the readability and language of this manuscript. All AI-generated content was reviewed, verified, and edited by the authors, who take full responsibility for the final published work.

## Abstract

Modern automotive infotainment systems sit at the center of the vehicle's digital ecosystem, yet their validation still relies heavily on manual testing, a process that is time-consuming, expensive, and increasingly incompatible with the pace of agile release cycles and over-the-air software updates. Traditional scripted automation offers only a partial remedy, as it creates tight coupling between test logic and implementation details, producing brittle suites with high maintenance overhead. Existing LLM-driven testing frameworks predominantly target web or mobile applications, while employing single-agent or dual-agent architectures that overload one or two models with perception, planning, action selection, and validation simultaneously, making them prone to hallucination-style failures and unproductive exploration loops when faced with the complexity of automotive infotainment interfaces. In this paper, we present ARIA (Autonomous Real-time Infotainment Assessment), a multi-agent framework that leverages Large Language Models to autonomously execute end-to-end test scenarios on Android-based infotainment systems through visual interface interaction, orchestrating a closed-loop pipeline of four specialized agents per interaction step, complemented by a dedicated report-generation stage. From single-sentence natural-language scenario descriptions alone, each specifying a navigation path, an action to perform, and an expected outcome to verify, it autonomously executes the corresponding interactions on the infotainment system and produces structured reports, reproducible action scripts, and visual evidence for each step. ARIA was evaluated in an industrial setting on a physical test environment running the Android-based infotainment system of a car manufacturer, executing 30 scenarios spanning diverse system functionalities. Of the 30 scenarios, 28 (93.3%) completed the full multi-agent pipeline and produced a verdict, while 2 terminated prematurely with execution errors. Of the 28 completed scenarios, 20 (71.4%) matched the ground truth. ARIA detected all 5 known functional defects in the test setup, so no genuine fault was ever passed as working; the 8 false positives among completed scenarios are attributable to LLM navigation and image-interpretation limitations and to unsupported interaction gestures. These findings demonstrate that multi-agent LLM architectures can autonomously execute end-to-end infotainment test scenarios in an industrial setting, while also exposing the precision challenges that a low false-positive tolerance imposes. A single-agent baseline ablation on the same scenarios confirms the value of the multi-agent decomposition: on the first pass, before revisitation with a stronger model masks the difference, the single agent produces a substantially higher false positive rate (72.0% versus 52.6%) due to the conflation of navigational difficulty with system failure. We separately report first-pass and post-revisitation results and quantify token consumption, LLM-call counts, and monetary cost per scenario for both pipelines, and repeated execution of a representative subset of scenarios confirms that outcome stability correlates with scenario complexity, with fault detection remaining perfectly consistent across runs, indicating a path toward integrating visual test execution into continuous integration pipelines.

## 1 Introduction

Modern automotive infotainment systems have evolved into highly complex software platforms integrating navigation, media, connectivity, vehicle settings, and driver-assistance interfaces into a single cohesive experience [6, 8]. As the primary interface between the driver and the vehicle's digital capabilities, the infotainment system sits at the center of an ecosystem of individually developed electronic control units [12, 1], so its failures carry disproportionate consequences, directly undermining the user experience and customer trust, particularly for premium manufacturers [12, 28]. Because these systems are assembled from the contributions of many teams responsible for different subsystems and UI components, ensuring they function correctly together makes end-to-end testing essential [24].

This integration validation has traditionally relied heavily on manual testing: human testers follow scripted procedures on physical or virtual hardware, interacting with the system as an end user would and verifying each step [24, 17]. While thorough, this is time-consuming and expensive, and defects that could have been caught early are instead discovered late, when remediation is costlier [16]. The problem is amplified by over-the-air updates and agile release cycles, where each iteration demands regression testing that scales poorly with manual execution, motivating the "shift-left" principle of moving quality assurance earlier in the development life cycle [16, 18]. This burden demands a departure from traditional approaches toward intelligent, adaptive testing frameworks capable of reasoning about the system as an end user would [5, 13].

This work explores the use of Large Language Models (LLMs) to automate the execution of these manual test scripts. Rather than encoding test logic against internal APIs or system architecture, which creates tight coupling and fragile tests, the proposed system interacts with the infotainment UI exclusively through its visual interface, like a human user would [9]. By interpreting screenshots and navigating from high-level task descriptions, the LLM-powered agents remain decoupled from the underlying software architecture, making the approach resilient to internal refactoring and applicable across system versions. The system employs a multi-agent architecture in which specialized agents collaborate on each scenario, handling action planning, UI element identification, interaction validation, and outcome evaluation, mirroring the structured reasoning a human tester would apply [19, 7]. As the testing community increasingly turns to AI-driven automation to keep pace with continuous integration, this industrial context motivates frameworks that execute end-to-end scenarios autonomously, with the long-term vision of integrating visual test execution into regression pipelines [5, 18, 20].

To address this growing need, we propose ARIA (Autonomous Real-time Infotainment Assessment), a novel multi-agent framework for the automated execution and validation of end-to-end test scenarios on Android-based automotive infotainment systems. The main contributions of this work are as follows:

**(1)** A multi-agent architecture comprising four specialized LLM-powered agents that separates perceptual reasoning from implementation-level interaction, enabling autonomous navigation and evaluation of infotainment UIs through visual interface interaction alone.

**(2)** A natural-language-driven execution pipeline that accepts single-sentence scenario descriptions as input, enabling organizations to ingest and execute existing manual test scripts without modification or formalization.

(3) An industrial evaluation on a physical infotainment test environment, with 28 of 30 scenarios completing the pipeline and all 5 known functional defects detected, accompanied by a systematic root cause analysis that attributes the non-correct outcomes to LLM navigation and image-interpretation limitations and to unsupported gestures in the device interface.
(4) A single-agent baseline ablation demonstrating that the multi-agent decomposition reduces the first-pass false positive rate from 72.0% to 52.6% on the same scenario set, isolating the contribution of the architecture from that of the underlying model.
(5) A detailed accounting of token consumption, LLM-call counts, and monetary cost per scenario for both pipelines, with a clear separation of first-pass from post-revisitation results, together with a repeated-execution experiment that quantifies run-to-run variance and confirms that outcome stability is high for scenarios of moderate complexity, with fault detection remaining perfectly consistent across runs.

# 2 ARIA

## 2.1 System Architecture

ARIA is structured as a layered system with three principal components. The **LLM orchestration layer** sits at the top, providing a standardized interface through which any supported model provider can be integrated without modifying the logic below it, and managing agent sessions and model interactions. The **execution layer**, between the LLM services and the device, implements the closed-loop multi-agent pipeline: it coordinates the four specialized agents, manages scenario state, enforces step limits and retry policies, and persists execution artifacts. The **device interface layer**, at the bottom, encapsulates all communication with the system under test through Appium, translating high-level interaction commands into coordinate-based device primitives and capturing UI state as screenshots and XML element hierarchies. This separation, reflecting architectural principles identified in the literature, ensures that the LLM provider, the agent orchestration logic, and the device communication protocol can each be changed independently, and that the framework can be adapted to a different infotainment platform by modifying only the device interface layer (Figure 1).

### 2.1.1 LLM Service Abstraction

Each agent is instantiated as an independent session with its own system prompt, model assignment, and message history, so that agents cannot access or be influenced by one another's context, enforcing the information boundaries discussed in Section 4. The orchestration layer supports heterogeneous, plug-and-play model selection across agents. Communication follows a structured request–response pattern: prompts are multimodal messages combining text, files, and images, and responses are constrained to predefined JSON schemas through prompt engineering and post-response verification. When a response fails to conform, the layer automatically re-prompts the agent, tolerating up to five consecutive formatting failures before escalating an error, ensuring downstream agents always receive well-formed input.

### 2.1.2 Multi-Agent Execution Pipeline

The core of ARIA's operation is a closed-loop pipeline that iterates through four specialized agents per interaction step (Figure 2). Given a scenario described in natural language, the pipeline proceeds as follows.

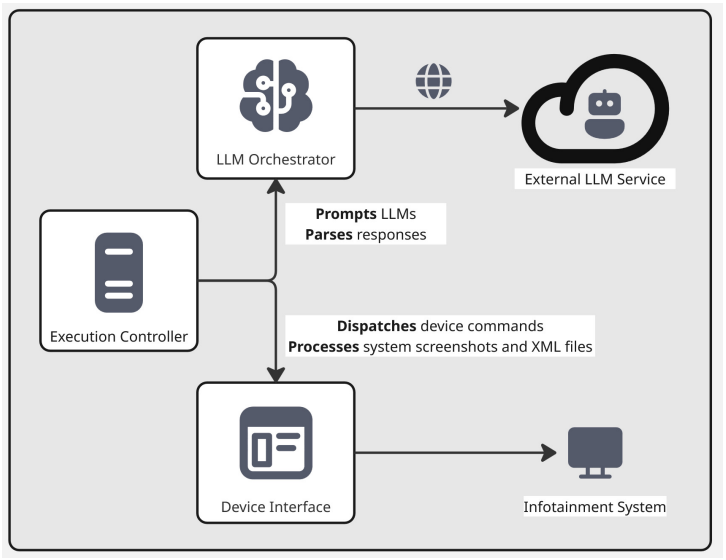

**Figure 1** ARIA's architecture layers diagram.

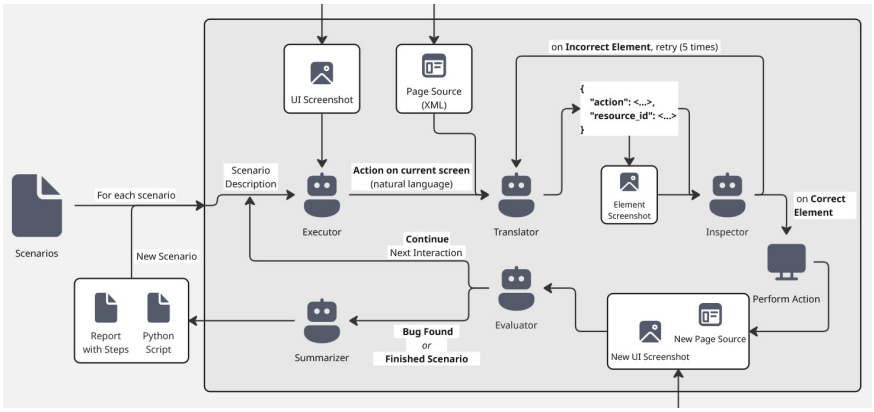

**Figure 2** ARIA's standard execution diagram.

The **Executor** agent receives the current screenshot and the scenario description; on its first invocation it establishes the high-level task, and on subsequent invocations it determines the next action from the updated screenshot. It is instructed to simulate human end-user behavior and operates without access to the XML element hierarchy, internal API specifications, or system documentation, basing its decisions solely on what is visually apparent on screen.

The **Translator** agent receives the high-level action together with the filtered XML page source, identifies the specific UI element that corresponds to the intended action, and produces a structured JSON object with the target's resource identifier, action type, and parameters; the system then resolves the element's bounding coordinates and interaction point. If the resource identifier does not exist in the current page source, the agent is re-prompted with an error message, up to a maximum of five retries before the scenario is terminated with an error status.

The **Inspector** agent receives the intended action and a cropped image of the screen region surrounding the element selected by the Translator, and returns a binary judgment (pass or fail) on whether the element appears semantically appropriate for the action. If the element is rejected, the Translator is re-prompted to select an alternative, providing a safeguard against incorrect element mappings before any interaction reaches the device.

Once the Inspector approves the element, the interaction is executed on the device and, after a fixed settling delay, a new screenshot is presented to the **Evaluator** agent, which compares the previous state, the action taken, and the resulting state and classifies behavior into one of three categories: *Correct* (the expected change occurred and the pipeline loops back to the Executor), *Finished* (the objective has been achieved and the scenario concludes successfully), or *Incorrect* (an unexpected behavior indicates a potential fault and the scenario terminates). A configurable maximum step limit terminates the scenario with an error status if the objective is not reached.

An additional agent, the **Summarizer**, operates outside the main loop: after each scenario completes, regardless of outcome, it turns the full execution log into a structured JSON report containing the scenario description, the overall result (`OK`, `BUG`, or `ERROR`), an optional failure description, and a chronological list of steps, persisted to disk and reflected in the run manifest, providing both human-readable documentation and machine-parseable records.

### 2.1.3 Device Interface

Communication with the system under test is mediated through Appium, an open-source mobile automation framework [4]: ARIA connects to the infotainment unit as a remote Android device over a WebDriver-compatible API, with device discovery performed automatically via ADB [10]. The interface provides tap, long-tap, swipe, and text-input primitives, each parameterized by screen coordinates; text input bypasses the on-screen keyboard by injecting characters directly through ADB shell commands. A fixed three-second delay follows each interaction to let the system settle, and every executed interaction is recorded with its type, coordinates, and parameters, enabling automatic generation of standalone replay scripts.

At each decision point the interface captures two complementary representations of UI state: a screenshot, and the XML element hierarchy from Appium's page source API. The raw XML is parsed and filtered to the actionable nodes that possess both a resource identifier and bounding coordinates, retaining a minimal attribute set (`bounds`, `text`, `content-desc`, `resource-id`, `clickable`, `checkable`) and further distilled into a compact `resource-id/bounds` CSV for coordinate lookup. Together with the screenshot, these constitute the device-state representation distributed to the agents at each step.

## 2.2 Execution Modes

ARIA supports four execution modes, each addressing a different concern of the validation process.

### 2.2.1 Standard Execution

Standard execution processes scenarios sequentially through the full pipeline. Each scenario begins from the home screen and runs the closed loop until it completes, a fault is detected, or an unrecoverable error occurs; a run manifest with a checkpoint index records per-scenario status and enables resumption after interruptions. The system returns to the home screen between scenarios, and any scenario that ends in `BUG` or `ERROR` is automatically queued for re-visitation.

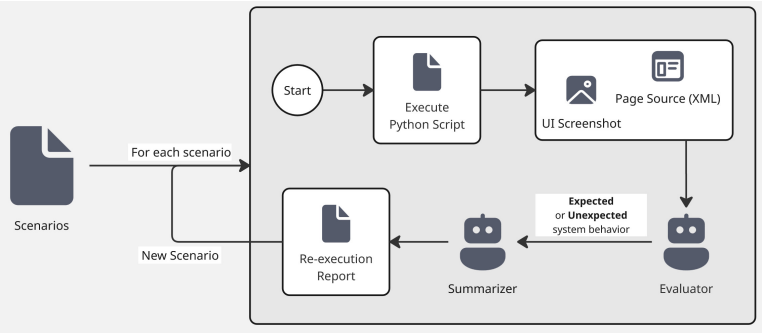

**Figure 3** Short-Circuit Replay mode's execution diagram.

### 2.2.2 Short-Circuit Replay

Short-circuit replay enables deterministic re-evaluation without the cost of the full pipeline: previously generated action scripts are replayed on the device as sub-processes, bypassing the Executor, Translator, and Inspector, and a standalone Evaluator classifies the final state against the scenario description. If the same interactions on an updated software version yield a different final state, the discrepancy is flagged, providing an efficient mechanism for detecting regressions introduced between software iterations (Figure 3).

### 2.2.3 Re-visitation with Stronger Models

Re-visitation targets scenarios that previously concluded with `BUG`, `ERROR`, or `PENDING` status (which happens when the program crashes during the execution of a scenario), re-executing them through the full pipeline with a more capable model. Motivated by the observation that execution failures are often model limitations (incorrect element selections or misinterpreted screenshots) rather than genuine defects, it provides a second evaluation that reduces false positives and improves confidence in results that persist across both runs.

### 2.2.4 Scenario Transformation

Scenario transformation converts existing manual test cases into natural-language scenario descriptions without a device connection: a generation agent reformulates batches of manual test definitions into the navigation–action–verification format expected by the Executor, letting organizations feed existing test repositories into the framework without manual re-authoring.

## 2.3 Simulating Human User Behavior

A central design principle is that the Executor reasons about the system as a human user would, achieved through deliberate information restriction: it receives only the current screenshot and the natural-language scenario, with no access to the XML hierarchy, internal APIs, or documentation, forcing decisions based on visual cues, spatial layout, and interface conventions. The separation between the Executor (perceptual level) and the Translator (implementation level, resolving intentions into coordinates via the XML) prevents implementation knowledge from contaminating the user-centric perspective. As a result, the agent can encounter the same usability issues, navigational confusion, or misleading interface elements that a real user would, increasing the validity of the automated execution.

## 2.4 Limitations

Despite its capabilities, ARIA's current implementation is subject to several limitations that must be considered when interpreting results.

**Model Limitations.** Agents may reference elements that do not exist on the current screen, misidentify a visible element's function, or propose unavailable actions. The Inspector and the Translator's identifier verification mitigate this, but Executor-level mistakes (such as believing a menu is open when it is not) propagate through the pipeline before they can be caught, sometimes causing correct system behavior to be classified as an error and necessitating the re-visitation mechanism.

**Execution Speed.** Each step requires sequential invocations of four agents, each a round trip to an external LLM service, compounded by the fixed post-interaction settling delays. Per-scenario times are therefore substantially longer than scripted automation, acceptable for nightly regression runs but precluding rapid in-loop feedback during active development.

**Token Consumption.** Transmitting screenshots at every decision point yields high per-scenario token consumption, translating directly into operational cost that may constrain the scale and frequency of test campaigns.

**Interaction Pattern Constraints.** The interface supports tap, long-tap, swipe, and text input; compound gestures such as long-press-and-drag or coordinated swipes between element positions, and interactions that depend on detecting rapid transient UI changes, are not currently supported, so scenarios requiring them must be excluded or simplified.

# 3 Evaluation

## 3.1 Experimental Design

The evaluation of ARIA was designed as an industrial case study conducted on a physical infotainment test environment running a baseline software version with known characteristics. Following the structure of comparable industrial evaluations in LLM-based test automation, the study is organized around four research questions, each targeting a distinct aspect of the framework's design, capability, and practical applicability.

**RQ1.** How can LLM-powered multi-agent architectures be designed to autonomously execute end-to-end test scenarios on automotive infotainment systems through visual interface interaction?

**RQ2.** To what extent can a vision-based, natural-language-driven testing framework reliably detect genuine system faults while minimizing false positives in an industrial infotainment validation environment?

**RQ3.** What are the primary failure modes, limitations, and architectural trade-offs involved in delegating GUI test execution to LLM agents operating through coordinate-based interaction primitives?

**RQ4.** What are the practical challenges and prerequisites for integrating LLM-based test execution frameworks into existing automotive validation workflows and continuous integration pipelines?

## 3.2 Experimental Setup

The test setup operates as a standalone unit disconnected from a vehicle, so functionalities dependent on vehicle state, sensor input, or active network services were unavailable. Core functionalities were operational except for the climate control subsystem, which was purposefully disabled to serve as a benchmark for expected faulty behavior. ARIA connected to the unit remotely via Appium, with device discovery handled through ADB.

Thirty test scenarios were selected, spanning home screen navigation, widget interaction, application launching, search operations, settings manipulation, climate controls, connectivity toggles, status bar interactions, and deep menu traversal. Scenarios requiring external dependencies (active phone connections, internet access, radio reception, navigation services, or specific account configurations) or with ambiguous verification criteria were excluded.

Execution used the standard mode with `claude-sonnet-4.6` as the default model [3], a maximum of ten steps per scenario, and five translation retries. Scenarios terminating with BUG or ERROR status were automatically revisited using `claude-opus-4.6` [2], with the system returning to the home screen between scenarios to ensure a consistent starting state.

### Model Selection

To justify the choice of LLM models, a preliminary validation study was conducted using a representative subset of six scenarios selected from the full evaluation set, spanning scenarios of varying complexity including simple status bar checks, connectivity toggles, settings navigation, application search, and a known system defect. Five candidate models were evaluated: `claude-sonnet-4.6`, `claude-opus-4.6`, `gpt-4.1`, `gpt-5.3-codex`, and `gpt-5.4`. All models were evaluated under identical conditions using the same multi-agent pipeline configuration. The ground truth for these scenarios was established in advance: five scenarios expected to classify as OK and one expected to classify as BUG. Table 1 summarizes the results.

**Table 1** Model selection validation results across 6 representative scenarios. FP = false positives among completed scenarios; FN = false negatives among completed scenarios (the known defect completed but misclassified as OK). Cost estimated from premium request counts. * GPT-4.1 uses a separate billing model and is considered free.

| Model | Completed | Correct | FP | FN | Cost (est.) |
|---|---|---|---|---|---|
| `claude-sonnet-4.6` | 4/6 | 4/4 | 0 | 0 | $8.28 |
| `claude-opus-4.6` | 5/6 | 4/5 | 1 | 0 | $28.56 |
| `gpt-4.1` | 1/6 | 1/1 | 0 | 0 | $0.00* |
| `gpt-5.3-codex` | 0/6 | – | — | – | $4.24 |
| `gpt-5.4` | 2/6 | 1/2 | 1 | 0 | $4.08 |

The OpenAI model family exhibited substantially lower pipeline completion. `gpt-5.3-codex` completed none of the six scenarios, terminating with errors due to persistent failures in producing JSON conforming to the required agent schemas, while `gpt-4.1` and `gpt-5.4` completed only one-sixth and one-third respectively, in both cases error-terminating on the buggy scenario itself, so neither ever produced a verdict on the known defect, struggling with the structured multi-turn interaction the Translator requires.

Among the Anthropic models, `claude-sonnet-4.6` achieved perfect classification on completed scenarios (4/4, zero false positives) at the lowest cost ($8.28 across 207 LLM calls), whereas `claude-opus-4.6` completed one additional scenario (5/6) but introduced a false positive at roughly 3.4× the cost (238 calls, $28.56); both correctly detected the known defect. These results motivated selecting `claude-sonnet-4.6` as the primary execution model for its accuracy, cost, and reliability trade-off, and `claude-opus-4.6` as the revisitation model for its higher completion rate, acceptable since revisitation applies only to the subset needing re-execution. Open-weight models were not evaluated, as their visual reasoning at the time fell short of the multimodal demands of reliable element identification and behavioral classification.

## 3.3 Results

To establish ground truth, manual inspection was performed on each of the 30 evaluated scenarios after execution, determining the expected outcome from the known state of the infotainment software and the capabilities available in the test environment, classifying each result as a correct assessment or a misclassification, and documenting the root cause of any discrepancy.

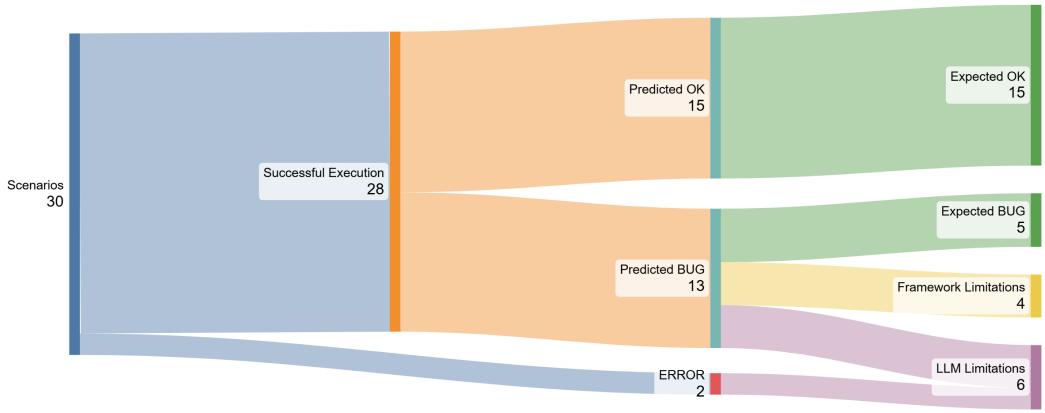

**Figure 4** Outcome distribution across 30 evaluated scenarios.

The outcome distribution across all thirty scenarios is depicted in Figure 4. All figures reported in this subsection are post-revisitation; the separation between first-pass and post-revisitation outcomes is analysed in Section 3.4. Under our revisitation protocol, a scenario that produced a BUG verdict on the first pass retains that verdict when the subsequent revisitation with the stronger model yields only an execution error, since revisitation is intended to resolve uncertain results rather than to discard verdicts already obtained. Of the 30 scenarios, 28 completed the full multi-agent pipeline and produced a classification (93.3% completion), while the remaining 2 terminated prematurely due to execution errors; among the 28 completed, 15 were classified as OK and 13 as BUG.

Manual inspection against the ground truth revealed 15 scenarios correctly classified as OK and 5 correctly identified as genuinely faulty. The remaining 10 disagreed with the ground truth: 8 false positives, classified as BUG although their expected outcome was OK,

and 2 error terminations. Their root causes split across two categories: 4 attributable to LLM limitations and 4 to framework interaction limitations, such as unsupported gestures and transient UI states.

**Table 2** Confusion matrix for fault detection (28 completed scenarios). All five genuinely faulty scenarios were detected as defects.

| | **Predicted OK** | **Predicted BUG** |
|---|---|---|
| **Expected OK** | 15 | 8 |
| **Expected BUG** | 0 | 5 |

**Table 3** Summary of evaluation metrics.

| **Metric** | **Value** |
|---|---|
| Pipeline Completion Rate | 28/30 = 93.3% |
| Fault Detection Recall | 5/5 = 100% |
| Fault Detection Precision | 5/13 = 38.5% |
| Accuracy (completed scenarios) | 20/28 = 71.4% |

## 3.4 Single-Agent Baseline

To justify the multi-agent decomposition and provide a baseline for interpreting the results, the same 30 scenarios were executed using a single-agent configuration in which a single LLM agent is responsible for all cognitive subtasks: visual perception, action planning, element identification, coordinate resolution, and outcome evaluation. Both configurations used `claude-sonnet-4.6` as the underlying model and followed the same revisitation procedure with `claude-opus-4.6`. Table 4 compares both pipelines, contrasting their first-pass and post-revisitation outcomes.

In the single-agent pipeline, one agent session alternates two turns per interaction step. In the *action turn*, the agent receives the current screenshot, the full filtered XML page source, and a resource identifier reference file, and returns a single JSON response selecting a UI element by its resource identifier, the action type (tap, swipe, or text input), and the intended interaction; an invalid identifier triggers a re-prompt with that identifier banned, analogous to the Translator's retry mechanism. In the *evaluation turn*, it receives the resulting screenshot and classifies the outcome as Finished, Correct, or Incorrect. Both turns share the same conversation context, so the full message history accumulates throughout the scenario. The deterministic coordinate lookup and device execution are shared with the multi-agent pipeline, ensuring any performance difference is attributable solely to the agent decomposition rather than to the device interface.

After revisitation, the two configurations converge to identical aggregate performance: both complete 28 of 30 scenarios, reaching 71.4% completed-scenario accuracy, 38.5% precision, and 5/5 fault-detection recall. This endpoint equivalence, however, masks a critical difference in first-pass behavior that the revisitation mechanism conceals (Table 4, Figure 5). On its initial execution with `claude-sonnet-4.6` alone, the single-agent classified 23 of 30 scenarios (76.7%) as BUG, producing 18 false positives with a precision of only 21.7% and an accuracy of 40.0%. In contrast, the multi-agent pipeline's first pass classified only 13 of 30 as BUG (43.3%) with 10 false positives, achieving 23.1% precision and 54.5% accuracy among the 22 scenarios it completed. The multi-agent pipeline thus commits far fewer false positives on

the first pass, but it also terminates more scenarios with errors (8 versus 0): rather than forcing a potentially incorrect verdict, its Translator and Inspector retry mechanisms exhaust their budget and abort, converting some would-be false positives into explicit errors that are trivially triaged. Because both pipelines use the same inexpensive first-pass model, this reduction is obtained without any increase in model tier: the multi-agent decomposition extracts more reliable verdicts from a weaker, cheaper model, reducing reliance on costly stronger-model revisitation, on which the single-agent pipeline depends far more heavily.

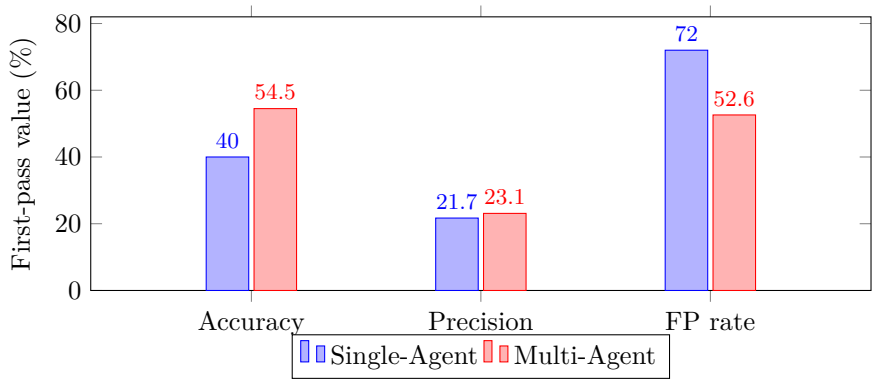

**Figure 5** First-pass performance of both pipelines under the same inexpensive `claude-sonnet-4.6` model. Higher is better for accuracy and precision; for the false-positive rate lower is better. The multi-agent decomposition substantially reduces the first-pass false-positive rate while improving accuracy, extracting more reliable verdicts from a weaker, cheaper model.

**Table 4** First-pass (`claude-sonnet-4.6`) versus post-revisitation (`claude-opus-4.6`) outcomes for both pipelines on the same 30 scenarios. Fault recall is reported over all five known defects; the two configurations converge to identical final performance but diverge sharply on the first pass.

| | Single-Agent | | Multi-Agent | |
|---|---|---|---|---|
| **Metric** | **First pass** | **Final** | **First pass** | **Final** |
| Pipeline Completion | 30/30 | 28/30 | 22/30 | 28/30 |
| Classified OK | 7 | 15 | 9 | 15 |
| Classified BUG | 23 | 13 | 13 | 13 |
| Terminated ERROR | 0 | 2 | 8 | 2 |
| True Positives | 5 | 5 | 3 | 5 |
| False Positives | 18 | 8 | 10 | 8 |
| Fault Recall | 5/5 | 5/5 | 3/5 | 5/5 |
| Accuracy (completed) | 40.0% | 71.4% | 54.5% | 71.4% |
| Precision | 21.7% | 38.5% | 23.1% | 38.5% |

Revisitation was applied to every scenario that concluded the first pass with a BUG or ERROR status. In the multi-agent pipeline, 21 scenarios were revisited and seven changed classification, all of them improvements: six were resolved to OK and one genuine defect that had error-terminated on the first pass was correctly recovered as BUG, while the remaining revisited scenarios retained their first-pass verdict. Revisitation was not strictly monotonic, as with four scenarios the stronger model regressed a first-pass BUG verdict into an execution error, and under the retention protocol described in Section 3 these keep their first-pass BUG classification, which is why they are counted among the 13 final BUG outcomes rather than as errors. In the single-agent pipeline, all 23 first-pass BUG scenarios were revisited: 8

were resolved to OK, 2 regressed to execution errors, and 13 remained classified as BUG. The heavier reliance of the single-agent pipeline on revisitation, resolving 8 of its 23 flagged scenarios, quantifies how much of its final accuracy is contributed by the stronger model rather than by its own first-pass reasoning.

The single-agent's first-pass over-reporting stems from conflating navigational difficulty with system failure: lacking structural separation, when it cannot interact with an element as expected or reaches an unplanned screen state, it cannot distinguish its own misnavigation from a genuine fault and defaults to classifying a defect. A revealing failure mode was self-contradiction between the action and evaluation turns, since the agent would correctly execute an action, then, with the full conversation context accumulated, misattribute what it had just done and conclude that the system misbehaved, a context-management failure largely absent under the stronger revisitation model. The multi-agent pipeline structurally eliminates this, as the Evaluator sees only the before and after screenshots and the action description, without the accumulated navigational history, and the Translator's retry mechanism absorbs element-identification errors, the Inspector catches incorrect mappings before interaction, and the Evaluator assesses outcomes independently of the preceding navigation. This decomposition reduces the first-pass false positive rate, defined over the non-faulty scenarios that actually produced a verdict, from 72.0% (18/25) for the single-agent pipeline to 52.6% (10/19) for the multi-agent pipeline. The two denominators differ because each counts only the expected-OK scenarios that the respective pipeline classified: the single-agent pipeline produced no first-pass errors and therefore returned a verdict on all 25 non-faulty scenarios (18 false positives and 7 true negatives), whereas the multi-agent pipeline aborted six non-faulty scenarios into explicit errors and classified only the remaining 19 (10 false positives and 9 true negatives). Far from inflating the comparison, this makes it conservative, since the scenarios the multi-agent pipeline converted into errors are precisely those most likely to have become false positives had a verdict been forced, so its rate is computed over a harder residue. The reduction thus provides meaningful mitigation against the hallucination-prone behavior that reviewers of single-agent approaches have identified as a fundamental limitation.

## 3.5 Run-to-Run Variance

To quantify the nondeterministic nature of LLM-based execution, a subset of six scenarios was selected for repeated execution, each run five times under identical conditions using `claude-sonnet-4.6`. The selection spans the full range of observed scenario complexity, from simple single-step verifications to multi-step deep menu navigations, and includes both correctly-functioning scenarios and a known system defect. Table 5 summarizes the per-scenario outcome distributions across the five runs.

**Table 5** Outcome distribution across 5 repeated runs per scenario. GT = ground truth. Avg Calls = mean ± standard deviation of LLM invocations per run.

| Scenario | GT | OK | BUG | ERR | Modal | Avg Calls |
|---|---|---|---|---|---|---|
| Status bar | OK | 5 | 0 | 0 | OK | 17.6 ± 1.4 |
| Bluetooth toggle | OK | 5 | 0 | 0 | OK | 26.2 ± 5.9 |
| System settings | OK | 4 | 0 | 1 | OK | 40.6 ± 5.0 |
| Seats app search | OK | 4 | 0 | 1 | OK | 41.6 ± 9.2 |
| Wi-Fi Access Point toggle | OK | 1 | 2 | 2 | – | 79.6 ± 5.5 |
| Language selection | BUG | 0 | 5 | 0 | BUG | 66.6 ± 18.0 |

Three of the six scenarios exhibited perfect stability, producing identical outcomes across all five runs: the status bar and Bluetooth toggle scenarios consistently classified as OK, and language selection consistently detected the known defect (BUG). Two further scenarios (system settings and the Seats app search) were mostly stable, producing the correct modal outcome in four of five runs, with a single spurious ERROR in one run each attributable to a translation retry limit being reached. The remaining scenario targeting the Wi-Fi Access Point toggle, which requires deep menu navigation through connectivity settings, was the most complex in terms of required interactions and exhibited the highest variance, with outcomes distributed across all three categories.

Across all 30 executions, 25 (83.3%) agreed with the modal result for their scenario and 24 (80.0%) matched the ground truth. Notably, fault detection was perfectly stable: the known defect was flagged in all five repetitions. The results reveal a clear correlation between scenario complexity and outcome variance, as scenarios requiring few navigation steps (one to three) were deterministic while those requiring extensive multi-step navigation (over seven) exhibited greater instability, consistent with the accumulation of stochastic decision points. Importantly, the dominant source of variance is not classification disagreement but pipeline completion: when a scenario reaches a verdict (OK or BUG), that verdict is consistent across runs with the same model, and the variance instead manifests as some runs terminating with an ERROR due to translation retry exhaustion or step limit violations, without ever producing a conflicting behavioral classification.

## 3.6 Computational Cost and Usage

Because operational cost and latency are decisive for pipeline integration, every LLM invocation was instrumented and token consumption, call counts, and monetary cost were aggregated for both pipelines. Cost is expressed in premium requests, the billing unit of the LLM service used, where each call is weighted by model (one for `claude-sonnet-4.6`, three for `claude-opus-4.6`) and converted to an estimated monetary figure at $0.04 per premium request. Cached prompt re-sends, which dominate raw input-token counts because the multimodal system prompts and prior screenshots are resubmitted at every step, are billed separately at a negligible rate and excluded from the fresh-input figures (Table 6).

**Table 6** Computational cost and usage for both pipelines over 30 scenarios, split into first-pass (`claude-sonnet-4.6`) and revisitation (`claude-opus-4.6`). Premium requests weight each call by model (Sonnet ×1, Opus ×3); estimated cost assumes $0.04 per premium request. Fresh input excludes cached prompt re-sends.

| | Multi-Agent | | | Single-Agent | | |
|---|---|---|---|---|---|---|
| **Metric** | **First** | **Revisit** | **Total** | **First** | **Revisit** | **Total** |
| LLM calls | 1,218 | 851 | 2,069 | 638 | 622 | 1,260 |
| Premium requests | 1,218 | 2,263 | 3,481 | 638 | 1,616 | 2,254 |
| Est. cost (USD) | 48.72 | 90.52 | 139.24 | 25.52 | 64.64 | 90.16 |
| Output tokens | 162.5k | 136.8k | 299.3k | 161.1k | 158.6k | 319.7k |
| Fresh input tokens | 2.89M | 2.20M | 5.09M | 2.16M | 3.33M | 5.49M |
| Cost per scenario (USD) | – | – | 4.64 | – | – | 3.01 |

The complete multi-agent run consumed 2,069 LLM calls and an estimated $139.24 across both passes, of which the first pass with `claude-sonnet-4.6` accounted for 1,218 calls ($48.72) and the revisitation pass with `claude-opus-4.6` for the remaining 851 calls ($90.52).

The revisitation pass, although covering only 21 scenarios, therefore dominates cost, both because `claude-opus-4.6` is billed at three times the per-call rate and because the hardest scenarios require the most steps. Averaged over all 30 scenarios, the whole pipeline costs approximately $4.64 per scenario; the first pass alone averages 40.6 LLM calls per scenario, ranging from 17 for a single-step status-bar check to 98 for a deep multi-step navigation, at roughly $1.62 per scenario. Wall-clock execution time, measured from scenario logs, averaged 8.4 minutes per scenario on the first pass with a median of 5.2, ranging from 1.5 to 48.7 minutes, confirming that per-scenario latency is dominated by the sequential agent round trips and the fixed three-second settling delay after each interaction, and that ARIA is suited to nightly regression runs rather than in-loop feedback.

Within a first-pass scenario, the four in-loop agents plus the summarizer are not invoked uniformly. The Translator is by far the most frequently called agent, accounting for 480 of the 1,218 first-pass calls (39.4%), because each element-identification retry and each Inspector rejection triggers an additional Translator invocation. The Executor (195 calls, 16.0%), Summarizer (193, 15.8%), Evaluator (182, 14.9%), and Inspector (168, 13.8%) are invoked in comparable proportions. This distribution indicates that element resolution, rather than high-level planning or evaluation, is the principal cost driver and the most promising target for optimization.

The single-agent baseline is markedly cheaper, consuming 1,260 calls and an estimated $90.16 in total ($25.52 first pass, $64.64 revisitation), roughly $3.01 per scenario, because it invokes a single model per turn rather than four specialized agents per step. This confirms that the multi-agent decomposition trades a higher token and monetary budget for its reduction in first-pass false positives, a trade-off that the short-circuit replay mode is designed to amortize over successive software versions by replacing the full four-agent loop with a single Evaluator invocation per scenario during regression re-runs.

## 3.7 Answers to Research Questions

**RQ1: How can LLM-powered multi-agent architectures be designed to autonomously execute end-to-end test scenarios on automotive infotainment systems through visual interface interaction?** The 93.3% pipeline completion rate demonstrates that the four-agent decomposition (Executor, Translator, Inspector, Evaluator) is operationally viable for autonomous test execution on a real infotainment system: in 28 of 30 scenarios the closed loop iterated without human intervention across multi-step navigation, text input, toggle interactions, and scroll gestures. The separation between the Executor (visual reasoning only) and the Translator (XML-based element resolution) provided a clean boundary between perceptual reasoning and implementation-level interaction. The single-agent baseline (Section 3.4) gives empirical support: without the decomposition, a single agent using the same model classified 76.7% of scenarios as defective on its first pass, versus 43.3% for the multi-agent pipeline, showing that concentrating all cognitive responsibilities in one reasoning chain leads to systematic over-reporting of false positives. Agent independence kept the Executor's user-centric perspective uncontaminated by system-level knowledge, while the enforced JSON format and automatic re-prompting proved essential for reliable inter-agent communication.

**RQ2. To what extent can a vision-based, natural-language-driven testing framework reliably detect genuine system faults while minimizing false positives in an industrial infotainment validation environment?** ARIA detected all five scenarios with genuinely incorrect system behavior, classifying each as BUG and producing zero false negatives (recall

5/5): no genuine fault was ever passed as working. Three of the detected faults corresponded to the deliberately disabled climate control subsystem, whose absent functionality the Evaluator correctly observed in each case; one of these was counted as detected per the run-to-run reasoning in Section 3 after intermittently error-terminating. Another involved a language selection operation where no alternative language could be selected, which the framework correctly flagged as a missing state change. The last was a system-wide black screen, a transient anomaly unrelated to the functionality under test, demonstrating the framework's ability to detect system-level issues that a narrowly scoped scripted test would likely miss.

Among the 28 completed scenarios, 20 (71.4%) were classified in agreement with the ground truth, with precision reaching 38.5%. The 8 false positives among completed scenarios are predominantly attributable to framework interaction and LLM limitations rather than fundamental failures of the multi-agent reasoning approach. The low precision highlights the need to decrease the false positive rate, mainly through collecting the relevant context of the system's expected behavior and supplying it to the Evaluator agent so that it can more accurately assess the system's state after every interaction.

**RQ3. What are the primary failure modes, limitations, and architectural trade-offs involved in delegating GUI test execution to LLM agents operating through coordinate-based interaction primitives?** Root cause analysis of all 8 non-correct scenarios revealed two distinct failure categories in equal proportion, as shown in Figure 4. LLM limitations (50.0%) manifested as the Executor navigating to incorrect menu paths or exhausting the step limit while searching for a target, the Translator repeatedly generating resource identifiers that the Inspector rejected, or the Executor misreading the effect of a status-bar interaction. These failures illustrate a fundamental trade-off of LLM-based execution: the flexibility that enables agents to reason about unfamiliar interfaces also permits them to generate plausible but incorrect action sequences.

Framework interaction limitations accounted for the other 50.0% of non-correct outcomes, arising from unsupported gesture types such as long-press-and-drag, transient UI states that cannot be captured through discrete screenshots, and insufficient contextual knowledge about specific element interaction requirements.

A qualitatively distinct observation emerged from the two home-screen swipe-up scenarios. In the final, post-revisitation results both are correctly classified as OK, but on the first pass with the base model one was flagged as a defect and the other error-terminated. Manual investigation revealed that the intended navigation requires a specific motion trajectory that is not visually communicated to the user; the base model, reasoning as a simulated human user, struggled with exactly this gesture before the stronger revisitation model completed it. This first-pass friction, although resolved in the final tally and therefore not counted among the non-correct outcomes, indicates that real users may encounter the same difficulty and illustrates that vision-based agents can surface unintuitive interaction patterns that would be difficult to detect through traditional scripted automation.

**RQ4. What are the practical challenges and prerequisites for integrating LLM-based test execution frameworks into existing automotive validation workflows and continuous integration pipelines?** The deployment of ARIA on the industrial test setup revealed several practical prerequisites for pipeline integration. The framework requires stable Appium connectivity with ADB-based device discovery; the checkpoint and manifest system mitigates network interruptions by enabling resumption from the last completed scenario, essential for

unattended execution. Existing manual test scripts can be ingested through the scenario transformation mode without a device connection, though the quality of the generated scenarios directly impacts execution reliability and benefits from review.

The primary scheduling constraint is execution latency: four sequential agent invocations per interaction step, each transmitting multimodal data to external LLM services, yield far longer per-scenario times than scripted automation, positioning ARIA for nightly regression runs rather than rapid in-loop feedback. Token consumption from per-step screenshots translates directly into operational cost, partially mitigated by the short-circuit replay mode's single Evaluator invocation, while the model abstraction layer lets different LLM providers be substituted without modifying execution logic as availability or pricing changes.

## 3.8 Threats to Validity

**Internal validity.** The ground truth was established through manual inspection by a single reviewer with knowledge of the test setup's capabilities, introducing subjectivity in ambiguous cases such as the interpretation of the first-pass friction on the two swipe-up scenarios as a usability concern. The non-deterministic nature of LLM inference means that individual outcomes may not be perfectly reproducible across runs; however, the repeated execution experiment (Section 3.5) demonstrates that 83.3% of individual runs agree with the modal result, with perfect consistency for fault detection and simpler scenarios.

**External validity.** All experiments were conducted on a single physical infotainment test environment disconnected from a vehicle. The 30 scenarios evaluated represent a fraction of the theoretically possible interaction sequences. With only 5 genuinely faulty scenarios, all of which were ultimately detected, the perfect recall figure (5/5) is derived from a small sample and should be interpreted with appropriate caution. The effectiveness of the framework at detecting regressions across software updates was not evaluated due to time constraints.

**Construct validity.** The Translator agent was provided with supplementary reference files mapping resource identifiers to UI element descriptions. While these do not expose internal APIs, they provide prior knowledge about the system's naming conventions, and their absence could reduce performance on undocumented systems.

# 4 Related Work

The emergence of Large Language Models has opened new avenues for automating the execution of GUI-based test scenarios [5, 23]. Rather than encoding interaction logic programmatically, these approaches exploit the reasoning and perception capabilities of LLMs to navigate user interfaces and perform high-level tasks. Agent-based architectures are particularly prevalent, because GUI exploration without a separation of responsibilities is prone to failures, such as selecting actions unavailable in the current interface state, repeating ineffective interactions, or otherwise deviating from the intended exploration policy [19]. By decomposing responsibilities such as planning, action execution, state observation, and reflection, these architectures externalize the control logic and state management that would otherwise be left to a single model, improving instruction adherence and reducing unproductive exploration loops.

**GUARDIAN** investigates LLM agents in automated feature-based UI testing for mobile applications [19]. It addresses two challenges inherent to LLM-driven execution: the tendency to fail at following complex domain-specific instructions, and the inability to re-plan when

exploration falls into repetitive loops. To mitigate these, GUARDIAN employs computation offloading, shifting state management and logical constraints from the LLM to an external orchestration layer, executing and validating a single UI action per round until the objective is reached.

**LLMDroid** takes a hybrid approach, enhancing traditional automated GUI testing tools by integrating LLM reasoning only when code-coverage growth slows [25]. Rather than querying the model for every action, it relies on a traditional tool for high-speed "Autonomous Exploration" and transitions to an "LLM Guidance" stage that summarizes explored pages and selects target functionalities with the highest potential for discovering unexplored paths when coverage plateaus.

**GERALLT** uses two specialized LLM agents, a "controller" and an "evaluator", for automated GUI testing [21]. The controller performs interactions to achieve loosely defined objectives from the current GUI state, documentation, and action history, while the evaluator analyzes before/after screenshots to detect unintuitive behaviors, visual inconsistencies, or functional errors. A GUI Parser translates visual elements into structured metadata, letting the agents reason about the interface without human interaction data.

The reviewed literature reveals several gaps that ARIA addresses. Firstly, most LLM-driven testing frameworks target mobile or web applications [29, 30, 11, 14]; solutions applied to the automotive infotainment domain remain scarce and insufficient for the specific constraints of this environment [26, 27, 15, 22].

Secondly, existing approaches such as GUARDIAN and LLMDroid predominantly employ single-agent or dual-agent architectures that concentrate multiple cognitive responsibilities (perception, planning, action selection, and validation) within one or two models [19, 25]. ARIA's four-agent decomposition pushes the multi-agent paradigm further by assigning each sub-task to a dedicated specialist, reducing brittleness and improving controllability compared to more monolithic approaches. Separating these responsibilities ensures, for instance, that an agent performing exploratory UI traversal cannot be influenced by information available to a separate agent responsible for classifying system behavior against specifications.

Thirdly, ARIA accepts existing manual test scripts as natural-language input, eliminating the need for test re-authoring or formalization into structured specifications, directly targeting the identified bottleneck: organizations do not lack test cases, they lack the capacity to execute them at the required pace.

Finally, ARIA's closed-loop interaction model enables the system to respond to the evolving interface state of the system under test. The translated interaction scripts are executed on the infotainment system; if no errors occur, a new state description is sent to the Executor agent for evaluation and subsequent action determination, while execution errors are relayed back to the Translator agent for correction before resubmission. By embedding evaluation from an end-user perspective after each action, the approach moves fault detection closer to the point of interaction, producing structured result reports, reproducible action scripts, and visual evidence for every executed step.

## 5 Conclusion

It can be concluded that, by decomposing the test execution process into four specialized agents, each responsible for a distinct cognitive subtask, ARIA demonstrates that LLM-powered architectures can autonomously navigate, interact with, and evaluate complex infotainment UIs without human intervention and without coupling to internal system APIs or implementation details.

The industrial evaluation, conducted on a physical Android-based infotainment test environment, yielded encouraging but qualified results. ARIA completed the full execution pipeline for 93.3% of the evaluated scenarios and, among completed scenarios, never passed a genuine fault as working, detecting all five known defects. The overall classification accuracy among completed scenarios reached 71.4%, and precision remained low at 38.5%, with the majority of non-correct outcomes attributable to agent-native and mechanical limitations of the interaction primitives rather than fundamental shortcomings of the multi-agent reasoning approach. A notable observation was that the home-screen swipe-up scenarios, although correctly classified once revisited, produced first-pass friction that mirrors a latent usability concern, demonstrating that vision-based agents simulating human user behavior can reveal unintuitive interaction patterns alongside software defects.

Several directions for future work emerge from these findings. The LLM limitations could be mitigated through richer contextual grounding, such as navigation maps or terminology glossaries, and self-verification mechanisms that compare the observed screen state against the agent's assumptions before proceeding. The framework limitations point to the need for extended interaction primitives supporting compound gestures such as long-press-and-drag and gestures anchored to element boundaries. The short-circuit replay mode, implemented but not evaluated for cross-version regression detection here, is a natural next step in a continuous integration setting with successive builds. Finally, the model abstraction layer positions ARIA to benefit from advances in LLM capabilities, as improvements in visual reasoning and instruction adherence should reduce the misclassification rate without architectural changes.

The results presented in this work demonstrate that LLM-powered multi-agent test execution is feasible in an industrial automotive context, while making clear that its current precision and error-rate leave meaningful work before unattended deployment in a continuous integration pipeline. By accepting natural-language scenario descriptions as input and producing structured reports, reproducible action scripts, and visual evidence for every step, ARIA is best positioned today as an early-stage, human-supervised aid for nightly regression campaigns, narrowing the gap between manual testing practices and the automated execution capacity that modern release cycles demand.

## Data Availability Statement

The data supporting this paper were obtained under a non-disclosure agreement with a software company. This agreement prohibits the sharing of source code, internal and derived artifacts, and specific details about the testing equipment and the intricacies of the testing environment. We have provided sufficient architectural detail about the framework and the infotainment system requirements in Section 2 to allow for replication in other organizational contexts.

# Specification Artifacts in Open-Source Pull Request Workflows Do Not Reduce Defects: An Empirical Test of Spec-Driven Development Claims

**Brenn Hill**
Independent Researcher, Germany

## Abstract

**Context.** Spec-driven development (SDD) tools claim that writing specifications before implementation reduces defects, prevents rework, and improves code quality. No vendor has published empirical evidence for these claims.

**Method.** We test five hypotheses derived from SDD vendor claims against 88,052 pull requests across 119 open-source repositories. What we measure is specification *artifacts* – overwhelmingly references to tracking issues and tickets – rather than SDD tool output, which no repository in the sample commits. We score 25,209 artifacts on the same quality dimensions SDD tools prescribe, measure rework from subsequent pull request activity, trace defects via the SZZ algorithm, and compare each developer's spec'd PRs to their own unspec'd PRs. Twelve robustness checks include propensity score matching, complexity stratification, and AI/human subgroup analysis.

**Results.** None of the five hypotheses are supported. After propensity score matching on just-in-time risk profiles, spec'd and unspec'd PRs are indistinguishable in defect introduction ($-0.6$ percentage points (pp), $p = 0.133$). Rework shows no protective effect either ($+1.2$pp, $p = 0.001$ within-author; $+0.5$pp, $p = 0.146$ matched). Specification quality predicts neither defects ($p = 0.164$) nor rework ($p = 0.860$), and specifications do not constrain the scope of AI-tagged changes ($p = 0.997$). The positive raw association between specification artifacts and defects is explained by task complexity: developers spec their hardest work. One subgroup runs the other way – in repositories with no detected AI use, specifications are associated with less rework ($-3.3$pp, $p = 0.014$) – but it is one of six subgroup tests and does not survive correction for multiple comparisons.

**Conclusion.** Specification artifacts proxy for task complexity, not quality improvement. SDD tool adoption itself remains untested: no repository in the sample commits such output.

## 1 Introduction

The rise of AI-assisted software development has produced a new category of developer tooling: specification-driven development (SDD) frameworks. These tools – including GitHub's Spec Kit [8] and Amazon's Kiro [6] – claim that writing formal specifications before implementation leads to fewer defects, less rework, and higher-quality code, particularly when AI agents perform the implementation.

© Brenn Hill;

Böckeler [4] defines spec-driven development as "writing a "spec" before writing code with AI" where "[t]he spec becomes the source of truth for the human and the AI," and examines three tools pursuing the approach. The GitHub Copilot Academy frames it more strongly: "Specifications don't serve code – code serves specifications" [1]. More broadly, SDD is positioned as an antidote to "vibe coding" – iteratively prompting AI without formal requirements – which practitioners associate with scope creep, rework, and defects.

The core premise is: if developers articulate what software should do before writing it, AI systems will produce more reliable output. Vendors state this as a set of specific, testable quality claims – fewer defects, less rework, higher accuracy, fewer costly rewrites [1, 23, 8] – which we quote verbatim and map to hypotheses in Section 3. They rest on a plausible causal chain: clearer requirements → less ambiguity → fewer defects. Yet vendors cite no empirical evidence for them in their marketing materials, documentation, or blog posts, and no study has tested SDD's quality claims on production-scale data prior to this paper.

This paper provides the first large-scale empirical test. We analyze 88,052 merged pull requests across 119 open-source repositories, after excluding 12,195 bot-authored PRs. Defects are traced to their introducing commits using the SZZ algorithm (named for Śliwerski, Zimmermann, and Zeller), which works backward from bug-fixing commits through version control history to identify which earlier commits introduced each bug. We compare each developer's spec'd PRs to their own unspec'd PRs to control for developer-level confounding, and derive five hypotheses directly from vendor claims. None of the five survive: once task complexity is accounted for, specification artifacts are unrelated to defects, rework, or the scope of AI-tagged changes.

## 2 Related Work

### 2.1 Requirements Engineering and Defect Prevention

The claim that upfront specification prevents defects has deep roots. Boehm's cost-of-change curve [5] argued that requirements defects are exponentially cheaper to fix early, but subsequent work challenged its universality: Shull et al. [21] found the cost multiplier depends on project context, and agile methods showed iterative refinement can outperform upfront specification [3]. Direct tests of whether requirements quality predicts defects have found weak or context-dependent effects: Mund et al. [15] found only weak evidence across two studies, and Femmer et al. [10] found that the relationship between requirements smells and downstream defects was context-dependent. Our study confirms this pattern at larger scale.

### 2.2 SDD Literature

The academic literature on SDD perpetuates the pattern of unsubstantiated claims. Piskala [18] claims "controlled studies showing error reductions of up to 50%," citing a Red Hat Developer blog post [16] and an InfoQ article [11]; neither contains any controlled study, experiment, or quantitative data, so the figure traces through a citation chain resting on practitioner opinion. Guo et al. [12] claim SDD "guarantees software quality" without empirical validation. Marri [14] reports a 73% security defect reduction from constitutional specs, but on a single project with the same developer implementing both conditions sequentially, acknowledging that "small sample size limits statistical power." Roy [19] proposes iterative spec-code co-evolution but reports no independently validated outcomes. Zietsman [25] runs small planted-bug experiments, is honest that they are "directional, not statistically significant," and contributes the useful observation that AI reviewers without specs suffer circular reasoning – but does not test defect reduction at scale.

Practitioner evaluations have been more skeptical. Eberhardt found Spec Kit roughly ten times slower than iterative development, producing thousands of lines of specification markdown that still resulted in buggy code [9]. Zaninotto argued that "SDD shines when starting a new project from scratch, but as the application grows, the specs miss the point more often and slow development" [24].

## 3 Hypotheses

We identified five empirical claims made by SDD tool vendors in their public documentation, blog posts, and marketing materials. Each claim is stated verbatim and mapped to a testable hypothesis.

SDD as vendors describe it is a chain with two links: a structured specification is authored before implementation, and an AI agent then implements it. Our data supports a test of the first link only. We observe whether a specification artifact exists and what it contains, but we cannot observe whether a tool generated it or whether an agent consumed it – and no repository in our sample commits SDD tool output (Section 6.3). The hypotheses below are therefore stated as vendors state them, because testing their claims as made is the point, but what they are tested *against* is the presence and quality of specification artifacts in ordinary pull request workflows. Section 7 returns to the distance between the two.

### Claim 1: Specifications reduce defects

GitHub's Spec Kit blog post promises "less guesswork, fewer surprises, and higher-quality code" [8]. Kiro claims specifications lead to "fewer iterations and higher accuracy" [23].

**H1.** Pull requests with specification artifacts have lower defect-introduction rates than pull requests without them, controlling for author and PR size.

### Claim 2: Specifications reduce rework

The GitHub Copilot Academy lists "reduced rework" among SDD's benefits [1]. Kiro claims to "prevent costly rewrites" [23]. GitHub's blog states that SDD enables "iterative development without expensive rewrites" [8].

**H2.** Pull requests with specification artifacts have lower rework rates than pull requests without them, controlling for author and PR size.

### Claim 3: Clearer specifications produce more reliable code

GitHub's Spec Kit blog states that "providing a clear specification up front, along with a technical plan and focused tasks, gives the coding agent more clarity, improving its overall efficacy" [8]. Kiro claims specifications enable "fewer iterations and higher accuracy" [23]. This implies a dose-response relationship: higher specification quality should predict fewer defects.

**H3.** Among pull requests with specifications, higher specification quality predicts lower defect-introduction rates, controlling for author and PR size.

**H4.** Among pull requests with specifications, higher specification quality predicts lower rework rates, controlling for author and PR size.

#### Claim 4: Specifications constrain AI-generated code scope

GitHub's Spec Kit blog describes tasks that give "the coding agent a way to validate its work and stay on track" [8]. Kiro claims specs provide "a North Star to guide the work of the agent, allowing it to take on larger tasks without getting lost" [6].

**H5.** Specifications reduce code churn (additions + deletions) for AI-tagged pull requests more than for human-authored pull requests, controlling for author.

# 4 Methods

## 4.1 Dataset

We collected pull request data from 119 open-source repositories spanning 17 programming languages, between March 28 and April 3, 2026, with a 365-day lookback window per repository. The resulting dataset spans April 2025 through early April 2026 (1st–99th percentile: April 8, 2025 to April 1, 2026), totaling 100,247 PRs. We excluded 12,195 bot-authored PRs (dependabot, renovate, and other automated accounts identified by username pattern and bot flags), leaving 88,052 PRs from human and AI-assisted authors.

For each pull request, we extracted: author, merge date, additions, deletions, files changed, linked issues, PR description, review comments, and co-author tags (used to identify AI-assisted contributions).

### 4.1.1 Sampling Frame and Inclusion Criteria

Repositories were selected purposively rather than randomly, and the sample was stratified on the constructs of interest rather than drawn from an enumerated population. The first wave of 43 repositories was stratified on specification practice, using issue-linking rate as the observable proxy: near-universal linking (8 repositories), 60–90% (12), 30–50% (6), and low linking (3), plus a stratum of 14 repositories with visible AI adoption. A second wave of 77 repositories, each verified on March 26, 2026 to have at least 200 merged pull requests in the preceding year, extended the same design with 33 repositories of expected strong process enforcement, 24 of weak or unknown enforcement, and 20 with heavy AI adoption; this wave also broadened language and domain coverage so that no single ecosystem would dominate. One further repository returned no merged pull requests in the observation window and is absent from the analysis, leaving 119.

Two features of this process require disclosure. First, the sample is deliberately *enriched* for strong specification practice: the strong-enforcement and near-universal-linking strata were selected precisely because they were expected to exhibit the benefit SDD vendors claim. Enrichment of this kind biases toward detecting an effect, not toward the null we report. Second, the sample size was not fixed in advance. Repositories were added while no effect was evident, and collection stopped at 119 once the null appeared stable across the checks in Section 5.6. Continuing to add data in search of an effect and failing to find one is conservative with respect to our central claim, but it does mean that sample composition is not independent of the analyses, and that nominal $p$-values should not be read as exactly calibrated. Optional stopping of this kind inflates false positives rather than false negatives, so it bears most directly on the one positive subgroup result (Section 5.6.6), which we already treat as suggestive rather than confirmatory.

The sample spans 17 programming languages, with Python (31 repos, 26%), TypeScript (26, 22%), Go (17, 14%), and Rust (13, 11%) predominating. The median repository has a 26.2% specification rate (IQR 16.0–41.1%). AI tagging is present in most repositories: the

**Table 1** Study dataset overview.

| Metric | Value | Notes |
|---|---|---|
| Repositories | 119 | purposive sample, 17 languages |
| PRs (post-bot exclusion) | 88,052 | 12,195 bots removed |
| Median PRs per repo | 517 | range 9–4,803 |
| Median spec rate (per repo) | 26.2% | IQR 16.0–41.1% |
| Median AI tag rate (per repo) | 1.2% | IQR 0.4–8.1% |
| SZZ-covered repos | 103 | 16 had unreachable merge SHAs |
| SZZ bug-introducing PRs | 9,754 | 12.5% of SZZ-covered PRs |
| Quality-scored PRs | 25,209 | 28.6% of total; 17,094 enriched with issue body |

**Table 2** Decomposition of the `specd` treatment by the criterion that fired (88,052 non-bot PRs, of which 24,298 are spec'd).

| Detection criterion | PRs | % of spec'd |
|---|---|---|
| GitHub issue `#N` with linking keyword | 11,348 | 46.7% |
| GitHub issue URL | 7,252 | 29.8% |
| Project-key ticket ID (`PROJ-123`) | 5,112 | 21.0% |
| External document URL (Docs, Linear, Confluence, Notion, Jira) | 561 | 2.3% |
| Filled requirements section in PR body | 24 | 0.1% |
| Total | 24,298 | 100% |

median AI tag rate is 1.2% (IQR 0.4–8.1%). The 5,989 AI-tagged PRs support the primary AI analyses, though a larger AI-tagged sample would be preferable as agentic workflows spread.

## 4.2 Variables

### 4.2.1 Specification Presence (`specd`)

A pull request is classified as "specified" (hereafter "spec'd") if its description or title references an upfront specification artifact. Classification is programmatic. We accept a GitHub issue reference (`#123`) only when it appears alongside a linking keyword (`fixes`, `closes`, `resolves`, `references`, `related to`) and outside blockquoted template examples; project-key ticket identifiers (`PROJ-123`) after filtering common false positives such as `RFC-`, `CVE-`, and `GPT-`; URLs to issue trackers and document hosts (GitHub issues, Jira, Confluence, Linear, Notion, Shortcut, Google Docs), excluding issue-*creation* template links; and filled requirements or specification sections in the PR body containing at least 20 words of non-placeholder content. 24,298 of 88,052 PRs (27.6%) are classified as specified.

Table 2 decomposes the treatment by which criterion fired, and the result governs how everything downstream should be read: 97.5% of spec'd PRs are identified by a reference to a tracking issue or ticket, while structured requirements text written directly into the PR body accounts for 24 PRs. Whatever else this measure captures, in practice it measures *issue- and ticket-reference presence*. We use the term "specification artifact" throughout in that concrete sense.

This operationalization is deliberately generous, capturing any form of upfront specification artifact (Section 7). Specification *presence* and *quality* are tested separately: H1/H2 test whether having any spec predicts fewer defects or less rework; H3/H4 test whether, among spec'd PRs, higher quality predicts better outcomes.

### 4.2.2 Specification Quality (`q_overall`)

For the subset of specified PRs with substantial descriptions (body length $> 50$ characters), we scored specification quality by prompting Claude Haiku (Anthropic) with the PR title and body and a structured rubric. The LLM scored each PR across seven dimensions: outcome clarity, error states, scope boundaries, acceptance criteria, data contracts, dependency context, and behavioral specificity. Each dimension is scored 0–100, and the overall quality score is the mean across dimensions.

The dimensions deliberately mirror what SDD tools themselves prescribe, so that we measure quality on the criteria vendors say matter. Spec Kit's template asks for "core requirements" (our outcome clarity), "acceptance criteria," "edge cases" (error states), "data models" and "API contracts" (data contracts), and "user stories" (behavioral specificity) [8]; Kiro asks for "clear requirements," "acceptance criteria," "system architecture," and "technology choices" [23]. Six of our seven have direct equivalents in Spec Kit's structure, and all seven are covered across both tools.

We validated the scoring against independent human ratings on a stratified random sample of 38 PRs, blind to LLM scores. Overall agreement was moderate (Spearman $\rho = 0.42$, $p = 0.01$; Pearson $r = 0.45$, $p < 0.01$), but uneven across dimensions: four agree significantly (behavioral specificity $\rho = 0.45$, scope boundaries 0.43, dependency context 0.40, outcome clarity 0.39) and three weakly (error states 0.22, data contracts 0.19, acceptance criteria 0.17). The LLM reliably detects whether specification content is *present* but cannot judge whether it is *correct* for the domain. Since even this completeness-oriented measure shows no defect benefit, the null is conservative.

25,209 PRs (28.6% of total) received quality scores across all 119 repositories. Scoring targeted spec'd PRs whose combined issue and description text exceeded 50 characters; 24,194 of the 24,298 spec'd PRs met that threshold, and a further 1,015 PRs scored under an earlier revision of the classifier were later reclassified as unspecified but retain their scores (excluding them leaves H3 and H4 unchanged, at $p = 0.168$ and $p = 0.829$). For PRs linked to GitHub issues, we fetched the issue body and scored the combined content; 17,094 scored PRs include linked issue content, and the remainder were scored on PR description alone. This subsample is non-random – it is restricted to PRs carrying substantial specification text.

A further limitation: we cannot distinguish specifications written before implementation from descriptions written after. Linked GitHub issues are the strongest available proxy for pre-implementation intent; we test this subset separately in Section 5.6.12. Quality scores for issue-linked PRs (median 50, $N = 13{,}081$) differ only trivially from description-only PRs (median 47, $N = 12{,}128$; $p < 0.001$ but a 3-point difference). The null result holds for both subsets.

### 4.2.3 Defect Introduction (`szz_buggy`)

We applied the basic SZZ algorithm [22] to 103 of 119 repositories, tracing 64,805 blame links from fix commits to bug-introducing commits. The remaining 16 repositories had unreachable merge SHAs (typically from squash-merge workflows). da Costa et al. [7] found that basic

SZZ misattributes 46–71% of bug-introducing changes. If this noise is non-differential with respect to specification presence, it attenuates associations toward the null rather than creating spurious reversals; Section 5.6.1 bounds both that case and the differential one. A PR is marked `szz_buggy = True` if any of its commits were identified as bug-introducing. 9,754 PRs (12.5% of SZZ-covered repos) are marked as bug-introducing.

### 4.2.4 Rework (`reworked`)

A pull request is classified as reworked if a subsequent PR within 30 days by any author modifies overlapping files and has a title or description indicating correction (matching patterns such as "fix," "revert," "bugfix," "hotfix," "regression," "broke," or "broken"). File overlap is computed by comparing the set of files changed in each PR pair; high-frequency files (touched by >30% of PRs in the repository) are excluded to avoid spurious attribution. 11,820 PRs (13.4%) are classified as reworked. The 30-day window was chosen based on sensitivity analysis: rework detection increases from 14 to 30 days but shows diminishing returns beyond 30 days (the spec–rework association is directionally consistent across 14-, 30-, 60-, and 90-day windows).

### 4.2.5 AI-Tagged (`ai_tagged`)

A pull request is classified as AI-assisted by two detection layers. A regex matches co-author tags (`Co-authored-by: Copilot`), generation attribution strings (`Generated with`, `Claude Code`), agent markers (`CURSOR_AGENT`, `coderabbit.ai`, `AI-generated`), and the robot emoji; separately, we parse the structured "AI Disclosure" and "AI Usage" sections some repositories include in PR templates. Validated against 537 PRs with clear self-reported disclosures, the combined classifier achieves 98.8% precision (1 false positive) but 24.2% recall, because many developers describe AI use in natural language our patterns do not capture. 5,989 PRs (6.8%) carry AI tags after bot exclusion – a lower bound.

### 4.2.6 Code Churn (`total_churn`)

Total code churn is defined as additions + deletions. We use $\log(1 + \text{churn})$ in regressions to normalize the heavily right-skewed distribution (median: 55, mean: 698).

## 4.3 Statistical Approach

For each hypothesis, we report three levels of analysis. Each level controls for more potential confounders than the last, so readers can see how the result changes as we account for more alternative explanations:

**Pooled.** Raw rates compared directly. This is the analysis that unadjusted claims would cite – it ignores all confounders.

**Controlled.** Logistic regression adjusting for PR size (log additions, log deletions, log files changed) and *repository fixed effects*, so the model compares spec'd and unspec'd PRs *within the same repo*. In two analyses (H1, H3), including 100+ repository adjustments caused singular matrices, so those estimates use size controls only.

**Table 3** Sample sizes by hypothesis.

| Hypothesis | PRs (pre-filter) | Within-author $N$ | Ident. authors |
|---|---|---|---|
| H1: specs → bugs | 77,814 (103 SZZ) | 72,046 | 2,181 |
| H2: specs → rework | 88,052 (all 119) | 81,647 | 2,524 |
| H3: quality → bugs | 22,672 (scored, SZZ) | 19,688 | 2,030 |
| H4: quality → rework | 25,209 (scored subset) | 21,881 | 2,297 |
| H5: spec × AI → churn | 88,052 (all 119) | 71,932 | 366 |

Within-author $N$ is after restricting to authors with ≥2 PRs and dropping rows with missing controls. Identifying authors are those with variation in both treatment and control conditions.

**Within-author.** The strongest test. We subtract each developer's own average from every variable, then run a linear regression on the residuals. This compares each developer's spec'd PRs to their own unspec'd PRs, eliminating all stable differences between developers – skill, experience, coding style, and organizational context are held constant because both "treatment" and "control" come from the same person.[1] Standard errors account for the fact that PRs from the same author are correlated (clustered at the author level). Primary models use size controls; Section 5.6 confirms results hold when adding Just-In-Time (JIT) defect prediction features [13] – a set of 14 code-change metrics (lines added, file age, developer experience, etc.) known to predict defect-introducing commits.

The effect is identified only from authors who have *both* spec'd and unspec'd PRs; those who always or never write specs contribute no information. We therefore restrict to authors with ≥2 PRs and report the number with treatment variation throughout, along with 95% confidence intervals from clustered standard errors, so readers can judge which effect sizes are compatible with the data.

We do not apply multiple-comparison corrections across the five hypotheses; at $\alpha = 0.05$, approximately 0.25 false positives are expected by chance, and we interpret all results with that in mind.

Sample sizes vary across hypotheses because of SZZ coverage, quality scoring, and within-author filtering:

## 5 Results

Our outcomes differ in how heavily they depend on the SZZ algorithm, and we weight them accordingly. Rework (H2) is derived from subsequent pull request activity and does not use SZZ at all. Propensity-matched defect rates compare spec'd and unspec'd PRs with equivalent just-in-time risk profiles. This neutralizes a mechanical artifact: larger PRs touching older files collect more `git blame` hits regardless of their true defect rate. These two are our primary evidence. Within-author estimates on unmatched SZZ outcomes are reported alongside them, and are informative about how the association behaves as controls accumulate, but they are secondary: as Section 5.6.1 sets out, SZZ noise on this particular treatment is unlikely to be non-differential.

[1] Technically: a linear probability model (LPM) with full author demeaning, equivalent to author fixed effects via the Frisch–Waugh–Lovell theorem. We use LPM rather than logistic regression because author demeaning is exact for OLS but produces biased estimates in logit due to the incidental parameters problem [17]. Chamberlain's conditional logit avoids this but requires discarding groups without outcome variation, reducing power. We follow Angrist and Pischke's recommendation [2].

**Table 4** H1: Specifications and defect-introduction rates, ordered from most to least adjusted. The propensity-matched row is the primary estimate; Section 5.6.9 gives matching detail and balance diagnostics.

| Method | Coefficient | $p$-value | Interpretation |
|---|---|---|---|
| Propensity-matched (primary) | −0.006 | 0.133 | No difference |
| Within-author + JIT controls | +0.006 | 0.229 | Not significant |
| Within-author, size controls | +0.014 [+0.005, +0.024] | 0.003 | +1.4pp, no cplx. adj. |
| Logistic (size only[†]) | 0.067 | 0.006 | Log-odds, not pp |
| Pooled (raw comparison) | OR = 1.20[a] | $< 0.001$ | Higher defect rate |

[a] Odds ratio: spec'd PRs are 1.20× as likely to introduce a defect as unspec'd PRs. [†] Including a separate adjustment for each of 100+ repositories caused the model to fail; this estimate adjusts for PR size only. Within-author 95% CI in brackets.

## 5.1 H1: Specifications Reduce Defects

Analysis restricted to 77,814 PRs in the 103 repositories with SZZ coverage. Table 4 reports estimates from most to least adjusted; the propensity-matched estimate is the primary result.

Within-author estimates are identified from 2,181 authors with treatment variation (out of 4,328 authors with ≥2 PRs).

**H1 is not supported.** After matching on just-in-time risk profiles, spec'd and unspec'd PRs are indistinguishable in defect-introduction rate (−0.6pp, $p = 0.133$, 17,375 matched pairs, with all 16 covariates – the 13 usable JIT features plus the three size controls – balanced). No protective effect appears at any level of analysis.

Reading up the table shows why the raw association exists. It is positive and strongly significant unadjusted, and it weakens monotonically as task complexity is controlled: within-author with size controls gives +1.4pp ($p = 0.003$), adding JIT risk features drops the coefficient by 55% and removes significance ($p = 0.229$), and matching eliminates it. This is *confounding by indication* – developers write specs for their hardest work, and harder work produces more defects.

The complexity-unadjusted +1.4pp estimate should not be read as evidence that specifications *cause* defects, for a reason specific to SZZ. Spec'd PRs add 1.8× more lines and touch 2.3× older files, so they present more `git blame` targets and accumulate defect attributions mechanically, independent of their true defect rate. This biases the unmatched estimate upward. It is one reason we treat the matched estimate as primary, and one reason H2 – which does not depend on SZZ at all – carries weight. Section 5.6.1 bounds both failure modes.

## 5.2 H2: Specifications Reduce Rework

Analysis includes all 88,052 PRs. Rework is our primary outcome: it is measured from subsequent pull request activity and is independent of SZZ, so the misattribution concerns that qualify H1 do not apply.

**H2 is not supported.** No specification of this model produces less rework for spec'd PRs. The within-author estimate is in the wrong direction – the same author's spec'd PRs have a 1.2 percentage-point higher rework rate than their unspec'd PRs ($p = 0.001$), about one

**Table 5** H2: Specifications and rework rates, ordered from most to least adjusted.

| Method | Coefficient | $p$-value | Interpretation |
|---|---|---|---|
| Propensity-matched | +0.005 | 0.146 | No difference |
| Within-author + JIT controls | +0.009 | 0.024 | Attenuated; more rework |
| Within-author, size controls | +0.012 [+0.005, +0.019] | 0.001 | +1.2pp *increase* |
| Logistic (size + repo) | 0.178 | $< 0.001$ | Log-odds; persists |
| Pooled (raw comparison) | OR = 1.18[a] | $< 0.001$ | Higher rework rate |

[a] Odds ratio: spec'd PRs are 1.18× as likely to be reworked as unspec'd PRs. Within-author estimates identified from 2,524 authors with treatment variation (out of 4,892 with ≥2 PRs).

extra rework event per 83 PRs – and matching on task complexity removes the difference rather than reversing it (+0.5pp, $p = 0.146$). The claimed benefit is absent whether or not complexity is adjusted for, and this outcome does not rely on SZZ.

## 5.3 H3: Specification Quality Reduces Defects

H1 and H2 tested specification *presence*. H3 and H4 test specification *quality* – whether, among PRs that already have specifications, better-written ones predict better outcomes. This is the stronger version of the SDD claim: not just "write a spec" but "write a *good* spec." Quality is the seven-dimension rubric score from Section 4.2. We treat H3 and H4 as *exploratory* rather than confirmatory, because the measure has limited construct validity: human–LLM agreement is only moderate, and the rubric captures *formal* completeness rather than *functional* correctness – a specification can score highly on every dimension and still specify the wrong behavior.

Of the 22,672 quality-scored PRs in SZZ-covered repos, 19,688 remain after restricting to authors with ≥2 PRs and dropping rows with missing controls, identified from 2,030 authors with treatment variation.

**H3 is not supported.** Adjusting for PR size alone, the quality coefficient is −0.002 ($p = 0.080$), which approaches significance but corresponds to a negligible effect: a 10-point quality improvement predicts a 2 percentage-point defect reduction.[2] The within-author estimate is an order of magnitude smaller and not significant, −0.0003 (95% CI $[-0.0007, +0.0001]$, $p = 0.164$), implying that a 10-point improvement predicts a 0.3pp reduction. The quality signal does not survive stronger controls, and is non-significant across all robustness checks (Section 5.6).

## 5.4 H4: Specification Quality Reduces Rework

**H4 is not supported.** Specification quality has no meaningful relationship with rework. The within-author coefficient is effectively zero, +0.000 (95% CI $[-0.000, +0.000]$, $p = 0.860$), and the controlled logistic regression adjusting for size and repository is likewise non-significant (−0.000, $p = 0.920$). Estimates are identified from 2,297 authors with treatment variation, the same scored subsample as H3.

[2] Including a separate adjustment for each of 100+ repositories caused this model to fail, so the estimate adjusts for PR size only.

## 5.5 H5: Specifications Constrain AI Scope

Analysis uses log code churn (additions + deletions) as outcome. PRs with zero churn are excluded (these represent missing data rather than true zero-change events). AI detection combines regex pattern matching with structured AI disclosure parsing (Section 4.2), identifying 5,989 AI-tagged PRs – 2.3× more than co-author tags alone.

Within-author, specifications accompany larger PRs in both populations: +0.120 for AI-tagged PRs ($p = 0.030$, identified from 224 authors with treatment variation) and +0.140 for human-authored PRs ($p < 0.001$). The spec × AI interaction is +0.000 (95% CI $[-0.101, +0.102]$, $p = 0.997$, identified from 366 authors).

**H5 is not supported.** Rather than constraining scope, specifications accompany *larger* PRs for both AI-tagged (+12.0%) and human-authored (+14.0%) work. The interaction term is effectively zero ($p = 0.997$): specifications have the same relationship with code churn for AI and human PRs alike – the same confounding-by-indication pattern seen in H1 and H2. Harder tasks get specs and produce more code.

## 5.6 Robustness Checks

Twelve additional analyses test whether the null result is an artifact of our primary measures or insufficient controls.

### 5.6.1 SZZ Misattribution Sensitivity

da Costa et al. [7] report that basic SZZ misattributes 46–71% of bug-introducing changes. Because SZZ underpins H1, we bound the consequences in both directions.

If misattribution is *non-differential* with respect to specification presence, it attenuates the observed coefficient toward zero. Treating the reported rates as an approximate attenuation factor, the within-author estimate of +0.014 [+0.005, +0.024] corresponds to a disattenuated interval of roughly $[+0.9, +4.4]$pp at 46% misattribution and $[+1.7, +8.3]$pp at 71%. Both intervals remain entirely positive. Non-differential noise cannot convert a positive association into the protective one SDD vendors claim; it can only make a positive association look smaller than it is. These are order-of-magnitude bounds rather than estimates: da Costa et al. report a misattribution rate, not a decomposition into sensitivity and specificity, so the correction is approximate and we do not carry the disattenuated intervals into any results table.

If misattribution is instead *differential*, the attenuation argument does not apply. We consider differential noise likely here, because spec'd PRs add 1.8× more lines and touch 2.3× older files and therefore present more `git blame` targets; this would bias the unmatched SZZ estimate upward. Propensity score matching addresses precisely this mechanism – it matches on size, file age, change entropy, and developer experience – and returns a null (Section 5.6.9). Rework (H2) provides an independent check that does not use SZZ at all, and shows the same absence of benefit.

The two failure modes thus have a common answer, and neither yields support for a protective effect. Under non-differential noise the association stays positive; under differential noise it disappears once complexity is matched.

### 5.6.2 Alternative Outcome Measures

We tested two additional outcomes beyond SZZ-traced defects and rework: *escaped defects* (PRs whose CI passed but were subsequently followed by a fix or revert) and *strict escaped* (escaped PRs where the follow-up explicitly indicates a fix or regression). Both are directionally positive (specs accompany more escapes, not fewer) but not significant (escaped: $p = 0.333$; strict escaped: $p = 0.108$; within-author LPM, $N = 81{,}647$). No outcome measure shows specifications reducing defects at $p < 0.05$.

### 5.6.3 Incremental Validity Beyond JIT Features

We tested whether specification information adds predictive power beyond the 14 JIT defect prediction features [13] on 61,192 PRs with complete JIT features and SZZ outcomes. Spec presence is statistically significant when added to the JIT model ($p = 0.003$) but adds negligible predictive power ($\Delta R^2 = 0.0002$). Spec quality adds nothing ($p = 0.142$). JIT features account for nearly all the predictive power; knowing whether a PR has a specification tells you almost nothing beyond what the code-change metrics already reveal.

### 5.6.4 Quality Dimensions: Individual and Validated Subsets

We tested each of the seven quality dimensions independently against SZZ bugs and rework (within-author LPM, 19,688 PRs). No individual dimension is significant for defects at $p < 0.05$; every coefficient rounds to zero. Scope boundaries ($p = 0.053$) and behavioral specificity ($p = 0.083$) are closest, but neither survives Bonferroni correction for seven simultaneous tests ($p < 0.007$ required). No dimension shows any relationship with rework.

To test whether measurement noise in weakly validated dimensions attenuates the quality signal, we compared composites restricted to the four dimensions with significant human–LLM agreement ($\rho = 0.39$–$0.45$: behavioral specificity, scope boundaries, dependency context, outcome clarity) against composites using the three unvalidated dimensions ($\rho = 0.17$–$0.22$: acceptance criteria, error states, data contracts).

All three composites are non-significant for defects: all seven dimensions together give $-0.0003$ ($p = 0.164$), the four validated dimensions alone $-0.0002$ ($p = 0.184$), and the three unvalidated dimensions alone $-0.0003$ ($p = 0.158$). The validated and unvalidated composites therefore perform almost identically, which is what one would expect if the quality score were capturing noise rather than a real defect-predictive signal. For rework the three composites give $+0.0000$ ($p = 0.860$), $+0.0000$ ($p = 0.913$), and $+0.0001$ ($p = 0.663$) respectively – all indistinguishable from zero.

### 5.6.5 Repo-Level Analysis

Aggregating to the repository level ($N = 98$ repos with $\geq$50 PRs), specification rate has no relationship with either defect rate (Spearman $\rho = -0.11$, $p = 0.27$) or rework rate ($\rho = -0.05$, $p = 0.64$). Repos that write more specs do not have fewer bugs or less rework.

### 5.6.6 Subgroup Analysis

SDD tools are marketed primarily for AI-assisted workflows. We test whether the null result holds across human-only PRs, AI-tagged PRs, and repos stratified by AI adoption rate. As in all analyses, bot PRs are excluded.

**Table 6** Subgroup analysis: specification effects across populations.

| Subgroup | → bugs coef | $p$ | → rework coef | $p$ |
|---|---|---|---|---|
| All non-bot PRs (88,052) | +0.014 | 0.003 | +0.012 | 0.001 |
| Human-only, no AI (82,063) | +0.015 | 0.003 | +0.011 | 0.004 |
| AI-tagged, non-bot (5,989) | +0.011 | 0.424 | +0.010 | 0.399 |
| Zero AI-tagged repos (3,562) | −0.016 | 0.377 | −0.033 | 0.014[†] |
| Low-AI repos (51,877) | +0.019 | 0.001 | +0.009 | 0.061 |
| High-AI repos (32,613) | +0.010 | 0.185 | +0.018 | 0.003 |

[†] Nominal $p$-value. This is one of six subgroup tests; under Bonferroni correction the threshold is $\alpha = 0.0083$, which this result does not meet. Row counts apply to the rework columns; defect columns use the smaller SZZ-covered subset (77,814; 72,490; 5,324; 1,596; 45,007; 31,211). The zero-AI row shrinks most, so its defect estimate is the least precise here – but the result discussed below is its *rework* estimate, on the full 3,562.

One label needs defining precisely. "Zero AI-tagged repositories" means repositories in which no pull request carries a marker our classifier detects. Since that classifier has 98.8% precision but only 24.2% recall (Section 4.2), the label means *no detectable AI use*, not *no AI use*. Undetected AI-assisted work is expected in these repositories, and we have no way to bound how much. Any claim we make about this subgroup is a claim about repositories where AI use is invisible to our instrument, not about AI-free development.

One subgroup runs the other way. In repositories with no detected AI use, specifications are associated with *less* rework (−3.3pp, nominal $p = 0.014$). It is the only estimate in the dataset pointing in the direction the SDD rework claim predicts, and we are deliberately cautious about it. It rests on a small subsample (3,562 PRs); it is one of six subgroup tests, and does not meet the Bonferroni-corrected threshold of $\alpha = 0.0083$; and, as Section 4.1.1 notes, our sample size was not fixed in advance, which inflates false positives rather than false negatives and so bears on this result more than on any other in the paper. It is consistent with weak protection, but it is not significant under correction, and we do not build on it.

Two further observations qualify it. The subgroup is defined by absence of *detected* AI use, so it is not a clean human-only stratum. And if the effect were real, its location would still be awkward for the vendor claim: a protective association appearing where AI is invisible, and not where AI is tagged, is the opposite of the pattern one would expect if specifications were *most* valuable for AI-assisted work.

For all other subgroups, the pattern holds. For human-authored PRs, specs are associated with *more* defects and *more* rework – the confounding-by-indication pattern. For AI-tagged PRs, the coefficients are positive but not significant ($p = 0.42$ for defects, $p = 0.40$ for rework). The null holds whether a repo has low or high AI adoption.

### 5.6.7 High-Quality Specs Only

A likely reviewer objection is that our `specd` measure is too loose – that linked Jira tickets are not "real" specifications in the SDD sense, and only high-quality structured specs should show the benefit. We test this directly by restricting to top-quartile (quality score $\geq 58$) and top-decile ($\geq 66$) specs. Quality thresholds are computed from the scored subset's distribution (median = 48, p75 = 58, p90 = 66).

No quality threshold produces a significant defect reduction. The top-quartile result (−0.7pp, $p = 0.190$) and top-decile result (−0.5pp, $p = 0.545$) are both non-significant – the opposite of a dose-response gradient. The AI + high-quality spec result ($p = 0.790$), the closest test to the agentic SDD workflow vendors are selling, shows no signal.

**Table 7** High-quality specification thresholds vs. defect rates.

| Test | → bugs coef | $p$ | Ident. authors |
|---|---|---|---|
| Top-quartile specs vs. all others | −0.007 | 0.190 | 1,370 |
| Top-decile specs vs. all others | −0.005 | 0.545 | 751 |
| High-quality vs. no spec (low-quality excluded) | −0.006 | 0.348 | 1,117 |
| AI-tagged + high-quality spec | −0.005 | 0.790 | 175 |

We also test a three-tier dose-response, splitting PRs into three mutually exclusive groups – high-quality specs (top-quartile, $N = 5{,}253$), any other spec'd PR (below top-quartile or unscored, $N = 16{,}505$), and no specification artifact ($N = 56{,}056$, the reference group) – within-author, with the bug analysis restricted to the 103 SZZ-covered repos. If quality matters, the tiers should show a monotonic gradient. They do not. High-quality specs show a raw defect rate of 12.6%, indistinguishable from the 12.0% of PRs with no spec, while ordinary specs show the highest rate at 14.5%. Within-author, high-quality specs give a non-significant −0.4pp reduction ($p = 0.566$) and ordinary specs a significant +2.0pp *increase* ($p < 0.001$); for rework both tiers are positive (+0.017, $p = 0.006$; +0.010, $p = 0.012$). The pattern is consistent with confounding, not a quality gradient.

### 5.6.8 JIT Features as Primary Controls

A reviewer concern is that size controls (log additions, deletions, files) are insufficient – the JIT defect prediction framework [13] captures task complexity dimensions (entropy, file age, developer experience) that may confound the specification–defect association. We re-run H1 and H2 with 13 JIT features as additional controls alongside size controls (subsystem experience excluded for zero variance).

For H1, the spec coefficient falls from +0.014 ($p = 0.003$) to +0.006 ($p = 0.229$) – a 55% reduction that also removes significance. For H2 it falls from +0.012 ($p = 0.001$) to +0.009 ($p = 0.024$), a 23% reduction that leaves the estimate significant. A discrepancy with PSM (below), which finds $p = 0.146$ for rework, likely reflects functional form: the JIT regression assumes linearity while matching does not. Either way, the rework association is directionally *positive* under both methods – the direction never supports the SDD claim.

### 5.6.9 Propensity Score Matching

We pair each spec'd PR with an unspec'd PR having a similar JIT complexity profile[3], testing whether confounding by indication explains the association.

All 16 covariates are well-balanced after matching. Across 17,375 matched pairs, spec'd PRs introduce defects at 14.7% against 15.2% for their unspec'd matches, a difference of −0.6pp ($p = 0.133$): matching eliminates the raw association entirely. Across 19,648 pairs, rework runs at 15.2% against 14.7%, a difference of +0.5pp that is likewise not significant ($p = 0.146$). Both associations are explained by the JIT risk profile of the tasks that receive specifications. These are the estimates reported as primary in Tables 4 and 5.

[3] Nearest-neighbor matching on propensity scores (predicted probability of being spec'd based on JIT features), caliper = 0.05 SD.

**Table 8** Issue-linked specifications vs. other operationalizations (within-author LPM).

| Test | → bugs coef | $p$ | → rework coef | $p$ |
|---|---|---|---|---|
| Issue-linked vs no spec | +0.011 | 0.037 | +0.014 | $< 0.001$ |
| AI + issue vs AI + no spec | +0.014 | 0.436 | +0.017 | 0.192 |
| Human + issue vs human + no spec | +0.012 | 0.035 | +0.013 | 0.002 |
| Top-20% quality issue vs no spec | −0.007 | 0.363 | +0.019 | 0.007 |
| Issue-linked vs ticket-only | +0.007 | 0.637 | +0.026 | 0.025 |

### 5.6.10 Temporal Analysis: The SDD Era

We restrict to the most recent three months (January–March 2026), when specification rates are highest (29.3%) and AI adoption most prevalent (8.8%), to test whether the null result is a historical artifact.

In the period of highest SDD adoption, specifications are associated with more rework (+0.016, $p = 0.001$, against +0.012 in the full dataset) and directionally more defects (+0.004, $p = 0.435$, against +0.014). Among AI-tagged PRs in this window, specifications affect neither defects (+0.003, $p = 0.822$) nor rework (+0.016, $p = 0.212$), and the spec × AI interaction remains null (+0.011, $p = 0.861$). The null result therefore persists in the data most representative of the SDD era. SZZ-traced defect rates for recent months are likely underestimates due to right-censoring, but this affects absolute rates, not the relative spec'd versus unspec'd comparison.

### 5.6.11 Complexity Stratification

We stratify by the top 20% of three complexity measures (code churn, change entropy, composite JIT risk) to test whether specifications help most on the hardest tasks.

The result is opposite to the SDD prediction. In the top quintile, specifications are associated with substantially *more* defects and *more* rework: +0.040 and +0.051 for churn (both $p < 0.001$), +0.024 ($p = 0.057$) and +0.039 ($p < 0.001$) for entropy, and +0.028 ($p = 0.028$) and +0.039 ($p < 0.001$) for JIT risk. In the corresponding bottom-80% strata every coefficient collapses toward zero and none approaches significance for defects (churn +0.007, $p = 0.114$; entropy +0.000, $p = 0.986$; JIT risk +0.002, $p = 0.713$). Confounding by indication is thus strongest precisely where specifications should help most, and the association disappears on simpler tasks. Specification quality (H3/H4) is null across all strata.

### 5.6.12 Issue-Linked Specifications

A further objection is that our `specd` measure admits weak signals such as bare ticket identifiers. We therefore restrict to the 18,600 PRs that link to a GitHub issue – the closest available proxy for a pre-implementation specification, and, per Table 2, roughly three quarters of the treatment rather than a narrow subset of it.

Issue-linked specifications show the same pattern: defect associations are positive or null, never protective. Even top-20% quality GitHub issues show no defect reduction ($p = 0.363$). For AI-tagged PRs with issue-linked specs, both defects ($p = 0.436$) and rework ($p = 0.192$) are non-significant.

### 5.6.13 Summary

The null holds across four outcome measures, JIT controls, matching, SZZ misattribution bounds, seven quality dimensions, PR- and repo-level analysis, six subgroup cuts, five complexity strata, issue-linked specs, quality thresholds, dose-response, and temporal restriction. The only estimate pointing the other way is rework in repositories with no detected AI use ($-3.3$pp, nominal $p = 0.014$), which does not survive correction for six tests. No specification measure robustly predicts fewer defects under any operationalization.

## 6 Discussion

### 6.1 Confounding by Indication

The two hypotheses about specification *presence* follow an identical pattern: unadjusted analysis suggests specifications accompany worse outcomes; within-author analysis attenuates but does not eliminate the reversed association; propensity score matching on JIT features eliminates it entirely, confirming confounding by indication [20]. Developers rationally invest specification effort in proportion to task complexity. The remaining three fail differently rather than following the same arc: specification *quality* (H3, H4) shows no association with either outcome at any level of adjustment, and specifications accompany larger AI-tagged and human changes alike (H5), with an interaction that is effectively zero.

JIT risk profiles confirm this: spec'd PRs have more lines added (1.8×), touch older files (2.3×), and involve more prior developers (1.3×), while their authors have *less* experience (median 64 vs. 116 prior commits) – consistent with specifications being a support mechanism for harder tasks.

The null admits two readings – specifications genuinely have no effect, or a small protective effect is concealed by residual task selection – and observational data cannot separate them. What we can say is that estimates are *directionally reversed* across most tests and that matching eliminates both associations. Any protective effect is smaller than this study can detect.

### 6.2 Why Specifications May Not Prevent Defects

For a specification to prevent a defect, every link in a long causal chain must hold. The developer must correctly identify the problem, know in advance what will solve it, and know how to execute that solution. They must then describe the solution in natural language precisely enough that the AI does not misinterpret it, and the AI must implement that description without introducing bugs of its own. Finally, the specification must contain no substantial omissions – which requires the developer to specify what they do not yet know they do not know. Each condition is individually uncertain, and the probability of the full chain holding diminishes rapidly as they compound. Defects arise precisely where human understanding is incomplete, and specifications are written by the same humans whose incomplete understanding produces those defects.

SDD vendors conflate *directing* the AI (telling it what to build) with *ensuring quality* (fewer defects, less rework). Specifications may be effective at direction, but an agent faithfully executing a spec will reproduce every gap, ambiguity, and wrong assumption in that spec. Direction is not quality.

## 6.3 Vendor Evidence

No SDD tool vendor has published empirical evidence for these quality claims. GitHub describes Spec Kit as "an experiment" [8] with no effectiveness data. Third-party evaluations are negative (Section 2).

The sample contains no SDD tool output to measure, established two ways. A text search across all 100,247 collected PRs – titles, descriptions, and changed-file paths – returns zero matches for `.specify/`, `.speckit/`, `.kiro/`, or `spec-kit`. A file-tree audit of all 119 repositories, checking each default branch for the directories these tools create, likewise finds none; we ran this manually at data collection (April 2026) and programmatically in July 2026, with the same result both times.

The audit does find three repositories that exclude SDD tool output from version control: `apache/airflow` and `apache/spark` ignore `.kiro/` (in Airflow's case among AI-tool exclusions alongside `.claude/` and Cursor), and `grafana/grafana` ignores `.specs` with the comment "Spec-kit files shouldn't be committed without a major design process." Where these tools are used at all here, their artifacts are deliberately kept out of the repository and are therefore invisible to any artifact-based measurement, including ours – the concrete reason we test specification artifacts rather than SDD tool adoption (Section 7). Vendors have the data to conduct controlled evaluations; the absence of published results alongside specific quality claims is a gap experiments could close.

We do not argue that thinking about requirements is wasted effort. We argue that the *products* claiming to reduce defects through specification artifacts have not demonstrated that they do.

# 7 Threats to Validity

## 7.1 Construct Validity

Three gaps separate what we measure from what SDD vendors claim, and the largest is the distance between a specification artifact and spec-driven development as a practice. Spec Kit and Kiro generate structured documents through a guided workflow that an agent then implements; a pull request referencing a tracking issue is not that, and Table 2 shows such references constitute 97.5% of our treatment. Our result concerns specification artifacts in ordinary pull request workflows and should not be read as a measurement of SDD tool adoption – a claim not merely untested here but untestable in this sample, since no repository commits SDD tool output and the three mentioning such tools do so to exclude their output from version control (Section 6.3). The nearest approximation available is the top-quartile quality subsample, scored on the dimensions the tools prescribe, and it too shows no robust effect.

A second gap concerns artifacts versus processes: if the benefit comes from the thinking rather than the document, our measure is too coarse to detect it. Two features of the design limit this without eliminating it. The within-author comparison holds constant any consistent habit of thought a developer brings to their work, and H3 and H4 test quality *within* spec'd PRs – if deeper thinking yielded better artifacts, those artifacts ought to predict better outcomes. They do not.

Third, we cannot observe agentic workflows directly. Even where an AI-tagged PR carries a specification, we do not know whether it was supplied to the agent as input, written after the fact, or never read. The 175-author subsample combining AI tags with high-quality specifications is the closest proxy we have, and a loose one.

## 7.2 Internal Validity

Defect detection is noisy, and the noise may not be random with respect to our treatment. SZZ's high misattribution rate compounds with the fact that spec'd PRs present more `git blame` targets (Section 5.6.1). This is why we do not rest the defect result on unmatched SZZ estimates: matching removes the association entirely, and rework provides an outcome that does not use SZZ at all and shows the same absence of benefit (Section 5.6.1 bounds both cases). Even so, confounding by indication and differential SZZ noise remain difficult to disentangle fully.

Confounding by indication is the primary threat to the causal reading. The within-author design removes stable differences in skill, style, and context, but not task selection *within* a developer – the same person may reserve specifications for their harder work. The JIT-controlled models and matching address this directly, and both return a null for defects. The estimator also assumes an author's skill and tooling are stable across the window, which over twelve months of rapid change in AI tooling is unlikely to hold exactly.

Three measurement limitations remain. Our quality rubric is LLM-applied with limited human validation and captures *formal* quality – whether error states are described – rather than *functional* quality – whether the *right* ones are; it was also applied only to PRs with substantial description text, producing a non-random subsample. The control group may be contaminated: some PRs classified as unspec'd may have been specified verbally or in an external tool we cannot see, attenuating any true effect toward zero. And AI detection depends on voluntary tagging, with 98.8% precision but 24.2% recall, so roughly three quarters of AI-assisted work is invisible – diluting the H5 comparison and contaminating any subgroup defined by the absence of AI tags.

## 7.3 External Validity

All 119 repositories are open-source, while SDD tools are marketed principally to commercial teams whose specification practices, review norms, and defect economics differ from those of public projects. Our results speak to open-source pull request workflows and should not be extrapolated to commercial development.

The sample is also purposive rather than random, and Section 4.1.1 sets out how it was built and what follows from that. Repositories were stratified on specification practice and AI adoption and deliberately enriched for strong specification practice, which biases toward finding an effect rather than toward the null we report; but the sample was not drawn from an enumerated population, and results cannot be generalized beyond it.

Finally, most pull requests in the window predate widespread agentic coding tools. Within the 5,989 AI-tagged PRs, specifications affect neither defects ($p = 0.424$) nor rework ($p = 0.399$), but a genuinely agentic workflow – a specification authored as agent input and implemented end to end by the agent – is barely represented here, and we cannot rule out that it would behave differently.

## 7.4 Conclusion Validity

We test five hypotheses without correcting across them, so roughly 0.25 false positives are expected by chance at $\alpha = 0.05$; within the subgroup analysis we do correct, and the single positive result fails the Bonferroni threshold for six tests (Section 5.6.6). Power does not explain the AI interaction result: identified from 366 authors, the estimate is not merely non-significant but effectively zero ($p = 0.997$) with a tight interval around it.

All analyses are post-hoc, and sample size was not fixed in advance (Section 4.1.1). The twelve robustness checks show the null to be stable across outcome definitions, control sets, subgroups, and estimators, but stability across post-hoc specifications is weaker than a pre-registered confirmatory test – the obvious next step for anyone wishing to settle the question.

## 8 Conclusion

We tested five SDD vendor claims against 88,052 pull requests across 119 repositories, scoring specification artifacts on the same quality dimensions SDD tools prescribe and comparing each developer's spec'd work to their own unspec'd work. None of the five hypotheses are supported. Once task complexity is matched, spec'd and unspec'd PRs are indistinguishable in defect introduction, and rework shows no protective effect under any specification of the model. Specification quality predicts neither defects nor rework, and specifications do not constrain the scope of AI-tagged changes. Across twelve robustness checks, the null holds. Specification presence proxies for task complexity, not quality improvement.

A single estimate points the other way: in repositories with no detected AI use, specifications are associated with less rework ($-3.3$pp, nominal $p = 0.014$). It does not survive correction for six subgroup tests, and we report it as suggestive rather than as a finding.

Three caveats bound these results (Section 7): we test specification artifacts – in practice, references to tracking issues and tickets – not SDD tool output, which no repository in the sample commits; SZZ carries 46–71% misattribution noise, which is why matched estimates and the SZZ-independent rework measure carry the argument; and the sample is purposive and open-source. Whether purpose-built SDD tooling would produce different results is a question vendors can answer with the data they already have.

Specifications may still have value – as auditable records of intent, as task-batching mechanisms for AI agents, and as accountability artifacts that invite review scrutiny. These are real benefits. They are not "fewer defects," and the evidence does not support the claim that specifications are most valuable when AI implements the code.

## Abstract

Software migrations are frequent and high-stakes industrial activities. Although large language models (LLMs) are increasingly used in software development, their suitability for migration remains uncertain because migration requires semantic preservation, project-specific context, security, and production accountability. We investigate why practitioners undertake software migrations, what motivates and constrains the use of LLMs for migration, where LLM assistance is considered acceptable, and which factors determine trust in LLM-migrated code. We conducted a practitioner survey with 61 retained industry respondents, combining an internal industrial sample with an open professional survey. We analyzed closed and Likert-style items quantitatively and interpreted open-ended responses thematically. Migration was primarily framed as a bundled quality-risk activity: maintainability, scalability, and security were the dominant motives, while cost reduction rarely appeared as a standalone driver. Respondents valued LLMs mainly as accelerators for exploration, prototyping, and routine transformation, but not as autonomous migration agents. Acceptability was strongly bound by scope and control: 62.3% considered LLMs acceptable most of the time or almost always for single-file migration, compared with only 4.9% for entire-project migration. Trust depended chiefly on semantic correctness, project-context awareness, security, verification evidence, and provenance disclosure. Practitioners do not reject LLM-assisted migration outright; rather, they adopt a conditional trust model. LLMs are viewed as useful migration accelerators, but acceptable production use depends on bounded scope, human review, assurance evidence, traceability, and clear accountability.

## 1 Introduction

Software migration is a central activity in software maintenance and evolution, enabling systems to remain maintainable, scalable, and secure amid changing requirements and ecosystems. Industrial migrations, such as language transitions, framework upgrades, or architectural shifts, are often large-scale, costly, and error-prone, as they require extensive code transformation while preserving system behavior and operational constraints [14, 12, 23].

In parallel, large language models (LLMs) have rapidly emerged as a powerful paradigm for software engineering tasks. Recent work has demonstrated their effectiveness in code generation, refactoring, bug fixing, and documentation support [5, 24, 6]. These capabilities have led to widespread adoption of LLM-based tools in industrial development workflows, where they are primarily used to accelerate coding tasks and reduce repetitive effort [6, 40, 28].

More recently, both research and practice have begun exploring the use of LLMs for code transformation and migration tasks, such as translating code across programming languages, adapting APIs, or restructuring legacy code [24, 5, 10]. While these approaches show promising results in controlled settings, they typically focus on functional correctness at the snippet or file level, often evaluated through benchmarks or small-scale experiments [24, 26, 33, 36]. Existing repository-level translation studies show that performance on fine-grained translation tasks does not directly scale to full repositories. While prior approaches improve scalability by decomposing programs into smaller translation units and using dependencies primarily to determine translation order, they often translate interdependent components in isolation. This can lead to integration inconsistencies, as strong fragment-level translation accuracy does not guarantee correctness at the repository level, where inter-file dependencies, build constraints, and system-level validation are essential [35, 16, 31, 38].

Industrial software migration introduces requirements that go beyond these settings. Migration tasks must preserve semantic behavior across complex systems, maintain compatibility with existing architectures, adhere to organizational coding standards, and satisfy strict quality and security constraints. In this context, even small deviations, such as mishandled edge cases or incorrect assumptions about system context, can lead to significant failures in production. As a result, the applicability of LLMs to real-world migration remains uncertain. This creates a fundamental tension: LLMs promise productivity gains and reduced effort, yet industrial migration demands high trust, reliability, and verifiability. Despite growing interest in LLM-assisted development, there is limited empirical evidence on how practitioners perceive and adopt LLMs for software migration in real-world settings. Existing research has largely focused on model capabilities, while questions of trust, adoption boundaries, acceptable usage scope, and perceived risks remain underexplored, particularly in industrial contexts. Understanding these factors is essential, as they ultimately determine whether and how LLM-based approaches can be integrated into production migration workflows.

This study was motivated by industrial migration experience at CHECK24, where practitioners had performed large-scale software migration in production systems and encountered the practical question of whether, where, and under what conditions LLMs could support such work. These experiences highlighted a broader industrial problem: LLMs may accelerate migration tasks, but migration work also requires semantic preservation, project-specific context, security, reviewability, and accountability. To investigate this problem systematically, we conduct a practitioner survey on LLM-assisted software migration, combining responses from CHECK24 practitioners with an open survey of developers across organizations. This design allows us to capture both context-rich insights from a concrete industrial migration setting and broader practitioner perspectives on the motivations, risks, and trust conditions surrounding LLM-assisted migration. We structure our investigation around the following research questions:

**RQ1 (Migration intentions).** What are the intentions (business and engineering) driving software migrations in industry, and how do these vary by role, production exposure, and migration type?

*This RQ characterizes why organizations initiate migrations (e.g., maintainability, scalability, security, cost, ecosystem constraints). It also examines whether prioritization of these intentions differs across practitioner roles, exposure to production migrations, and the categories of migrations performed.*

**RQ2 (Motivations for using LLMs).** What motivates practitioners to use LLMs for migration work, and what conditions (risk perceptions, required assurance, review effort) gate their willingness to use LLM-generated migration code in production?

*This RQ captures the perceived value proposition of LLMs for migration tasks (e.g., productivity, reduced barrier of entry, faster exploration) and the factors that constrain adoption. It focuses on production readiness by eliciting the assurances, verification evidence, and review processes required before accepting LLM outputs.*

**RQ3 (Acceptability scope and conditions).** Where (and under what conditions) are LLMs acceptable for migration tasks?

*This RQ operationalizes acceptable usage boundaries by studying which migration granularities practitioners tolerate (e.g., small parts, single files, entire projects) and how this changes between non-production and production contexts. It also covers attitudes toward partial versus full automation and the expected role of human oversight.*

**RQ4 (Trust determinants).** What risks, failure modes, and quality expectations determine trust in LLM-migrated code?

*This RQ identifies the principal sources of distrust (e.g., semantic drift, mishandled edge cases, security concerns, increased review burden) and the quality attributes practitioners consider non-negotiable for migrated code. It relates these expectations to perceived impacts on key outcomes such as code quality, maintainability, security, and review effort.*

Our results reveal a consistent pattern across both the company-internal and open-survey samples. Practitioners recognize LLMs as useful tools for supporting localized migration tasks, such as transforming small components or accelerating exploratory work. However, they express strong reservations regarding fully automated migration, particularly in production environments. Instead, developers favor partial automation combined with human review, reflecting a cautious, control-oriented adoption model. Trust in LLM-generated migration code is primarily shaped by concerns about semantic correctness, handling of edge cases, integration with system-specific context, and security implications. Moreover, respondents tend to treat LLM-generated migration code as draft material requiring substantial review rather than as production-ready output.

In summary, this paper makes the following contributions:

- Empirical evidence on how industrial practitioners perceive LLM-assisted code migration.
- A characterization of acceptable usage boundaries, highlighting the role of granularity and human oversight.
- An analysis of trust determinants, including risks, failure modes, and quality expectations.
- Actionable insights into adoption barriers and enabling conditions for integrating LLMs into migration workflows.

By grounding LLM-assisted migration in practitioner perspectives, this work contributes to a more realistic understanding of how such techniques can be applied in industrial software migration.

## 2 Related Work

Software migration and code translation have long been studied in software maintenance and evolution, including concrete settings such as Java-to-Kotlin migration and C-to-Rust translation, where migration must preserve behaviour, integrate with the target ecosystem, and satisfy quality and safety constraints beyond syntactic rewriting [23, 14, 12]. Neural and LLM-based translation work has shown both the feasibility and limitations of automation: early approaches demonstrated unsupervised program translation [26], while recent benchmarks and empirical studies report semantic mistakes, edge-case failures, and translation bugs in multilingual translation [36, 24, 33, 37, 7]. Related work on API and library migration shows that LLMs can support more specific migration tasks, but correctness and validation remain central challenges [39, 2].

Recent work has moved from isolated translation tasks to repository-, system-, and industrial-scale migration, showing that local translation accuracy does not directly scale to whole systems where inter-file dependencies, build constraints, and cross-component consistency become central [16, 35, 38]. To improve validation, other approaches combine LLMs with tests, static or dynamic analysis, call graphs, or human feedback [27, 31, 21, 10]. Industrial experience reports, including large-scale LLM-assisted migration at Google, demonstrate practical potential while still relying on review, validation, and developer oversight [40].

Recent practitioner studies have examined how developers use AI and GenAI tools for code-related tasks. Wang et al. show that practitioners expect code completion to be correct, context-aware, controllable, and usable [34], while Liang et al. find that AI programming assistants are valued for reducing effort and accelerating implementation, but remain difficult to steer when suggestions violate functional or non-functional expectations [19]. Li et al. further show that adoption is shaped not only by individual productivity motives, but also by organizational factors such as policy, privacy, training, and knowledge sharing [18]. Recent studies also identify risks around GenAI-generated code, including licensing, provenance, ownership, and long-term effects on expertise and accountability [32, 8]. Overall, this work shows that practitioners view AI coding assistants as useful but conditional support tools; however, it mainly studies general coding, code completion, productivity, adoption, or legal concerns. To the best of our knowledge, prior survey work has not examined LLM-assisted software migration as an industrial trust and acceptability problem. We address this gap by combining internal and broader practitioner responses to characterize the conditions under which LLMs are viewed as useful, acceptable, and trustworthy for production migration workflows, rather than evaluating a specific migration technique.

## 3 Methodology

We designed a survey to address the research questions introduced in Section 1, following established guidelines for survey research in software engineering [25, 20, 29, 30]. The survey aimed to examine how software practitioners with varying levels of experience perceived, used, and trusted LLMs in software migration tasks. We adopted a mixed-methods design: closed and Likert-style questions collected structured evidence on migration experience, LLM usage, perceived usefulness, acceptability boundaries, quality expectations, and trust, while open-ended questions captured explanations, contextual constraints, and concerns not covered by predefined response options.

## 3.1 Survey Instrument

We iteratively developed the survey instrument (Table 1) from literature-derived constructs aligned with our research questions. The survey included closed, multi-select, Likert-style, top-$k$ selection, and open-ended questions. Likert-style items measured degree-based constructs, including self-rated experience, familiarity with LLMs, importance of migration drivers and quality expectations, and perceived LLM impact on software-engineering outcomes. Open-ended questions followed selected structured items to elicit explanations and additional themes. To ensure practical relevance, we conducted formative scoping interviews with six practitioners from CHECK24, one of the largest comparison-platform companies in Germany. Their feedback on migration challenges and LLM-use concerns informed the questionnaire's structure, wording, and response options. The interviews were used only to improve construct validity and real-world applicability and were not analyzed or reported as an independent empirical dataset.

**Table 1** Survey questions mapped to research questions with measured constructs. Legend: C = Closed, L = Likert, O = Open-ended, B = Both.

| RQ | Question | Measured Construct | Type |
|---|---|---|---|
| **RQ0** | Q1: Primary role (Developer, Manager) | Practitioner role | C |
| | Q2: Role experience (Developer/Manager experience) | Seniority | C |
| | Q3: Have you migrated a project/system? | Migration exposure | C |
| | Q4: Type(s) of migration performed | Migration expertise | C |
| | Q5: Self-rated migration experience | Migration expertise | L |
| | Q6: Familiarity with LLMs | LLM awareness | L |
| | Q7: Used LLMs for work before | LLM exposure (work) | C |
| | Q8: Experience using LLMs for coding | LLM coding usage | C |
| | Q9: Experience using LLMs for migrations | LLM migration usage | C |
| | Q12: LLMs used for work | LLM usage (work) | C |
| | Q13: LLMs used in general | LLM usage (general) | C |
| | Q14: Preferred LLM for coding | LLM preference | C |
| | Q15: Coding assistants used for work | Assistant usage (work) | C |
| | Q16: Coding assistants used in general | Assistant usage (general) | C |
| | Q17: Most frequently used coding assistant | Assistant preference | C |
| | Programming language background | Technical ecosystem | C |
| **RQ1** | Q10: Migration intentions (e.g., scalability, maintainability, cost) | Migration drivers | L |
| | Q11: Other migration intentions (free-text) | Additional drivers | O |
| **RQ2** | Q18: Contexts of LLM usage (general, coding, migration) | Usage contexts | C |
| | Q19: Drivers of LLM adoption in workplace | Adoption motivation | C |
| | Q28: Workflow advantages using LLMs | Workflow benefits | B |
| | Q29: Advantages in LLM-generated migration code | Migration-specific benefits | B |
| | Q37: Adoption hurdles of LLMs | Barriers and constraints | C |
| **RQ3** | Q20: Acceptability by migration granularity | Scope acceptance | C |
| | Q21: Reasoning for acceptability (free-text) | Justification | O |
| | Q22: More critical in production vs non-production | Production sensitivity | C |
| | Q23: Comfort reviewing full-project LLM migrations | Review confidence | C |
| | Q24: Willingness to improve LLM migration systems | Engagement readiness | C |
| | Q25: Stance on automation (full vs partial) | Automation preference | C |
| | Q38: Willingness to actively support LLM migration adoption | Adoption participation | C |
| | Q39: Confidence reviewing full-project migration before deployment | Deployment readiness | C |
| | Q40: Willingness to deploy automated migrations in production | Production deployment stance | C |
| | Q41: Acceptance of full automation | Automation stance | C |
| | Q42: Acceptance of partial automation | Automation stance | C |
| **RQ4** | Q26: Workflow issues when using LLMs | Workflow failure modes | B |
| | Q27: Issues in LLM-generated migration code | Migration failure modes | B |
| | Q30: Importance of quality expectations | Required quality attributes | L |
| | Q31: Additional expectations (free-text) | Extended quality attributes | O |
| | Q32: Deviating standards for LLM vs manual migration | Standard differences | O |
| | Q33: Whether LLMs or humans are held to higher standards | Trust baseline | C |
| | Q34: Trust depending on code source and disclosure | Source-based trust | C |
| | Q35: Importance of outcome dimensions | Outcome importance | L |
| | Q36: Perceived impact of LLMs on outcomes | Outcome impact | L |
| | Q37: Adoption hurdles affecting trust | Trust barriers | C |

The questionnaire consisted of five parts. First, we collected participant context, including role, professional experience, migration experience, familiarity with LLMs, prior use of LLMs and coding assistants, and programming-language background, to characterize the sample and contextualize later responses. Second, we examined software migration experience and intentions. Respondents rated the relevance of common business and engineering drivers, including maintainability, scalability, cost reduction, security, and ecosystem constraints, and provided open-ended responses for additional intentions not covered by predefined options. Third, we assessed LLM usage and adoption, including general and workplace use of LLMs and coding assistants, use for coding and migration, perceived adoption drivers, workflow advantages, and migration-specific advantages of LLM-generated code. Fourth, we evaluated the acceptability of LLM assistance for migration tasks across granularities, including single files, small system components, and entire projects. We also examined production sensitivity, confidence in reviewing LLM-migrated projects, willingness to support LLM-based migration adoption, and attitudes toward partial and full automation. Fifth, we investigated trust, risks, failure modes, and quality expectations, including workflow issues, migration-specific issues in generated code, required quality attributes, differences between LLM-performed and manual migrations, source-based trust, and perceived impacts on productivity, maintainability, security, code quality, and review effort.

## 3.2 Participants and Sampling

The target population comprised software practitioners with experience in software development, software migration, LLM-assisted development, or combinations thereof. We collected responses from two complementary non-probabilistic samples. The first was an internal industrial sample from CHECK24, selected through purposive sampling: practitioners were invited because they had participated in industrial software migration work, including language migration in production systems. This provided first-hand migration experience from an organizational setting. The second was an open survey of professional developers outside the internal organization, recruited through convenience sampling via the authors' professional networks, primarily LinkedIn and related contacts, to broaden the study beyond one organization and capture other industrial perspectives. Accordingly, we do not claim statistical representativeness; rather, the samples provide empirically grounded evidence on practitioner perceptions, adoption conditions, and trust boundaries for LLM-assisted software migration.

## 3.3 Data Collection

Data were collected between January 2026 and April 2026. Accordingly, the findings represent practitioner perceptions during this period and should be interpreted in the context of the LLM capabilities and tooling available at that time.

We invited 73 practitioners from the internal organization who have migration experience. The internal practitioners survey yielded $N = 25$ responses. The open survey yielded $N = 42$ raw responses. The internal sample was analyzed as an industrial migration-practitioner sample. The open sample was filtered to retain respondents who were employed industry developers and provided usable survey data. Because the open survey was distributed through LinkedIn and professional contacts, the total number of recipients was not known, and a response rate could not be computed. Prior to participation, respondents were informed that the survey was strictly anonymous, required no personally identifiable information, and would take approximately 15 minutes. While the questionnaire was presented in English,

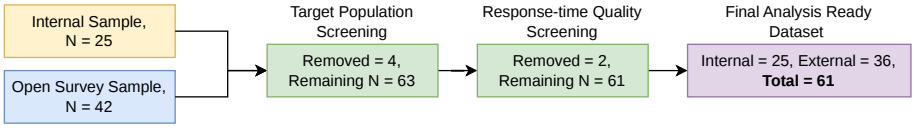

**Figure 1** Filtering process for the full survey sample.

free-text responses were accepted in either English or German. Participants were encouraged to answer precisely or provide custom feedback if predefined options were inadequate. Finally, any voluntarily disclosed company affiliations are used solely to demonstrate sample diversity, ensuring no identifiable organizational data is reported.

## 3.4 Data Filtering and Preparation

We applied a two-step conservative filtering strategy to the full set of collected responses. The first filtering step checked target-population membership. For the internal sample, this criterion was satisfied by design because practitioners were invited based on involvement in industrial software migration. For the open survey, we explicitly applied the same criterion and removed four responses from participants who were not currently employed as industry developers and provided no substantive answers beyond the screener, reducing the open-survey sample from $N = 42$ to $N = 38$. The second step screened response-quality risks using completion time. Among screened responses, the mean completion time was 18.76 minutes, the median was 11.58 minutes, and the 5th percentile was 5.23 minutes. We therefore used completion time below five minutes as a conservative threshold and applied it to both samples. Two open-survey responses fell below this threshold and were excluded; one also showed straight-lining across Likert-style items, with all detected Likert-style answers marked neutral. No internal response fell below the five-minute threshold. After filtering, the final dataset comprised $N = 61$ practitioner responses: $N = 36$ open-survey respondents and $N = 25$ internal respondents. Respondents were not excluded solely for lacking migration experience; instead, migration experience was used as a contextual variable, enabling comparisons between migration-experienced respondents and other industry developers while retaining data on general LLM adoption, perceived trust, and acceptability. Figure 1 summarizes the two-step filtering process for the full survey sample, distinguishing the open-survey and internal samples.

For subgroup analyses, screening questions classified respondents by general, production, or migration experience. Closed, multi-select, and Likert-style items were encoded as categorical, binary, and ordinal variables. Since Likert intervals were treated as unequal, we analyzed them using medians, interquartile ranges, and distributions; top-k questions by frequency; and valid open-ended/custom responses as coding units for thematic analysis.

## 3.5 Sample Coverage and Scope of Inference

The final dataset comprises $N = 61$ valid practitioner responses, including an open survey sample ($N = 36$) and an internal sample ($N = 25$). It provides empirical coverage of the target phenomenon: 57 respondents had participated in software migrations, 46 with production-environment experience, and 32 had used LLMs for migration tasks. Although non-probabilistic and not statistically representative of the broader population, this complementary sample offers sufficient depth for the exploratory and descriptive aims of this study.

## 3.6 Quantitative Analysis

We analyzed categorical data using frequencies and percentages, and evaluated ordinal Likert responses through distributions, medians, and interquartile ranges.

For within-respondent comparisons, we employed Friedman tests [11] (effect size: Kendall's W [17]) followed by Holm-corrected Wilcoxon signed-rank post-hoc tests [13]. We assessed exploratory between-group differences via Mann-Whitney U tests (effect size: rank-biserial correlations)[22, 9], interpreting these as indicative trends rather than population-level effects due to limited sample sizes. Finally, to address RQ2, we fitted an exploratory logistic regression, reporting odds ratios, 95% CIs, and p-values, to examine factors influencing perceived LLM helpfulness without inferring causality [1, 15].

Additionally, we systematically evaluated the research questions from distinct perspectives. RQ1 examined migration intentions across practitioner backgrounds; RQ2 analyzed LLM usage scenarios, adoption drivers, and barriers in migration tasks; RQ3 assessed developer acceptability and review confidence across migration granularities and automation levels; and RQ4 examined failure modes, trust mechanisms, quality expectations, and perceived impacts on code quality, security, and productivity.

## 3.7 Qualitative Analysis

We analyzed open-ended responses using thematic analysis [3, 4] via a four-step process: data familiarization, open coding, theme extraction (e.g., semantic drift, review burden), and mapping to research questions. Using a hybrid inductive-deductive approach guided by core survey constructs, two authors independently coded an initial subset, resolved disagreements to standardize a codebook, and then analyzed the full sample. The resulting qualitative themes were used to explain and contextualize our quantitative findings.

## 3.8 Integration of Quantitative and Qualitative Results

This study integrates quantitative and qualitative results to provide a comprehensive analysis. Quantitative data identified dominant response patterns, while qualitative feedback explained the underlying reasoning. For instance, the preference for LLM assistance in small migration tasks over full-project automation was driven by concerns regarding semantic preservation, missing context, security, and increased review effort. This mixed-methods approach moves beyond merely reporting frequencies, ultimately revealing the trust boundaries that shape practitioners' acceptance of LLM-assisted migration.

# 4 Results

We received 25 responses from the internal invitation wave sent to 73 practitioners and 42 responses from the external open survey. After filtering (Figure 1), the final analysis-ready sample comprised 61 practitioners: 25 internal respondents and 36 external respondents. The internal response rate was 34.2%; an external response rate could not be computed because the open survey was distributed publicly rather than through an invite-tracked sampling frame.

As presented in Figure 2 final sample was strongly practitioner-centric. Of the 61 respondents, 60 identified as developers and 14 also reported managerial responsibilities. Migration experience was widespread: 57 respondents reported some migration experience and 46 reported production migration experience. Prior LLM exposure was also high, with 54 respondents reporting LLM use for work, 57 for coding tasks, and 32 specifically for migration-related tasks. These distributions indicate that the sample is suitable for analysing practitioner experience with both software migration and LLM-supported development.

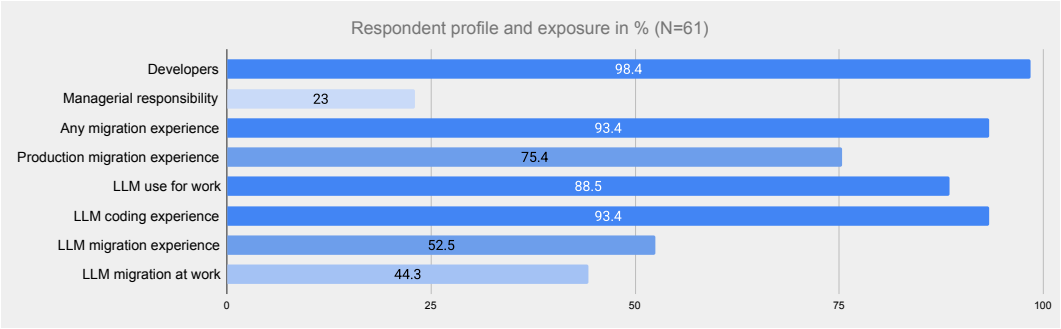

**Figure 2** RQ0: Respondent profile and exposure to migration/LLM-assisted development.

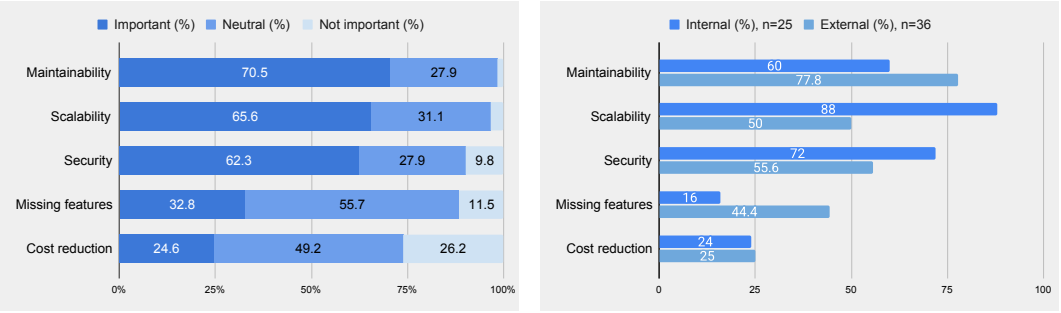
This baseline matters for interpreting the remainder of the study. The results should not be read as novice or purely speculative opinions about LLMs. Rather, the dataset predominantly captures views from respondents who have both migration exposure and practical familiarity with LLM-assisted coding, making later differences in acceptance and trust particularly informative.



## 4.1 RQ1: Migration Intentions

As shown in Figure 3a, migration was most often associated with maintainability, scalability, and security: 70.5%, 65.6%, and 62.3% of respondents rated these drivers as important, respectively. Missing features in the previous ecosystem or language were rated important by 32.8%, and cost reduction by 24.6%. Thus, in this sample, migration was framed primarily as a quality, evolvability, and risk-management activity rather than as cost optimisation.

The item-level responses further suggest that these drivers were bundled rather than isolated. Across the retained sample, 58/61 respondents (95.1%) rated at least one of maintainability, scalability, or security as important; 45/61 (73.8%) rated at least two; 18/61 (29.5%) rated all three; and only 3/61 (4.9%) rated none of them as important. Cost reduction was also non-isolated: although 15/61 respondents (24.6%) rated it as important, all of them also rated at least one of maintainability, scalability, or security as important. Similarly, among the 20 respondents who rated missing features as important, 19 also rated at least one of these three quality- and risk-oriented drivers as important. Cost and capability gaps therefore appeared as part of a broader evolvability and risk profile rather than as standalone migration motives.

The within-respondent ordering of migration drivers differed significantly across items, Friedman $\chi^2 = 45.88$, $p < 0.001$, Kendall's $W = 0.19$, indicating modest agreement in driver rankings. Maintainability, scalability, and security formed the highest-rated group, with no large separation among them, supporting the view that migration motives cluster as jointly important concerns rather than a sharp hierarchy.

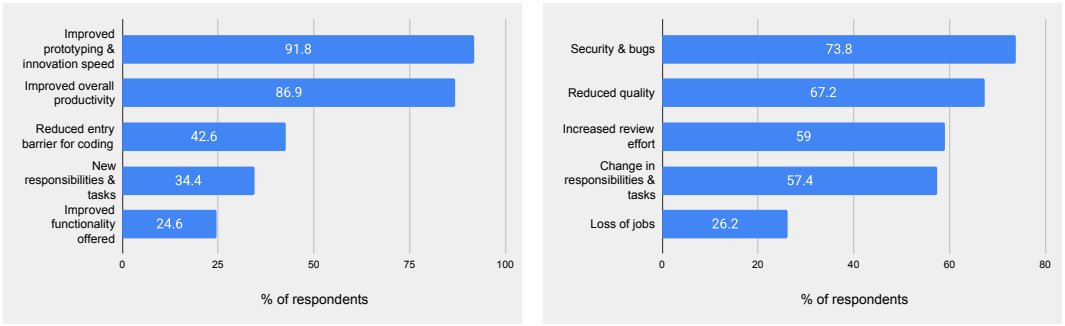
Figure 3b summarizes the company-internal practitioners(internal)–open-survey respondents(external) comparison. Internal respondents rated scalability higher than external respondents, mean 3.80 vs. 3.44, Mann–Whitney $p = 0.004$, rank-biserial effect $\approx 0.36$; external respondents rated missing ecosystem/language features higher, mean 3.33 vs. 2.76, $p = 0.010$, effect $\approx 0.35$ in the opposite direction. These results describe a difference between the CHECK24 sample and the external sample. Production experience may contribute to this pattern, but the groups also differ in organizational context, technology stacks, migration types, roles, and recruitment channels. The comparison is therefore associative and does not establish why the groups rated these drivers differently.

**(a)** Migration intention ratings ($N = 61$). **(b)** Proportion rating each driver as *Important*.

**Figure 3** RQ1: Migration intentions.

Migration type was also associated with perceived motives: respondents with infrastructure-migration experience rated scalability higher than those without such experience, mean 3.72 vs. 3.47, $p = 0.043$, effect $\approx 0.25$. This suggests that migration intentions partly depend on the technical locus of change, with infrastructure-oriented migrations particularly associated with scalability concerns.

Qualitative responses added pressures not captured by the Likert items: end-of-life technologies, unsupported frameworks or dependencies, hardware constraints, platform shifts, vendor/provider mandates, and organizational changes in ownership, team responsibility, or governance. Thus, migration intentions extend beyond technical debt or desired quality improvement to ecosystem expiry, external constraints, and organizational restructuring.



**Summary of RQ1.** *Migration was framed mainly as a bundled quality-risk activity, with maintainability, scalability, and security often co-occurring and cost reduction rarely appearing alone. Motives varied by context: scalability was stronger among internal and infrastructure-migration respondents, while external respondents emphasized ecosystem or language gaps. Qualitative responses added external constraints, ecosystem expiry, and organizational restructuring.*

## 4.2 RQ2: Motivations for using LLMs and gating conditions

Respondents perceived a strong value proposition for LLMs in migration, but mainly as support for acceleration rather than autonomous execution.

As shown in Figure 4a, the leading workplace adoption drivers were improved prototyping and innovation speed, selected by 56/61 respondents (91.8%), improved overall productivity, 53/61 (86.9%), and reduced barriers to unfamiliar coding tasks, 26/61 (42.6%). A separate workflow-advantage item showed the same migration-process pattern: faster migration and prototyping, 48/61 (78.7%); reduced manual effort and repetitive work, 44/61 (72.1%); and lower entry barriers for unfamiliar technologies, 41/61 (67.2%). Together, these results suggest that practitioners value LLMs mainly as accelerators for exploration, prototyping, and first-draft transformation, not as substitutes for human-controlled migration work.

This bounded interpretation is reinforced by context-specific helpfulness ratings. Respondents rated LLMs as more helpful in general and for coding than for migration, Friedman $\chi^2 = 20.18$, $p < 0.001$, Kendall's $W = 0.20$. Post-hoc Wilcoxon tests showed lower helpfulness for migration than for coding, $p = 0.003$, and general use, $p = 0.002$, while general and coding helpfulness did not differ reliably. Thus, respondents did not transfer general confidence in LLM-assisted programming directly to migration, treating it as a more constrained and higher-risk context.

**(a)** Adoption *drivers*: perceived benefits motivating LLM use in the workplace.

**(b)** Adoption *hurdles*: barriers constraining LLM use.

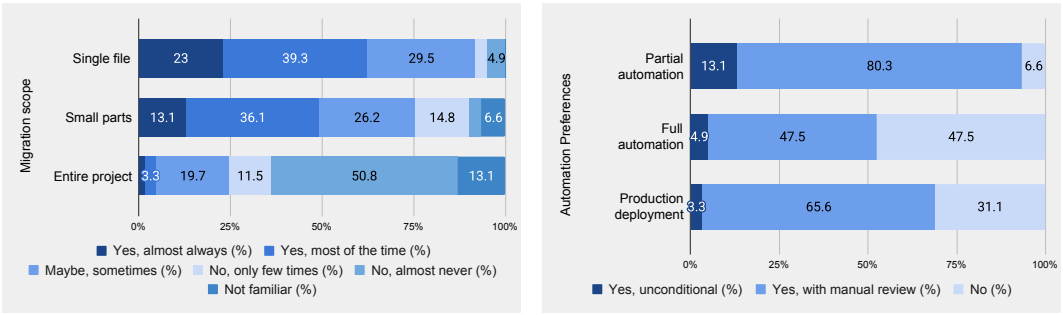


**Figure 4** RQ2: Adoption drivers and hurdles for LLM-assisted migration.

The exploratory logistic regression supports this distinction, but should be interpreted cautiously given the sample size and model specification. Rating LLMs as helpful for migration was strongly associated with having used LLMs for migration at work, OR = 9.30, 95% CI [1.99, 43.43], $p = 0.0046$. Managerial responsibility in addition to development was also positively associated with migration helpfulness, OR = 5.97, 95% CI [1.19, 30.08], $p = 0.030$, although this result is tentative because the confidence interval is wide and role may be confounded with seniority, decision responsibility, or migration-planning exposure. Generic LLM familiarity was positive but not statistically reliable. Thus, task-specific exposure to LLM-based migration appears more informative for migration-specific helpfulness than general LLM enthusiasm.

However, perceived usefulness did not imply unconditional production acceptance. Respondents imposed strong assurance gates: 46/61 (75.4%) were more critical of LLM-migrated code in production than in non-production settings. For automated LLM migration deployment in production, only 2/61 (3.3%) gave an unconditional "yes", while 40/61 (65.6%) supported deployment only with sufficient manual review and intervention, and 19/61 (31.1%) rejected it. For reviewing full-project LLM migrations before deployment, only 15/61 (24.6%) felt comfortable, 30/61 (49.2%) did so only under experienced supervision, and 16/61 (26.2%) did not. Adoption is therefore constrained not by categorical rejection of LLM assistance, but by the conditions under which LLM outputs become production-relevant.

Figure 4b summarizes the adoption hurdles behind these gates. The leading barriers were security and bugs, 45/61 (73.8%); reduced quality, 41/61 (67.2%); increased review effort, 36/61 (59.0%); and changes in responsibilities or tasks, 35/61 (57.4%). This reveals a central tension: LLMs may reduce implementation effort while increasing validation, review, and accountability costs. The tension was systematic: all 61 respondents selected at least one positive adoption driver, but 59/61 also selected at least one hurdle. Thus, the key adoption question is not whether LLMs are useful, but under which assurance conditions their outputs can be accepted.

The perceived advantages of LLM-generated migration code also indicate a bounded value proposition. Respondents most often selected code-level benefits related to target-technology conventions and routine migration hygiene: encoding common best practices, 35/61 (57.4%); avoiding common routine-migration mistakes, 30/61 (49.2%); applying standard architectural patterns, 28/61 (45.9%); and producing clear structure, separation of parts, and naming as prompted, 26/61 (42.6%). In contrast, only 8/61 (13.1%) selected less hidden and more explicit behaviour in code. Respondents therefore valued LLM-generated migration code mainly as structured first-draft scaffolding around known conventions, not as evidence of deep semantic assurance.

**(a)** LLM acceptability by migration scope. **(b)** Automation preferences.

**Figure 5** RQ3: Acceptability scope and automation preferences.

Qualitative responses further explain this boundary. Respondents justified caution through large-context confusion, opaque business logic, incomplete knowledge of undocumented systems, and the need for humans to understand and own high-stakes production changes. The main adoption gate is therefore not only whether an LLM can generate plausible migrated code, but whether the resulting changes can be reviewed, understood, secured, and accepted as organisationally accountable.

**Summary of RQ2.** *Practitioners valued LLMs mainly as migration accelerators: tools for exploration, prototyping, routine transformation, and reducing manual effort. However, perceived usefulness did not imply unconditional production acceptance; adoption remained gated by reviewability, assurance evidence, security, quality, and human accountability.*

## 4.3 RQ3: Acceptability scope and conditions

As shown in Figure 5a, acceptability declined sharply with migration scope. LLMs were considered acceptable most of the time or almost always by 38/61 respondents (62.3%) for single-file migration and 30/61 (49.2%) for small parts of a system, but only by 3/61 (4.9%) for entire-project migration. For entire-project migration, 38/61 respondents (62.3%) answered either "no, only very few times" or "no, almost never", 12/61 (19.7%) selected "maybe, sometimes", and 8/61 (13.1%) selected "not familiar". Thus, respondents did not reject LLM-assisted migration categorically; rather, acceptability collapsed when the unit shifted from localized code to whole-project transformation.

The scope effect was statistically and practically strong: within-respondent acceptability differed across migration scopes, Friedman $\chi^2 = 74.96$, $p < 0.001$, Kendall's $W = 0.72$. Post-hoc Wilcoxon tests showed a significant drop from single-file to small-part migration, $p = 0.023$, with a small effect, and much larger drops from small-part to entire-project and from single-file to entire-project migration, both Holm-adjusted $p \approx 4.0 \times 10^{-9}$. Scope therefore emerged as a central boundary condition: practitioners were comparatively open to bounded local assistance, but not to system-wide migration autonomy.

A second boundary concerns automation mode, summarized in Figure 5b. Support was strongest for partial automation: 57/61 respondents (93.4%) endorsed it conditionally or unconditionally, and only 4/61 (6.6%) rejected it. However, support was mainly review-preserving: 49/61 (80.3%) supported partial automation only with sufficient manual review and intervention, while 8/61 (13.1%) supported it unconditionally. Full automation was

weaker: 3/61 (4.9%) supported it unconditionally, 29/61 (47.5%) only with sufficient manual review and intervention, and 29/61 (47.5%) rejected it. Production deployment followed the same pattern: 2/61 (3.3%) supported automated LLM migration deployment unconditionally, 40/61 (65.6%) only with sufficient manual review and intervention, and 19/61 (31.1%) rejected it. Automation preferences differed significantly within respondents, Friedman $\chi^2 = 32.43$, $p < 0.001$, Kendall's $W = 0.27$. Pairwise tests showed stronger support for partial automation than for full automation, $p = 1.17 \times 10^{-6}$, and production deployment, $p = 2.67 \times 10^{-5}$, both with large effects. Full automation and production deployment did not differ reliably, $p = 0.072$, suggesting that respondents treated both as high-stakes escalation points relative to partial, human-controlled automation.

Review capability formed another practical boundary: only 15/61 respondents (24.6%) felt capable of performing the final review of full-project LLM-migrated code before production deployment; 30/61 (49.2%) would do so only under experienced supervision, and 16/61 (26.2%) would not. Thus, full-project migration was rejected not only because generation is difficult, but also because review itself is perceived as difficult, high-risk, and experience-dependent. Internal and external respondents showed the same overall acceptability boundary. External respondents were somewhat more accepting of small-part migration, Mann–Whitney $p = 0.047$, effect $\approx 0.30$, but there was no meaningful internal–external difference for single-file or full-project migration. Given the exploratory subgroup analysis, this difference should be interpreted cautiously. Overall, disagreement concerned where the safe bounded zone ends, not whether whole-project autonomy is broadly acceptable.

Prior LLM migration use did not remove this boundary. Among respondents who had used LLMs for migration at work, 14/27 (51.9%) supported full automation conditionally or unconditionally, compared with 18/34 (52.9%) among others. For production deployment, 19/27 respondents with LLM migration work experience (70.4%) supported deployment conditionally or unconditionally, compared with 23/34 (67.6%) among others. However, none of the experienced respondents supported production deployment unconditionally, and only 1/27 (3.7%) considered entire-project migration acceptable most of the time or almost always. Thus, caution about large-scope autonomy persisted even among respondents with task-specific LLM migration experience. Caution did not imply disengagement. Asked whether they would help drive and optimize automated LLM-based code migration at work, 31/61 respondents (50.8%) would take initiative, 11/61 (18.0%) would participate given an existing initiative, and 15/61 (24.6%) answered maybe if an opportunity arose. Only 2/61 (3.3%) would not participate, and 2/61 (3.3%) were unsure. Respondents were therefore willing to engage with LLM-assisted migration under bounded, reviewable, human-controlled conditions.

Qualitative answers explain this boundary consistently. Respondents associated larger migration scopes with context-window limitations, difficulty recovering implicit business logic from legacy systems, non-standard implementation patterns, weak project-specific knowledge, and higher costs of security or correctness failures. The acceptability boundary is therefore principally a context-and-control boundary rather than a simple capability boundary: practitioners are willing to use LLMs where the task remains local, reviewable, and human-owned, but not where migration becomes system-wide, autonomous, or production-critical.

**Summary of RQ3.** *Acceptability was strongly bounded by migration scope and automation mode. Respondents were comparatively open to LLM assistance for local, reviewable migration tasks, especially partial automation with manual intervention, but acceptance collapsed for entire-project migration, full automation, and production deployment.*

## 4.4 RQ4: Trust determinants, failure modes, and quality expectations

Trust in LLM-migrated code was shaped by three related factors: expected failure modes, non-negotiable quality attributes, and provenance transparency/accountability. Respondents did not frame trust mainly as syntactic correctness or stylistic polish; instead, trust depended on whether LLM-generated migrations preserved behaviour, captured project-specific context, avoided security regressions, and remained reviewable.

At the workflow level, the leading issues were LLMs misunderstanding or missing project aspects, 45/61 (73.8%); missing company-internal knowledge, 34/61 (55.7%); ignored project requirements, 30/61 (49.2%); and inconsistent results across runs, 25/61 (41.0%). At the generated-code level, the leading concerns were incorrect or missing edge-case handling, 39/61 (63.9%); changed semantic behaviour, 36/61 (59.0%); unnecessary code, changes, or revisions, 33/61 (54.1%); and code not meeting project requirements, 25/61 (41.0%). Thus, dominant failure modes were semantic and context-sensitive rather than merely syntactic: respondents worried whether LLMs could preserve system behaviour, respect implicit requirements, and handle project-specific knowledge. The quality-expectation ratings reinforce this interpretation. The highest-rated requirements were semantic equivalence, rated important or very important by 90.2% of respondents, median = 5; absence of syntax errors, 86.9%, median = 5; and security, 83.6%, median = 5. Test cases were also highly rated, with 78.7% rating them important or very important. Thus, trust in LLM-migrated code depends on more than whether the output compiles. Respondents expected migrated code to preserve behaviour, remain secure, and be supported by verification evidence.

Security emerged as a strong trust boundary: it was both a highly rated quality expectation and the only engineering outcome with a net negative perceived impact from current LLMs. Respondents were optimistic about productivity, 86.9% positive, mean impact = 0.87, and developer experience, 67.2% positive, mean = 0.62, but more cautious about review process, code quality, maintainability, and bug detection. Security stood out: 36.1% reported a negative impact, versus 14.8% positive, yielding a mean impact of -0.21. This suggests selective optimism: practitioners expect LLMs to improve speed and developer experience, but not necessarily the assurance properties needed for production trust. Subgroup comparisons suggest that trust expectations varied by context. Internal respondents placed higher importance on security than external respondents, mean 4.72 vs. 3.97, Mann–Whitney $p = 0.003$, effect $\approx 0.41$; external respondents placed higher importance on tests, mean 4.50 vs. 3.64, $p < 0.001$, effect $\approx 0.58$. These results indicate different emphasis in the CHECK24 and external samples: internal respondents rated security more highly, whereas external respondents rated test evidence more highly. The study cannot determine whether these differences arise from production exposure, organizational context, technology stacks, migration experience, or other group characteristics. These subgroup interpretations remain associative rather than causal.

Trust was strongly shaped by provenance disclosure. A repeated-measures comparison across four code-source conditions showed a large effect, Friedman $\chi^2 = 85.03$, $p < 0.001$, Kendall's $W = 0.50$. Explicit notice increased trust for both LLM- and human-written code: LLM-authored code rose from mean 2.70 without notice to 3.74 with notice, Wilcoxon $p = 5.42 \times 10^{-10}$; human-written code rose from 3.50 to 4.17, $p = 2.84 \times 10^{-9}$. Descriptively, LLM-written code with explicit notice was trusted more than human-written code without notice, suggesting that provenance transparency can partly offset source-based distrust. However, disclosure did not remove the source effect: even with notice, human-written code was trusted more than LLM-written code, 4.17 vs. 3.74, $p = 0.00135$. Thus, trust depended not only on human or LLM authorship, but also on traceability and explicit provenance;

notice improved reviewability and accountability, while LLM authorship retained a residual trust penalty. The internal–external split also appeared in perceived outcome impacts. External respondents were more optimistic than internal respondents about current LLMs' impact on maintainability, $p < 0.001$, code quality, $p < 0.001$, bug detection, $p = 0.001$, and developer experience, $p = 0.015$. Internal respondents were more sceptical of these outcomes and rated expected security impact less favorably. Across several measured outcomes, the CHECK24 sample expressed more cautious perceptions than the external sample. These differences should be interpreted as company-associated sample differences rather than as effects of production experience alone.

One nuance is that respondents did not generally claim that LLM outputs are held to a higher explicit standard than human outputs: 35/61 (57.4%) said people are held to a higher standard, 17/61 (27.9%) said the standard is equal, and only 3/61 (4.9%) selected LLMs. This does not imply a lower practical bar for LLM-generated migration code; rather, it suggests different default accountability. Human-generated migration code is expected to carry stronger ownership and responsibility, whereas LLM-generated code is treated as draft material requiring additional review before it can be trusted.

Qualitative responses support this interpretation. Respondents described LLM output as useful starting material, but not something to accept without deeper checking. They emphasized verifying semantic equivalence, inspecting edge cases, accounting for project-specific knowledge, and ensuring that humans understand and own high-stakes production changes.

**Summary of RQ4.** *Trust depended on semantic preservation, project context, security, verification evidence, and provenance transparency. Practitioners valued productivity gains but treated security as the main risk area. Provenance disclosure helped, yet LLM output remained draft material requiring substantial human review.*

## 5 Discussion

Overall, the results frame LLM-assisted migration as assurance-gated: useful for acceleration, but acceptable only when outputs are reviewable, verifiable, traceable, and human-owned.

**LLM-based Migration Challenges in Practices.** A key implication of RQ1 is that software migration is driven by long-term quality and security preservation rather than cost reduction. Consequently, LLM assistance cannot be evaluated solely by generation efficiency; it must support fundamental assurance goals. While LLMs accelerate the workflow, they simultaneously introduce substantial verification overhead. This conditional productivity highlights a critical trade-off: the implementation effort saved by LLMs must ultimately outweigh the added assurance burden required for validation.

Our findings reveal systematic practitioner ambivalence, marked by a clear distinction between partial automation and full autonomy. Practitioners accepted localized LLM support with manual review but rejected full-project automation and direct production deployment, regardless of prior experience. This suggests that they view LLMs as tools rather than accountable agents. Accordingly, migration tools should avoid end-to-end autonomous designs and instead support bounded migration units, expose intermediate transformations, and preserve human control over acceptance decisions.

**Scope exposes the limits of local code-generation evidence.** The sharp decline in acceptability from single-file to entire-project migration indicates that repository-level migration introduces systemic risks, including cross-file dependencies and implicit logic, making local correctness insufficient for industrial trust. To address this gap, we propose a three-level evaluation framework: local evidence, based on compilation and testing; integration evidence, based on cross-component consistency; and assurance evidence, based on reviewability, security, and accountability. Future evaluations should assess LLM-assisted migration across all three tiers rather than relying solely on localized functional metrics.

**Trust depends on assurance, provenance, and accountability.** Results from RQ4 indicate that trust in LLM-migrated code relies on an assurance context of provenance disclosure, reviewability, and accountability, rather than a mere preference for human authors. While practitioners acknowledge LLMs' productivity benefits, their distinct concerns regarding security reveal a separation between productivity gains and production-level trust. Because LLM-generated code lacks the implicit accountability of human developers, mere provenance disclosure is insufficient. Consequently, industrial LLM-assisted workflows must tightly integrate assurance mechanisms, such as security reviews, static analysis, and human inspection, rather than treating them as optional post-processing steps.

## 6 Implications for stakeholders

Our findings suggest that LLM-assisted migration should be designed and adopted as an assurance-gated workflow, with different responsibilities.

**Practitioners.** Practitioners should treat LLM-assisted migration as a scope- and evidence-gated activity, not as end-to-end automation. LLMs are best suited for bounded tasks such as single-file migration, API adaptation, boilerplate transformation, and exploratory first drafts. Before production use, teams should require semantic validation, regression tests, integration checks, security review, provenance information, and a named human owner. This shifts the workflow from "generate and deploy" to "generate, inspect, validate, and own".

**Tool builders.** Tool builders should design migration copilots rather than autonomous migration agents. Tools should decompose migrations into reviewable units, expose intermediate transformations, preserve links between prompts, outputs, and changed files, and highlight assumptions made during migration. Beyond code generation, tools should reduce assurance effort by integrating build checks, test support, static analysis, dependency checks, security scanning, and reviewer-oriented change summaries. The design goal should be inspectable and traceable migration support, not only higher generation accuracy.

**Engineering managers and organizations.** Engineering managers should assess LLM-assisted migration beyond speed, since reduced coding effort may be offset by review, validation, and accountability work. Organizations should define policies for acceptable scope, required evidence, provenance retention, reviewer responsibility, and production approval. For production-critical systems, LLM-assisted migration should follow controlled change management with rollback plans, auditability, security gates, and explicit human ownership.

**Researchers.** Researchers should evaluate LLM-assisted migration beyond snippet-level correctness or local translation accuracy. Industrial acceptance depends on semantic preservation, project context, cross-component consistency, security, reviewability, provenance,

and accountability. Future studies should include repository-level dependencies, realistic build/test environments, reviewer workload, assurance evidence, and production-readiness criteria. The key question is not only whether LLMs can migrate code, but what evidence makes their output acceptable in practice.

## 7 Threats to Validity

We discuss the main threats to validity and the steps taken to mitigate them, while clarifying the scope of inference for our results.

**Construct validity.** Key constructs such as migration experience, maintainability, trust, acceptability, helpfulness, and automation may have been interpreted differently depending on respondents' roles, organizations, and prior experience. We mitigated this by deriving the questionnaire from survey guidelines, combining predefined options with open-ended responses, and refining the instrument through formative practitioner feedback. Respondents also based their answers on heterogeneous experiences with different LLMs, model versions, coding assistants, interfaces, organizational policies, and usage workflows. We aggregate these experiences under the broader category of LLM-assisted migration and do not estimate model- or tool-specific perceptions. Consequently, the findings characterize perceptions across heterogeneous LLM experiences and should not be interpreted as applying uniformly to every model, assistant, or migration workflow.

**Internal validity.** The study relies on self-reported data, which may involve recall bias, social desirability, or inaccurate estimates of migration experience, LLM usage, review willingness, and production readiness. We mitigated this by probing related constructs from multiple angles: scope, production sensitivity, review confidence, automation preference, quality expectations, and failure modes. We also applied a two-step filter based on target-population membership and completion time. Responses below the five-minute threshold were manually checked before exclusion; one also showed straight-lining, and no internal CHECK24 response fell below the threshold.

**External validity.** The final sample is limited and not statistically representative. The internal sample provides context-rich industrial evidence but may reflect one company's engineering culture, technology stack, migration history, and organizational policies. The open survey broadens the sample but remains a convenience sample distributed through professional networks. Pooling the two samples increases the breadth of perspectives but is not methodologically neutral, because aggregate patterns may be influenced by the specific organizational context represented by the 25 internal respondents. We therefore interpret the combined results as patterns within two complementary samples rather than as estimates for migration practitioners generally, and use subgroup comparisons to expose rather than eliminate possible contextual differences.

**Conclusion validity.** The quantitative analyses are exploratory. The sample size limits statistical power, especially for subgroup comparisons and logistic regression, and internal–external differences may be confounded by organization, role, migration type, production exposure, or prior LLM experience. We therefore avoid causal claims, use non-parametric tests for ordinal data, apply correction for post-hoc comparisons where appropriate, and interpret statistical results as associative tendencies in this sample.

**Qualitative, temporal, and scope limitations.** Open-ended responses helped explain quantitative patterns, but coding remains interpretive; we mitigated this through independent initial coding by two authors, disagreement resolution, and a shared codebook. Because LLM capabilities and industrial tooling evolve rapidly, the findings are a snapshot of practitioner perceptions at data collection time.

## 8 Conclusion

This study examines practitioner perceptions of LLM-assisted software migration through a survey of 61 industry professionals. The survey results show that practitioners value LLMs for improving productivity in localized, routine tasks but reject full-project automation and autonomous production deployment. Trust in LLM-generated code depends on semantic preservation, security validation, and explicit human accountability, with security identified as the primary risk factor. We therefore characterize LLM-assisted migration as an "assurance-gated" adoption problem. Future migration tools should align with industry expectations by prioritizing bounded scopes, reviewable artifacts, automated security checks, and clear human ownership.

## Abstract

Configuration changes – modifications to feature flags and service parameters – are important to operating services, but they can cause severe outages (SEVs) with substantial service disruption. While code diff risk prediction is well studied, configuration diff risk has received little attention. The code-oriented Diff Risk Score (DRS) model provides limited discriminatory power for config diffs because config risk stems not from code complexity but from the importance, blast radius, and operational readiness of the affected services. We describe the development of `CORA` (**CO**nfig **R**isk **A**nalyzer), a dedicated risk model for config diffs. A key insight is that the config-path-to-service mapping bridges from what changed to which services are affected, enabling risk assessment in terms of service criticality rather than code properties.

`CORA` evolved through three iterations. A logistic regression model with config-specific features achieved an 11% improvement in recall at 5% gating over the DRS model on config diffs. Used for a freeze period, it reduced config gating while outage impact decreased and config diff landing volume increased 91.4%. A unified LightGBM model trained on Meta-wide data achieved a 25.95% improvement in recall at 10% gating, with organization-level improvements ranging from 15% to 66%. An enhanced model with enriched service features and SEV-severity-aware training (having also explored Bayesian hyperparameter optimization) achieved a 22% improvement in recall at 15% gating, intercepting meaningful additional high-severity outage impact in backtesting. To our knowledge, `CORA` is the first system to apply predictive risk modeling specifically to configuration changes.

## 1 Introduction

Changes to software configuration are necessary to operate, tune, and optimize services, but these changes may introduce defects that lead to outages (SEVs). Researchers have studied the risk of source code changes extensively in the defect prediction literature [30, 22] and in industrial deployments of diff risk scoring [17, 1], but the risk of *configuration* changes

© Weiyan Sun, Audris Mockus, Brian Ellis, Jun Ge, Madigan Kim, Sahil Kumar, Gursharan Singh, Matt Steiner, Siri Uppalapati, and Nachiappan Nagappan;
licensed under Creative Commons License CC-BY 4.0

remains largely unexplored. Config changes (modifications to Sitevar, Gatekeeper, JustKnob, and Configerator artifacts [27]) constitute a meaningful fraction of all diffs and cause some of the more disruptive SEVs, including multiple SEV1s (the highest severity level, reserved for outages with large-scale user impact).

Mockus et al. [17] developed the Diff Risk Score (DRS) system to predict the risk of code diffs causing SEVs. DRS uses logistic regression models trained on historical data linking diffs to the SEVs they caused, with features drawn from code complexity, software supply chain centrality, and author expertise. The system gates diffs that exceed a risk threshold during code freeze periods, with thresholds tunable to different gating levels: 5% for weekends, 10% for yellow (medium-risk) zones, and 50% for red (high-risk) zones. Abreu et al. [1] extended DRS with LLM-based approaches that further improved recall at these gating levels.

However, these code-oriented features provide little discriminatory power for config diffs, whose risk stems not from logical errors in source code but from the importance, number, and interactions among the services affected by the configuration change. During the Freeze 1 code freeze, the DRS model missed several config-related SEV1s, prompting undifferentiated config gating that imposed a burden on development teams. As a concrete example, one Freeze 1 SEV1 was triggered by a small change to a feature-flag config path consumed by a high-criticality service: because the diff modified only one artifact and carried no code-complexity signal, the code-oriented DRS scored it as low risk and did not flag it, even though the affected service's criticality and broad blast radius made the change inherently risky. The challenge in config risk prediction is mapping from *what changed* (the config path) to *who is affected* (the services) and assessing the criticality, blast radius, and operational readiness of those affected services.

In this paper, we report on a longitudinal industrial case study following the iterative action research methodology [25, 4] as applied in [17]: we develop and refine the model across three cycles, with each iteration motivated by findings from the previous one. The study is participatory in the action-research sense rather than a purely retrospective case study: a cross-functional team of researchers and practitioners (reliability engineers and config-safety experts) jointly diagnosed each problem, decided on and implemented the interventions, deployed them into production, and reflected on the outcomes to plan the next cycle (Table 1). The evaluation combines quasi-experimental backtesting (retrospective simulation on historical data with chronological splits) for model-vs-model comparisons (RQs 1, 3, 4) with an observational before/after comparison (RQ 2) and a partial ablation isolating the contributions of individual enhancements (RQ 4).

We describe `CORA` (**CO**nfig **R**isk **A**nalyzer), a dedicated risk model for config diffs. The key insight behind `CORA` is that the config-path-to-service mapping provides a natural bridge from the diff to the service dependency graph, enabling the model to reason about risk in terms of service criticality, blast radius, and testing maturity rather than code complexity.

`CORA` has evolved through three iterations, progressively improving both model architecture and scope (here and throughout, $\text{Org}_A$ through $\text{Org}_E$ denote large, autonomous product organizations within Meta, anonymized for confidentiality):

- A logistic regression model with config-specific features, used for $\text{Org}_A$ before Freeze 2, achieving an 11% improvement in recall at 5% gating over the code-oriented DRS model on config diffs;
- A unified gradient boosting tree (LightGBM) model trained on Meta-wide data, achieving a 25.95% improvement in recall at 10% gating; and
- An enhanced model with enriched service features and SEV-level-aware training (with Bayesian hyperparameter optimization also explored), achieving a 22% improvement in recall at 15% gating with additional outage impact intercepted in backtesting.

**Contributions.** We build on and extend the DRS work [17, 1] along four dimensions. First, we address the different risk profile of config changes, where risk derives from service-level properties rather than code logic, using the config-path-to-service mapping as the enabling structural insight. Second, we demonstrate that tree-based models outperform logistic regression for config diff risk, complementing the LLM-based improvements shown for code diffs in [1]. Third, we introduce SEV-severity-weighted training that differentiates the learning signal by outage severity. Fourth, we extend the evaluation framework beyond recall to include outage impact intercepted, directly quantifying the operational benefit of improved gating.

### 1.1 Research Questions

We address the following research questions, organized around the progressive development of `CORA`:

**RQ 1.** *Config-Specific Risk Model.* Can a dedicated config diff risk model outperform the code-oriented DRS model on config diffs?
**RQ 2.** *Impact.* How effective was `CORA` during the Freeze 2 risk management period?
**RQ 3.** *Unified Tree-Based Model.* Can a gradient boosting tree model trained on Meta-wide data outperform the logistic regression model for config diff risk prediction?
**RQ 4.** *Enhanced Model.* Can enriched service features, SEV-level-aware training, and hyperparameter optimization further improve the unified tree model?

The remainder of this paper is organized as follows. Section 2 provides background on code freeze practices and risk modeling. Section 3 describes the methodology, data collection, features, models, and evaluation approach. Section 4 presents the results for each research question. Section 5 discusses implications for developers. Section 6 addresses threats to validity. Section 7 concludes.

## 2 Background and Related Work

**Code freeze and software risk prediction.** Code freezes (temporary restrictions on changes) protect systems during high-risk periods [28, 24, 2]. Organizations apply code freezes during periods of high traffic or reduced engineering availability, restricting individual diffs based on predicted risk rather than blanket prohibitions [17]. Freeze periods are organized into tiered zones with progressively stricter gating: *weekend freezes* gate the top 5% riskiest diffs, *yellow zones* (medium-risk periods) gate 10–15%, and *red zones* (highest-risk periods) gate 45–50%. A gated diff must receive explicit approval before landing. The gating thresholds are tunable, allowing the balancing of productivity against risk tolerance for each zone.

Statistical software risk models predict defects at the file level [18, 20, 8] or at the change level (just-in-time prediction) [19, 10, 30, 22]. Common predictors include code churn, cyclomatic complexity, authorship patterns, and prior defect history. A recurring challenge is operationalizing "defect": many studies rely on noisy SZZ heuristics [29, 6]. In our setting, the incident response team manually determines each SEV's trigger diff, providing high-quality labeled data [17].

The software supply chain framework [15, 16] captures risk arising from dependencies among code artifacts, developers, and organizations. Katz centrality [11] propagates importance through the dependency network; both DRS and `CORA` use it. For defect prediction, tree-based models such as LightGBM [12] show strong results [13, 30], and LLM-based approaches outperform logistic regression on code diffs [1].

**Risk prediction: DRS.** The DRS system is described in two prior publications. Mockus et al. [17] introduced risk models, progressing from expert-selected file paths to diff-level logistic regression, to selectively gate risky diffs during code freezes. The `DiffModel` uses features from defect history, interdependencies, coordination, expertise, and file complexity. At 27.3% gating, it captures 60.8% of SEVs. During a prior freeze period, only 16% of diffs were gated while landed diffs increased 42% and SEVs decreased 52%.

Abreu et al. [1] extended DRS with LLM models. A risk-aligned iDiffLlama-13B captures 1.40×, 1.52×, and 1.05× as many SEVs as logistic regression at 5%, 10%, and 50% gating. `CORA` builds on this DRS infrastructure but addresses the different domain of config diffs, where code content features are unavailable and service-level properties drive risk.

**Configuration change management.** Despite the impact of configuration changes on systems, the research literature on config change risk prediction is thin. Configuration testing [21] focuses on verifying software behavior under different configurations, which is orthogonal to predicting the risk of a configuration *change*. Several industrial reports document config changes as a common source of outages, but none propose predictive models. To our knowledge, `CORA` is the first system that applies predictive risk modeling specifically to configuration changes.

## 3 Methodology and Data

In this section, we describe how we extend the DRS code diff risk modeling framework to config diffs. We first discuss the differences between config and code changes that motivated this work. We then describe the data collection, the features specific to config changes, the evolution of modeling approaches from logistic regression to gradient boosting trees, the feature selection process, the SEV-severity-aware training, the explainability methods, and the outcome measures we use to evaluate model performance.

### 3.1 Why Config Diffs Require a Dedicated Risk Model

The DRS model [17, 1] predicts the risk of code diffs causing SEVs (Section 2). While config diffs go through the same diff-based review and landing process as code diffs, their risk profile differs. Code diff risk derives from logical errors in source code, and its predictors are drawn from file complexity, authorship networks, and code interdependencies (see Tables 1 and 2 in [17]). Config changes, however, rarely contain logical errors in the traditional sense. Instead, the risk of a config change derives from the *importance*, *number* (blast radius), and *interactions* among affected services (Section 1).

This motivates a dedicated config risk model, `CORA`, that runs concurrently with the code-focused DRS model.

### 3.2 Discovering the Context

Following the participatory action research approach [25, 4] as applied in [17], we initiated the `CORA` effort after the Freeze 1 incident where the DRS model missed several config-related SEV1s (e.g., S1 and S2, anonymized identifiers of two specific config-triggered incidents, not to be confused with severity levels). A cross-functional V-team (a virtual, cross-organizational working team) of researchers, reliability engineers, and config safety experts identified the config-path-to-service mapping as the main structural insight, enabling the model to reason about risk in terms of a service's criticality, operational readiness, and maturity rather

**Table 1** Action research cycles in `CORA` development.

| Diagnose | Plan & Act | Evaluate | Reflect |
|---|---|---|---|
| DRS misses config SEV1s (Freeze 1) | Config features + GLM | RQ 1 backtest, RQ 2 deploy | GLM cannot capture non-linear interactions |
| Logistic regression limits; org-specific models | Unified GBT on Meta-wide data | RQ 3 backtest | Default GBT beats tuned GLM; feature leakage found |
| Default hyperparameters sub-optimal | Bayesian tuning, SEV-aware weights, enriched features | RQ 4 backtest, Freeze 3 deploy | Simultaneous precision + recall gains |

than file-level churn. The team comprised two researchers who designed the models and evaluation, three ML engineers who implemented and deployed the models, and domain experts from each organization who provided feature candidates, validated risk interpretations, and resolved conflicts between model accuracy and deployment constraints (e.g., feature latency, explainability requirements). Table 1 maps each iteration to the canonical action research phases.

## 3.3 Data Collection

Consistent with the data collection procedure described in [17], we collect data from multiple sources and link them via diff identifiers and timestamps.

**Config diff data.** We obtain config diffs from Phabricator [23], including creation and landing times, affected config paths, author, reviewers, and test plans. We identify a config diff by the type of configuration artifact it modifies: Sitevar, Gatekeeper (GK), JustKnob (JK), or Configerator [27].

**SEV data.** As described in [17], a system tracks **every** SEV across the organization and records its trigger, which, in the case of config-related outages, is a config diff. The incident response team manually determines the trigger link from SEV to diff, providing labeled data that is rarely available in published research [19]. SEVs fall into four severity levels: SEV1 (highest user impact), SEV2, SEV3, and SEV4.

**Service metadata.** Config diffs, unlike code diffs, require service-level data. We collect service metadata from two primary source tables:

- **Service registry** [26]: provides service criticality tier, number of hosts, RAM allocation, service dependencies (used-by and uses relationships), and resource governance configurations;
- **Service maturity metrics**: provides integration testing [5] coverage and false positive rates, canary false positive rates, staged rollout coverage, capacity stress testing coverage, and deployment pipeline metadata. These correspond to the "Service testing," "Service health," and "Service metadata" feature categories in Table 3.

The config-path-to-service mapping links each config path modified by a diff to the set of services that consume that configuration. This is a many-to-many relationship: a single config path may affect multiple services, and a single service may consume multiple config paths.

**Table 2** Features for CORA inherited or adapted from the DRS DiffModel [17]. The notation follows [17]: $d$ denotes a diff, $f$ a file, $d_f$ indicates diff $d$ modifies file $f$, $d_{sev}$ indicates diff $d$ caused a SEV, $a$ is the author, $cent(\cdot)$ is Katz centrality. All features are computed at the diff level; features that depend on files or services are aggregated (max/sum) over all files modified by or services affected by $d$.

| Category | Measure | Description | Direction |
|---|---|---|---|
| Defects | $weighted\_caused\_sev(d)$ | Weighted sum of prior SEV severity for files modified by the diff (Equation 1). Decays over time. Replaces binary *had_sev*. | Positive |
| Interdependencies | $centrality(d)$ | Maximum Katz centrality of the config files in the diff, computed on the co-change, authorship, and call-graph network | Positive |
| | $num\_of\_files(d)$ | Number of config files modified by the diff | Positive |
| Coordination | $log\_diff\_author\_count(d)$ | log of the number of distinct authors who have previously modified the config files in the diff | Positive |
| | $has\_same\_team\_approver(d)$ | Whether the diff has an approver from the same team group as the author | Negative |
| Expertise | $is\_original\_author(d)$ | Whether the diff author is the original creator of the config file | Negative |
| Diff | $substantial\_line\_count\_ratio(d)$ | Ratio of substantial (non-whitespace, non-comment) lines changed to total file size | Positive |
| Codebase | $owning\_pillars(d)$ | Organizational pillar that owns the config path | Positive |

**Supply chain data.** We retain the supply chain network data from the DRS model: co-change networks, authorship networks, and call-graph centrality, computed as described in [17]. These features remain relevant for config diffs because the config files reside in the same monorepo and the same population of engineers author and review them.

We define the following notation used throughout. Let $d$ denote a config diff, $f$ a config file/path modified by $d$, $s$ a service affected by $f$, and $d_{sev}$ an indicator that diff $d$ caused a SEV. We write $d_f$ to indicate that diff $d$ modifies config path $f$, and $f \to s$ to indicate that config path $f$ is consumed by service $s$. The set of services affected by a diff $d$ is then $S(d) = \{s : \exists f, d_f \wedge f \to s\}$.

## 3.4 Model Features

At a high level, we follow the same feature selection procedure as in [17]: for each conceptual dimension, we select candidate measures from domain knowledge and prior literature, investigate correlations among them, and retain measures that are both predictive and easy to interpret. The main difference is that CORA introduces an entirely new dimension of features, *service-level properties*, that have no analogue in the code diff risk literature.

The features fall into six categories. Tables 2 and 3 show the full set of features used in the CORA models.

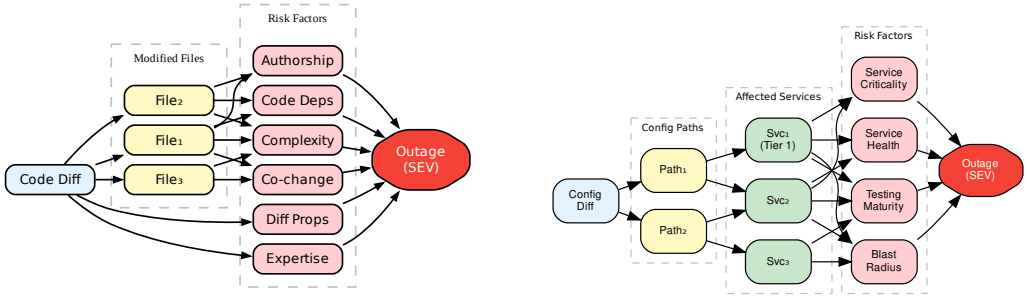
**DRS-inherited features.** Several features from the DRS DiffModel [17] remain relevant for config diffs. The most predictive is SEV history. Unlike the binary *had_sev* in the original DRS model, CORA uses a *weighted* and *decayed* measure of prior SEV involvement. The weight reflects SEV severity (SEV1=10, SEV2=3, SEV3=2, SEV4=1), and the temporal decay reduces the influence of older SEVs. This captures the intuition that a config path recently involved in a severe outage is much riskier than one involved in a minor incident years ago.

Supply chain centrality [11, 15] captures structural importance: the Katz centrality of a config file in the co-change/authorship/call-graph network reflects how central it is. Diffusion measures (number of files), coordination measures (number of prior authors, same-team approver), and expertise measures (original authorship) transfer directly from the DRS model.

**Config-specific features: service criticality and blast radius.** A distinctive characteristic of CORA is its explicit mapping from config paths to the services they govern. This mapping lets the model reason about risk in the context of what will be *affected* rather than what was

**Table 3** Config-specific features introduced in CORA. These features have no analogue in the code-oriented DRS model. $d$ denotes a diff, $f$ a config path, $s$ a service, $S(d) = \{s : \exists f, d_f \wedge f \rightarrow s\}$ is the set of services affected by diff $d$. Max/sum aggregations are over $S(d)$.

| Category | Measure | Description | Direction |
|---|---|---|---|
| Service criticality | $max\_hosts(d)$ | Maximum number of hosts serving any affected service $s \in S(d)$ in the past 24 hours | Positive |
| | $tw\_median\_ram(d)$ | Median RAM allocated to the most resource-intensive affected service | Positive |
| | $is\_tier1(d)$ | Whether any affected service is classified as Tier 1 (highest priority) | Positive |
| Blast radius | $uses\_service\_count(d)$ | Maximum number of upstream services consumed by any affected service $s \in S(d)$ | Positive |
| | $used\_by\_service\_count(d)$ | Maximum number of downstream services that depend on any affected service $s \in S(d)$ | Positive |
| Config properties | $has\_materialized\_JSON(d)$ | Whether the config change has materialized JSON output (indicator of change type) | Positive |
| | $num\_non\_generated\_files(d)$ | Number of non-generated (human-authored) config files in the diff. Replaces raw $num\_of\_files$ based on user feedback | Positive |
| Service testing | $servicelab\_coverage(d)$ | Maximum integration testing coverage percentage across affected services | Negative |
| | $servicelab\_false\_positive(d)$ | Maximum integration testing false positive rate across affected services. High false positive rates indicate unreliable safety nets | Positive |
| Service health | $tumbleweed\_coverage(d)$ | Staged rollout coverage breadth across affected services | Negative |
| | $canary\_false\_positive(d)$ | Canary test false positive rate for the most impacted service | Positive |
| Service metadata | $service\_primary\_conveyors(d)$ | Number of primary pipelines [9] for affected services, indicating process complexity | Positive |
| | $tw\_uses\_entitlement(d)$ | Whether any affected service uses resource governance | Positive |
| | $is\_kfs\_covered(d)$ | Whether the affected service has monthly capacity stress testing coverage | Negative |
| | $is\_ICSP\_service(d)$ | Whether the service is classified as an infrastructure service | Positive |



*changed*. When a config diff touches a path consumed by a high-criticality, widely depended-upon service, CORA can weigh that risk against the service's operational readiness while reducing noise on changes to low-impact services.

Service criticality comprises: the number of hosts ($max\_hosts$), indicating the scale at which the service operates; the allocated RAM ($tw\_median\_ram$), proxying computational importance; and the service tier classification ($is\_tier1$), reflecting the assessed level of criticality.

The *service dependency graph* captures blast radius. The number of upstream services ($uses\_service\_count$) measures how many services the affected service consumes; the number of downstream services ($used\_by\_service\_count$) measures how many other services depend on the affected service's outputs. A config change to a service with many downstream dependents has higher blast radius.

Figure 1 illustrates the config diff supply chain. Unlike the code diff supply chain (Figure 1 in [17]), where risk flows through code interdependencies, the config supply chain routes risk through the config-path-to-service mapping and the service dependency graph.

**Service testing, health, and config properties.** Unlike code diffs where researchers measure test coverage at the file level, config diffs require service-level testing measures: integration testing coverage and false positive rate capture the reliability of safety nets, while staged

**(a)** Code diff: risk via dependencies, co-changes, authorship, expertise, diff properties

**(b)** Config diff: risk via config-path-to-service mapping, criticality, blast radius, testing

**Figure 1** Comparison of risk propagation for code diffs vs. config diffs. In (a), risk derives from file-level code properties and supply chain networks. In (b), risk derives from the services affected by the config change.

rollout coverage and canary false positive rate reflect broader service health (Table 3). Two config properties refined through user feedback, *has_materialized_JSON* (distinguishing production from non-production changes) and *num_non_generated_files* (excluding auto-generated artifacts), improve precision by reducing false positives.

## 3.5 Models

We describe the three model architectures we evaluate for `CORA`, corresponding to the evolutionary progression to the enhanced model.

**Logistic Regression (`CORA`-GLM).** The initial `CORA` model uses logistic regression, consistent with the DRS model [17, 1]. The same practical considerations motivate this choice: simplicity of fitting, low latency prediction (a single vector multiplication of fitted coefficients and predictors), and interpretability via coefficient signs and magnitudes. We $\log_{1p}$-transform all continuous variables due to their skewed distributions. As in [17], we exclude measures that do not meaningfully contribute to explaining the variance (p-value $< .1$ or a difference in deviance under 2.6 for the likelihood ratio test).

The `CORA`-GLM model uses 33 features, including base features from Tables 2 and 3, interaction terms (e.g., SEV history × config type, materialized JSON × JustKnob type), log-transforms, and additional indicator variables for service properties (programming language, monitoring posture, automation state, capacity category), config artifact types, and review process quality (approver count, test plan length). Config paths known to be low-risk are identified via a in_config_safe_paths feature. Tables 2 and 3 list the base features from which the full set of 33 production features are derived; the remaining features are interaction terms, log-transforms, and indicator variables constructed from these base measures.

We initially train separate `CORA`-GLM models for $\text{Org}_A$ and $\text{Org}_E$ on organization-specific data to account for different config change patterns and SEV rates.

**Gradient Boosting Trees (`CORA`-GBT).** While logistic regression is simple and interpretable, it cannot capture non-linear relationships between features and risk. This limits config diff risk prediction, where interactions between features matter. For example, a config change to

a Tier 1 service may be low risk if that service has high integration testing coverage, but high risk if coverage is low. Logistic regression cannot model this interaction without explicit interaction terms, which are cumbersome to enumerate and evaluate.

We switch to Gradient Boosting Trees (GBT), specifically LightGBM [12], for the unified `CORA` model. GBTs naturally capture non-linear feature interactions, tolerate outliers in service metadata, and reduce the need for manual feature engineering and correlation management [7].

We train the `CORA`-GBT model on *Meta-wide* config diff data, unifying the previously separate $\text{Org}_A$ and $\text{Org}_E$ models. This increases the training data volume and diversity, allowing the model to learn patterns common across organizations while retaining the ability to differentiate organization-specific risk profiles via the *owning_pillars* feature. After backward feature elimination (Section 3.6), the final model uses 30 features. The final feature count is lower than the 33 features in `CORA`-GLM because GBTs learn interactions implicitly through tree splits, eliminating the need for the explicit interaction terms and indicator variables that accounted for roughly a third of the GLM feature set.

**Enhanced GBT (`CORA`-GBT+).** The enhanced model extends `CORA`-GBT with three methodological improvements, presented here in decreasing order of their measured contribution (Section 4.4): enriched service features, SEV-severity-aware training, and hyperparameter optimization.

**Enriched service features.** The enhanced model expands the feature set with three additional groups of signals, informed by deeper collaboration with config safety SMEs and operational experience:

- **Service metadata:** deployment pipelines [9] (*service_primary_conveyors*), resource governance (*tw_uses_entitlement*), capacity stress testing coverage (*is_kfs_covered*), and infrastructure service classification (*is_ICSP_service*).
- **Service healthiness:** staged rollout coverage and canary false positive rate, reflecting the breadth and reliability of safety nets beyond integration testing.
- **User-feedback-informed features:** replacing raw "number of files" with "number of non-generated files" (*num_non_generated_files*), discounting auto-generated artifacts that do not meaningfully increase risk.

**SEV-level-aware training.** We introduce tiered sample weights by SEV severity. Previously, training used a binary label (0/1) with weight = 1 for every sample, treating all SEVs as equally important. This dilutes the learning signal from more severe incidents. The enhanced model assigns:

$$w(d) = \begin{cases} 10 & \text{if } d \text{ caused a SEV1} \\ 3 & \text{if } d \text{ caused a SEV2} \\ 2 & \text{if } d \text{ caused a SEV3} \\ 1 & \text{if } d \text{ caused a SEV4 or no SEV} \end{cases} \tag{1}$$

This focuses the gradient boosting loss function on highest-impact events (SEV1s, which may cause large service disruption) while preserving calibration for lower-severity cases. The weights approximate average relative operational losses across severity levels, derived from historical incident data: SEV1s cause roughly an order of magnitude more disruption than SEV4s, SEV2s roughly three times, and SEV3s roughly twice. We treat these weights as fixed *a priori* rather than as tunable hyperparameters: they are set from these historical

operational-loss ratios, not selected to maximize validation accuracy, so we do not perform a hyperparameter sweep over them. The dominant lever is the up-weighting of SEV1s relative to the SEV3/SEV4 majority; what matters is the ordinal structure ($w_{\text{SEV1}} > w_{\text{SEV2}} > w_{\text{SEV3}} > w_{\text{SEV4}}$) rather than the exact magnitudes, and moderate perturbations (e.g., an SEV1 weight of 5 or 15) preserve the rank ordering of gradient contributions and thus the ranked risk list that gating operates on. Because gating decisions depend only on this ranking, we therefore do not expect the results to be sensitive to the precise weight magnitudes; a full factorial sweep over the weight vector remains future work. They are deliberately the same as those in the *weighted_caused_sev* feature (Table 2), though the two serve different purposes: the feature weights aggregate historical SEV severity for a config path, while the training weights up-weight the gradient contribution of high-severity samples during model fitting.

**Hyperparameter optimization.** The initial `CORA`-GBT model uses default LightGBM hyperparameters. For the enhanced model, we additionally explored Bayesian hyperparameter optimization over the space controlling the bias-variance tradeoff:

- *learning_rate* and *n_estimators* govern shrinkage and boosting depth;
- *num_leaves*, *max_depth*, and *min_data_in_leaf* set tree complexity;
- *feature_fraction* and *bagging_fraction* control stochastic sampling; and
- $\lambda_{L1}$ and $\lambda_{L2}$ affect regularization strength.

We use Bayesian optimization via Optuna [3] with a Tree-structured Parzen Estimator (TPE) sampler. Each trial samples a candidate configuration from the search space (using `suggest_int`, `suggest_float`, or `suggest_categorical` depending on parameter type) and evaluates it with LightGBM's built-in stratified $k$-fold cross-validation (`lgb.cv`, $k$=5), scored by binary log-loss on the held-out folds. The TPE surrogate model learns from completed trials to prioritize promising regions of the search space rather than exploring exhaustively. We run 50 trials, sufficient for the nine-dimensional parameter space to converge while remaining tractable for the training data volume. Because the log-loss objective is not aligned with recall at a fixed gating percentage, this tuning did not improve recall at the operating gating levels in our reconstruction (Section 4.4); the deployed `CORA`-GBT+ therefore retains the default tree depth.

## 3.6 Feature Selection

For `CORA`-GLM, we select candidate features based on domain knowledge, examine correlations among features (we do not include features with $r > 0.7$ together), and exclude features that do not improve the likelihood ratio ($p < .1$, deviance difference $< 2.6$). For `CORA`-GBT, we expand the feature pool to 85 candidates. We use backward feature elimination, iteratively removing the least important feature by LightGBM's split-based importance and re-evaluating on the validation set, converging at 30 features. We check all features for potential leakage through systematic offline/online consistency checks, and remove any feature whose value at prediction time could differ from its value at training time.

## 3.7 Explainability

Practical deployment requires that engineers understand *why* their diff was gated. For `CORA`-GLM, we infer feature importance through coefficient signs and magnitudes. For GBT models, we employ SHAP values [14] for per-prediction explanations and Partial Dependence Plots (PDP) for internal analysis of non-linear feature effects. We remap raw model scores to a 0–100 percentile scale for intuitive interpretation.

## 3.8 Evaluation Methodology

We evaluate all models using time-based data splits to prevent data leakage, consistent with [17, 1]. Table 4 shows the data splits for the two GBT model versions. Data retention policies limit the availability of historical feature values, so we cannot retroactively evaluate later models on earlier test sets, nor score earlier models on later data with features that did not yet exist. Each RQ therefore uses the test set and feature set available at the time of that iteration; cross-RQ comparisons of relative improvements reflect changes in model, features, training data, and test period simultaneously. Only the end-to-end bootstrap comparison (Table 11) evaluates both endpoints on the same test set. We consider absolute recall values sensitive and do not report them; all comparisons use relative improvements. To give a sense of scale: the baseline `CORA`-GLM captures fewer than one in four SEV-causing diffs at 10% gating and fewer than one in six at 5% gating, reflecting the difficulty of the prediction task at a 0.28% base rate. For `CORA`-GBT, we use a separate evaluation set for feature selection and early stopping. For `CORA`-GBT+, we fold the evaluation set into the training window to maximize recency, and run the hyperparameter search via $k$-fold cross-validation on the training set (Section 3.5) rather than a held-out evaluation split.

**Table 4** Time-based data splits for `CORA` model training and evaluation.

| | Duration (CORA-GBT) | Duration (CORA-GBT+) | SEV rate |
|---|---|---|---|
| Train | 18 months | 33 months | 0.283% |
| Eval | 4 months | – | 0.288% |
| Test | 9 months | 7 months | 0.261% |

We train the `CORA`-GBT model on 450,492 config diff samples with a SEV rate of 0.283%. The `CORA`-GBT+ training window extends further (Table 4), approximately doubling the training data relative to `CORA`-GBT. SEV-causing diffs account for fewer than 0.3% of all config diffs; the `CORA`-GBT models use *sample weighting* rather than resampling to address this imbalance, with severity-differentiated weights in the enhanced model (Equation 1). We evaluate models on both $\text{Org}_A$-specific and Meta-wide config diffs.

The primary outcome measure is the fraction of SEV-causing diffs captured at a given level of gating:

$$\texttt{CapturedSEVs}(g) = \frac{|\{d : d_{sev} \wedge r(d) \geq p_g\}|}{|\{d : d_{sev}\}|} \tag{2}$$

where $r(d)$ is the model's predicted risk for diff $d$ and $p_g$ is the threshold such that a fraction $g$ of all diffs exceed it. We evaluate at gating levels from 5% (weekend freeze) to 50% (red zone). At a SEV rate of 0.28%, gating 5% of diffs yields a precision of roughly 1% by construction; the gating percentage is a management decision that balances the number of engineers affected against the fraction of SEVs intercepted, not a model-tunable parameter. `CORA` also introduces an outage-impact measure that quantifies the operational severity of the SEV-causing diffs a model would gate:

$$\texttt{ImpactCaptured}(g) = \sum_{\{d : d_{sev} \wedge impact(d) > 0 \wedge r(d) \geq p_g\}} impact(d) \tag{3}$$

where $impact(d)$ is the operational loss attributed to the SEV caused by diff $d$ (zero if the SEV caused no measurable loss). We use "captured" (and, in the results, "intercepted") deliberately in place of "prevented": in backtesting this measure sums the historical impact of SEV-causing diffs that the model *would have flagged* for review at gating level $g$. It does

not establish that gating those diffs would have averted the corresponding outages, since a gated diff may still land after approval, be resubmitted, or have its underlying issue surface through another change. It quantifies the severity-weighted risk surfaced by the model, not a proven reduction in outages.

**Statistical comparison methodology.** When comparing two models (e.g., CORA-GLM vs. DRS, or CORA-GBT vs. CORA-GLM), we use the following procedures:

**Recall comparison at fixed gating.** For each gating level $g$, we compute CapturedSEVs for both models on the same test set and report the relative improvement $\Delta = (\text{recall}_{\text{new}} - \text{recall}_{\text{base}})/\text{recall}_{\text{base}}$. Because the test sets are identical across models and the outcome (SEV) is binary, the comparison is paired: both models score the same diffs, and improvements reflect genuine reranking of SEV-causing diffs rather than sampling variation.

**Multiple gating levels.** We evaluate at 5%, 10%, 15%, 20%, 45%, and 50% gating. Because these are nested thresholds on the same ranked list, no multiple-comparison correction is applied. Organization-level breakdowns (Table 8) are descriptive stratified analyses showing heterogeneity in improvement magnitude, not independent hypothesis tests.

**Year-over-year production comparison.** The RQ 2 comparison (Freeze 1 vs. Freeze 2) is a natural experiment with a difference-in-differences (DiD) structure: the treatment is the deployment of CORA, and the outcome is both the gating rate and the outage rate. However, because the treatment applies to the entire population simultaneously (no concurrent control group), we cannot isolate the CORA effect from other concurrent changes (e.g., improved engineering practices, different config change mix). We therefore report the YoY comparison as descriptive evidence of production impact rather than a causal estimate.

**Confirmatory bootstrap analysis.** Following the iterative action research design, RQs 1, 3, and 4 each informed the next iteration; applying statistical testing at each intermediate step would conflate exploratory model development with confirmatory evaluation. We therefore reserve statistical testing for the *cumulative* improvement of the final model (CORA-GBT+) over the initial deployed baseline (CORA-GLM). We compute 95% bootstrap confidence intervals by resampling all test-set diffs with replacement ($B$=10,000 iterations), computing the recall difference $\Delta$recall for each bootstrap sample, and reporting the 2.5th and 97.5th percentiles. A confidence interval that excludes zero confirms that the improvement is reliable.

**Ablation analysis.** For the enhanced model (CORA-GBT+), we isolate the contribution of three of the four enhancements (enriched service features, SEV-level-aware training, and hyperparameter optimization) by adding them incrementally to a reconstructed CORA-GBT baseline on a common training window and measuring the marginal change in CapturedSEVs on the held-out test set; the extended training window is held fixed and not separately ablated. Full tables and the deployed end-to-end comparison appear in the supplementary material.

## 3.9 Operational Use

When a config diff is submitted for landing, CORA computes a risk score in real time; if the score exceeds the threshold for the current freeze period, the diff is gated. The risk score, top risk factors (via SHAP for GBT models), and the current gating zone appear in the

**Table 5** CORA-GLM vs. DRS on $\text{Org}_A$ (Freeze 1 backtest).

| Gating | Impr. |
|---|---|
| 5% | +11% |
| 20% | +8.3% |
| 50% | +5.7% |
| 60% | – |

**Table 6** Freeze 1 vs. Freeze 2 ($\text{Org}_A$ config diffs). Changes may reflect CORA, concurrent improvements, or config mix.

| Metric | Freeze 1 | Freeze 2 | Change |
|---|---|---|---|
| Gating (overall) | 27.1% | 21.7% | −5.4pp |
| Gating (high-risk) | 100% | 85% | −15pp |
| Diffs landed | 14,277 | 27,322 | +91.4% |
| Diffs/developer | 4.7 | 5.9 | +25.5% |
| Bypass rate | 83.8% | 51.6% | −32.2pp |
| Outage impact | high | reduced | ↓ |
| SEVs delayed | – | 4 | – |

Phabricator UI [1]. CORA operates concurrently with the DRS model: we classify diffs as "config" or "code" based on the artifact type and apply the appropriate model. Diffs modifying both receive scores from both models, with the maximum determining the gating decision.

### 3.10 Implementation

All models are implemented in Python. Logistic regression (CORA-GLM) uses `statsmodels` GLM with a binomial family and logit link. Gradient boosting trees (CORA-GBT, CORA-GBT+) use LightGBM [12]; the initial CORA-GBT uses default hyperparameters (which already outperform tuned logistic regression), while CORA-GBT+ uses Bayesian optimization via Optuna [3] with a TPE sampler and `lgb.cv` for candidate evaluation. Explainability uses the SHAP library [14] and scikit-learn's Partial Dependence Plots; scores are remapped to a 0–100 percentile scale using `QuantileTransformer`.

## 4 Results

### 4.1 RQ 1. Config-Specific Risk Model

*Can a dedicated config diff risk model outperform the code-oriented DRS model on config diffs?*

To evaluate the benefit of config-specific features, we compare the CORA-GLM model (Section 3.5) against the DRS logistic regression model [17] applied to config diffs. Both models are logistic regressions; the only difference is that CORA-GLM includes config-specific features (service criticality, blast radius, and service testing) in addition to the DRS supply chain features. We evaluate on $\text{Org}_A$ config diffs using backtesting on the Freeze 1 period.

Table 5 shows the percentage of SEVs captured (`CapturedSEVs`) at various gating levels. CORA-GLM achieves an 11% improvement in recall at 5% gating and a 5.7% improvement at 50% gating relative to the code-oriented DRS model applied to config diffs. The improvement is larger at lower gating levels, where the model must be more discriminating. This is precisely the regime that matters for weekend and yellow-zone freezes, where gating overhead is tightly constrained.

At 60% gating, CORA-GLM captures 82% of all SEVs, 95% of SEVs with measurable impact, all 4 SEV1-causing diffs, and all 5 high-impact SEV-causing diffs. These are precisely the config diffs that the code-oriented DRS model missed, leading to the escalation of config gating to 100% during the Freeze 1 red zone. Because the RQ 1 test set contains a small number of SEV-causing diffs (fewer than 100), the recall improvements should be interpreted as exploratory; the confirmatory bootstrap analysis in Table 11 provides the rigorous end-to-end comparison.

The more discriminative config-specific features are *max_hosts*, *is_tier*1, and *used_by_service_count*, all absent from the code-oriented DRS model.

**RQ 1:** CORA-GLM achieves 11% improvement in recall at 5% gating over DRS. At 60% gating, it captures 82% of all SEVs and blocks all high-impact outage-causing diffs. Config-specific features (service criticality, blast radius, testing) are the main discriminators.

## 4.2 RQ 2. Impact

*How effective was CORA during the Freeze 2 risk management period?*

We deployed the CORA-GLM model for $\text{Org}_A$ config diffs in time for the Freeze 2 risk management window, comparing it to the Freeze 1 window when config gating relied on the code-oriented DRS model.

Table 6 summarizes the key metrics. Gating decreased while outage impact also decreased, despite a 91.4% increase in landing volume, and gating delayed four SEVs. The volume increase reflects two factors: (1) a major increase in the developer population landing config diffs in $\text{Org}_A$, and (2) the bypass rate on gated diffs dropped from 83.8% to 51.6%, consistent with increased trust in gating decisions, though alternative explanations (policy changes, different developer population) cannot be ruled out. The per-developer landing rate increased 25.5% after normalizing for headcount. As an observational before/after comparison within an active research program, CORA deployment is one plausible explanation for these improvements, but concurrent changes in engineering practices, config change mix, and headcount may also contribute.

**Coverage gap.** An important operational finding: 44% of config *changes* in $\text{Org}_A$ (measured by volume of changes, *not* by share of config-related SEVs) do not land through a reviewable diff. These non-diff changes include Gatekeeper rollouts performed through the UI, server-management updates, and other mechanisms that bypass the Phabricator diff-review process. Because CORA scores diffs at review time, these changes fall outside its scope: they produce no diff artifact and offer no review checkpoint at which a risk score could gate them. Extending risk prediction to non-diff config changes – reusing the same service-level features, which do not depend on a diff – is a promising direction for future work.

**RQ 2:** With CORA deployed, config gating decreased from 27.1% to 21.7% and outage impact decreased, while config diff landing volume increased 91.4%. The bypass rate dropped from 83.8% to 51.6%, consistent with increased trust in gating decisions. These are *observational* year-over-year changes: CORA's deployment coincides with concurrent changes in engineering practices, config mix, and headcount, so the effect cannot be attributed to CORA alone.

## 4.3 RQ 3. Unified Tree-Based Model

*Can a gradient boosting tree model trained on Meta-wide data outperform the logistic regression model for config diff risk prediction?*

We evaluate the CORA-GBT model (Section 3.5) against CORA-GLM. Tables 7 and 8 show the results.

The unified tree-based model achieves a 25.95% relative improvement (+6.3pp) in %SEV caught at 10% gating for Meta-wide config diffs and a 32.30% relative improvement (+4.2pp) at 5% gating for $\text{Org}_A$ config diffs, corresponding to additional outage impact intercepted.

**Organization-level analysis.** Training on Meta-wide data offers the advantage of learning patterns that transfer across organizations. The improvements range from 15% for $\text{Org}_A$ (which already has a well-tuned organization-specific model) to 66% for $\text{Org}_D$ (which benefits most from the shared training data and non-linear modeling). Organizations with smaller local datasets benefit more from Meta-wide training.

**Table 7** Recall improvement: CORA-GBT vs. CORA-GLM.

| Gating | Improvement | Scope |
|---|---|---|
| 5% | +32.30% | $\text{Org}_A$ |
| 10% | +25.95% | Meta-wide |

**Table 8** Organization-level improvement at 10% gating.

| Organization | Improvement |
|---|---|
| $\text{Org}_A$ | +15% |
| $\text{Org}_B$ | +22% |
| $\text{Org}_C$ | +38% |
| $\text{Org}_D$ | +66% |
| Meta-wide | +25.95% |

**Table 9** Recall improvement: CORA-GBT+ vs. CORA-GBT at gating levels.

| Gating Level | Recall Improvement | Outage Impact Intercepted | Freeze Scenario |
|---|---|---|---|
| 5% | +25% | – | Weekend |
| 15% | +22% | substantial | Low/med risk |
| 45% | +10.6% | moderate | High risk |

The more impactful features by SHAP value are *weighted_caused_sev* (prior SEV history), *centrality* (supply chain importance), *log_diff_author_count* (coordination complexity), and *substantial_line_count_ratio* (change magnitude). Config-specific service features (*max_hosts*, *is_tier*1, *uses_service_count*) complement the supply chain features. Partial Dependence Plots reveal non-linear relationships that logistic regression cannot capture: for example, risk escalates sharply for services with numerous hosts, and the interaction between service tier and test coverage is automatically captured by tree splits.

**Methodological insights from the transition.** *Empirical findings:* (1) GBTs with default hyperparameters already outperform tuned logistic regression, suggesting that non-linear feature interactions are a first-order effect in config risk; (2) systematic offline/online feature consistency checks identified discrepancies between training-time and prediction-time feature values, and resolving them improved production reliability; (3) a data-vs-code classification of config changes did not improve model performance. These findings informed the design of CORA-GBT+: the weighted, time-decayed SEV history measure replaced the binary *had_sev* flag, and GBT's implicit interaction modeling eliminated explicit interaction terms.

**RQ 3:** The unified CORA-GBT model achieves a 25.95% improvement in recall at 10% gating Meta-wide and 32.30% at 5% gating for $\text{Org}_A$. Organization-level improvements range from 15% ($\text{Org}_A$) to 66% ($\text{Org}_D$), demonstrating that tree-based models trained on Meta-wide data outperform organization-specific logistic regression.

## 4.4 RQ 4. Enhanced Model

*Can enriched service features, SEV-level-aware training, and hyperparameter optimization further improve the unified tree model?*

We evaluate the CORA-GBT+ model (Section 3.5) against the CORA-GBT baseline. The evaluation uses a test set shifted forward from the CORA-GBT test period to reflect recent SEV patterns.

**Overall performance.** Table 9 shows the recall improvement at gating levels corresponding to the three freeze scenarios.

The enhanced model achieves a 22% improvement in %SEV caught at 15% gating (for low/medium risk periods) with substantial incremental outage impact intercepted, and a 10.6% improvement at 45% gating (for high-risk periods) with moderate incremental outage impact intercepted. At 5% gating, the improvement is 25%, demonstrating that the enhancements are more effective at the lower gating levels where discriminatory precision matters most.

**Precision improvement.** Unlike many model upgrades that improve recall at the expense of precision, the enhanced model improves both: Meta-wide precision increases by over 20% at all gating levels. This is operationally valuable because higher precision means fewer engineers are gated unnecessarily, reducing friction while intercepting more SEVs.

**Org$_A$-specific results.** For Org$_A$ config diffs, the enhanced model achieves a 25% recall improvement at 5% gating and a 30.77% improvement in high-impact SEV recall. Org$_A$ config SEVs have direct and quantifiable operational impact, so the impact-weighted recall measures the model's ability to flag the more severe incidents for review.

**Ablation analysis.** A partial per-component ablation – isolating three of the four enhancements on a common training window and the shared test set – indicates that the *enriched config/service features* are the most consistent contributor to `CapturedSEVs`, in line with `CORA`'s central premise that config risk derives from service-level properties. SEV-level-aware training (Equation 1) has only a small effect on *overall* recall; its intended benefit is concentrated in *high-severity* (SEV1/SEV2) recall, which aggregate `CapturedSEVs` does not capture. Hyperparameter optimization, tuned to cross-validated log-loss, did *not* improve recall at the operating gating levels in our reconstruction – the log-loss objective is not aligned with recall at a fixed gating percentage – and the deployed `CORA`-GBT+ accordingly uses the default tree depth. The extended training window reduces temporal drift but is not separately ablated. Because the reconstructed base already trains on the full recent window, the marginal effects are small: much of the end-to-end `CORA`-GBT+ vs `CORA`-GBT gain reflects retraining on more recent data together with the enriched features. The full per-component tables (marginal `CapturedSEVs` at every gating level, Meta-wide and for Org$_A$) and the deployed end-to-end comparison are provided as supplementary material.

**RQ 4:** `CORA`-GBT+ achieves 22% improvement in recall at 15% gating and 10.6% at 45% gating. A per-component ablation attributes the gain primarily to enriched config/service features together with retraining on recent data; SEV-level-aware training targets high-severity recall, while hyperparameter tuning did not improve recall at the operating gating levels.

## 4.5 Summary of Results

Table 10 summarizes the progressive improvements achieved across the four `CORA` model versions.

Test$_1$ and Test$_2$ denote the non-overlapping test periods from Table 4; Test$_2$ is shifted forward to reflect recent SEV patterns. Because each RQ uses the test set available at that iteration (Section 3.8), per-RQ improvements are not directly comparable; only the bootstrap comparison in Table 11 evaluates both endpoints on the same test set.

The trajectory shows consistent improvement along three axes: model sophistication (logistic regression to enhanced GBT), scope (Org$_A$-only to Meta-wide), and outage impact intercepted (from flagging all high-impact SEVs in backtesting to incremental impact intercepted per cycle). We deployed `CORA`-GBT+ for the Freeze 3 (2025 Q4) risk-management

**Table 10** Evolution of CORA model performance.

| Version | Model | Scope | Recall Improvement | Period |
|---|---|---|---|---|
| RQ 1 | Logistic Regression | $\text{Org}_A$ | +11% at 5% gating vs. DRS | Freeze 1 |
| RQ 2 | (Retrospective) | $\text{Org}_A$ | reduced outage impact YoY | Freeze 2 |
| RQ 3 | LightGBM | Meta-wide | +25.95% at 10% gating | $\text{Test}_1$ |
| RQ 4 | Enhanced LightGBM | Meta-wide | +22% at 15% gating | $\text{Test}_2$ |
| | (Deployed) | $\text{Org}_A$ | +22% config SEV recall | Freeze 3 |

**Table 11** Bootstrap 95% CIs for recall difference: CORA-GBT+ vs. CORA-GLM.

| Gating | ΔRecall | Rel. Impr. | 95% CI | Scope |
|---|---|---|---|---|
| 5% | +3.1pp | +19.7% | [+0.1pp, +6.3pp] | Meta-wide |
| 10% | +4.6pp | +17.3% | [+1.1pp, +7.9pp] | Meta-wide |
| 15% | +4.0pp | +11.0% | [+0.4pp, +7.5pp] | Meta-wide |
| 45% | +8.9pp | +13.2% | [+5.2pp, +12.6pp] | Meta-wide |
| 5% | +5.2pp | +38.3% | [+0.7pp, +9.3pp] | $\text{Org}_A$ |
| 15% | +9.6pp | +30.7% | [+4.6pp, +14.7pp] | $\text{Org}_A$ |
| 45% | +12.1pp | +18.6% | [+6.8pp, +17.4pp] | $\text{Org}_A$ |

window; consistent with the backtested RQ 4 result, it improved config SEV recall by roughly 22%. We deliberately do *not* report a production outage-impact year-over-year figure for Freeze 3: config diff volume grew substantially year-over-year and the residual outage loss was dominated by diffs that bypassed gating, so a raw before/after comparison cannot be cleanly attributed to CORA. We use `ImpactCaptured` (Equation 3) internally; specific values are organization-sensitive and we report only relative changes.

**Confirmatory statistical analysis.** As described in Section 3.8, we report bootstrap confidence intervals for the *cumulative* improvement of the final model (CORA-GBT+) over the initial deployed baseline (CORA-GLM).

Table 11 shows the 95% bootstrap confidence intervals (Section 3.8, $B$=10,000) for the recall difference between CORA-GBT+ and CORA-GLM on the test set (331,933 Meta-wide config diffs, 831 SEVs). All intervals exclude zero, confirming that the improvements are reliable. Since CORA-GLM already outperforms the code-oriented DRS model on config diffs (RQ 1), and CORA-GLM is a strict superset of DRS features, these confidence intervals are conservative estimates of the improvement over DRS.

## 5 Discussion

CORA follows the participatory action research methodology [25, 4] as applied in [17]: each iteration identifies a problem, develops a solution, evaluates it in production, and uses the findings to motivate the next cycle. The Freeze 1 incident (missed SEV1s) motivated CORA-GLM. The Freeze 2 deployment validated config-specific features and revealed limitations of logistic regression (inability to capture non-linear interactions). The transition to CORA-GBT addressed those limitations and produced new insights: default GBT hyperparameters already outperformed tuned logistic regression, indicating that non-linear feature interactions are a first-order effect in config risk; offline/online feature consistency checks uncovered discrepancies that improved production reliability; and data-vs-code config classification proved uninformative. The CORA-GBT+ iteration used these findings to add enriched service features and SEV-severity-aware training (and to explore Bayesian hyperparameter optimization), yielding simultaneous precision and recall improvements driven mainly by the enriched features and retraining on more recent data.

The per-component ablation in RQ 4 (supplementary material) isolates three of the four enhancements on a common training window and test set. It shows that enriched config/service features are the most consistent contributor, that SEV-severity weighting mainly shifts high-severity recall rather than aggregate recall, and that log-loss-tuned hyperparameter optimization did not improve recall at the operating gating levels. Because the enhancements were developed iteratively rather than in a controlled factorial experiment – and because the reconstructed base already trains on the full recent window – these marginal estimates are approximate and do not sum to the end-to-end gain, much of which reflects recent-data retraining. A fully factorial design (including the training window, held fixed here) could quantify each component's independent contribution, but doing so in a production system with time-varying data and evolving engineering practices remains a challenge for future work.

User feedback drives feature engineering throughout: *num_non_generated_files* and *has_materialized_JSON* emerged from engineer feedback on false positives, and the removal of interaction terms in the GBT models reduced the feature space without loss. Training on Meta-wide data rather than organization-specific subsets benefits organizations with smaller local datasets (RQ 3), consistent with transfer learning where shared patterns compensate for sparse local signal.

**Implications for practitioners.** Our experience suggests several recommendations: (1) use config-to-service mapping as the main enabler for config risk prediction; (2) differentiate config and code risk models, as code-oriented models both over-gate safe config changes and under-gate risky ones; (3) measure safety net reliability (false positive rates), not just coverage; (4) weight training by SEV severity to focus on the more severe incidents; and (5) iterate frequently with feedback.

## 6 Threats to Validity

**Generalizability.** Drawing general conclusions from empirical studies in software engineering is difficult because any process depends on a potentially large number of relevant context variables [17]. Some aspects of our study provide limited internal diversity, but we are careful not to overstate external validity. First, although the study is conducted within a *single company* (Meta), it spans multiple large, autonomous product organizations ($\text{Org}_A$–$\text{Org}_D$), each with different config change patterns and SEV rates. This is not equivalent to evaluation across independent companies: all of these organizations share Meta's infrastructure, tooling, and engineering culture, so external validity beyond Meta is not established. Second, we *hypothesize* that the central insight – that config risk derives from service-level properties (criticality, blast radius, operational readiness) rather than code-level properties – generalizes to other service-oriented architectures, because any organization that manages services through configuration faces the same mapping problem from what changed to which services are affected. This "reusable-blueprint" argument is a hypothesis grounded in the structure of the problem, not a finding validated outside Meta. Third, the specific features `CORA` uses (service criticality tiers, host counts, service dependencies, test coverage, canary infrastructure) are common across service-oriented architectures, but their predictive value in other organizations remains to be tested.

**Construct Validity.** Following [17, 1], we use SEV-causing diffs as the outcome variable for risk prediction. This operationalization has an advantage over many defect prediction studies: the incident response team manually determines the trigger diff for each SEV, avoiding the

noisy SZZ heuristics [29, 6] that many published studies use. However, this outcome captures only diffs that caused SEVs severe enough to be tracked; config changes that degraded performance without triggering a SEV are not captured as positive examples, potentially biasing the model toward catastrophic failures. For config changes specifically, gradual degradations (e.g., a config change that increases latency by 10% without triggering an alert) may be common but invisible to the model. The service-level features (criticality, blast radius) would plausibly flag such changes, but the model has no training signal to learn from them.

As noted in [17], the observational nature of the data creates challenges for interpreting individual feature effects due to latent confounding. For example, services with higher test coverage may appear *more* risky in the data, not because testing increases risk, but because high-risk services are more likely to have invested in testing. We mitigate this through feature selection favoring interpretable directional effects and SHAP-based per-prediction explanations, but the underlying confounding persists.

The evaluation metric (`CapturedSEVs` at a given gating level) directly measures what the code freeze system optimizes for. However, as noted in [1], other metrics such as the reduction in SEV count, developer productivity impact, and long-term behavioral changes are also important but harder to measure rigorously.

**Internal Validity.** The numerical results for Research Questions 1, 3, and 4 rely on backtesting: we simulate how the model would have performed had it been deployed during the evaluation period. Actual performance may differ, for example due to behavioral changes induced by gating (engineers modifying their diffs in response to risk scores). The partial ablation in RQ 4 isolates three of the four enhancements (enriched features, SEV-level-aware training, and hyperparameter optimization) on a common training window; the extended training window is held fixed and not separately ablated. Because the enhancements were developed iteratively within an action research cycle rather than in a controlled factorial experiment – and because the reconstructed baseline already trains on the full recent window – these marginal attributions are approximate, are subject to sampling noise at the observed SEV counts, and do not sum to the end-to-end gain. The confirmatory bootstrap analysis (Table 11) tests only the cumulative end-to-end improvement.

A second concern is temporal drift: risk patterns may change over time as the codebase, services, and engineering practices evolve. We mitigate this by using time-based data splits (Section 3.8) so that the model is always evaluated on data from a later period than its training data, and by extending the training window in the enhanced model (`CORA`-GBT+) to reduce the gap between training and deployment. Beyond temporal drift in feature distributions, *concept drift* may also occur: the nature of what constitutes a risky config change may shift qualitatively as the organization adopts new config mechanisms (the 44% of non-diff config changes in Section 4.2 illustrate this evolving landscape).

A third concern is the feedback loop created by deployment: when the model gates high-risk diffs, it prevents the SEVs that would have validated its predictions, making future evaluation harder. The bypass rate drop (83.8% to 51.6%) is itself evidence of behavioral change. Engineers may also modify their diffs in response to risk scores, altering the distribution of future training data in ways that are difficult to account for.

Finally, while SEV1 and SEV2 trigger attribution is likely high-quality (major incidents receive thorough investigation), SEV3 and SEV4 trigger attribution may be noisier. Since SEV3/SEV4 constitute the vast majority of positive labels, label noise at lower severity levels could affect model training, though the SEV-level-aware weights (Equation 1) partially mitigate this by down-weighting lower-severity samples.

**Conclusion Validity.** The primary threat to conclusion validity is the low base rate of SEV-causing diffs (<0.3% of all config diffs). While the total number of diffs in each test set is large (>100K), the number of positive samples (diffs that caused SEVs) is small: 831 in the Meta-wide test set and 446 in the $\text{Org}_A$ subset. As described in Section 3.8, we treat the intermediate comparisons (RQs 1, 3, 4) as exploratory and reserve confirmatory testing for the cumulative improvement of `CORA`-GBT+ over `CORA`-GLM. Bootstrap 95% confidence intervals (Table 11) confirm that the end-to-end improvement is reliable at all gating levels, with all intervals excluding zero. Nonetheless, individual high-impact SEVs can disproportionately affect the results, and the improvements should be interpreted in conjunction with the outage-impact-captured measure (Equation 3), which weights SEVs by their operational severity.

**Researcher and Organizational Bias.** The authors are practitioner-researchers who designed, built, deployed, and evaluated `CORA` within their own organization. This dual role is intrinsic to action research but introduces potential bias: feature selection, interpretation of results, and the choice of evaluation metrics and gating levels were made by the same team that developed the system and reflect the organization's operational priorities. Reporting relative rather than absolute figures (for confidentiality) also limits external scrutiny of the magnitudes. We mitigate these risks in three ways: the outcome measures and evaluation protocol are inherited from prior DRS work [17, 1] rather than devised to favor `CORA`; the SEV-to-trigger-diff labels are determined by an independent incident-response team, not by the authors; and confirmatory conclusions rest on bootstrap testing on a held-out, later-in-time test set (Table 11). An independent replication in a different organizational context would nonetheless provide stronger evidence.

## 7 Concluding Remarks

Configuration changes are a common source of outages, yet the defect prediction literature focuses almost exclusively on source code. We describe `CORA`, the first dedicated risk model for configuration diffs, and demonstrate its effectiveness through three iterations of participatory action research. A logistic regression model with config-specific features achieves an 11% improvement at 5% gating over the code-oriented DRS model and captures all diffs causing high-impact outages (RQ 1). During Freeze 2, config gating decreased while outage impact fell (RQ 2). A unified LightGBM model achieves 25.95% improvement at 10% gating Meta-wide, revealing that non-linear feature interactions are a first-order effect in config risk prediction (RQ 3). An enhanced model adding enriched service features and SEV-severity-aware training achieves 22% improvement at 15% gating with simultaneous precision gains, and was deployed for the Freeze 3 (2025 Q4) window, where it improved config SEV recall by roughly 22% (RQ 4).

The key insight is that config diff risk derives from service importance, blast radius, and operational readiness rather than code complexity. The config-path-to-service mapping provides the structural bridge enabling this reasoning, and applies to any organization managing configuration changes in service-oriented architectures.

## Abstract

Healthcare AI software teams face growing pressure to translate ethical principles and regulatory obligations into concrete requirements, design decisions, and assurance evidence. Day-to-day requirements engineering (RE) practice still lacks lightweight tool support for connecting abstract frameworks, such as the EU AI Act and the NIST AI Risk Management Framework, to actionable requirements work. This paper builds on a two-phase research project. In the first phase, we conducted an empirical interview study with healthcare AI practitioners spanning clinicians as end users of HealthAI systems and software engineers as developers of HealthAI software systems, which surfaced recurring concerns around transparency, accountability, and the difficulty of mapping regulatory obligations to concrete engineering tasks. Informed by those findings, in the second phase we designed, implemented, and conducted an initial evaluation of the *HealthAI Ethics Assistant*, an AI-enabled RE tool for healthcare AI software systems.

The tool supports practitioners in generating, validating, and comparing ethical requirements through a structured Create–Validate–Compare workflow. It was implemented as a full-stack web application and grounded in a structured knowledge base combining regulatory guidance (EU AI Act, NIST AI RMF) with practitioner concerns surfaced by the interview study. The work was conducted in close collaboration with an R&D engineer at a medical device manufacturer, who contributed to industrial problem framing and participated as the first practitioner evaluator in the case study reported here.

Our initial evaluation is exploratory, involving a single case study, and used the Technology Acceptance Model and the System Usability Scale. Traceable regulatory references were rated as the most valuable and trustworthy feature, highlighting the importance of explainability and evidence support in compliance-oriented requirements work. The main adoption challenge was not basic usability, but fitting the tool into existing engineering and regulatory workflows. We derive practice-oriented lessons for designing AI-enabled requirements tools in regulated domains: ground LLM outputs in explicit compliance sources, support multiple practitioner perspectives, make generated requirements reviewable rather than authoritative, and align tool use with existing assurance processes. These early results suggest that AI-enabled assistants can help bridge ethical AI principles and practical requirements engineering when designed as auditable, human-in-the-loop support tools rather than autonomous compliance solutions.

## 1 Introduction

Healthcare AI software systems (hereafter referred to as *HealthAISys*) development teams are under growing pressure to demonstrate that their systems meet ethical and regulatory standards such as the EU AI Act [10] and the NIST AI Risk Management Framework [22]. These frameworks set out clear expectations around transparency, accountability, and patient safety; the challenge is that these expectations are expressed at a level of abstraction that is difficult to act on directly in a software project. In practice, most engineering teams lack a clear process for translating a regulatory provision into something they can actually build or test. This gap between ethical guidance and requirements engineering (RE) practice is not new. Prior empirical work has documented that practitioners building AI-enabled systems regularly struggle to translate high-level principles into concrete engineering decisions [12, 25]. Existing tool support does not help much: enterprise compliance platforms carry significant overhead, and general-purpose LLM assistants will generate requirement text on demand, but without grounding in authoritative regulatory sources there is little basis for trusting what they produce [15]. Securing industry participation in *HealthAISys* research is itself a significant challenge: regulatory sensitivity, confidentiality obligations, and organisational risk aversion mean it is very difficult to get access to practitioners working on real projects.

To understand this gap from a practitioner perspective, we previously conducted a semi-structured interview study with 17 *HealthAISys* stakeholders and practitioners spanning clinicians as end users and software engineers as developers (currently under review at another venue). Participants consistently reported difficulty translating regulatory provisions into implementable requirements, uncertainty about which ethical dimensions applied to their specific product context, and a lack of lightweight tooling that could fit into their existing workflows without imposing compliance-specialist overhead. These findings directly shaped the design decisions of the tool described in this paper.

To address this, we developed *HealthAI Ethics Assistant* grounded in a knowledge base rather than open-ended LLM generation. The knowledge base combines regulatory guidance from the EU AI Act and the NIST AI RMF with practitioner-identified ethical concerns drawn from the interview study described above and scientific literature [13]. This grounds the tool in explicit, traceable sources: every generated requirement can be linked to a specific regulatory provision or a real practitioner concern, rather than general pre-training data. The tool is intentionally scoped as a working prototype, and this paper reports an exploratory evaluation with a practitioner – an R&D engineer at a medical device manufacturer who is also a co-author of this paper. The evaluation was designed to test feasibility and refine the study protocol ahead of a multi-site study. We hence make no claims of generalisability.

This paper describes the design, implementation, and exploratory practitioner evaluation of the *HealthAI Ethics Assistant*, an AI-enabled RE tool built to support healthcare AI software teams. The tool guides practitioners through a Create–Validate–Compare workflow and grounds every output in a structured knowledge base.

**Contributions.** This paper makes the following contributions:

**(1)** A description of the design and implementation of the HealthAI Ethics Assistant, including its Create–Validate–Compare interaction model and traceable regulatory knowledge base informed by practitioner findings from our interview study.

(2) Preliminary evaluation findings from an exploratory practitioner case study with an R&D engineer at a medical device manufacturer, collected using the Technology Acceptance Model [9] and the System Usability Scale [8].
(3) Lessons for designing AI-enabled RE tools in regulated healthcare domains.
(4) We make the tool demo interface [1] and the source code repository [2] publicly available.

## 2 Background and Related Work

AI ethics guidance has expanded rapidly, with broad frameworks such as the OECD AI Principles [19] and UNESCO Recommendation [24] establishing shared values around transparency, fairness, and accountability. Jobin et al. found that most guidelines offer little concrete guidance on how to act on them [14], and Mittelstadt stated that without implementation support, principle-level guidance risks becoming ethics washing rather than meaningful change [17]. More recently, governance has shifted to enforceable regulation: the NIST AI Risk Management Framework [22] provides a risk-based structure across Govern, Map, Measure, and Manage functions, while the EU AI Act establishes the first legally binding regional AI regulation, classifying healthcare AI as high-risk. Translating these frameworks into actionable engineering work remains a recurring challenge for practitioners [5, 16].

Within RE, Vogelsang and Borg argued that traditional RE methods are poorly suited to AI systems where quality attributes such as fairness and explainability are difficult to specify in verifiable terms [25]. Habibullah et al. surveyed practitioners on non-functional requirements for ML and found that fairness, transparency, and safety are frequently identified as important but rarely specified concretely [12]. Nalchigar et al. reported similar difficulties in a healthcare ML modelling case study [18]. LLM-assisted RE has emerged as a possible solution: a recent systematic literature review found 136% growth in LLM-for-RE studies between 2023 and 2024 [26], with tools like ReqBrain showing fine-tuned LLMs can generate practitioner-relevant requirements [11]. However, a trust problem remains: LLM outputs are difficult to audit without grounding in authoritative sources, motivating retrieval-augmented approaches [15]. This is the gap our paper aims to address.

Tool support for regulatory compliance is well established in other regulated domains. In privacy and data protection, a line of tools automates compliance checking against the GDPR: Torre et al. use conceptual models to check system compliance [23], Amaral et al. check the completeness of privacy policies against regulatory provisions [4], and Sleimi et al. [21] and later Abualhaija et al. [3] use semantic legal metadata to support downstream analysis, building on earlier results from Breaux and Anton on systematically extracting rights and obligations from regukatory text [7]. Two properties separate this body of work from our setting. It is predominantly verification-oriented, which means that an artefact already exists and the tool checks it against a source. And it targets provisions specific enough to formalise, whereas our sources span binding regulation and principle-level guidance that resists it.

**Positioning relative to prior work.** Unlike prior LLM-for-RE tools that evaluate outputs in isolation, our tool is grounded in a regulatory knowledge base and practitioner findings from our interview study, enabling traceability from the generated requirement to the source. This positions our tool as an auditable compliance aid rather than a generative assistant.

# 3 Methodology

This section describes the design rationale and technical implementation of the HealthAI Ethics Assistant.

## 3.1 Motivating Interview Study

Before designing the tool, we conducted a semi-structured interview study with 17 healthcare AI practitioners: five healthcare professionals, six healthcare researchers, and six software engineers, recruited from IT companies, clinics, hospitals, and universities in China (8), Australia (8), and India (1), with 1 to 24 years of professional experience. Interviews were conducted between February and July 2025, recorded, transcribed, and analysed using thematic synthesis. The study built on our previous systematic mapping study [13], which identified five ethical dimensions. Participants ranked these by priority, yielding privacy (mean 1.2), safety (2.2), bias (3.3), accountability (3.7), and transparency (4.5), and all five recurred in the interview data as sources of practical difficulty. These findings are encoded in `findings.json` and injected into the tool's Compare workflow to ground requirement refinement in real practitioner experience rather than synthetic examples. The full interview study is currently under review at another venue; this paper focuses on the tool that the study motivated and its initial evaluation.

## 3.2 Design Rationale

Our design decision was to ground the assistant's structured workflow in explicit, curated knowledge sources. This was motivated by a practical concern: in compliance-oriented requirements work, practitioners need to know *where* a requirement comes from, not just what it says. The knowledge base was assembled from two sources. The first is a set of regulatory frameworks, specifically the EU AI Act [10] and the NIST AI Risk Management Framework [22], they are encoded as structured JSON covering article titles, summaries, implementation guidance, applicable ethical dimensions, and source links. The second is the set of practitioner-identified concerns drawn from the interview study described in Section 3.1, stored as `findings.json` and covering the five ethical dimensions of privacy, safety, bias, transparency, and accountability. These five dimensions were adopted from an earlier systematic mapping study of generative AI ethics [13], and their recurrence in the interview data provided independent empirical validation that they are the right organising structure for the tool's outputs.

The two knowledge sources are used at different stages of the workflow through a lightweight structured RAG pipeline rather than embedding-based vector retrieval. For Create and Validate interactions, the backend retrieves regulatory entries using structured metadata such as ethical dimension and framework identifier; for Compare interactions, it retrieves practitioner findings by stakeholder role and ethical dimension. Retrieved records are formatted as grounding context and injected into a mode-specific prompt with explicit instructions that generated requirements and validation checks cite only the supplied guideline identifiers. The model returns structured JSON, which the backend post-processes to enrich citation metadata before rendering reviewable requirement cards.

We selected sources that are authoritative rather than advisory, that were formally published when we built the knowledge base, and that cover the regulations our interview participants raised most often. The knowledge base is a fixed snapshot: entries are edited by hand, nothing records which version of a framework an entry came from, and the tool does

not check whether two sources disagree. When two frameworks cover the same obligation but set different standards, both entries are injected and the generated requirement cites both, leaving the practitioner to decide which applies. This works at the current scale, but covering more jurisdictions would first require version tracking and automatic conflict detection.

## 3.3 Interaction Model

The tool enforces practitioner interaction through a **Create**–**Validate**–**Compare** workflow. In **Create** mode, the tool generates ethical concerns and implementable software requirements in response to a project or scenario description. In **Validate** mode, it checks an existing requirement against the built-in knowledge base and flags gaps or misalignments with regulatory guidelines. In **Compare** mode, it takes a draft requirement, compares it against practitioner findings from the interview study, and proposes a refined version. The backend automatically classifies user messages into one of these three modes via the `POST /ethics/chat` endpoint, removing the need for practitioners to explicitly select a mode.

To start a session, the practitioner clicks *New Chat*, which opens a configuration modal. Here, the practitioner selects a topic, assigns a chat name, chooses a persona, and optionally provides a project context. Three fixed personas are available: Healthcare Professional, Software Engineer, and Healthcare Researcher with a *Let System Decide* option that presents a 20-question behavioural questionnaire to help the user determine their persona. The frontend then passes a compact JSON persona description to the backend as prompt context, allowing the LLM to adapt the tone, specificity, and framing of generated requirements to the practitioner's background.

Each generated requirement is presented as a structured card that displays the ethical dimension covered, the requirement statement, and clickable regulation-reference blocks linking directly to specific EU AI Act articles and NIST AI RMF controls. Users can mark each requirement as Accept, Reject, or Clear, with accepted requirements exportable as a structured `.docx` document grouped by ethical dimension.

Figure 2 summarises the technology workflow. The backend is built with FastAPI and exposes a REST API consumed by a Vue 3 single-page application hosted on Cloudflare Pages. The LLM layer uses Google Gemini (`gemini-2.5-flash` by default), invoked via the `ethics_service.py` module, which constructs mode-specific grounded prompts by combining the selected persona context, project context, relevant knowledge-base entries, requirements preferences, and the current user message. Session data, chat messages, and requirement preferences are persisted in PostgreSQL in production and SQLite for local development. A lightweight document grounding mechanism available in developer mode allows practitioners to upload reference documents (`.md`, `.txt`, or `.json`) that are prepended to the LLM prompt as additional context. The tool can be accessed via our demo site [1]. The tool source code, knowledge base, and example session data are available in a replication package [2].

# 4 Exploratory Practitioner Study

To assess the HealthAI Ethics Assistant in a realistic industrial setting, we conducted an exploratory practitioner study with an R&D engineer at BMC Medical Co., Ltd., a Chinese medical device manufacturer specialising in respiratory healthcare. BMC has operated for over 20 years, ranks second globally in CPAP device sales, holds FDA certification, and distributes across more than 140 countries and regions [6]. The expert develops respiratory medical devices including ventilators and CPAP systems, products that fall within the EU AI Act high-risk category when AI-enabled. The expert (Cheng Zhang, co-author) had two

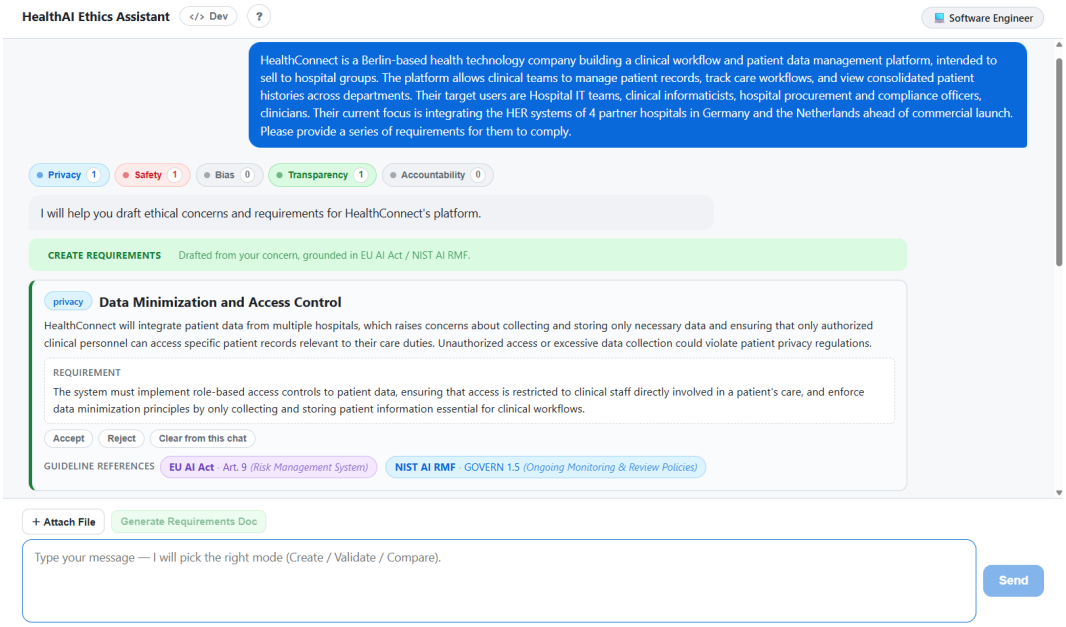

**Figure 1** A sample session showing a generated requirement card with traceable references.

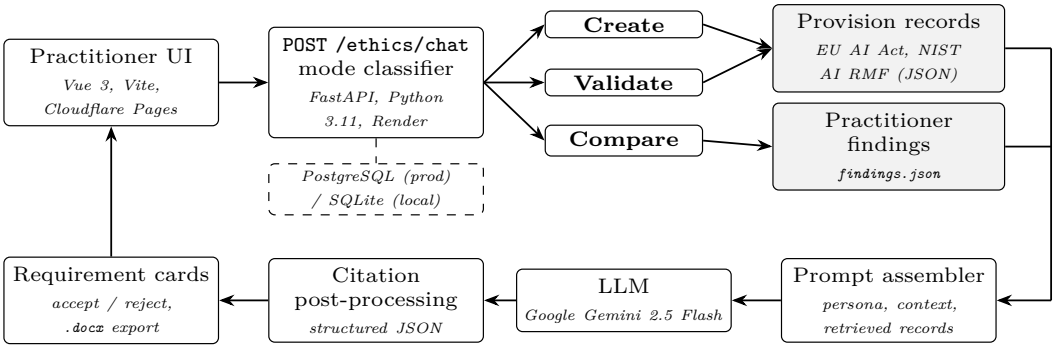

**Figure 2** Architecture and Create–Validate–Compare workflow of the HealthAI Ethics Assistant.

distinct roles in this research programme. In the *design phase*, he contributed to industrial problem framing by reviewing tool requirements derived from the interview study, validating that the Create–Validate–Compare workflow reflected realistic compliance needs in a medical device context, and advising on which regulatory dimensions were most pressing for his organisation. In the *evaluation phase*, he participated as the first practitioner evaluator, conducting an unstructured tool-use session followed by structured post-use assessment. This dual role reflects the industry–academia collaboration model for our project. We acknowledge that his involvement in the design phase is a source of response bias. To limit it, he was not shown the tool's implementation, the contents of its knowledge base, or any generated output before the session, and the session used a scenario he selected himself rather than one prepared by the research team. These measures reduce bias but cannot eliminate it; therefore, we treat the ratings as indicative rather than as an independent assessment.

The case study combined a tool-use session and a post-use evaluation using the Technology Acceptance Model (TAM) [9] and the System Usability Scale (SUS) [8], complemented by open-ended qualitative feedback. Qualitative feedback was collected through four open-ended

prompts administered after the structured instruments, asking which aspects of the tool were most and least valuable, what would prevent its adoption in the evaluator's organisation, and what functionality was missing. Responses were recorded in writing, and the first author grouped them into the observations. This approach is consistent with established practice in empirical software engineering for early-stage prototype evaluation [20]. Prior to the session, the expert received a brief overview of the tool's purpose and was asked to explore it freely using a scenario from their own engineering work. The expert chose to describe an in-development dual-level non-invasive home ventilator. The session continued over three interactions, each automatically classified by the backend into a different workflow mode.

**Create (initial scenario).** The expert described the target product with details: pressure range 4–30 $cmH_2O$, humidification 10 g/L, supporting CPAP, auto-CPAP, S, auto-S, PCV, and ASV modes, with full respiratory-event logging. The tool returned a Safety requirement on reliable operation in home environments, grounded in EU AI Act Art. 9 (Risk Management System) and Art. 15 (Accuracy, Robustness and Cybersecurity), and NIST AI RMF MEASURE 2.3 (AI System Performance and Validity). A second requirement addressed Privacy, focused on secure handling of respiratory event data with encryption at rest and in transit and anonymisation for research use. Both requirements were accepted by the expert.

**Create (extended context).** The expert added that the product is developed in China but distributed across China, the US, India, and Europe, with EMC IEC 61000 testing and CE certification in place. The tool returned a Bias requirement on algorithmic performance across demographic, genetic, and cultural populations (EU AI Act Art. 10; NIST AI RMF MEASURE 2.11) and a Transparency requirement on region-specific regulatory disclosure (Art. 13; MAP 1.5).

**Compare.** The expert further asked: *"I want to know what detailed additional certifications are needed in the US, Europe, and India."* The backend classified this as a Compare interaction. The tool found three practitioner findings from the interview study knowledge base on the accountability dimension: a perspective from a healthcare professional discussing AI malpractice liability across the supply chain, an interview quote from a clinician on human oversight requirements, and a view from a healthcare researcher on model versioning and reproducibility. Each finding was annotated with a "Consider:" prompt suggesting concrete refinements to the certification scope.

## Evaluation Results

Given that this is a preliminary evaluation with a single expert, all results are treated as exploratory rather than conclusive. We organise findings across three lenses: system usability (SUS), technology acceptance (TAM), and open qualitative feedback.

For the System Usability Scale (SUS), the composite score was 70. With a single respondent, this figure carries no inferential weight, and we make no comparison against population benchmarks, which are means across many respondents and studies. The item-level pattern in Figure 3 is more informative. Six of the eight usability items were rated at 3 or 4: the evaluator found the tool not unnecessarily complex (SUS2 = 4), easy to use (SUS3 = 4), quick for most people to learn (SUS7 = 4), well integrated (SUS5 = 3), consistent (SUS6 = 3), and not cumbersome (SUS8 = 3). Of the remaining two, he was neutral on whether technical support would be needed (SUS4 = 2) and disagreed that the tool could be used without first learning a good deal (SUS10 = 1), the lowest of the SUS items. Both

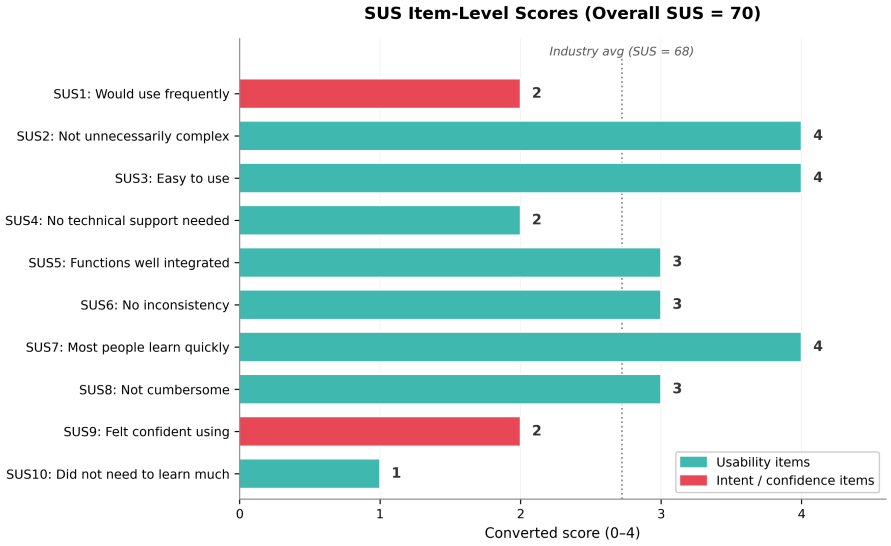

**Figure 3** SUS item-level scores.

concern onboarding rather than the interface, and both are consistent with the persona configuration difficulty reported under TAM Q3 below. Across all eight usability items the average was 3.0 out of 4. The two intent and confidence items sat at the scale midpoint (SUS1 = 2, SUS9 = 2); the evaluator attributed both explicitly to role mismatch rather than to dissatisfaction with the tool, noting that compliance requirement drafting falls outside the primary responsibilities of an R&D engineer.

For the Technology Acceptance Model (TAM), the most prominent TAM finding was Q10: traceable regulatory references received a maximum score of 5, the highest rating in the evaluation. The expert identified this as the most valuable aspect of the tool in open feedback: *"Traceable regulatory specifications, indexing of related legal clauses and international standards make me understand clearly which legal provisions are involved."* This directly validates the design decision to ground the tool in explicit knowledge sources rather than open-ended LLM outputs. Ease-of-use items rated positively (Q2 = 4 on learning without training; Q1 = 3 on navigation; Q4 = 3 on the accept/reject interface). Q3 (clarity of persona onboarding) received a 2, with the expert noting that the three role categories are *"a bit vague, better to define product engineer, software engineer, hardware engineer, and market manager separately."* Perceived Usefulness items (Q5–Q8) were rated neutral at 3 each. Q11 (transparency of reasoning) received a 3, suggesting that while regulatory grounding was well received, the explanation of *why* a specific requirement was generated could be made more explicit. The two Intention to Use items were the lowest TAM ratings (Q12 = 2 on future use; Q13 = 2 on recommending the tool to colleagues), again reflecting role fit; the expert noted these would likely score higher for a product engineering or regulatory affairs respondent. Table 1 summarises the full TAM responses. Two signals in Table 1 are actionable. Eight of the thirteen items sat at the midpoint, which the evaluator attributes to requirements that restate knowledge already standard for a device engineer and to the absence of device-level parameters. And the gap between Q10 = 5 and Q11 = 3 suggests source citation and reasoning explanation are separate properties: the tool shows which provision a requirement links to, but not why it was selected, which will be the priority for the next iteration.

**Table 1** TAM evaluation responses (1 = Strongly Disagree, 5 = Strongly Agree).

| Aspect | Item | Question (abbreviated) | Score |
|---|---|---|---|
| PEOU | Q1 | Easy to use and navigate | 3 |
| | Q2 | Easy to learn without training | 4 |
| | Q3 | Persona onboarding was clear | 2 |
| | Q4 | Accept/reject interface was intuitive | 3 |
| PU | Q5 | Improves compliance drafting | 3 |
| | Q6 | Relevant and useful information | 3 |
| | Q7 | Five-dimensional indicator useful | 3 |
| | Q8 | Mixed persona produced useful output | 3 |
| TT | Q9 | Trusted the generated requirements | 3 |
| | Q10 | Traceable references increased trust | 5 |
| | Q11 | Transparent in why output generated | 3 |
| ITU | Q12 | Would use in future projects | 2 |
| | Q13 | Would recommend to colleagues | 2 |

**Open Qualitative Feedback.** The expert identified traceable regulatory specifications and the indexing of relevant legal clauses as the most valued aspect of the tool, stating that it enables a clear understanding of the legal obligations involved in healthcare AI development. This directly aligns with the strong trust rating observed for Q10.

The expert identified three barriers to adoption. First, the tool's built-in knowledge base covers EU and US regulatory frameworks, but R&D teams operating under other jurisdictions require broader coverage. The tool's document-grounding mechanism allows practitioners to upload additional regulatory documents, but it places the burden of sourcing and formatting them on the practitioner rather than providing built-in coverage. Second, certain generated requirements constitute standard industry knowledge for device engineers and offer no practical benefit to that role. Third, device-level parameters such as pressure ranges for CPAP and ventilator modes are essential for generating requirements under real product constraints, and their absence limits the tool's applicability for R&D work.

## 5 Discussion

The evaluation shows that the tool functions well as an interface, but its practical value depends heavily on the practitioner's role. The expert's work as an R&D engineer focuses on device-level details such as pressure tolerances, hardware constraints, and component specifications. The HealthAI Ethics Assistant is designed to generate compliance requirements based on regulatory frameworks, which explains why the expert found the tool conceptually useful but limited in direct applicability. In medical device organisations, compliance work typically falls to product engineers and regulatory affairs teams; the tool would likely be perceived as more useful in those hands. The feature that worked consistently across the evaluation was traceable regulation references: knowing that a generated requirement links back to a specific guideline makes it far easier to defend in a design review or audit. The five ethical dimensions are not equally easy to turn into requirements. Privacy, safety, and bias correspond to provisions that state concrete engineering obligations, and the tool handled them readily. Accountability is harder because obligations regarding liability and oversight depend on who within the organisation is answerable, and until that is decided, there is little for the tool to specify. Our interview study showed the same pattern, with accountability ranked fourth of five, and in the evaluation session it appeared only through Compare, as retrieved findings rather than generated requirements.

## 5.1 Design Recommendations

**R1: Expand the built-in regulatory coverage.** The current knowledge base covers the EU AI Act and NIST AI RMF, but does not reflect the wider regulatory landscape that international teams must navigate. Future versions should incorporate Chinese AI governance standards, relevant IEC/ISO medical device standards, and region-specific disclosure requirements. A curation roadmap driven by practitioner-reported gaps would help prioritise which frameworks to add first. The document upload feature is a viable short-term workaround, but should be supplemented with guided templates to reduce the formatting burden on practitioners.

**R2: Refine role and context awareness.** The persona questionnaire treats SE as a single category, but compliance responsibility varies significantly across roles. Future versions should offer a finer-grained role taxonomy (e.g., R&D engineer, product engineer, clinical lead) and adapt the tool's positioning accordingly: for roles with direct compliance responsibility, the tool should function as a primary drafting aid; for roles with peripheral compliance involvement, it should present itself as a reference and awareness resource rather than a workflow tool. This shift in framing, rather than a change in functionality would likely improve perceived usefulness for roles like the expert's without requiring new features.

## 5.2 Lessons Learned

**L1: Traceability builds trust faster than reasoning quality** . The evaluation showed that what mattered most to the practitioner was not the quality of the LLM's reasoning or the breadth of its output, but that every generated requirement could be traced to a specific regulatory article or practitioner finding. This trust was achieved through structured JSON prompt grounding, a lightweight mechanism that does not require a full RAG pipeline. The practical implication is that teams building compliance-oriented LLM tools should treat source traceability as a first-class design concern, not an audit feature added later.

**L2: Role fit determines adoption, not usability.** Another finding from the evaluation was not an interface problem but a positioning problem: the tool was used by the right *organisation* but the wrong *role*. This is predictable for compliance tools in large organisations, where the person with domain knowledge (R&D engineer) and the person with compliance responsibility (product or regulatory engineer) are different people. For teams building AI-enabled RE tools in regulated domains, the design question "who will use this?" should be answered at the level of job role and compliance responsibility, not just domain.

**L3: Practitioners stress-test scope before evaluating features.** The expert didn't explore the tool's features systematically. He threw a real, hard problem at it and watched where it broke. This is how practitioners evaluate tools. The implication is that graceful boundary behaviour matters as much as core functionality: a tool that clearly signals its limits is trusted more than one that produces plausible-sounding output beyond its competence.

**L4: Embedded ethics knowledge surfaces blind spots.** The expert flagged some requirements as "standard industry knowledge". However, what is standard to a 20-year veteran might not be to a new hire, a contractor, or developer teams in healthcare from adjacent domains. Ethics and compliance requirements that feel obvious to experts are genuinely non-obvious to others. AI-enabled tools that encode ethical dimensions may matter less as expert aids and more as organisational awareness tools – surfacing ethical obligations to people who would not otherwise know to ask about them.

## 6 Threats to Validity

This study has several limitations that should be considered when interpreting the findings. First, the evaluation involved a single expert, which limits the generalisability of the results; findings are exploratory rather than validated conclusions. The single-expert design was a deliberate choice for this phase: the goal was to assess fit between the tool and real industrial practice before investing in a broader multi-site study, consistent with early-stage prototype evaluation guidelines [20]. Furthermore, as noted in the introduction, securing any industry participation in healthcare AI research carries significant access barriers, making even a single engaged practitioner from a real medical device organisation a meaningful empirical contribution at this stage. Second, the expert was an R&D engineer, whereas the tool is primarily designed for product engineers and regulatory affairs specialists. Our future study will address these three limitations. We will recruit practitioners from several healthcare AI organisations, selected by compliance responsibility rather than technical domain, so the sample includes product engineers, regulatory affairs specialists, and clinical leads alongside R&D engineers, none of whom will have helped design the tool. Each will complete two sessions, one on a shared scenario and one on a product from their own work. Third, the evaluator was also briefly involved in the tool design phase, which may have introduced response bias toward positive assessments. Fourth, the knowledge base currently covers only the EU AI Act and NIST AI RMF, which may not reflect the regulatory context of teams operating under other jurisdictions. Generalisability is limited in three respects: one region, one role, and one product, the last being a single home ventilator chosen by the evaluator. These results may not hold in other regulatory contexts, for other roles, or for other kinds of product. Future iterations will incorporate Chinese AI governance standards and relevant IEC/ISO medical device standards.

## 7 Conclusion

This paper presents the design, implementation, and initial practitioner evaluation of the HealthAI Ethics Assistant, an AI-enabled requirements engineering tool built to help healthcare AI software teams translate regulatory guidance into concrete ethical requirements. The tool was motivated by a semi-structured interview study with healthcare SE practitioners spanning clinicians and software engineers, whose reported difficulties in mapping regulatory obligations to engineering tasks directly shaped the knowledge base design and workflow structure (full study currently under review). The tool is grounded in a structured knowledge base combining the EU AI Act, the NIST AI RMF, and practitioner findings from that study, and supports a Create–Validate–Compare workflow with traceable regulatory references.

An initial evaluation was conducted with an R&D engineer from BMC Medical Co., Ltd., using the Technology Acceptance Model and the System Usability Scale, along with open-ended qualitative feedback. The tool received generally positive usability ratings and a strong endorsement of its traceable regulatory references, which were identified as its most trustworthy feature. The main adoption challenge was not basic usability but role fit. From this, the paper derived practical design recommendations on expanding regulatory and ethics coverage and improving role awareness, alongside transferable lessons on the importance of source traceability and clear workflow positioning for AI-enabled tools in healthcare.

Future work will extend the evaluation to a multi-case study covering multiple roles across several healthcare organisations and broaden the knowledge base to include additional regulatory frameworks. Together, these findings suggest that AI-enabled assistants can

meaningfully support the translation of ethical AI principles into practical requirements engineering work, provided they are designed as auditable, human-in-the-loop tools that align with the practitioners' actual responsibilities.

## Abstract

End-to-End (E2E) testing of modern web applications simulates real user interactions to verify the complete application flow, ensuring seamless integration of UI, functionality, and data. It is, in general, costly to create and maintain, especially when the backend is a smart city platform with a data lake and complex user flows that introduce additional complexity. Recent advances in Large Language Models (LLMs) offer new opportunities for automating parts of this process, but their practical adoption in real development environments remains challenging, particularly when privacy, monetary cost, deployment, and control requirements call for local rather than cloud-based models.

This paper investigates the feasibility of introducing local LLMs into the E2E testing process of a real-world smart city web application, the ENEA PELL-IP portal for monitoring public lighting infrastructures. We developed and evaluated GenE2E, a two-stage pipeline that generates test cases from use case specifications and transforms them into executable Playwright tests. The approach was integrated with an existing testing environment and evaluated against manually written baseline tests.

Our findings show that local LLMs can effectively support E2E test generation, but not yet as fully autonomous tools. In our setting, Llama 3.3 outperformed CodeLlama mainly due to its larger context window; single-test generation improved focus and coverage, whereas batch processing reduced model invocations and showed lower generation time in our setup, but the timing results are hardware-dependent and based on a single run; broader efficiency claims require repeated measurements on representative hardware. We also observed that specification quality, completeness of Page Object Model (application-specific API wrapping HTML pages), and use case dependency management had a major impact on generated test quality. Based on this feasibility study, we derive preliminary lessons for practitioners considering local LLMs for E2E test generation.

## 1 Introduction

End-to-end (E2E) testing [13] is a critical phase of software quality assurance that validates the overall system behaviour from the user's perspective. Traditional E2E testing relies heavily on manual procedures or semi-automated frameworks requiring significant human effort for creating, maintaining, and executing test cases. These conventional methods face challenges in scalability and maintenance due to the dynamic nature and evolvability of modern web applications with complex interfaces and business logic. Modern web applications adopt a multi-tier architecture where the implementation is scattered across different layers and run on different machines. When the backend is a smart city platform with a data lake, deeper interaction flows introduce additional complexity, requiring validation across distributed services, heterogeneous data sources, and dynamic system behaviors.

Large Language Models (LLMs) have emerged as transformative AI tools offering new opportunities for automating software lifecycle tasks [6, 18], including test generation. LLMs can transform natural language specifications into structured test scenarios and executable scripts, potentially reducing manual effort and improving testing productivity. However, most existing studies focus on cloud-based models and controlled experimental settings, while practical adoption in industrial environments raises additional challenges related to privacy, deployment constraints, monetary cost, and the need for operational control. These factors often motivate the use of *self-hosted* (local) LLMs, whose effectiveness in real-world E2E testing pipelines remains underexplored. Moreover, current research has largely focused on unit or specialized testing (e.g., accessibility or security), while E2E testing – due to its broader scope and dependency on system-level context – remains comparatively less investigated [3, 12].

Conventional E2E testing involves multi-stage manual analysis of use case scenarios to produce comprehensive test suites covering typical and edge-case user flows. Automation frameworks (like Playwright[1]) simulate user interactions programmatically, but developing such scripts remains resource-intensive and prone to maintenance issues. LLMs' capabilities in contextual reasoning and code generation promise substantial benefits, potentially automating the E2E testing process and improving efficiency, coverage, and adaptability.

This paper reports our experience introducing local LLMs into the E2E testing process of a real-world smart city application, namely the ENEA PELL-IP web portal for monitoring public street lighting infrastructures [1]. To this end, we developed GenE2E, a two-stage pipeline that first generates test cases from use case specifications and, then, transforms them into executable Playwright scripts. The approach follows a *pipe-and-filter* architecture and has been integrated into an existing industrial testing workflow.

Rather than presenting a field deployment or a mature experience report, this study provides an initial feasibility assessment of using self-hosted LLMs to generate executable E2E tests within an existing industrial testing environment. Its core contribution is demonstrating that a complete requirements-to-test pipeline can be instantiated for a real-world web application under practical constraints such as local deployment, integration with an existing Page Object Model, and use-case dependencies. The evaluation is conducted offline by comparing generated tests with pre-existing manually written tests; therefore, our findings characterize the current capabilities, limitations, and trade-offs of the approach rather than its impact on an operational development process.

[1] Popular open-source automation tool for testing modern web applications `https://playwright.dev/`

The results show that local LLMs can provide a useful starting point for E2E test development, but the generated artifacts still require human review and correction. Based on the observed outcomes, we derive preliminary guidance for practitioners.

This paper is organized as follows. Section 2 reports on related work. Section 3 presents the web application under test, clarifying the overall domain-related scope. Section 4 describes the GenE2E software architecture based on LLMs. Sections 5 and 6 present the design and results of an empirical evaluation of GenE2E. Sect. 7 discusses lessons learned, limitations, validity threats, and actionable lessons for practitioners, while Sect. 8 concludes the paper.

## 2 Related Work

This section reviews LLM-based E2E test generation, focusing on preliminary empirical studies and two approach families: *feature inference* and *multi-stage generation* from requirements.

### Preliminary studies

Several empirical studies have evaluated the effectiveness of LLM-supported test automation. The study in [15] compares manual coding, capture-and-replay techniques (CRT), and natural language translation (NLT) using Gherkin specifications[2]. It reports that manual implementation requires the highest effort, CRT achieves the fastest development with minimal human intervention, and NLT provides an intermediate solution but suffers from scalability limitations. However, CRT sacrifices maintainability due to poor script reuse. Similarly, [24] explores the use of LLMs to translate Gherkin specifications into Selenium scripts, showing that LLM-based approaches can reduce repetitive test engineering tasks and provide a promising baseline for automation.

In [14], four approaches are compared: manual coding, ChatGPT Lite, ChatGPT Max, and GitHub Copilot. All approaches rely on Gherkin descriptions, Selenium WebDriver[3], and JUnit. Results show that manual coding is the most time-consuming (54 sec/LOC), followed by ChatGPT Lite (47 sec/LOC) and Copilot (45 sec/LOC), while ChatGPT Max – leveraging iterative prompt refinement – achieves the best performance (38 sec/LOC). These studies emphasize that existing LLM-based solutions mainly act as development assistants requiring human interaction and refinement, whereas GenE2E aims to substantially automate the lifecycle from requirements to executable tests, while retaining human oversight for feasibility filtering and validation, and to support their integration into a CI/CD pipeline for continuous testing.

GenE2E differs by addressing requirement-based E2E testing of web applications, starting from use case scenarios, handling use-case dependencies, and generating Playwright tests through a two-stage local-LLM pipeline.

### Feature inference approaches

Feature inference approaches generate E2E tests by directly exploring application behavior rather than relying on predefined requirements. AutoE2E [3] autonomously navigates web applications, observes UI states, and uses probabilistic scoring to identify features, which are then transformed into action sequences for testing. However, its one-to-one mapping between features and test cases may limit coverage in complex scenarios.

[2] The semi-formal Gherkin language is an intermediary specification to address the gap between test requirements and executable test scripts.

[3] `https://www.selenium.dev/`

Scriptless testing [29] follows a similar philosophy by dynamically generating test sequences through GUI exploration, selecting actions using strategies such as random exploration, model-based inference, or reinforcement learning. GPTDroid [16] further refines this concept by iteratively extracting GUI context, encoding it into prompts, and translating LLM responses into executable actions.

XUAT-Copilot [30] extends this paradigm with a multi-agent architecture, where LLM-based agents collaborate on action planning, state checking, and parameter selection, supported by modules for state sensing and test case rewriting. This system has been validated in a production environment (WeChat Pay).

While these approaches enable high levels of automation, they do not rely on requirements specifications. Instead, they infer features purely from observed behavior, which may conflict with established testing principles and introduce a circular dependency: the correctness of generated tests depends on the correctness of the application under test.

### Multi-stage generation from requirements

Multi-stage approaches instead use requirements as input to progressively derive test scenarios and executable scripts. The work in [8] adopts a two-step pipeline: deriving Gherkin acceptance tests from user stories and then translating them into executable Cypress scripts using knowledge of the HTML structure. While aligned with requirement-driven testing, it does not consider dependencies among test cases. GenIA-E2ETest [12] proposes a multi-level prompting strategy to guide the LLM across three tasks: restructuring and modularizing test scenarios, identifying and refining UI elements, and generating executable scripts. Although it supports natural language scenarios, it does not start from use case requirements.

Overall, multi-stage approaches better align with traditional testing practices by grounding test generation in requirements. In this context, GenE2E advances the state of the art by aiming at full automation of the entire process, from requirements analysis to executable E2E test generation, while addressing limitations such as test completeness and dependency handling.

## 3 Running example: the ENEA PELL-IP web portal

The Italian National Agency for New Technologies, Energy and Sustainable Economic Development (ENEA) focuses on improving the management of energy-intensive urban infrastructures. To support this objective, ENEA developed the smart city platform PELL (Public Energy Living Lab) [1], which collects, organizes, processes, and monitors infrastructure data at a national scale, enabling more effective and data-driven management.

Public street lighting has been selected as a primary application domain, as it accounts for nearly 40% of municipal energy consumption in Europe [21, 23]. Despite the availability of advanced solutions such as LED technologies, solar-powered systems, and data-driven tools, many municipalities still operate inefficient legacy systems [7]. The PELL-IP platform [2] addresses this issue by collecting and analyzing both static and dynamic data to continuously assess infrastructure performance in terms of functionality, energy use, and costs. The platform relies on public administrations conducting infrastructure censuses and adopting smart meters to enable accurate energy consumption monitoring.

Figure 1 shows a portion of the PELL-IP platform dashboard section, which provides users with a tailored interface composed by a set of widgets describing the data acquired. Each user has its own dashboard according to specific scopes and interests (e.g. citizen, municipality, utility, regional administrators, national administrators). In this specific case, a geo-referenced map shows the lighting spots located nearby the Genoa port. Each lighting spot can be navigated and its features visualized through a popup.

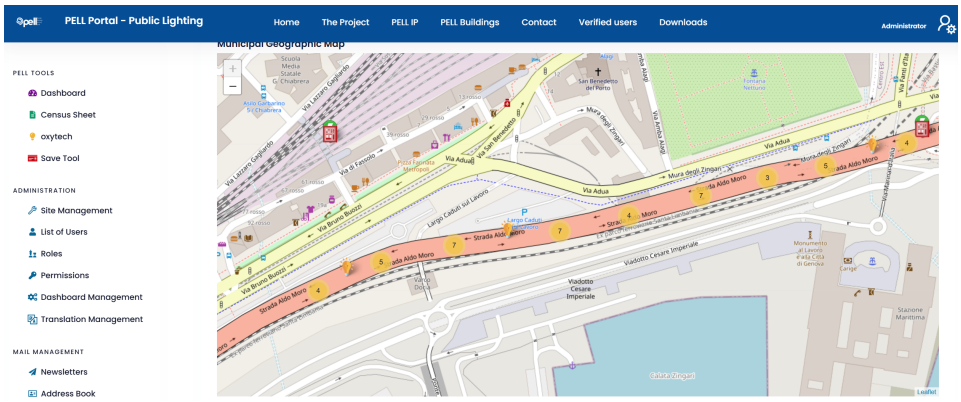

**Figure 1** PELL IP web portal dashboard.

The PELL-IP portal implements 41 use cases, all of which are available for reference in the ENEA GitLab repository [4]. Of the existing use cases and their test cases, a subset (related to the PELL tools Census Sheet and Dashboard) has been considered for representation of the portal's operational scenarios, ensuring a reference suite of test cases.

## 4 The GenE2E framework

The goal is the automated generation of comprehensive test cases and their corresponding Playwright test code from high-level use case descriptions. To achieve this, we first present the key requirements that GenE2E must fulfill, along with an overview of how these requirements are addressed by the proposed solution. Then we describe GenE2E's architecture, illustrating how its components interact to support the automated generation process.

### 4.1 GenE2E requirements and implementation overview

GenE2E was designed to meet the following key requirements:

- *Automated test generation from use cases*: The system shall generate both test cases and executable JavaScript code compatible with the Playwright framework, directly from textual descriptions of use case scenarios. *Limited human intervention*: The system shall reduce manual effort by automating the main test-generation steps, while retaining human oversight for feasibility checks, validation, and correction of generated artifacts when needed.
- *Modular architecture*: The system shall adopt a modular architecture that enables independent operation of components for different use cases and scenarios.
- *Open-source and on-premises solutions*: The system shall support open-source and on-premises solutions for the main building blocks of the framework, deployed on local server infrastructure. This requirement addresses privacy and security concerns, provides fine-grained control over the generation process, ensures reliable data persistence, and reduces the recurring monetary costs associated with cloud-based LLMs, especially since continuous test generation is a token-intensive activity.

[4] `https://gitlab.com/fmoretti/pell2.0-automation-testing`

- *Integration with a pre-established testing toolchain*: The generated test scripts are to be structured to operate within a pre-established testing environment. This environment leverages the Playwright tool for test execution and Python-based utility modules for common functionalities such as test reporting and data persistence. The test scripts are designed to invoke functions from these utility modules, ensuring seamless interaction with the framework's reporting and storage mechanisms.

To meet all requirements listed above, we built GenE2E on a preexisting testing framework, wherein test cases were manually generated from requirements expressed as use case scenarios, and subsequently implemented in Playwright. This previous framework was built upon the conventional structure of a Playwright project, enhanced with environment variable support for parameter configuration and a utility component (called *TestResultReporter*) for common functions (e.g., database persistence of all test execution steps). We further enhanced the previous testing framework by introducing, at the initial stage of the pipeline, an additional module (the GenE2E framework) powered by LLMs to automate the test generation and coding process. To this purpose, the GenE2E architecture was designed as a modular pipeline comprising two independent LLM-augmented sub-systems that can operate both sequentially and individually, providing flexibility in deployment and usage scenarios.

We also considered and evaluated different design alternatives according to the following dimensions: *execution mode*, single or batch processing (explained later in the paper); *type of LLM*; and *prompting technique* (zero-shot, one-shot, and few-shot). The primary development phases encompassed comprehensive system design and prompt engineering optimization to maximize model performance.

Note that the primary objective of this work was on "building the system that integrates LLMs" rather than to "benchmark or compare the performance of a broader range of LLMs available on the market" for the scope. For this reason, only two models, Meta Llama 3.3 70B [9] and CodeLlama [26] 70B (a foundational model for code generation tasks, built on top of Llama 2 [28]), were employed during the first development of GenE2E, while a comparison with other LLMs was postponed as future work. The selection of the LLM was guided by the need for open-source foundation models that could be executed locally, ensuring full accessibility without reliance on proprietary cloud services. While this constraint limits the use of other models available remotely, it offers key benefits such as reduced operational costs, improved data privacy, and independence from network latency.

Moreover, these two specific models were selected for conducting a comparative performance analysis between a general-purpose language model (Llama 3.3) and a fine-tuned one from the same family for software development tasks (CodeLlama). The goal of such a comparison was that of obtaining insights about the effectiveness of specialized versus generalized foundational models for our scope of automating test code generation from use case scenarios. The most significant difference between these two models is the context window dimension (131072 of Llama 3.3 against 2048 of CodeLlama). This difference, as will be shown in the evaluation results, considerably influence on the quality and comprehensiveness of generated test code, particularly when dealing with complex test scenarios that require extensive contextual information with test case dependencies.

GenE2E was implemented as a CLI tool in Python, designed for easy integration into development workflows and CI pipelines. It was developed upon the Ollama framework[5] to manage and run local language models efficiently on local hardware.

[5] `ollama.com/`

## 4.2 GenE2E framework

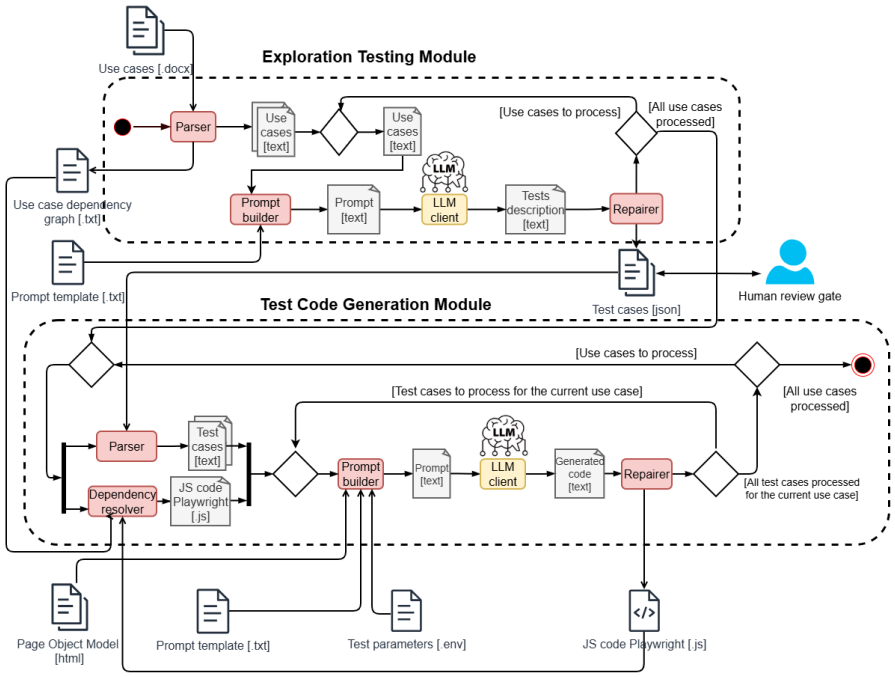

**Figure 2** GenE2E workflow (single processing mode).

The framework follows a pipeline architecture composed of two main stages: the *Exploration Testing Module*, which generates test cases from requirements, and the *Test Code Generation Module*, which converts these test cases into executable Playwright scripts.

To balance quality and efficiency, the framework supports two execution modes: *single* and *batch*. In single processing mode (Fig. 2), each use case and test case is processed individually, allowing the LLM to focus on a limited context and typically producing higher-quality outputs, at the cost of longer execution time. In contrast, batch processing reduces the number of LLM invocations by generating multiple test cases or scripts in a single call, improving throughput but potentially degrading output quality due to increased prompt complexity and context dilution.

### 4.2.1 Exploration Testing Module

The first module automatically derives test cases from textual use case descriptions stored in *.docx* documents. A *Parser* extracts the use case information and converts it into a structured JSON representation, while also constructing a *dependency graph* (a DAG capturing use case relationships such as *include*, *extend*, and *generalization*). This graph is later used to manage dependencies across test cases.

Each use case is then processed by a *Prompt Builder*, which embeds its description into a predefined prompt template and sends it to the *LLM Client*. The latter invokes Llama 3.3 (temperature 0.3), producing a structured JSON output containing multiple test cases. Each test case includes identifiers, descriptions, execution steps with expected outcomes, pre/postconditions, classification (positive/negative), and priority. Table 1 reports a universally known scenario for the the *Login* use case, while Listing 1 shows a natural-language test case generated from its base flow by the *Exploration Testing Module*.

**Table 1** Use Case Scenario: User Login.

| | |
|---|---|
| **Use Case** | User Login |
| **Summary** | Authentication of a user registered in the system |
| **Actors** | Region, Mayor, Supplier, Designer, Citizen |
| **Precondition** | The user is not authenticated |
| **Postcondition** | The user is authenticated and aware that the operation was successful |
| **Base Sequence** | 1. The user enters credentials in the form<br>2. The user starts the authentication process by clicking the "Login" button<br>3. The user sees a message indicating the operation was successfully completed |
| **Branch Sequence** | 2.1 The user is asked to change their initial access password<br>2.2 The user enters the new password and confirms |
| **Exception Sequence** | 3. The user sees a message indicating the operation was completed with an error related to the exception (e.g., incorrect credentials, password mismatch, etc.)<br>4. The user can restart from step 1 of the base sequence |

To ensure robustness, a *Repairer* component automatically validates and cleans the generated JSON file by enforcing JSON well-formedness. The resulting test cases are then persisted and passed through a lightweight human review gate, allowing practitioners to filter infeasible, underspecified, or non-reproducible outputs before code generation.

### 4.2.2 Test Code Generation Module

The second module transforms test cases into executable test scripts. A *Parser* reformats the JSON test cases into a textual representation suitable for prompting. A *Dependency Resolver* uses the previously built dependency graph to retrieve relevant code fragments from dependent use cases, focusing on "happy path" scenarios, which are then reused to improve consistency and reduce test code duplication.

The *Prompt Builder* plays a central role in this stage by assembling prompts enriched with multiple sources of contextual information. In particular, it injects knowledge of the web application structure through the Page Object Model (POM) API, ensuring that only

}
```

relevant page objects are included to limit token usage and avoid context dilution. Additional information, such as input constraints embedded in POM methods and environment variables from configuration files, is also incorporated to guide the model toward generating valid and executable code.

Dependency handling is explicitly supported by incorporating previously generated code into the prompt when needed. This enables reuse of existing functionality, although its effectiveness depends on proper code modularization; poorly structured code may lead to duplication or inconsistencies, especially in the presence of long dependency chains.

Prompt design follows the TELeR taxonomy [27], using a fixed configuration (*Turn=Single, Expression=Instruction, Role=defined, Level=5*) to ensure consistency. The framework supports zero-, one-, and few-shot prompting; in the latter case, the number of examples is limited to two, based on evidence of diminishing returns beyond this threshold [5] and to control token consumption. Prompt templates and prompt examples are available in the online replication package[6], together with data and code artifacts.

The *LLM Client* (temperature 0.0) generates deterministic JavaScript code for Playwright tests, along with execution statistics such as runtime and token usage. Finally, a *Repair* component extracts the generated code from the model output, fixes import statements, and adapts it to the target testing project structure, ensuring compliance with the testing team's Playwright best practices before saving the final artifacts.

## 5 Evaluation design

This section presents the experimental design we followed to evaluate the GenE2E framework (Section 5.1) and the approach we followed to analyze the experimental results (Section 5.2).

We considered the following research questions. RQ1 (Test Generation Feasibility): Can GenE2E generate correct executable test cases? We examine whether (Stage 2) of GenE2E can produce test cases that are both syntactically well-formed and semantically valid with respect to the intended testing scenarios. RQ2 (Alignment): To what extent do the test cases generated by GenE2E align with the reference tests manually defined by engineers? We investigate whether GenE2E can generate test cases that comply with the coding style, structural conventions, and implementation constraints observed in human-written tests (considered the *gold standard*), thereby approximating the practices of human testers. RQ3 (Effectiveness) What is the effectiveness of the tests generated by GenE2E compared to the baseline test suite? RQ4 (Efficiency): What is the cost of executing the GenE2E?

### 5.1 Methodology

Following the implementation of the GenE2E framework, we designed our experiments to systematically assess the system's performance in automatically generating test cases and producing Playwright-compatible test code that accurately reflects the specified test scenarios. Due to space constraints, we focus the main evaluation on the *Test Code Generation Module*, while reporting only summary data for the *Exploration Testing Module*. In the evaluation, we refer to existing E2E tests – manually scripted Playwright tests for test cases derived from UML use case scenarios – as our *baseline*. Table 2 provides a comprehensive overview of a suite of 18 test cases that constitute this baseline.

[6] Software artifacts and supplementary material are available in the replication package, which also includes an appendix with key examples and details: `https://zenodo.org/records/21629002`

**Table 2** List of all test cases that are part of the baseline (translated from Italian).

| Use case | Test case | Description |
|---|---|---|
| 1 | 1 | User login with correct credentials |
| 1 | 2 | User login with incorrect credentials |
| 2.1 | 1 | Download PDF |
| 2.2 | 1 | Search lighting systems |
| 2.3 | 1 | View general data table |
| 2.4 | 1 | KPI benchmarking by municipality |
| 3.1 | 1 | View census records |
| 3.2.1 | 1 | Search census record by name |
| 3.3 | 1 | Upload census record |
| 3.4 | 1 | Action on census record |
| 3.4.1 | 1 | Download census record |
| 3.4.2 | 1 | Delete census record |
| 3.4.2 | 2 | Delete census record with operation cancel |
| 3.4.3 | 1 | Edit census record |
| 3.4.4 | 1 | Freeze census record |
| 3.4.5 | 1 | Census record details |
| 5 | 1 | Select language |
| 6 | 1 | User logout |

**Table 3** Experiment configurations.

| Configuration | Processing | Prompt technique | Model |
|---|---|---|---|
| 1 | Single | Zero-shot | Llama3.3 |
| 2 | Single | Zero-shot | CodeLlama |
| 3 | Single | One-shot | Llama3.3 |
| 4 | Single | One-shot | CodeLlama |
| 5 | Single | Few-shot | Llama3.3 |
| 6 | Single | Few-shot | CodeLlama |
| 7 | Batch | Zero-shot | Llama3.3 |
| 8 | Batch | Zero-shot | CodeLlama |
| 9 | Batch | One-shot | Llama3.3 |
| 10 | Batch | One-shot | CodeLlama |
| 11 | Batch | Few-shot | Llama3.3 |
| 12 | Batch | Few-shot | CodeLlama |

In our experiments, we compare 12 distinct configurations of the Test Code Generation Module that are detailed in Table 3. We compared two different processing approaches: *single* (where the test specifications and the code alternate in the LLM context) and *batched* (where first all test specifications are provided in the context and then all the code follows), to understand the impact of input format. We compared three different prompting schemes (depending on the number of test specifications and examples in the context): *zero-shot*, *one-shot* and *few-shot* (with two examples), to assess the impact of *in-context learning* [5]. We compare two different LLMs, namely Llama 3.3 [9] and CodeLlama [26], to understand the difference between a generic model and one specialized in code generation.

To evaluate the considered configurations, we resorted to the test cases extracted using the *Exploration Testing Module*. For the Exploration Testing Module, we executed three independent generation rounds for each of the 41 use cases and using three prompting strategies (Zero-Shot,One-Shot, and Few-Shot), resulting in 369 generated test-suite outputs.

These generated test specifications were manually post-processed and filtered to ensure that only test cases that are feasible and really reproducible are forwarded to the *Test Code Generation Module* LLM[7]. After this data curation step, we obtained a dataset of 95 natural-language test cases; each of the 12 configurations of the second LLM was used to generate the code for all test cases in this dataset. We resorted to greedy decoding to ensure a deterministic output generation. We do not exclude the evaluation of other decoding schemes, which is now out of the scope of this work.

We run our experiments on a workstation running Ubuntu server 24.04.2 and equipped with AMD Ryzen Threadripper PRO 7985WX 64-Cores CPU, 256 GB RAM and a GeForce RTX 4090 GPU. Concerning LLMs, we experimented with the pre-trained Llama 3.3 70B (`Q4_K_M` quantization, CPU offloading and 131072 tokens context) and Instruction tuned CodelLlama 70B (`Q4_0` quantization and 2048 tokens context) as baseline.

## 5.2 Metrics

For the evaluation, we resorted to a quantitative approach. For evaluating the test generation feasibility (RQ1), we checked the syntactic validity of the generated test cases and ran them to assess their successful or unsuccessful execution (compared to the 18 baseline test cases). For code alignment (RQ2), we also analyzed the generated test cases statically, comparing their code syntactically and semantically to that of the 18 references. Additionally, we analyzed the effectiveness (RQ3) and the efficiency (RQ4) of the generated tests for all 95 test cases produced by the Exploration Test Module.

**Test Generation Feasibility.** For the test execution evaluation, we considered the following aspects: *compilation success*, *execution with no errors*, and *assertion validity*. Compilation success indicates whether the code compiles successfully without errors. Although JavaScript is an interpreted language, this refers to errors identifiable through static code analysis. Execution with no errors indicates whether the code executes successfully to completion without raising any runtime exceptions. Assertion validity determines whether the test case passes all embedded assertions, indicating functional correctness of the generated code against the specified requirements and expected behaviors.

**Test Code Alignment.** Given the test code generated for a test case and the corresponding baseline test code, we measured their similarity both syntactically and semantically. In both cases, we resorted to metrics and techniques coming from the NLP area.

We measured syntactic similarity using the BiLingual Evaluation Understanding (BLEU) [22] and CodeBLEU [25] metrics. Both metrics compute the similarity measuring the overlapping of tokens in the compared string sequences. BLEU was originally designed to evaluate the quality of machine translation output [11, Chapter 25], it provides a quantitative assessment of surface-level textual correspondence. We used the implementation available with the *NLTK* library [4]. CodeBLEU extends traditional BLEU specifically for source code evaluation by incorporating code-specific characteristics. We resorted to the CodeXGLUE implementation[8], setting the target language to JavaScript. BLEU and CodeBLEU should be interpreted only as approximate indicators of syntactic alignment with the reference

[7] Some test scenarios can not be implemented in Playwright as it does not support certain operations, especially those involving backend processes or server-side events, like triggering errors during a PDF download.

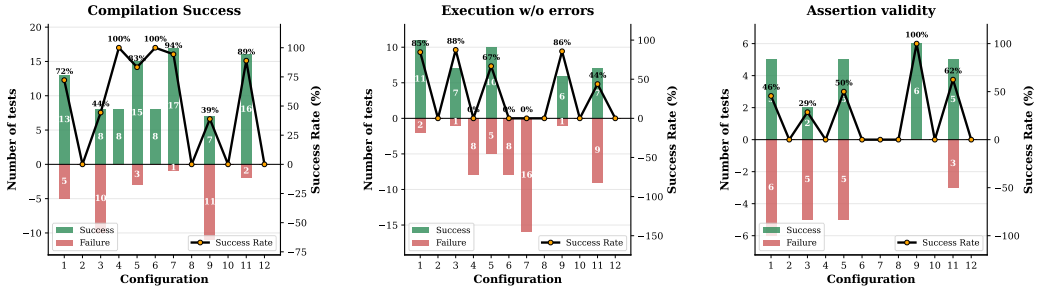
[8] `https://github.com/k4black/codebleu`

implementation. Because multiple Playwright implementations may correctly operationalize the same test scenario, low overlap with a single reference does not necessarily indicate an incorrect test. We therefore complement these measures with compilation success, execution without runtime errors, and assertion validity.

Semantic similarity was computed resorting to more recent deep learning based approaches. We used an encoder language model (namely *jina-embeddings-v2-base-code* [10]) to generate embeddings of the compared pieces of code. These embedding represent a piece of code in a semantically meaningful space. Computing the *cosine similarity* between a pair of embeddings gives us a measure of the semantic similarity between the two pieces of code. Before embedding the code we pre-processed it to remove extraneous elements including comments, import statements, multiple consecutive empty lines, and leading/trailing whitespace characters, ensuring that the similarity assessment focuses on the core functional content.

**Effectiveness metrics.** To understand the effectiveness of the GenE2E we consider two metrics: *test case coverage* and *test execution rate*. The former is the proportion of test scripts successfully generated and executed relative to the total number of feasible test cases created from the Exploration Testing Module, and the latter is defined as the number of test scripts that are successfully executed.

**Efficiency measures.** The analysis of efficiency is designed to inform us on the costs of the GenE2E framework. We considered two key factors for this analysis: *generation time* (i.e., the time required to generate the test code) and *number of processed tokens* (divided into number of prompt tokens and generated response tokens). For these two metrics, we report the average values and the total across all generated tests.



## 6 Evaluation results

Across the Stage 1 evaluation, the *Exploration Testing Module* produced 369 test-suite outputs, corresponding to 41 use cases, three prompting strategies, and three independent generation rounds. The average number of test cases per generated suite was 5.44 for Zero-Shot, 7.84 for One-Shot, and 5.09 for Few-Shot. On the first generation attempt, Zero-Shot and One-Shot produced syntactically valid JSON in all cases (123/123 each), whereas Few-Shot produced 92/123 syntactically valid outputs (74.8%). When both syntax and structure were considered, the fully valid outputs were 108/123 for Zero-Shot (87.8%), 119/123 for One-Shot (96.7%), and 86/123 for Few-Shot (69.9%). JSON repair was automatic and implemented by the `Repairer` compiler; feasibility filtering, instead, was performed through human review before forwarding test cases to Stage 2.

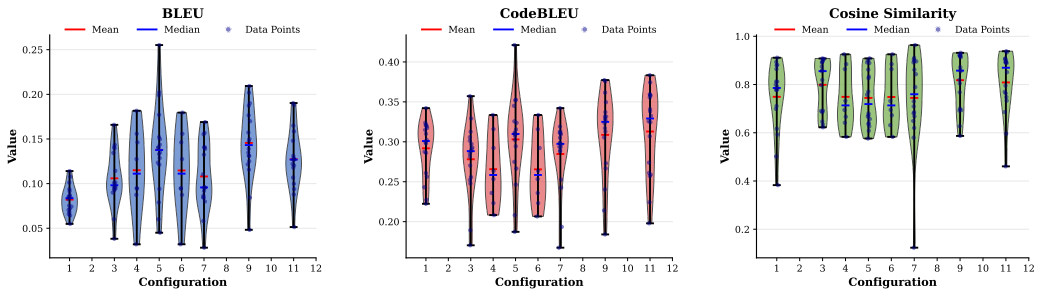
In the following subsections, we report and comment on the results coming from the quantitative analysis of the Stage 2. In general, we noticed that the limited context window of the CodeLlama model made the generation of code almost impossible, subsequently impacting all metrics. Moreover, the presence of highly restrictive safeguards implemented in CodeLlama required to alter slightly the prompt as mitigation to the inability of the model to generate test cases connected to the login for safety reasons.

### 6.1 Test Generation Feasibility – RQ1

Figure 3 reports test execution metrics, including the number of successfully generated tests (out of 18 baseline test cases).

**(a)** Successful compilation **(b)** Successful execution **(c)** Assertion validity

**Figure 3** Analysis of execution metrics histograms.



As anticipated, CodeLlama frequently fails to generate even a single test case. We obtained executable code for evaluation only in configurations 4 and 6. While all CodeLlama-generated tests compile successfully, none execute without runtime errors.

Llama 3.3 performs better, successfully generating code across all its configurations. In single processing mode, zero-shot and few-shot prompting each produce five tests that pass all assertions. The best overall result is obtained by batch processing with few-shot prompting, with seven tests passing all assertions.

When interpreting assertion failures, it is important to account for differences in assertion granularity. Although the generated and manually written baseline tests originate from the same use cases, the baseline tests generally validate fewer, higher-level outcomes, whereas GenE2E may generate an assertion for the expected result of each test step. Consequently, some generated tests correctly execute the intended interaction flow but fail on an additional requirement-derived assertion that is not present in the corresponding baseline test and is not satisfied by the current portal implementation. For example, the login use case specifies the display of a successful-operation message, whereas the corresponding baseline test checks successful authentication without asserting the presence of that message. We retained these outcomes as assertion failures in the reported metrics; however, they do not necessarily indicate errors in the generated interaction logic. In these cases, the generated tests are therefore more closely aligned with the documented specification than the corresponding baseline tests.

Further manual analysis identified inadequate details in the initial use case specifications as the primary cause of runtime errors in generated tests. This ambiguity propagates to the test cases created by the Exploration Testing Module, preventing the LLM from inferring the correct implementation. A secondary error source involves input parameters: LLMs rely exclusively on parameters provided through environment variables, whereas some required variables were hard-coded in baseline source code rather than being exposed through the environment.

Concerning compilation errors, we identified significant challenges in dependency management, particularly for tests with extensive dependency chains spanning multiple sources. The *Repair* component of the GenE2E framework is limited to correcting dependency paths for folder structure consistency but cannot insert missing import statements. While static analysis could detect missing dependencies, automatically determining the appropriate source files for importing specific methods remains challenging. Another prevalent issue in batch processing is the invocation of non-existent POM methods. We attribute this to context dilution that occurs when processing large amounts of information simultaneously. As

**(a)** BLEU score (syntactic)

**(b)** CodeBLEU score (syntactic)

**(c)** Code embedding cosine similarity (semantic)

**Figure 4** Analysis of code syntactic and semantic similarity.

documented in the literature, model parameter count significantly influences in-context recall performance [17]. Consequently, employing larger models could potentially mitigate these issues.

Finally, errors coming from the use of deprecated Playwright methods are likely attributable to the model's training data cutoff, which presumably references outdated library versions.

## 6.2 Test code alignment – RQ2

Figure 4 reports the code similarity scores. Overall, we observe that similarity scores increase with the number of shots, meaning that using few-shot learning is not only helping the LLM to solve the task, but also capture the expected style presented in the examples.

From a syntactic perspective, both BLEU and CodeBLEU scores exhibit consistent monotonic improvement across configurations, with configuration 11 being the exception. In that case, CodeBLEU more accurately captures the actual overlap between generated and reference code compared to BLEU. The progressively higher scores suggest that providing multiple examples enables the LLM to better reproduce patterns found in the reference samples. These scores indicate closer alignment with one particular implementation, however, and should not be interpreted as direct evidence of greater functional correctness. This effect is particularly pronounced in batch processing configurations.

From a semantic perspective, we observe analogous trends when applying batch processing. In batch processing, semantic similarity plateaus after incorporating a single example, mirroring the behavior observed for syntactic similarity. Conversely, in single processing mode, increasing the number of examples degrades semantic similarity performance.

## 6.3 Effectiveness – RQ3

The first part of Table 4 presents test effectiveness metrics. CodeLlama fails completely on this task, while Llama 3.3 demonstrates consistent capability across all prompting techniques.

Single processing achieves better test case coverage compared to batch processing, suggesting that focusing on the most recent information helps the LLM maintain attention on the current test case. Conversely, batch processing may introduce additional complexity through the alignment step between inputs and outputs.

One-shot learning procedures the worst results in terms of both test case coverage (39%) and test execution rate (11%). Zero-shot and few-shot learning yield comparable results, with zero-shot showing marginally better test case coverage. This suggests that excessive

**Table 4** Effectiveness and efficiency results (efficiency values of bach processing configurations are scaled on the batch size).

| Conf. | No. test cases | Test effect. [%] | | Time [hh:mm:ss] | | No. of tokens | | | |

examples may constrain the model's generative flexibility or introduce bias toward specific testing patterns that fail to generalize across diverse scenarios. In batch processing, the absence of examples in zero-shot led to critical errors that made the tests not runnable. When compared to the 55% baseline of manual tests, most configurations fall short in coverage, but configuration 11's (batch processing, few shot learning and Llama 3.3) execution rate approaches a reasonable threshold.

## 6.4 Efficiency – RQ4

Results on efficiency (LLM processing time and processed tokens) are reported in the second part of Table 4. We reported the scores on the generated test cases out of the available 95 specifications. Single scores refer to the average over all the generated tests. The reported generation times should be interpreted as measurements of the evaluated configurations in our specific execution environment, rather than as general efficiency estimates for GenE2E or the considered model families. In particular, the 70B models did not fit entirely within the 24 GB GPU memory available on the experimental machine, requiring CPU offloading and making the observed runtimes dependent on the hardware configuration. Each configuration was executed once on a shared workstation. Therefore, although greedy decoding and a temperature of 0 make the generated outputs reproducible under the same setup, the timing measurements may be affected by transient system load and were not collected with the repetitions required for a statistically robust performance analysis. Thus, we use generation time only to describe the relative behavior observed in this experimental run, not to establish statistically supported performance differences among configurations.

The most relevant performance difference emerges between single and batch processing modes. In fact, batch processing turns out to have a better throughput as its prompt are shorter and so are the generated responses (if scaled on number of generated tests), thus requiring less inference time. The prompting technique itself does not substantially impact total execution time, with configuration 1 being an exception. Regarding model performance, CodeLlama exhibits reduced execution times compared to Llama 3.3. We attributed this to the slight architectural differences between the models and the weights quantization approaches.

Token count is primarily determined by the prompting technique. Specifically, transitioning from zero-shot to few-shot learning increases prompt size proportionally with the number of examples provided. This represents a critical constraint for models like CodeLlama with its 2048-token context limit.

Beyond the execution and effectiveness challenges, which we acknowledge as significant limitations for current LLMs, an important consideration for the proposed GenE2E framework concerns the time required for automated test code generation compared to manual implementation by human developers. The mean execution time of 2 minutes and 30 seconds observed in the optimal configuration represents a substantial efficiency gain over manual implementation. Human developers typically require variable amounts of time depending on test complexity, ranging from minutes for simple cases to several hours per test for complex scenarios [14, 15].

Regarding RQ4, batch processing reduced the number of model invocations and the associated token-processing overhead, indicating a potential throughput advantage. However, the wall-clock measurements are specific to a single run on our shared, hardware-constrained workstation. They should therefore be regarded as descriptive observations rather than general evidence of the efficiency of the configurations or models.

**Summary.** The evaluation showed that there is no optimal configuration. In our setup, Llama 3.3 was the only model that consistently generated outputs for all input requests. A plausible explanation is its much larger context window, which better accommodates the contextual information required by E2E test generation.

While not effective as a fully autonomous solution, GenE2E proved highly valuable as an assistive tool, reducing developer workload and generating more diverse functional tests, thereby achieving broader test coverage than the manual baseline.

# 7 Discussion

## 7.1 What configuration should a team use?

Our results do not identify a universally optimal configuration. Instead, they reveal a set of practical trade-offs that teams should consider when adopting local LLMs for end-to-end (E2E) test generation. The most appropriate configuration depends on whether the team prioritizes test coverage, execution reliability, generation throughput, or reduced post-processing effort. Table 5 summarizes the main practical recommendations.

First, we do not recommend using CodeLlama 70B in the current setup. Although CodeLlama is specialized for code generation, its limited context window made it unsuitable for complex E2E testing scenarios involving use case descriptions, POMs, dependencies, examples, and execution constraints. In our experiments, this limitation had a stronger negative impact than the potential benefits of code specialization.

Second, Llama 3.3 should be preferred as the default model. Despite being a general-purpose model, it consistently produced usable outputs across configurations. Its larger context window made it better suited to the amount of contextual information required for realistic E2E test generation.

Third, single processing with zero-shot or few-shot prompting is preferable when coverage is the main objective. Processing one test case at a time helps the model focus on the current scenario and reduces context dilution. This configuration is therefore more suitable when the goal is to generate a broader set of candidate tests, even at the cost of longer generation time.

**Table 5** Recommended GenE2E configurations for different practical goals.

| Goal | Recommended configuration | Rationale |
|---|---|---|
| Use CodeLlama 70B in the current setup | Not recommended | Context window limitations outweigh code-specialization benefits. |
| Minimize manual repair | Llama 3.3, single processing | Lower risk of dependency and alignment errors. |
| Maximize generated test coverage | Llama 3.3, single processing, zero-shot or few-shot | Better focus on individual scenarios and less context dilution. |
| Improve throughput | Llama 3.3, batch processing, few-shot | Faster generation, but requires stronger post-processing. |

Fourth, batch processing with few-shot prompting is preferable when throughput is the main objective and the team can tolerate additional post-processing. Batch processing reduces generation time and token consumption per test, but it also increases the risk of misalignment between inputs and outputs, missing dependencies, or calls to non-existing POM methods. For this reason, batch few-shot prompting is promising when teams need faster generation and have a review or repair step in place.

Thus, rather than selecting a single "best" configuration, practitioners should treat GenE2E as a configurable assistant. For teams prioritizing correctness and coverage, single processing with Llama 3.3 is the safest starting point. For teams prioritizing scalability and generation speed, batch few-shot prompting with Llama 3.3 can be effective, provided that a subsequent validation and repair phase is included.

## 7.2 Limitations and threats to validity

We discuss here the main limitations and threats to the validity of the proposed GenE2E approach, along with the mitigation strategies adopted. *Internal validity* may be affected by hallucinations introduced by LLMs. Specifically, LLMs may infer functional steps that are incorrect or do not exist or also add hard-code for client/environmental conditions creating assumptions purposefully. These potentially result in not executable test codes. To mitigate this threat, we configure the temperature to 0 to reduce randomness in generation. Moreover, instead of feeding all use case specifications to the LLM, we split and process each use case individually. This decomposition helps the LLM focus more precisely on the semantics of a specific use case scenario and related test cases, improving inference accuracy. In addition, we feed the LLM with a context model, including client/environmental conditions. In general, we enriched the prompt template trying to reflect the structure and content of a standard test code script from what we consider our golden test set[9]. Most of the cases where we obtained not runnable hard-code/template-code by the LLM are due to the fact that some conditions were missing in the context model.

*External validity* is primarily threatened by the quality of use case specifications. Use cases with incomplete or low quality scenario descriptions pose significant challenges for test case inference. To address this and make our approach more robust, the LLM-augmented generation pipeline includes a human-powered manual inspection task that examines each generated test case description (on average, 5/6 test cases per use case) to filter out (before feeding the LLM for test code generation) test case descriptions that look like under-specified or untestable or do not cover the expected behavior.

[9] A predetermined collection of expert-curated test case scripts.

Another issue is that our study is restricted to test only one web application, the ENEA PELL-IP web portal. However, this web portal encompasses most mainstream features of common web applications and complex and deep interaction workflows typical of smart city platforms. So we are confident that the proposed E2E testing approach is generalizable and applicable to other web applications.

*Construct validity* is also affected by the use of BLEU and CodeBLEU against a single reference implementation: these metrics capture alignment with that implementation but cannot account for the full set of functionally equivalent Playwright tests. We mitigate this limitation by jointly considering compilation, runtime execution, and assertion validity.

## 7.3 Actionable Lessons and Hypotheses for Practitioners

Based on our experience with GenE2E, we derive the following practical lessons for teams aiming to introduce local LLMs into E2E test generation.

**Lesson 1: Specification quality dominates test quality.** *Context.* GenE2E relies on use case scenarios and contextual artifacts as primary inputs. *Evidence.* Many runtime failures stemmed from incomplete or ambiguous specifications, propagating errors to generated test cases. *Recommendation.* Teams should make specifications "LLM-ready" by clearly defining preconditions, expected outcomes, input constraints, alternative/exception flows, and test data. Priority should be given to high-quality use cases and well-documented POMs, as LLMs cannot compensate for missing context or unclear requirements.

**Lesson 2: Context capacity may be critical for E2E test generation.** *Context.* E2E test generation requires handling heterogeneous contextual inputs, including use cases, POMs, dependencies, constraints, examples, and generated code. *Evidence.* Llama 3.3 outperformed CodeLlama in our experiments; however, this comparison is confounded because the models differ not only in code specialization, but also in model generation, training data, quantization, and especially context-window size. Our results do not isolate whether the observed gap is due to context capacity or to other model differences. *Implication.* We therefore report this as a tentative hypothesis rather than a definitive recommendation. Future work should compare recent code-specialized local models with larger context windows to assess the relative impact of context capacity and code specialization.

**Lesson 3: Batch generation improves throughput but increases fragility.** *Context.* Batch mode reduces LLM calls and improves efficiency. *Evidence.* It also increased issues such as context dilution, misalignment, missing dependencies, and invalid POM calls. *Recommendation.* Use batch generation only when throughput is critical and downstream validation or repair mechanisms are available.

**Lesson 4: A small human gate is still necessary.** *Context.* Some generated test scenarios may be infeasible or not executable via the UI. *Evidence.* Filtering test cases before code generation prevented invalid scenarios from propagating. *Recommendation.* Introduce a lightweight human review step focused on feasibility, testability, and coverage.

**Lesson 5: Manual baselines are not always perfect ground truth.** *Context.* Manual tests are typically used as evaluation baselines. *Evidence.* Generated tests sometimes captured requirements missing from manual ones. *Recommendation.* Treat manual tests as reference points rather than absolute oracles, leveraging LLM outputs to identify gaps in existing test suites.

## 8 Conclusion and future directions

This paper presents GenE2E, a LLM-enhanced framework to support the generation of end-to-end test suites and executable test scripts from use case specifications for web applications.

The main goal of this work was to assess the feasibility, rather than the operational maturity, of introducing self-hosted LLMs into an existing E2E testing process and to evaluate their effectiveness in a realistic industrial setting. In particular, we compared two models from the same family, Llama 3.3 and CodeLlama, as an initial feasibility baseline. However, this comparison cannot be interpreted as isolating the effect of general-purpose versus code-specialized capabilities, since the two models also differ substantially in context-window size, generation, training data, and quantization. The experimental evaluation on the ENEA PELL-IP web portal showed that local LLMs can effectively support test generation, although their role remains primarily assistive rather than fully autonomous. The evaluation explored 12 configurations varying processing strategies, prompting techniques, and model choice. Overall, the evidence supports the feasibility of GenE2E as an assistive test-development tool, but not yet its use as an autonomous replacement for human test engineers.

As future work, we plan to extend this study in several directions. First, we aim to replicate the evaluation on additional web applications to strengthen the validity and generalizability of the findings. Second, we intend to deepen the investigation of local LLM variants, including recent code-specialized models with larger context windows, such as Qwen2.5-Coder and similar alternatives, to disentangle the effects of context capacity and code specialization on E2E test generation performance. Third, we plan to complement the current quantitative evaluation with a qualitative assessment of the generated test scripts, adopting both an expert assessment and an LLM-based evaluation approach (LLM-as-a-judge, as proxy of expert evaluation). Finally, we aim to further automate the framework by integrating mechanisms for the automatic retrieval of contextual information (e.g., POMs and UI structure), potentially leveraging LLM-based agents to reduce manual configuration effort and improve scalability. This is a promising research avenue, as proposed in [20].

# Trust-Calibrated Code Review: A Participatory Design Study of Review Workflows for LLM-Generated Multi-File Changes

**Lo Gullstrand Heander**
Lund University, Lund, Sweden

**Agnia Sergeyuk**

## Abstract

**Background.** Developers increasingly review multi-file code changes generated by LLM-based agents, yet no validated end-to-end workflow or IDE tooling design exists for this scenario.

**Aims.** We investigate (RQ1) the challenges developers face when reviewing LLM-generated multi-file changes and (RQ2) how developers envision effective workflows for this task.

**Method.** In collaboration with JetBrains, we conducted a participatory design study structured using the double-diamond design process with Discover, Define, Develop, and Deliver phases. Industry practitioners participated in the Discover phase (N=17); seven of these returned for the Develop phase. The Define phase was an author-led synthesis. The Deliver phase produced a conceptual design and a high-fidelity semi-interactive prototype evaluated through a follow-up survey with N=43 practitioners.

**Results.** Participants identified trust-calibration as the central challenge. The study yielded a three-level review workflow (overview, file-analysis, code snippet review) supported by seven design constructs (chunk, risk-per-line, risk-per-file, judge, walk-through, zooming in/out, and security cage). In the validation survey, all three workflow levels scored above the neutral midpoint (means 3.50–3.91 on a five-point scale). Of the respondents, 63% expected reduced overall review effort, and 52% reduced trust-assessment effort, relative to their current tools. These findings suggest that the design constructs indicate a positive direction for future tool development.

**Conclusions.** Reviewing LLM-generated multi-file changes is a trust-calibration problem rather than a diffing problem. The three-level workflow and the seven constructs we report give tool designers a conceptual framework for building AI-ready code review tools that surface risk and confidence signals at the granularity at which developers allocate attention.

## 1 Introduction

Development teams that adopt LLM-based code generation are expecting substantial productivity gains, but reviewing the large amounts of code generated by LLMs is a new challenge that can easily become a bottleneck in the software delivery process. Change sets are larger, human reviewers have no author whose account of reasoning or intent they can hold to, and the LLM signals uniform confidence across high- and low-risk code segments [4]. LLM-generated code seems harder, not easier, to review [32]. This potentially leads to surface-level reviews [11], declining code quality [18], and bugs in production, e.g. [25]. In collaboration with JetBrains, a leading software tools provider, we conducted a participatory design study to develop tools that support code review of LLM-generated code effectively.

While substantial work addresses automated code review (where LLMs review code), this work examines augmentation: designing interfaces and workflows that support and improve human judgment when reviewing LLM-generated code. Consider a concrete scenario: Junie[1] (an LLM-based coding agent) submits a change touching 10 files in your repository. As the reviewer, how do you assess whether this change is correct, maintainable, and aligned with your architecture? This scenario, reviewing substantial multi-file changes from LLM agents, is the focus of this work. We investigate what features and workflows developers need to effectively review LLM-generated code while preserving the benefits of modern code review [2]. Our aim is to design tooling that augments rather than replaces human reviewers [19].

Based on existing literature, we consider code review as a process with four stages: context building and orientation, inspection, discussion and iteration ("shepherding the change"), and the decision to merge [13, 16]. In review of LLM-generated code, the human reviewer is often also the prompter. In those cases, orientation collapses, and the work concentrates in the analytical stage, on evaluating the proposed solution. Acceptance is also less final: Reviewers may accept suggestions conditionally, which triggers further LLM iterations and makes the decision process more dynamic and provisional, shifting the reviewer's role toward that of a collaborator and auditor.

**RQ$_1$** What are the challenges for developers when reviewing LLM-generated multi-file changes in their IDE?

**RQ$_2$** How do developers envision effective workflows for reviewing LLM-generated multi-file changes?

Through a participatory design study of these research questions we report four contributions: (1) an empirical characterization of trust-calibration as the dominant reviewer challenge; (2) a three-level IDE workflow co-designed with seventeen practitioners; (3) a

[1] Junie, the AI coding agent by JetBrains, https://www.jetbrains.com/junie/

conceptual framework of seven design constructs to support reasoning about the design of AI-ready code review tools; and (4) a high-fidelity prototype validated through a survey of forty-three professional developers.

## 2 Background and Related Work

Modern code review is an informal, lightweight, and asynchronous process in which one or more developers inspect a peer's proposed change before it is merged into the shared codebase [24, 26]. Although defect detection remains a stated goal, practitioners and researchers consistently report that the value of review is broader: knowledge transfer, shared ownership, design feedback, and informal mentoring [2, 26]. Recent cognitive accounts characterize the activity as a sequence of decision-making episodes that move through orientation, inspection, shepherding, and a final integration decision [16, 13]. The activity is, in other words, a human-centered exercise in which a reviewer reconstructs a peer's intent and weighs it against project context.

When code is LLM generated, several assumptions on which this exercise rests no longer hold. The LLM can be asked to explain its intent, and current models produce fluent accounts on request. Such an account is nonetheless reconstructed after the fact rather than recovered from the generation process, and is itself subject to confabulation [4]. The rationale that a peer reviewer would normally elicit through discussion is therefore available only in a form whose fidelity the reviewer cannot verify. Also, while the strengths and weaknesses of a human author can be learned, the competence profile of an LLM is stochastic and uneven. The change set is typically larger and spans more files than a human-authored commit [32], yet confidence is presented uniformly across heterogeneous segments, leaving reviewers without a means of allocating attention proportional to risk. LLM tooling additionally introduces an action-space concern that has no analog in peer review: an insufficiently sandboxed LLM-tool can modify files, install dependencies, or execute commands as a side effect of the proposed change. The result is a review task in which the established interpersonal benefits are at risk of being lost while new, LLM-specific failure modes appear. The cost falls directly on practitioners; review effort is distributed without regard to risk, and acceptance decisions are made without visibility into LLM reasoning.

Prior solution attempts fall into three categories. Cognitive-load research on human-authored review has produced two-phase reading strategies and chunking guidelines that scale review effort to working-memory limits [14, 3]. A second category investigates AI-as-reviewer systems that comment on human-authored changes [30], adopting an augmentation stance orthogonal to the present work, where the AI is the author and the human the reviewer. A third, the *Code Review as Decision-Making* (CRDM) cognitive model, positions review as an orientation phase followed by an iterative analytical phase [16], motivating focused study of the analytical phase in isolation; we return to its applicability in Section 5. To our knowledge, this is the first artifact-producing study to elicit reviewer needs for this scenario through participatory design rather than feature speculation, and to validate the resulting workflow with a separate practitioner sample.

## 3 Method

The study design is based on pragmatist epistemology with participatory design values [8], seeking to model the needs of the community through its active participation in research and evaluation. We adopted the Double Diamond design framework [10] to address our

research questions. This process supports the transition from problem identification to solution delivery through four distinct phases: **Discover**, **Define**, **Develop**, and **Deliver**. This framework is particularly well-suited for a participatory design approach [28], as it allows researchers to employ the expertise of the professional community to address complex outstanding issues. Since external participants' time is valuable, and committing to four multi-hour workshops is daunting for most busy software professionals, we prioritized involving them in the expansive Discover and Develop phases. For the contractive Define and Deliver phases, we held workshops internally in the research group. Holding these phases internally kept participant demand proportionate, at the cost of admitting researcher influence into two products that never passed through participant hands: the twelve Define-phase topics and the Deliver-phase conceptual design (Section 6 reports the mitigations and residual risk).

**Workshop I (Discover)** and **Workshop III (Develop)** followed pre-defined protocols that were, in both cases, first tested and refined in pilot workshops held approximately one week before each workshop. The participants in the pilot workshops were colleagues of the authors with a high degree of software and research experience, enabling both full participation and valuable feedback on the workshop protocol.

In **Workshop I**, participants (professional developers) identified specific challenges inherent in reviewing LLM-generated code and evaluated a set of literature-derived solutions for effective code review by ranking them according to importance and feasibility. For complete workshop protocols, see Section 7.

**Workshop II (Define)** used a more exploratory format. As study authors, we each familiarized ourselves individually with the findings of Workshop I. The analysis itself was carried out jointly, on a shared digital whiteboard, where we coded the notes, consolidated and revised the resulting topics, and derived a prioritized list of problems with opportunity for intervention. The topics and the problem list emerged together over the course of the session rather than in sequence. The problems were described in more detail and used as input for Workshop III.

In **Workshop III**, developers used these prioritized problems to co-design review tools through low-fidelity prototyping using pre-drawn IDE mockups and tactile craft materials. As the last exercise in the workshop, they arranged their design sketches into a multi-level workflow for end-to-end code review of LLM-generated code.

For **Workshop IV (Deliver)**, we created a conceptual design [20] grounded in a persona and use cases derived from our observations and notes from the two participant workshops. The workshop outputs, the persona, and the use cases were used to systematically produce the conceptual design, which in turn formed the foundation for a high-fidelity semi-interactive prototype. The visual design and user experience of the prototype were developed by author 5, a professional industry designer.

To validate the prototype, we distributed a survey to participants in previous workshops and pilots, and to software professionals via social media. For the full survey questionnaire, see Section 7. The survey presented an animated walk-through of the prototype, demonstrating each level of the three-level workflow and the seven design constructs. After the animation, participants rated their agreement with a series of statements on a five-point Likert scale (1 = Strongly disagree, 5 = Strongly agree). Three further Likert statements and two comparative-effort questions allowed participants to rate the overall impression. Free-text questions in each section collected comments on the prototype and suggestions for improvements.

## 3.1 Participants

To ensure the quality and relevance of the co-design process, we employed a rigorous screening process based on three primary criteria: professional experience, AI tool proficiency, and specific experience in reviewing LLM-generated code. Only developers with active roles in software engineering were considered. Participants were also required to have used AI coding assistants for at least three months, with a usage frequency of at least once per week. A critical requirement was experience in reviewing multi-file LLM-generated changes (3 or more files). The co-design workshops were held on site in Belgrade, so participants also had to be able to attend in person. Recruitment ran through local Serbian software engineering communities rather than through JetBrains product channels, so the cohort is not drawn from a single vendor's user base. We initially recruited a cohort of professional developers ($N = 17$) to participate in the Discover phase. For the Develop phase, 7 of the original 17 participants returned to continue the co-design process.

**Table 1** Detailed Profiles of Study Participants ($N = 17$).

| ID | Job Role | Coding Exp. | AI Rev. Exp. | Co. Size | Primary Product Domains | Primary IDE | WSIII |
|---|---|---|---|---|---|---|---|
| P1 | SW Eng. | 6–10y | 1–2y | 1,001–5,000 | Cloud, Web Services, Business Apps | IntelliJ | Y |
| P2 | SW Eng. | 1–2y | < 6mo | Just me | Dev Tools, Rendering, Websites | Cursor | N |
| P3 | SW Eng. | 6–10y | < 6mo | 2–10 | AR/VR, Mini-apps | Android Studio | Y |
| P4 | SW Eng. | 6–10y | 1–2y | 51–500 | Dev Tools | PyCharm | N |
| P5 | SW Eng. | 11–15y | 1–2y | 11–50 | Cloud, Mini-apps, Websites, Business Apps | Cursor | Y |
| P6 | Data Scientist | 6–10y | 6–12mo | 5,000+ | Finance, IT Infra, Analytical SW | VS Code | N |
| P7 | SW Eng. | 11–15y | 6–12mo | 1,001–5,000 | Cloud, Finance, Business Apps | PyCharm | N |
| P8 | SW Eng. | 6–10y | 1–2y | 501–1,000 | Entertainment, Web Services, Business Apps | Goland | N |
| P9 | DevOps Eng. | 6–10y | 6–12mo | 11–50 | Cloud, Hardware, IT Infra | Cursor | Y |
| P10 | AI Researcher | 1–2y | 6–12mo | 51–500 | IT Infrastructure, Websites | PyCharm | Y |
| P11 | SW Eng. | 6–10y | 6–12mo | 51–500 | Security, Websites, Business Apps | PyCharm | N |
| P12 | AI Researcher | 6–10y | 1–2y | 501–1,000 | Security | VS Code | N |
| P13 | AI Researcher | 11–15y | 1–2y | 5,000+ | IT Infrastructure | PyCharm | N |
| P14 | AI Researcher | 11–15y | 6–12mo | 2–10 | Business Apps, Analytical SW, AI Apps | Cursor | Y |
| P15 | SW Eng. | 1–2y | 1–2y | 11–50 | Business Applications | VS Code | Y |
| P16 | Physics Res. | 11–15y | 6–10y* | 51–500 | (No specific product) | PyCharm | N |
| P17 | SW Eng. | 16+y | 1–2y | 51–500 | Bioinformatic Pipelines | RustRover | N |

*Note: SW Eng. = Software Engineer; AI Rev. Exp. = Years using AI tools for development/review; Co. Size = Total employees. WSIII = Participated in Workshop III (all participated in Workshop I). Participants were recruited based on their experience with code review of multi-file LLM-generated code.*

The participants represented a high level of professional expertise and diverse technical backgrounds (see Table 1). The cohort was notably senior; over 70% of participants possessed more than 6 years of professional experience, with several exceeding 11 and 16 years in the industry. The majority of participants identified as Software Developers/Engineers, supplemented by AI/ML Engineers and Team Leads. The majority of the participants were using tools such as ChatGPT, Cursor, and GitHub Copilot on a daily basis. Most had been integrating these tools into their workflow for over six months, with several being early adopters (2+ years). All participants were active in code review, with most performing reviews daily or several times per week. Ninety percent of the selected participants confirmed they had reviewed LLM-generated changes involving three or more files "multiple times", providing the necessary depth of knowledge for the study.

For the validation survey, we received a total of 97 responses. However, 54 of these responses were flagged as LLM-generated based on time to complete the survey, similarity to other responses, referrer link, and evident prompt leaking. This left $N = 43$ legitimate respondents, predominantly experienced practitioners: 70% reported 6 or more years of professional coding experience. The most common job roles were software developers or engineers (42%) and AI/ML engineers (19%). All participants had used AI tools for software

development for at least six months; 74% for one year or more. AI tool use was intensive: 91% used AI tools at least several times per week. Participants were also active code reviewers, with 70% reviewing code several times per week or more. The most common case (37%) was that 31-60% of the code reviewed was LLM-generated. Survey participants used several different AI coding tools. The most widely used tools were Claude Code (58%), ChatGPT (51%), and OpenAI Codex (47%). Of the respondents, 35% had participated in one of the previous workshops while the rest had found the survey on social media (LinkedIn). Complete demographics are available in the replication package, see Section 7.

## 3.2 Data Analysis

Workshop I generated 60 post-it notes capturing 64 participant-identified challenges, each annotated with a severity and feasibility rating, which the participants themselves arranged into four challenge groups: "Trust", "Lack of control", "Quality", and "UI". In Workshop II, all four study authors re-analyzed the notes through an iterative consensus-based process. Across a series of joint sessions we coded and re-coded each note by asking which challenge it pointed to, discussing every assignment until interpretative convergence was reached, and arriving at the twelve topics listed with their occurrence counts in Section 4. The participants' four challenge groups were held as background context during this work rather than used as a coding frame, so that the topics were derived from the notes themselves. The fourth author had not facilitated Workshops I or III and joined the synthesis at the convergent Workshops II and IV, providing an outside reading of the divergent-phase data and a form of investigator triangulation [9] embedded in the team composition. We did not compute an intercoder-reliability coefficient. Such coefficients presuppose that coders apply a fixed scheme independently, whereas our scheme and our assignments were built in the same joint sessions; a coefficient computed over negotiated codes would describe the outcome of the discussion rather than independent agreement. We instead support dependability and confirmability through negotiated agreement and an audit trail linking every raw challenge to the topic in which it ended. The resulting digitized post-it dataset, complete with thematic coding, is included in the replication package (Section 7).

The same sessions also produced the prioritization: Drawing on the twelve topics alongside the severity and feasibility ratings participants assigned in Workshop I, the authors derived a prioritized list of eleven problems warranting intervention. The two signals do not attach to the same partition of the data: Occurrence counts across the twelve topics reflect how the authors chose to split the material, whereas the severity votes attach to the four challenge groups the participants formed themselves. Where the two signals disagreed, we followed severity over frequency, since severity is grounded in the participants' own judgment rather than in the granularity of our coding. The final problem list is in this sense grounded in the Workshop I data rather than in author preference alone.

Workshop III produced low-fidelity sketches. These artifacts were analyzed collectively by the authors following the same consensus-based approach, to extract recurring design constructs and a common workflow structure. The construct extraction was driven by the data: constructs were included only when they appeared in multiple participant sketches, were voted for by multiple participants, or were highlighted in workshop discussion transcripts.

The validation survey was analyzed by computing mean Likert scores for each of the levels as well as descriptively by plotting the responses centered around the neutral midpoint (Figure 6). While Likert scores are ordinal variables, research shows that computing means give the correct interpretation especially when summing over several questions and respondents [22]. The "Overall" section of the survey contains three singular Likert questions as

well as two questions using a scale from “Much more” to “Much less”. For these questions, we instead analyze and present the percentages of respondents who choose the different alternatives. Free-text answers were analyzed using thematic analysis by author 1 and author 4 independently, with the themes then combined to form a consensus.

# 4 Results

## 4.1 Discover Phase

**Figure 1** Post-it notes with challenges, grouped into clusters by the participants. **Takeaway:** The trust cluster received the most high-severity votes.

In the Discover phase workshop, the participants contributed 64 post-it notes capturing challenges in reviewing LLM-generated code, categorized into four groups: “Trust”, “Lack of control”, “Quality”, and “UI”. The small paper strips in green, yellow, and red (see Figure 1) denote votes for the groups as “easy”, “annoying”, and “dangerous”, respectively. In our sample, the “Trust” cluster attracted most of the high-severity votes, receiving 12 of the 17 red (dangerous) votes cast across all groups; “Lack of control” attracted the remaining 5, while “Quality” and “UI” received yellow and green votes only. With 17 participants voting, these counts indicate where this cohort located severity rather than measuring how prevalent each challenge is in the wider population. For full per-group vote counts and digitized post-it notes, see Section 7.

## 4.2 Define Phase

In the Define phase, we re-analyzed the same challenges independently of the participants’ grouping, coding each note by the challenge it pointed to. This produced 12 topics that cut across the four groups: “Broken code” (13 occurrences), “Intent misalignment” (8), “Bad UI/UX” (6), “Overcomplexity” (6), “Cognitive load” (6), “Lack of trust” (5), “Lack of transparency/explainability” (5), “Inconsistent style” (4), “Insufficient context window” (4), “Increased tech debt” (3), “Redundancy” (2), and “Overtrust/overreliance” (2). Although “Broken code” and “Intent misalignment” attracted the highest occurrence counts, these challenges are more appropriately addressed during code generation rather than during code review. In addition to “Lack of trust” directly, several of the remaining topics are indirectly

linked to trust, such as "Lack of transparency/explainability", "Overtrust/overreliance", and parts of "Cognitive load". Trust-related topics surface as the most salient for the review stage: The "Trust" group alone attracted 12 of the 17 red (dangerous) votes in the workshop, a count attached to the participants' own grouping rather than to our twelve topics. We therefore focus the problem definition on this theme.

### 4.2.1 Problem Background

Trust is complicated in the case of review and integration of LLM-generated code, especially when the agent creates or changes multiple files to solve a more complex issue description or prompt. The problems center on several themes:

**Explainability.** The agent gives no information about its chain of thought, references, or why it chose a given solution, and presents neither alternative implementations nor its assumptions. This makes it hard to judge whether the solution meets the functional requirements.

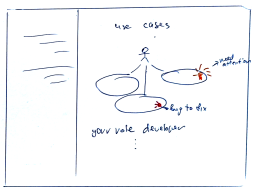
**Transparency.** Segments across files can carry very different generation confidence, yet are presented as equal, forcing the reviewer to carefully check all code regardless of actual risk.

**Inconsistent attention to detail.** Even when specified in the prompt or context, the agent may get package or API versions wrong, likely defaulting to whatever was most common in its training data, producing code that looks correct but fails or behaves unpredictably.

**Insufficient sandboxing.** Agents may be insufficiently sandboxed, able to execute commands in the programming environment beyond what the task requires, risking the reviewer's files or environment.

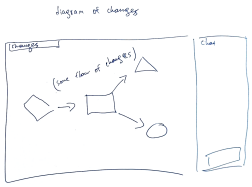
**Overconfidence and gaslighting.** The agent writes as if certain of its solution, yet can reverse direction entirely when challenged, which confuses the reviewer and erodes trust.

### 4.2.2 Problem Definition



An appropriate level of trust is necessary to complete the review of LLM-generated code efficiently, without excessive mental fatigue or frustration. This may mean low trust for complex code where the agent's internal confidence is low, or high trust where the code is simple and the probability of correct tokens is high. The problem lies in giving the reviewer enough information to place the correct level of trust in the correct parts of the solution, so that they experience confidence in the system as a whole, trusting it to surface the code sections that need more careful review.

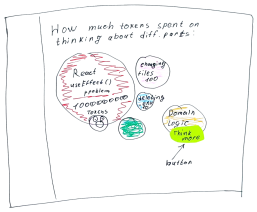
The user wants to: A) verify the LLM-proposed solution to avoid merging bugs, security risks, performance bottlenecks, and other issues into production; B) efficiently evaluate large, complex LLM-generated changes, since reading every line is error-prone, fatiguing, and time consuming.



## 4.3 Develop Phase

In the Develop Phase workshop, the participants created short solution suggestions written on post-it notes, design sketches for some of these solutions, and workflows describing where some of these design sketches could fit into a code review workflow. The participants proposed a three-level workflow: 1) overview, 2) file-analysis, and 3) code snippet review.

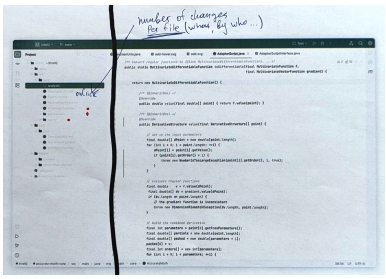
In the *overview* level, the user can choose from several different views (Figure 2) that give higher abstraction-level explanations of the proposed code changes. Two proposed views highlight the changes and potential issues in diagram form, as an architectural diagram



**(a)** Sketch of architectural diagram highlighting code changes and potential issues.

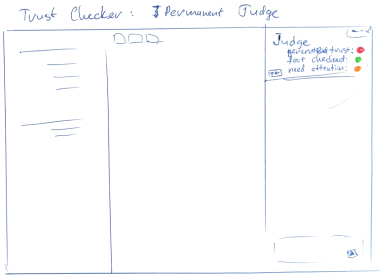
**(b)** Sketch of data flow diagram.

**(c)** Sketch of an LLM-generated walkthrough explaining the rationale and implementation choices behind the proposed change.



**(d)** Sketch of token cost diagram.

**Figure 2** Participant sketches for the *overview* level. **Takeaway:** Overview level zooms out and provides abstract perspectives on the LLM-generated solution.



(Figure 2a) and a data flow diagram (Figure 2b). A third proposal introduces an LLM-generated walkthrough of the code and the reasoning behind it (Figure 2c). The final view shows tokens spent by the LLM on the different parts of the code and the design, to give the reviewer an indication if some parts have been neglected or overcomplicated (Figure 2d).

**(a)** Sketch of the security cage view.

**(b)** Sketch of the risk analysis view.

**(c)** Sketch of the judge view.

**Figure 3** Participant sketches for the *file-analysis* level. **Takeaway:** File-analysis level zooms in for whole-file assessment concerning trust and risk calibration.

After the reviewer understands the solution proposal at the architectural and conceptual levels, they move to the *file-analysis* level (Figure 3) where the IDE guides them through assessing one file at a time. Three proposed views are central to this level. The first is a security cage that limits the actions the agent can take in the user's IDE, for increased safety and trust. The cage also provides a safe environment for running health checks on the proposed solution and alerts the reviewer to potential failures and security risks. The second is a file-level and line-level risk analysis based on the frequency of change of files and lines (Figure 3b). If the file as a whole, or specific lines, have been changed very rarely throughout the project's history, the changes are considered higher risk than if the file and lines are changed very frequently. The third proposed view was named the "Judge" view by the workshop participants (Figure 3c). This view shows an LLM's assessment of the code, acting as a judge. The judge performs issue detection, fact checking, security verification, and presents areas needing attention by the reviewer as traffic lights.

Finally, in the *code snippet review* level, a view breaks down the proposed solution into its smallest independent parts: *chunks*. Each chunk is a set of changes across one or more files that belong together. They must be applied as a unit for the code to compile and the

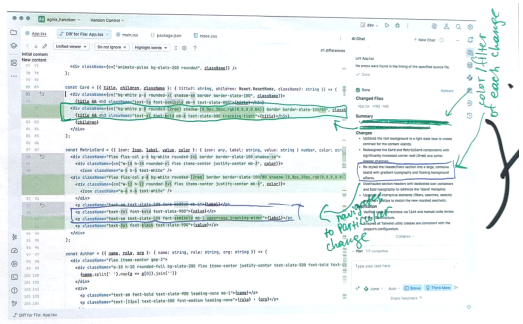


**Figure 4** Participant sketch for the *code snippet review* level. **Takeaway:** Code snippet review level zooms all the way in, and breaks the proposed solution into *chunks*, the smallest logically cohesive code units.

test suite to pass. A proposed solution could consist of a single chunk if all changes depend on each other, or of several chunks if the solution has several orthogonal parts that can be applied independently. Breaking the solution into chunks helps the reviewer understand, analyze, and approve it at a more granular level. As seen in Figure 4, each chunk is linked to the corresponding parts of the prompt and the chain-of-thought segments in the LLM response.

## 4.4 Conceptual Design

The sketches and workflows from the Develop phase were refined by the authors into a conceptual design [20]: five concepts and six metaphors below. Seven of these eleven are the design constructs referenced throughout this paper and surveyed in the validation study (Table 2): *chunk*, *risk-per-line*, *risk-per-file*, *judge*, *walk-through*, *zooming in/out*, and *security cage*. *Proposed solution* is the object under review, not a construct; *token cost*, *de-tangling*, and *traffic light* support the surveyed constructs rather than adding to them.

**Table 2** Mapping of the three workflow levels to the seven design constructs, the trust signal each level exposes, and the mean survey rating on a five-point scale (midpoint 3). Zooming in/out is not level-specific and instead moves the reviewer between all three. **Takeaway:** Each level answers a different trust question at a different granularity, and all three were rated above the neutral midpoint, with the finest granularity rated highest.

| Level | Granularity | Constructs | Trust signal exposed | Mean |
|---|---|---|---|---|
| Overview | change set | Walk-through | Intent and reasoning | 3.50 |
| File-Analysis | file | Risk-per-file, Judge, Security Cage | Risk location; action-space limits | 3.69 |
| Code Snippet Review | chunk | Chunk, Risk-per-line | Independently judgeable units | 3.91 |

**Concept: Proposed Solution.** The proposed solution is the whole of the LLM's proposed file changes aimed at fulfilling the task described in the latest prompt iteration. The user can edit it manually or ask the LLM to modify it before merging.

**Concept: Risk-per-line.** Different source code lines carry different risk if modified: Some are important to logic, performance, or security, while others control more peripheral behavior.

**Concept: Risk-per-file.** Similarly to risk per line, changing a file could have higher or lower potential consequences on the behavior of the system as a whole.

**Concept: Chunk.** A chunk is the smallest subset of code changes in the proposed solution that could be applied together without breaking code compilation or test suites.

**Concept: Token Cost.** LLM providers typically charge by the number of "tokens" processed and generated. Surfacing this cost helps the user balance solution complexity and size against their budget.

**Metaphor: Walk-through.** Like a colleague walking you through the factory floor to explain its processes, the system gives a guided tour through the proposed solution, explaining the rationale, reasoning, and implementation choices.

**Metaphor: Judge.** An AI agent analyzes and criticizes the *proposed solution*. In participants' sketches, the verdict is presented as traffic lights for potential bugs, fact checks, and security issues; red or yellow areas are highlighted for closer manual inspection, and the Judge's explanations guide what the reviewer should look for.

**Metaphor: Security Cage.** The AI agent's actions are restricted by well-defined limits on what it is allowed to do, surfaced to the reviewer. This mitigates action-space risk and helps the reviewer trust that nothing unexpected changed in their workspace.

**Metaphor: Zooming in and out.** Like a telescoping camera lens, zooming in and out lets the user move between the different levels of abstraction in the three-level workflow.

**Metaphor: De-tangling.** De-tangling code separates complex changes into chunks connected by shared logic, letting the user analyze the solution part-by-part. Used to create and show chunks in the *code snippet review* level.

**Metaphor: Traffic Light.** A quick visual signal for assessments of the proposed solution: red for parts needing immediate attention, yellow for potential issues, and green for likely-correct code. Used to communicate the AI judge verdict at the *file-analysis* level.

## 4.5 High-Fidelity Prototype

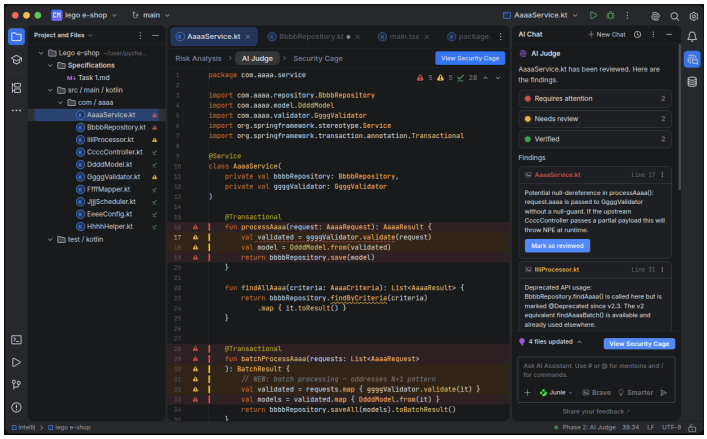

**Figure 5** High-fidelity prototype screenshot example: the AI Judge verdict panel from the file-analysis level. **Takeaway:** The prototype operationalizes all seven constructs and implements the three-level workflow, providing a concrete artifact for survey-based validation.

The conceptual design and the task scenarios were realized as a high-fidelity, semi-interactive prototype implemented in JavaScript using the React framework. The prototype renders the three-level workflow as an embedded panel within a mock IDE and instantiates

each of the seven design constructs, i.e., chunk, risk-per-line, risk-per-file, Judge, walk-through, zooming in/out, and security cage, through dedicated views. Example screenshot in Figure 5. Navigation between levels, file and chunk expansion, Judge verdict toggling, and risk indicator traversal are fully interactive. The underlying LLM assessments, chain-of-thought excerpts, and walk-through narration are pre-rendered and static, avoiding confounds from live model variability while preserving the fidelity needed to elicit informed feedback. The animated prototype demonstrations are included in the replication package (Section 7).

## 4.6 Prototype Validation Survey

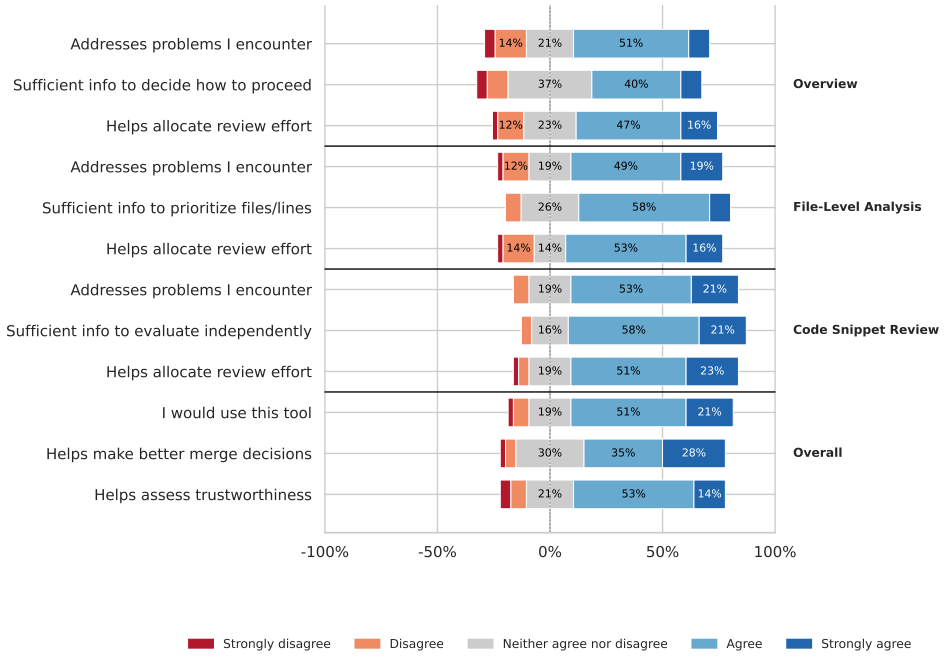

**Figure 6** Likert responses for the three levels and overall tool assessment, rated on a five-point scale (1 = Strongly disagree, 5 = Strongly agree). **Takeaway:** All three levels scored above the neutral midpoint, with the Code Snippet Review level receiving the highest mean rating (3.91), suggesting that chunk-level decomposition resonated most strongly with survey participants.

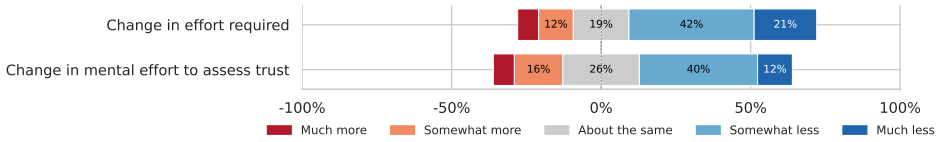

**Figure 7** Comparison of perceived effort between the proposed tool and participants' existing code review tools, for overall review and for trust assessment. **Takeaway:** A majority of respondents estimated that the proposed tool would reduce effort compared to their current tools, both for general review (63%) and for assessing trustworthiness (52%).

The survey results, summarized in Figure 6, indicate that participants responded positively to all three levels of the proposed workflow. The *Code Snippet Review* level received the highest mean rating (3.91 on the five-point scale, where 3 is the neutral midpoint), followed

by the *File-Analysis* level (3.69) and the *Overview* level (3.50). All three levels scored above the scale midpoint, suggesting that the workflow structure and its supporting constructs were well-received by the survey participants. That the respondents rated the *Code Snippet Review* level the highest is also reflected in the free-text responses discussed below.

Concerning overall tool assessment, 72% of respondents agreed or strongly agreed that they would use a tool with these features; 63% agreed or strongly agreed that the tool would help them make better merge decisions; and 67% agreed or strongly agreed that the tool would help them assess the trustworthiness of LLM-generated code changes. These findings indicate that guiding reviewers through progressive levels of detail, while surfacing risk and trust signals, aligns with what developers perceive as useful support for the review of LLM-generated multi-file changes.

Regarding comparative effort (Figure 7), 63% of respondents estimated that the proposed tool would require less or much less effort than their existing code review tools for the overall review task. For the specific task of assessing trustworthiness, 52% estimated a reduction in effort. While the trust-assessment figure is more modest, it is noteworthy given that none of the participants' current tools are designed to surface trust signals explicitly. The result suggests that even a prototype demonstration could shift developers' perception of how much effort trust assessment demands.

Free-text responses reinforced and qualified the Likert findings. The *security cage* construct drew the most skepticism: several respondents described its purpose as unclear or redundant, given that sandboxing is typically configured at the agent level rather than surfaced to the reviewer. We retain it in the framework because it is the only construct targeting action-space rather than information-space risk. For the *Code Snippet Review* level, multiple respondents wrote that chunk-level decomposition aids understanding even when chunks cannot be applied independently, reinforcing the high Likert score. Many participants wished for traffic light color-coding of the chunks to convey LLM confidence. Across levels, several respondents preferred free navigation between views rather than a fixed three-level sequence, wanted support for multiple collaborating reviewers, and suggested integrating live test-coverage data into the Judge view. Taken together, the survey results provide initial evidence that the three-level workflow and the seven conceptual design constructs resonate with practitioners' needs. However, the prototype was semi-interactive and the evaluation rested on a video demonstration rather than on hands-on use. Furthermore, what we measured is perceived usefulness, not effectiveness: Review speed, defect detection rate, change in reviewer trust, and merge decision quality were all outside the scope of this survey. These findings should therefore be read as directional rather than conclusive (see Section 6).

## 5 Discussion

Prior empirical characterizations of the code review challenge position diff comprehension, cognitive load, and defect-detection pressure as the primary obstacles to effective review [14, 3]. These framings are well-motivated for human-authored change sets, where the reviewer's core difficulty is one of reconstruction: understanding what a colleague intended, how the change fits the architecture, and whether the implementation is correct. The present data suggest that, when the author is an LLM agent, this comprehension framing captures downstream effects rather than the root cause.

The Discover-phase challenge clusters reveal a more fundamental difficulty. Reviewers cannot allocate attention proportionate to segment-level risk because the agent provides no signal about its own confidence or the reasoning behind its implementation choices.

Reviewers fall back to reading every line because any line could be wrong, which is the rational response to an agent that presents heterogeneous-quality output with homogeneous confidence. The burden is amplified because agents typically generate large volumes of code, requiring reviewers to inspect substantially more material. Cognitive-load challenges in the data are largely traceable to this opacity rather than to difficulty parsing the code itself.

We therefore propose *trust-calibration*, defined as the capacity to allocate review effort proportionate to segment-level risk when the author cannot be interrogated about its confidence or reasoning, as the organizing problem for reviewing LLM-generated multi-file changes. This framing is consistent with recent work arguing that trust in AI assistants for software development requires rethinking when the assistant is the author rather than the helper [4]. The design implication follows directly: tool designs that address comprehension without addressing trust calibration may improve efficiency for low-stakes changes while leaving the more consequential failure mode, systematic misallocation of review effort toward low-risk segments and away from high-risk ones, unaddressed.

## 5.1 A Conceptual Framework for Trust-Signal Exposure

The co-designed workflow and seven constructs share a common mechanism: each makes a specific type of epistemic uncertainty visible at a specific granularity (Table 2). At change-set granularity, the walk-through surfaces intent and reasoning, while zooming in/out lets the reviewer move between granularities as understanding develops. At file granularity, risk-per-file, the Judge verdict, and the security cage prioritize attention and bound the agent's action space before line-level reading begins. At chunk granularity, risk-per-line and the chunk decomposition itself support decisions around each independently-judgeable segment. Neither line-level details read without an architectural overview nor architecture-level information alone suffices for decision-making, and the three-level structure is a proposed answer to that problem.

The structure also has theoretical motivation in prior cognitive models of review. The CRDM model [16] describes review as an orientation phase, in which the reviewer selects a change request and establishes its context and rationale, followed by an iterative analytical phase in which the change is understood, assessed, and integration decisions are taken. In the setting studied here, the reviewer is also the prompter, and each of these is settled before review begins. Orientation collapses in this sense, and the work concentrates in the analytical phase, where the reviewer has to evaluate the implementation without a commit message that reliably describes it and without a competence profile against which to weigh the implementation choices. All three levels therefore serve the analytical phase. The *overview* level establishes what the implementation does at change-set granularity, which is the precondition for judging it against intent the reviewer already holds. The *file-level analysis* level inserts a risk-stratification step into the *assessing change* action in CRDM, made necessary by the combination of larger change sets and uniform confidence presentation. The *code snippet review* level recovers the analytical-phase granularity of prior models, augmented by chunk decomposition and chain-of-thought linkage. The three levels thus extend the analytical phase of CRDM by adding a risk-stratification layer and by grounding each decision in agent-provided reasoning. We believe most of these constructs would strengthen the analytical phase for human-authored changes as well, and that LLM authorship makes the need acute rather than creating it.

Two constructs merit separate consideration because their standing in the framework is less settled. The *security cage* is the only construct targeting action-space rather than information-space risk; survey reception was mixed (see Section 4), which we interpret as

reflecting genuine ambiguity about whether sandboxing is a reviewer concern or an agent-configuration concern upstream of review. We retain it in the framework because action-space risk is otherwise unrepresented and because Develop-phase participants placed it explicitly within the file-analysis level rather than treating it as infrastructure. The *Judge* construct carries its own epistemic tension: its verdicts are themselves LLM outputs and therefore subject to the same opacity that motivates the broader framework. We believe the Judge is nonetheless useful as an attention-routing device, provided that the interface communicates that its assessments are probabilistic rather than authoritative.

Concerning $\mathbf{RQ_1}$, the Discover and Define phases converge on trust-calibration, i.e., the inability to allocate review effort proportionate to segment-level risk in the absence of transparent confidence signals from the LLM, as the primary challenge when reviewing LLM-generated multi-file changes; the remaining challenge topics are interpretable as inputs to or consequences of this problem. Concerning $\mathbf{RQ_2}$, the three-level workflow and the seven constructs constitute a practitioner-co-designed conceptual framework for IDE tooling that exposes trust signals at change-set, file, and chunk granularity. This framework was co-designed with seventeen practitioners across two workshops and received directional support in a follow-up survey of forty-three professionals (means 3.50–3.91 on a five-point scale), suggesting that the constructs address a recognized practitioner need.

## 5.2 Alignment with Evolving Tool Landscape

Our results should be interpreted against a rapidly maturing product landscape in which reviewing LLM-generated code is becoming a distinct workflow: GitHub now publishes dedicated guidance for reviewing LLM-generated code [12] and reports that Copilot code review accounts for more than one in five code reviews on the platform [31].

Several of the identified metaphors already have partial industrial counterparts. For example, variants of walk-through or overview support appear in CodeRabbit [7] and Harness AI [17]. The AI Judge metaphor has clear analogs too: Claude Code launches multiple reviewer agents that tag findings by severity [1], Codex focuses GitHub review comments on higher-priority P0/P1 issues [23], and CodeAnt prioritizes findings using severity and risk signals such as blast radius and historical volatility [6]. Graphite's stacked PRs are the closest current analog to our chunking idea, splitting large tasks into independently reviewable units across multiple PRs rather than disentangling a single generated proposal. Token usage and sandboxing, by contrast, are usually treated as operational controls rather than reviewer-facing trust signals; for example, Claude Code documents token tracking for cost management and defaults to a read-only, approval-based execution model.

The novelty of our proposal therefore lies less in inventing isolated features than in combining them into a trust-calibrating, progressively disclosed workflow for reviewing multi-file LLM-generated changes.

## 5.3 Hierarchical Review as Cognitive Scaffolding

A further interpretation of the concepts produced in the design workshops is that developers were not only asking for more information, but for information organized across usable levels of abstraction. The proposed workflow moves from overview-level representations of the change, through file-level risk differentiation, to chunk-level review, while constructs such as zooming in/out, risk-per-file, risk-per-line, walk-through, and chunk make it possible to traverse these levels rather than inspect a large diff as an undifferentiated sequence of lines. This three-level progression mirrors Shneiderman's visual information-seeking

mantra: "overview first, zoom and filter, then details-on-demand" [27], and is consistent with cognitive load theory [29]: when a task contains many interacting elements, poorly organized representations consume processing capacity that could otherwise support understanding and decision-making, whereas chunking reorganizes complex, multi-file LLM suggestions into manageable semantic units that reduce extraneous load. In software specifically, this progressive disclosure supports top-down program comprehension [5]. Developers form high-level hypotheses about system behavior and subsequently validate them against granular code fragments, making a purely line-by-line diff view a poor fit for multi-file LLM-generated changes. By presenting architectural and data-flow diagrams during the overview phase, the tool equips developers with the context to generate these hypotheses, while localized snippet review provides the targeted details needed for verification. From this perspective, our constructs function as cognitive scaffolding for trust-calibration.

The framework also carries implications for reviewers who cannot wait for new tooling: Three practices follow from the constructs without requiring any tool support. First, establish an overview of the solution before reading lines by asking the agent for a walk-through of the change set and checking it against the architecture. Second, allocate reading time by risk rather than by diff order, treating files with logic, security, or performance consequence as the first stop. Third, treat any AI-produced verdict, including the agent's own summary of its work, as a probabilistic pointer rather than an assessment to accept outright. These practices are available today; the three-level workflow's contribution is to make them systematic rather than improvised.

## 5.4 Connection to Prior Work

We position the contribution against three categories of prior work. First, the two-phase reading model of Gonçalves et al. [14] is consistent with the workshop's three-level result; we extend it with a file-level differentiation layer that becomes necessary when authorship is non-human. Second, the CRDM model [16] distinguishes orientation from analysis, but its orientation phase is already settled when the reviewer is the prompter. The analytical phase is therefore the locus of the work, and is where our three levels intervene. Third, the AI-as-reviewer paradigm represented by Vijayvergiya et al. [30] adopts an *augmentation* stance in which the AI comments on human-authored code; the present work concerns the inverse configuration and is therefore complementary.

## 5.5 Future Work

We identify several directions for future work, each driven directly by signals in the validation survey or by limitations of the current artifact.

**Free vs. Phase-Locked Navigation.** Five survey respondents recommended skipping the division into levels and letting the reviewer move freely between views. A within-subjects study of fixed-level and free-navigation variants of the prototype could disambiguate whether the three-level scaffolding aids attention allocation or constrains reviewers unnecessarily.

**Test-Coverage Integration.** Several respondents suggested integrating test-coverage data into the Judge view. This could strengthen the Judge construct as a trust signal by grounding its verdicts in observable test behavior, rather than in static analysis alone.

**Hands-On Longitudinal Prototype Evaluation.** The current evidence base is a survey of N=43 practitioners responding to a prototype walk-through. Evaluating a fully operational prototype by hands-on longitudinal use within development teams could upgrade the directional findings reported here to confirmatory evidence, and could surface potential adoption frictions. This could also confirm if the security cage is a viable construct for code review or better solved on the agent configuration level. Such an evaluation would also enable a measurement instrument for trust-calibration, which the present survey does not provide.

## 6 Threats to Validity

Following Lago et al. [21], we treat validity analysis as an active design concern rather than a post-hoc checklist. Because the study is a pragmatist participatory design study with a follow-up survey, we organize threats using Guba's qualitative trustworthiness framework [15], since Guba's criteria align with the naturalistic, co-constructed character of the workshop data. For each criterion we name the threat, the mitigations operating in the design, and the residual risk that mitigation does not eliminate.

**Credibility.** Under the pragmatist stance, knowledge claims are evaluated by their utility in practice. Two mitigations operate in the study design. First, member checking was embedded in the workflow: Workshop III opened by presenting the Workshop II problem framings to the seven returning participants and inviting feedback before the co-design activity began (Section 3). Second, the constructs and workflow are triangulated across elicitation modalities, appearing in Workshop I post-its, Workshop III sketches, and the validation survey free-text and Likert responses. Several threats nonetheless persist. The follow-up survey evaluated a semi-interactive prototype via a video demonstration rather than hands-on use in a realistic review task, so it tests *perceived* usefulness rather than enacted usefulness. The survey respondents may carry acquiescence bias that inflate Likert ratings, and the survey is a single-snapshot measurement without a behavioral anchor. The label *trust-calibration* is also an authorial synthesis: participants independently identified trust as the dominant challenge, and the term was mentioned at the start of Workshop III, but no participant challenged the label or the construct. Taken together, these limitations bound what the study can claim: It speaks to a perceived need for trust-calibration support and to the plausibility of the proposed design, and it does not demonstrate that the workflow improves calibrated trust, appropriate reliance, or review accuracy. The residual risk is that the constructs and workflow may be wanted and plausible to practitioners with relevant experience while not yet being shown to change reviewer behavior or outcomes in a live, multi-file review; a hands-on longitudinal evaluation is required to close this gap (see Section 5.5).

**Transferability.** Under pragmatist epistemology, findings transfer by analytical generalization rather than statistical sampling, and the boundary conditions for transfer must be stated explicitly. Two boundaries apply. The participant profile defines the first: all workshop participants held professional software engineering roles, had used AI coding assistants for at least three months at least weekly, and had reviewed multi-file LLM-generated changes; claims should not be extended to junior developers, infrequent AI tool users, or teams where multi-file LLM-generated changes are not yet routine. The prototype was also presented in a mock JetBrains-style IDE, so reception may differ for reviewers whose primary editor differs. The study period defines the second: the four workshops and the validation survey were conducted within a two-month window, which kept the AI tool environment effectively static

across data collection. Forward-transfer is the more substantive temporal threat: as tool capabilities shift toward more agentic, multi-file, and self-explanatory behavior, the salience of individual constructs (Section 4) may shift with them, with constructs such as *solution plan* and *walk-through* most exposed to absorption by the tools themselves. Recruitment also introduced volunteering bias: participants self-selected in response to a call, likely over-representing developers with positive prior experience with AI coding tools. Similar volunteering bias exists in the validation survey.

**Dependability.** Dependability concerns whether the synthesis process was repeatable and consistent across the research team. Four procedural mitigations operate in the design, each described in Section 3: investigator triangulation through a fourth author who joined only at the convergent phases; pilot workshops approximately one week before each divergent workshop; consensus-based iterative joint coding across all four authors; and member checking of Workshop II problem framings at the opening of Workshop III. The replication package supports dependability by exposing the workshop protocols for inspection (Section 7). The residual risk is that investigator triangulation is partial rather than full: three of the four authors were continuous across phases.

**Confirmability.** Under the pragmatist stance, the researcher's situated judgment is constitutive of how meaning is produced. Confirmability therefore concerns whether artifacts trace back to participant data rather than author preference. Three traceability mitigations operate in the design (Section 3). First, the Workshop II prioritization of eleven problems was constrained by participant-assigned severity and feasibility ratings combined with cluster frequency, not author preference alone. Second, the Workshop III construct-admission rule required constructs to appear in multiple independent participant sketches and in discussion transcripts before admission, a stated rule that can be re-applied. Third, the validation survey filtering procedure (54 of 97 responses removed) is documented with the raw responses. The filter keyed on authenticity signals rather than answer content, so no response was removed for how favorably it rated the prototype: Signals included implausible country/referrer combinations, burst submission timing (e.g., eight responses in three seconds), verbatim text reuse, and leaked LLM prompt instructions. The replication package supports confirmability by exposing the audit trail from raw post-its and sketches to clusters and constructs (Section 7). The residual risk is that re-analysis remains possible but unperformed, and that the response filter is heuristic rather than validated.

## 7 Conclusions

Through a four-phase Double Diamond participatory design study with seventeen practitioners across two co-design workshops (seven of whom returned for the Develop phase) and a follow-up validation survey with forty-three software professionals, our participants converged on *trust-calibration* as the primary obstacle to effective review of LLM-generated multi-file changes ($\mathbf{RQ_1}$). The participants converged on a three-level IDE workflow (overview, file-analysis, and code snippet review) supported by seven design constructs: chunk, risk-per-line, risk-per-file, judge, walk-through, zooming in/out, and security cage ($\mathbf{RQ_2}$). A high-fidelity semi-interactive prototype operationalizing these constructs was rated above the neutral midpoint on every workflow level, and a majority of survey respondents expected reduced review effort (63%) and reduced effort for trust assessment (52%) compared with their existing tooling. The trust-calibration framing challenges the prevailing assumption that

diff-view tooling scales to agent-authored changes; opacity of model confidence and the absence of chunk-level decomposition emerge as distinct, addressable failure modes. The constructs together form a conceptual framework that designers can use to reason about next-generation AI-ready code review tools.

## Data Availability Statement

Research data from this study, including workshop protocols for the Define and Develop workshops, the survey questionnaire, animations showing the prototype, source code for generation of figures and tables, and scanned and transcribed post-it notes and sketches from the workshops are available at `https://doi.org/10.5281/zenodo.20124352`. The replication package is licensed under MIT License and contains a README file with instructions for navigating the data. The high-fidelity semi-interactive prototype contains parts of proprietary software and cannot be shared in source code form.

# When Review Alone No Longer Scales: Layered Supervision in AI-Assisted Software Engineering

**Markus Stolze**
OST Eastern Switzerland University of Applied Sciences, Rapperswil, Switzerland

**Mirco Strässle**
smartive AG, St. Gallen, Switzerland

## Abstract

AI-assisted development tools enable software engineers to generate implementations at substantially higher speed and volume than in traditional workflows. Software teams have long relied on guardrails – standing control mechanisms such as code review, linting, testing, and CI/CD pipelines – to maintain quality and coordination. High-throughput AI-assisted generation increases pressure on these guardrails – straining their capacity to keep pace with the volume and rate of generated changes – and reshapes how organizations supervise development workflows, yet relatively little is known about how existing guardrails evolve in response.

We conducted a qualitative interview study with five software engineering practitioners, situated within a broader practitioner survey. Our findings indicate that organizations distribute the work of supervision across multiple guardrail layers: preventive guardrails (produced by externalizing architectural intent and conventions into machine-interpretable form), executable guardrails (linting, testing, and CI/CD repurposed as scalable supervision infrastructure), and human oversight (shifting from line-by-line inspection toward supervisory interpretation focused on architectural reasoning, explainability, and long-term maintainability). We characterize this as a transition from review-centric guardrails toward *layered supervision*, in which no single guardrail carries the supervision load alone.

## 1 Introduction

AI-assisted development tools enable software engineers to generate implementations at substantially higher speed and volume than in traditional development workflows. By *AI-assisted development tools* we refer to large language model-based coding assistants and agentic development systems – for example, IDE-integrated assistants, chat-based code generation tools, and autonomous coding agents – that generate, modify, or refactor production code based on natural-language or code-context input. Recent advances in such tools have intensified discussions regarding productivity gains, code generation quality, and changing

software engineering practices [14, 19]. At the same time, AI-assisted generation also raises new challenges regarding how generated artifacts are constrained, validated, and supervised within organizational development environments.

Software engineering workflows have long relied on *guardrails* – standing control mechanisms such as code review, linting, testing, CI/CD pipelines, and architectural validation – to support software quality, coordination, and maintainability [10, 16, 7]. AI-assisted generation, however, substantially increases implementation throughput while producing artifacts that may remain difficult to validate contextually despite appearing locally plausible or functionally correct [17]. Organizations therefore face growing pressure to supervise AI-assisted development at scales that cannot rely on downstream human review alone. Throughout, we use *guardrail* for any standing control that constrains or checks generation, whether preventive (e.g., specifications, steering files) or detective (e.g., linting, tests, code review), and whether enacted by automated tooling or by humans, and *supervision* for the overarching function of monitoring and steering generation that these guardrails collectively serve. We adopt this term deliberately over narrower alternatives such as *quality assurance mechanism* or *software testing practice*, which do not naturally extend to preventive, upstream constraints such as specifications or steering files that act before any output exists to test.

While prior research has focused strongly on productivity, developer interaction with coding assistants, and validation of generated code [14, 19, 17], comparatively few studies examine how organizations operationally constrain and supervise AI-assisted software engineering workflows. In particular, relatively little is known about how existing software engineering guardrails evolve in response to high-throughput AI-assisted implementation activity.

To address this gap, we conducted a qualitative interview study with five software engineering practitioners.

## 2 Related Work

### 2.1 AI-Assisted Software Engineering

Early empirical work on AI-assisted coding focused on productivity and developer–tool interaction, including controlled studies of GitHub Copilot [14], qualitative studies of developer validation behavior [17], and broader practitioner studies [19]. More recent industry-scale evidence indicates that AI-assisted development now produces code at a volume incompatible with exhaustive human inspection: the 2025 DORA report finds approximately 90% developer adoption and frames AI as a multiplier of existing engineering capability rather than a standalone productivity intervention [5], while a large-scale study of 302,600 AI-attributed commits across 6,299 GitHub repositories reports that AI-introduced quality issues persist and accumulate as technical debt [12]. Studies of agentic coding tools document mixed effects and call explicitly for provenance, supervision, and selective deployment [1], while complementary qualitative work surfaces practitioner concerns about trust and governance in agentic workflows [18]. These quality-risk findings are not unanimous, however: a preregistered two-phase experiment with 151 professional developers found no significant difference in subsequent maintainability – measured by independent developers evolving the resulting code – between AI-assisted and unassisted contributions [3], suggesting that downstream quality effects depend on task and context rather than being a uniform property of AI assistance. Our study characterizes how organizations operationally respond to these pressures.

## 2.2 Externalized Constraints and Executable Governance

Software engineering has long relied on linting, testing, CI/CD pipelines, and architectural validation to support quality and coordination [10, 16]. A complementary thread examines the externalization of organizational and architectural intent into machine-interpretable form. Foalem et al. provide the first large-scale empirical study of Policy-as-Code adoption across 399 open-source repositories [7], and practitioner-oriented work on architectural fitness functions and architecture-as-code similarly emphasizes a shift from governance-by-inspection toward governance-by-rule [8]. In AI-assisted development specifically, recent work examines developer-provided context artifacts such as AGENTS.md files, Cursor rules, and structured specification files as configuration substrates for agentic tools [9] – the same authors have since retitled a later revision of this study *Harness Engineering for Agentic AI Coding Tools* (arXiv:2602.14690), converging with practitioner discourse that treats a coding agent's harness, everything beyond the model itself, as an attempt to "externalise and make explicit what human developer experience brings to the table" [2], a formulation that closely echoes our own use of externalization for the preventive and executable guardrail layers below. Osmani situates this harness one layer below what he terms loop engineering, the design of automated, self-triggering agent cycles operating with reduced moment-to-moment human involvement [13]; our third layer, human oversight, addresses precisely the coordination question this raises as agentic workflows move toward such loops. Our study examines how such externalized constraints proactively guide AI-assisted generation upstream of review.

## 2.3 Human Oversight of AI-Assisted Development

A growing literature examines developer trust, automation bias, and oversight behavior in AI-assisted workflows. Qualitative studies report that developers often over-trust AI suggestions and may reduce vigilance when code appears plausible, particularly with respect to security [11]. Broader work on human oversight of AI systems, including Article 14 of the EU AI Act, distinguishes monitoring, interpretation, and intervention as separable oversight functions [6]. Our findings contribute to this discussion by characterizing how oversight in AI-assisted software engineering shifts from post-hoc inspection toward supervisory interpretation focused on architectural reasoning, contextual appropriateness, and long-term maintainability.

# 3 Methodology

## 3.1 Study Design and Data Collection

This study employed an exploratory qualitative interview approach to investigate how software engineering practitioners concretely constrain, supervise, and govern AI-assisted development workflows. Semi-structured interviews focused on AI-assisted coding workflows, code review practices, externalization, executable guardrails, and human oversight.

## 3.2 Participants

We conducted semi-structured interviews with five practitioners selected from a broader practitioner survey (Section 3.3), intentionally including a mix of roles (engineers, architects, technical leads, engineering managers) and organizational contexts (small product companies, large enterprises, agencies, industrial firms). Table 1 summarizes the participants; we refer to them as P1–P5 throughout. The interviews were intended to provide in-depth insight into emerging supervision practices rather than statistically representative coverage.

**Table 1** Interview participants and organizational contexts. Team size and governance posture are reported from each participant's survey response.

| ID | Role | Domain | Team size | Governance posture |
|---|---|---|---|---|
| P1 | Software Architect / CTO | Enterprise software | Small (2–9) | Informal, AI-recommended |
| P2 | Staff Engineering Manager | Energy utility frontend | Large (10+) | Clear guidelines |
| P3 | Engineering Team Lead | Construction software | Large (10+) | Clear guidelines |
| P4 | Senior Frontend Engineer | Digital agency | Small (2–9) | Informal arrangements |
| P5 | Senior UI Engineer | Industrial technology | Small (2–9) | No explicit rules |

## 3.3 Survey Context

To situate the interview findings, we draw on aggregate responses from a survey conducted in November–December 2025 within our institution's computer science alumni network. The survey was co-developed by the first author and a colleague based on practical experience with AI-assisted tools, reviewed by one external practitioner for clarity, but not formally piloted. Approximately 100 alumni were personally invited; 50 completed the survey. Respondents were predominantly senior software engineers (16/50) and technical leads or architects (26/50), working mostly in small teams of 2–9 (34/50). Because the survey relied on convenience sampling and an unpiloted instrument, we do not interpret its aggregate responses as inferential evidence; we use them to provide indicative context for the qualitative findings.

## 3.4 Data Analysis

The interview material was analyzed using an iterative thematic analysis approach following the six-phase framework of Braun and Clarke [4]. Analysis began with close reading of interview transcripts and follow-up email responses, followed by open coding focused on recurring practices, tensions, supervision mechanisms, and organizational responses. Codes were iteratively refined into a scheme of six top-level categories (reconfiguration of validation, transformation of code review, understanding and explainability, guardrails and AI control mechanisms, context and maturity, and risks and failure modes), with three to eleven subcodes each; the full scheme is available in the supplementary material. Findings were continuously mapped back to supporting interview excerpts to strengthen traceability.

### AI-supported analysis

The analysis was conducted by a single researcher (the first author), with ChatGPT used under researcher direction for auxiliary tasks: translation of German excerpts into English analytical paraphrases, surfacing recurring phrasing to support code consolidation, and drafting preliminary thematic summaries. All coding decisions, theme construction, evidence-to-theme mapping, and quote selection were made and verified by the researcher against the original transcripts. For the camera-ready revision, Claude (Anthropic) was used under the same direction to re-verify all directly quoted material against the original transcripts and correct several participant-attribution errors this process identified; all resulting changes were reviewed and approved by the first author.

### Member-checking session

After the initial round of coding and thematic synthesis, we conducted a structured member-checking session with four of the five interview participants (P1, P2, P4, P5; P3 was unavailable) in late March 2026, in which preliminary findings were presented and discussed. Participants confirmed, qualified, or contradicted specific claims, and contributed additional examples and clarifications. The session was audio-recorded and transcribed with participant consent. Material from the session was incorporated into the final analysis: in particular, several illustrative examples and reframings reported in Section 4 and Section 5.5 originate from the member-checking session rather than from the original interviews.

### Limitations of the analytical approach

Single-coder qualitative analysis without independent inter-rater reliability assessment introduces interpretive risk, which we partly mitigated through iterative refinement, written follow-up clarifications with each participant, and the member-checking session described above. We further discuss the limitations of the study, including sample size and the situated nature of the findings, in Section 5.7.

## 4 Findings

We report findings as five themes (F1–F5). Each quoted phrase is attributed to its participant; "participants" is reserved for statements supported by all five.

### 4.1 F1: Review-centric guardrails no longer scale, and specification quality becomes consequential

Participants consistently described AI-assisted development as substantially accelerating implementation while leaving review and validation constrained by human contextual reasoning. As P2 emphasized, code writing has become *"very cheap"* [P2] under AI-assisted development, with *"the bottleneck clearly moving to review"* [P2]. P1 quantified this concretely: manual review of an AI-assisted one-shot implementation typically takes *"three to four times as long"* [P1] as the generation itself (Section 4.2) – a ratio between the review and generation phases of the AI-assisted workflow, not a before/after-AI comparison. P1, P2, P4, and P5 described AI-assisted development as intensifying rather than reducing pressure on review-centric practices. For context, code quality and long-term maintainability were the most frequently selected risks in the survey (43 and 40 of 50 respondents respectively).

P1 observed that what has changed is not the existence of upstream specification work, which experienced teams have long invested in [8], but its *consequentiality*: specification quality now propagates directly into generated code, with weak input producing weak output that LLMs do not push back against the way an experienced engineer would. This makes upstream effort more consequential, not merely more abundant.

A recurring concern involved generated solutions that appeared correct at first glance while remaining difficult to validate contextually – a phenomenon we refer to as *false correctness*. P2, P4, and P5 described generated artifacts as syntactically correct and locally coherent, yet problematic regarding architectural consistency, explainability, or long-term maintainability. P2 reported being unable to change parts of a system because he could no longer trace *"why they are now where they are"* [P2], and P5 summarized the pattern in words he had already used in his own written survey response before the interview: *"functionally correct,*

*but nobody understands why"* [P5]. False correctness shifted the burden of validation away from behavioral testing toward reasoning about architectural intent, contextual consistency, explainability, and long-term maintainability.

## 4.2 F2: Teams externalize implicit context into upstream guardrails

P4 and P5 described existing repositories, documentation, and architectural guidelines as often insufficient for AI-assisted generation: AI systems inferred incomplete, outdated, or locally plausible patterns without reliably capturing intended architectural direction. P5 further noted that different artifacts and implementation signals could contradict each other or evolve independently, creating ambiguity about authoritative guidance.

In response, participants described externalizing contextual intent more explicitly before generation. P1 estimated that *"two thirds of the time go into specification refinement"* [P1], and P4 confirmed a similar shift in his own team: substantially longer architectural planning at the start of a task, with correspondingly shorter time spent actually writing code [P4]. These practices also appeared selectively in the survey: 13/50 respondents reported using steering files such as `.cursor/config` or `claude.md`, and 6/50 reported structured prompt workflows (Requirements → Design → Tasks) – suggesting that externalization practices are emerging but not yet widespread.

P4 emphasized that once a recurring constraint was identified, it had to be handed off to automatic enforcement: *"If a rule is relevant, it must be enforced through linting"* [P4] – the point at which externalization (identifying and formalizing the constraint) meets executable guardrails (Section 4.3). P1 additionally described orchestration sub-agents that monitor for drift during generation (discussed further in Section 5.6). These practices convert tacit knowledge into reusable *preventive* guardrails that shape generation upstream, rather than only *detective* guardrails that catch problems downstream. P4 and P5 noted important limits, however: not all architectural assumptions or organizational conventions can be formalized in advance, which is why teams complemented these upstream guardrails with executable ones embedded in the build (Section 4.3).

## 4.3 F3: Executable guardrails expand in importance

P1, P2, P4, and P5 described linting, unit testing, CI/CD pipelines, and automated validation as increasingly critical guardrails for AI-assisted workflows. P1 and P2 reported extending existing executable enforcement with additional checks detecting architectural violations, code duplication, dependency misuse, and deviations from organizational implementation constraints. P2 and P4 described how such executable enforcement made the build system itself the arbiter: violations of encoded rules would break the build rather than being caught by human reviewers. P5 illustrated the deliberate character of this stance in his own monorepo: he consciously chose not to relax automated conventions even though doing so would have been easy – *"as long as I can do it automatically it costs me nothing . . . I really want this convention to be strictly upheld"* [P5]. These executable guardrails were not limited to syntactic correctness but extended toward architectural conformance and organizational implementation policies.

P4 emphasized important limits: contextual interpretation, architectural tradeoff reasoning, and long-term maintainability assessment frequently could not be checked automatically. Executable guardrails thus carried part of the supervision load but did not replace human oversight, reducing recurring review burden while leaving contextual and interpretive assessment unresolved.

## 4.4 F4: Human oversight shifts toward supervisory and operational explainability

Despite increasing reliance on preventive and executable guardrails, participants consistently rejected fully autonomous workflows. P1, P2, and P4 emphasized that AI-generated artifacts continued to require a human guardrail layer in situations involving architectural tradeoffs, contextual ambiguity, or organizational constraints that could not be encoded reliably. As P1 summarized, AI-assisted development was *"no fire-and-forget"* [P1].

P1 described the human guardrail as more supervisory and intervention-oriented: rather than reviewing artifacts only after implementation completion, developers *"observe step-by-step . . . interrupt early"* [P1] when generation diverged from intended direction. Here intervention is an act of supervision triggered when a guardrail – whether an automated drift-detector or the observing developer – surfaces a problem. P4 additionally emphasized that the human guardrail focused on architectural reasoning and long-term maintainability rather than complete line-by-line comprehension. In place of full comprehension, P4 described *operational explainability*: the requirement that generated systems remain diagnosable and reconstructable on demand, supported by abstraction layers, visualization mechanisms, logs, and higher-level interpretive tooling that make the human guardrail effective without line-by-line reading.

The strength of the explainability requirement varied by stakes. P1 noted that organizational tolerance differed sharply by use case: a short-lived UX prototype may not require any line-level developer understanding, whereas a database migration or a feature in a system with strict recovery-time requirements demands precise comprehension of every statement. Operational explainability is therefore not a single threshold but a context-dependent capability calibrated to system criticality and longevity.

P2 and P4 raised concerns about the sustainability of such interpretive oversight, particularly for less experienced developers, a concern recently elevated to a broader profession-level question by Russinovich and Hanselman [15] (see also Section 5.7). Survey responses indicated related concerns: 23/50 respondents wished for targeted support on review standards for AI-generated code, and 15/50 on monitoring and traceability tools.

## 4.5 F5: Guardrail configurations vary along identifiable dimensions

The five participants varied substantially in how they combined the three guardrail layers – preventive guardrails, executable guardrails, and human oversight. We identify three dimensions along which configurations differed: (i) *governance posture* – the presence and formality of organizational AI-tool guidelines; (ii) *system criticality and homogeneity* – the longevity and consistency of the codebase under AI-assisted modification; and (iii) *team composition* – the distribution of senior and less experienced developers and the resulting supervisory capacity. We deliberately avoid the term "maturity" here, since it suggests a linear progression that our data does not support.

Along the governance dimension, P2 and P3 described environments with clear, formal AI-tool guidelines and structured review procedures, whereas P1, P4, and P5 reported predominantly informal arrangements or no explicit rules. Survey responses suggest similar heterogeneity beyond the interview sample: asked how AI-tool use is governed or monitored, 24 of the 50 respondents reported clear organizational guidelines and 23 reported only informal arrangements or no monitoring at all. Asked separately how collaboration had changed, 8 respondents reported that responsibility for AI-assisted code had become more diffuse.

System criticality and homogeneity strongly shaped which mechanisms worked. P1 explicitly framed his team's practices as contingent on a modern, low-legacy, highly conformant codebase, and was explicit that the same mechanisms would likely not transfer to grown legacy systems. P5 correspondingly described legacy repositories as particularly challenging because inconsistent patterns and undocumented assumptions increased ambiguity.

P2 and P5 observed that teams with stronger architectural expertise used executable constraints more extensively. The lower bound is worth naming: teams that adopt AI tools widely without proportionate senior supervisory capacity may accumulate risk not visible from within the team, a concern consistent with broader observations on AI's seniority-biased effects [15].

# 5 Discussion

## 5.1 From Review-Centric to Layered Supervision

Participants responded to the pressures identified in Section 4 by distributing supervision across three guardrail layers: preventive guardrails, executable guardrails, and human oversight. No single layer proved sufficient: preventive guardrails cannot capture all architectural tradeoffs in advance, executable guardrails cannot evaluate contextual appropriateness, and the human guardrail cannot scale to AI-generation throughput.

## 5.2 Pressure Toward Upstream Externalization

Traditional artifacts such as repositories, documentation, and architectural guidelines relied on human interpretation to be useful; in AI-assisted workflows, we read our data as indicating that this interpretive layer is largely absent in the traditional sense – not because AI systems process context without any interpretive mechanism at all (a probabilistic model plausibly performs a form of interpretation of its own), but because the human sense-making step that traditionally connected a written artifact to a considered action is no longer a reliable intermediary. Specification refinement, architectural planning, orchestration workflows, and the preventive guardrails they produce therefore take on a new role: they shape permissible generation trajectories ahead of implementation rather than only documenting decisions already made. Externalization does not eliminate the need for supervision, however: contextual assumptions, architectural tradeoffs, and organizational expectations can only ever be partially formalized, and it is often unclear in advance whether a given level of externalization is sufficient to reliably steer AI-assisted generation.

A natural question is where externalization ends and executable guardrails (Section 4.3) begin, since both act on generation before a human reviews the output. We distinguish the two by mechanism rather than by sequence. Externalization produces preventive guardrails – specifications, steering files, architectural plans – that guide what an AI system generates but are not themselves automatically checked; their effect depends on whether the generation process actually consults them. Executable guardrails, by contrast, are automatically evaluated against generated output regardless of how that output was produced. In practice the two run concurrently rather than as sequential stages: a steering file (a preventive guardrail produced through externalization) encoding a convention and a linting rule enforcing the same convention (an executable guardrail) typically coexist, so that the executable check still catches violations when the steering artifact is outdated, ignored, or absent from a particular generation trajectory. Externalization thus shapes generation *ex ante*; executable guardrails verify it *ex post*, independent of whether the ex-ante shaping succeeded.

## 5.3 What Changes Relative to Pre-LLM Software Engineering Governance

The individual mechanisms participants described – linting, CI/CD-based enforcement, architectural fitness functions, policy-as-code, specification-driven workflows – are not in themselves new. Each has a substantial pre-LLM history in software engineering practice and research [10, 16, 7, 8]. Our findings suggest that what is changing is not the existence of these mechanisms, but their operational role, relative weight, and configuration.

We highlight three shifts. Guardrails move *upstream*: steering files, structured prompts, and specification refinement increasingly act as *preventive* guardrails that guide generation, rather than the field's traditional reliance on *detective* guardrails that inspect finished code (cf. Section 4.2). Executable guardrails are *promoted in priority*: P4 articulated a stance in which any sufficiently relevant rule is treated as a candidate for automatic linting enforcement (Section 4.2), reserving the human guardrail for what cannot be encoded (Section 4.3). Human oversight is *redistributed temporally*: P1 described monitoring generation step by step and intervening early [P1], shifting the human guardrail from post-hoc inspection toward concurrent supervision (Section 4.4). These shifts amplify and reconfigure existing practices under AI-induced throughput and contextual-opacity pressures, rather than replacing them.

## 5.4 Human Oversight Shifts from Inspection to Supervisory Interpretation

The reframing of oversight described in Section 4.4 carries an implication for expertise. Effective supervisory interpretation, abstraction-based assessment, and operational explainability all rest on architectural and contextual judgment that participants framed as in short supply. AI-assisted development may therefore shift professional expertise toward architectural reasoning, contextual interpretation, and supervisory intervention, with corresponding implications for how less experienced developers acquire this expertise – a profession-level question we return to in Section 5.6.

## 5.5 Risk–Productivity Trade-offs in Practice

The adoption of AI-assisted development introduces a tension between productivity gains and emerging validation costs. Participants described faster implementation and reduced effort in code-writing phases as genuine and substantial. As P4 emphasized during the member-checking session, organizations would not currently be investing this level of attention if the productivity gains were marginal – an inference we draw from participants' observed investment of time and organizational effort rather than a claim any participant stated directly in these terms. At the same time, these gains were highly contingent on guardrails. Without sufficient preventive, executable, and human guardrails, the gains were frequently offset by increased review effort, accumulated false correctness, and delayed defect detection.

P2 recounted one such trajectory: in a project where AI-generated changes accumulated over several months without proportionate review capacity, a substantive feature had to be discarded and reimplemented from scratch once its architectural problems became visible. P2 framed this as a failure mode rather than an inherent property of AI-assisted development: *"had this been done without an AI system, we would not have generated so much code . . . maybe we would have noticed earlier"* [P2]. The lesson is not that AI-assisted generation is unsafe, but that productivity gains and validation infrastructure need to be scaled together – an organizational choice rather than a purely technical optimization.

## 5.6 Implications for Software Engineering Practice

The participants' practices suggest several concrete patterns rather than recommendations, since they emerged in specific organizational contexts and require adaptation rather than direct transfer.

### Pattern 1: Promote recurring review findings into linting rules

P4 articulated a stance in which review effort is reserved for what cannot be encoded automatically (quoted in full in Section 4.2); P5 exemplified the operational consequence with the same deliberate strictness: *"I could leave it out – but I consciously chose not to. I really want this convention to be strictly upheld"* [P5]. The pattern is to treat each manually-recurring review concern as a candidate for promotion into an executable check, narrowing manual review toward the genuinely contextual. This aligns with established policy-as-code [7] and architectural fitness-function practice [8], applied as an explicit response to AI-generation throughput.

### Pattern 2: Front-load specification and architectural planning

P1 estimated that *"two thirds of the time go into specification refinement"* [P1], with P4 reporting longer architectural planning at the start of a task and considerably shorter coding time [P4]. Effort that previously sat in implementation has migrated upstream; organizations should budget for this redistribution rather than treating planning as overhead to compress.

### Pattern 3: Use sub-agents for concurrent supervision and independent review

Two complementary mechanisms emerged in P1's team. First, planner sub-agents constrain generation upstream: P1 described using *"three different planner sub-agents"* [P1] whose proposals are ranked by a further agent, with the explicit purpose of detecting when *"an agent has completely drifted"* [P1] from the intended plan – decoupling architectural-conformance checking from post-hoc review by embedding it concurrently with generation.

### Pattern 4: Shift validation toward higher-level abstractions

In some teams, the primary response to AI-generated code volume is not deeper line-by-line inspection but *validation through higher-level artifacts* – architecture plans, visual system overviews, sequence diagrams, and other intermediate representations that make large changes easier to reason about and verify. P4 framed this as particularly important in agency contexts with heterogeneous projects and limited review capacity, where teams shift effort from code-level toward architecture-level validation, sometimes using AI-generated visual overviews to check intended structure, change scope, and system fit during implementation. Returns on tooling that makes architectural state and implementation trajectories *legible at a glance* appear larger than returns on tooling that merely accelerates generation.

### A note on expertise

Across all patterns, effective application appeared to depend on architectural and contextual expertise that participants framed as in short supply (P2, P4). Whether organizations can sustain this expertise as implementation activities become increasingly automated is a broader question beyond the scope of this paper; we refer interested readers to recent profession-level discussions of the issue [15].

## 5.7 Limitations and Future Work

The findings are based on five interviews drawn from a single practitioner survey conducted within an alumni network through convenience sampling and an unpiloted instrument (Section 3.3); the practitioner population over-represents Swiss and Central European contexts, and practices in this space evolve rapidly. The analysis was conducted by a single researcher with AI-supported auxiliary work; we mitigated single-coder risk through iterative refinement, follow-up clarifications, and the member-checking session described in Section 3.4, though no independent inter-rater reliability assessment was performed.

One of the five interview participants (P4) is also a co-author of this paper, contributing the practitioner perspective required by the SEIP track. This dual role creates two distinct risks of bias. First, P4's own statements could have been selected or framed more favorably than other participants' during quote selection and writing. Second, P4's involvement in the project could have reshaped the coding scheme or thematic framing around his own contributions rather than the full dataset. We mitigated the first risk by having the first author verify all quotations attributed to P4 against the original interview and member-checking transcripts independently, without P4's input on selection or wording. We mitigated the second by finalizing the coding scheme and thematic framing before P4 joined as co-author, so that his subsequent contribution was limited to reviewing and co-writing the manuscript rather than to re-deriving the analysis.

The study captures reported practices and perceptions rather than direct longitudinal observation. Future work could complement interview-based findings with ethnographic observations, repository analyses (cf. [12, 1]), or longitudinal studies; cost-economic drivers of AI adoption, identified by participants as primary motivations but outside our analytic scope, also warrant investigation. Due to confidentiality agreements, full interview transcripts cannot be shared; the coding scheme, survey instrument, and anonymized evidence table are openly available in our supplementary Zenodo repository (`https://doi.org/10.5281/zenodo.21611622`).

# 6 Conclusion

AI-assisted development appears not to automate implementation in isolation but to redistribute supervision across the development process. Based on a qualitative interview study with five practitioners and a member-checking session, we identified a transition from review-centric guardrails toward *layered supervision*, in which the supervision function is distributed across three guardrail layers: preventive guardrails, executable guardrails, and human oversight. Existing engineering infrastructure – linting, testing, CI/CD, architectural validation – gains a new role as scalable supervision infrastructure for AI-assisted generation, while the human guardrail shifts from line-by-line inspection toward supervisory interpretation focused on architectural reasoning, explainability, and long-term maintainability.

# Faster Than the Team, Faster Than the Customer: Tool Integration, Collaboration, and Organisational Lag in AI-Assisted RE

**Jan-Philipp Steghöfer**
XITASO GmbH Software & IT Solutions, Augsburg, Germany

## Abstract

The impact of applying generative AI tools to requirements engineering (RE) in industrial practice remains poorly understood. This paper examines how AI-assisted RE tools are used in industrial practice at XITASO, a medium-sized enterprise for high-tech software engineering, and how they reshape workflows, tool integration, and PO–developer relationships. We combine a 2024 company-wide use-case survey with two rounds of semi-structured interviews with eight product owners (POs) in late 2025 and spring 2026, covering an in-house chatbot and seven commercial AI tools. We identify 15 distinct use cases across four categories: product backlog management, tender management, requirements and domain understanding, and document and artifact creation. Three findings emerge. First, the effect of AI on PO–developer interaction is mixed: the prevailing single-user interaction model can substitute for collaborative dialogue, and developers do not always welcome AI-generated artefacts. Second, tool integration – not tool capability – is the binding constraint: where integration is in place, time savings are dramatic; where it is missing, POs fall back on manual workarounds. Third, AI advances faster than the surrounding organisational systems, so its benefits accrue to individual POs while team processes and customer readiness remain the bottleneck. The empirical GenAI-RE literature remains dominated by early-stage, lab-oriented evaluations of isolated tasks while practice has moved into territory it has not yet studied: practitioners are already assembling cross-tool integrations, navigating customer governance, and renegotiating role boundaries. From these patterns we derive a set of questions practitioners considering AI-assisted RE may ask of their own situation.

## 1 Introduction

Product owners and other practitioners are putting AI assistants to work on requirements engineering tasks every day. The tool landscape they face is heterogeneous and moving quickly: in-house GDPR-compliant chatbots, dedicated RE assistants integrated into platforms such as

© Jan-Philipp Steghöfer;
licensed under Creative Commons License CC-BY 4.0

Jira (e.g., Atlassian's Rovo[1]), and general-purpose AI tools wired into the existing toolchain via emerging protocols such as Model Context Protocol (MCP)[2]. What changes when these tools enter daily, multi-stakeholder RE practice is less clear.

While AI-based coding assistants have received substantial empirical attention [7, 32, 1, 30], work on AI-assisted requirements engineering (RE) in industrial practice is comparatively thin. Existing studies focus on isolated tasks in academic or controlled settings [2], on specific techniques [10], or on GenAI adoption in software engineering broadly [22]. RE-specific industrial experience – what tools practitioners actually use, how they wire them into existing toolchains, and what changes in everyday RE work as a result – remains scarce.

In this paper, we examine how AI-assisted RE tools are used in practice at XITASO, a medium-sized enterprise (SME) for high-tech software engineering, and how they affect requirements engineering work over time. The longitudinal nature of the study lets us capture not only what these tools do but also how their use, their integration, and the workflows around them have changed in a comparatively short period.

We follow a qualitative approach combining a 2024 company-wide survey of relevant use cases with two rounds of semi-structured interviews with eight product owners (POs) at XITASO, conducted in late 2025 and spring 2026. Our study covers an in-house chatbot and seven commercial AI tools used for RE, only two of which are specifically designed as RE tools. We also contrast the resulting picture of the state of practice with the current GenAI-RE literature. This tackles our research question:

**RQ** How does AI-assisted requirements engineering impact requirements engineering work in a software development organisation?

The contribution of this paper is threefold: (1) an overview of AI-assisted RE use cases and tools as deployed in industrial practice; (2) empirically grounded findings on how AI-assisted RE tools impact requirements engineering work in a software development organisation, distilled into a set of practitioner-facing questions for self-assessment; and (3) an empirical contrast between this practice and the current state of GenAI-RE research. This work provides industrial evidence for current research efforts on AI-assisted RE.

Three findings emerge. First, the effect of AI on the relationship between POs and developers is mixed: developers may not register the quality improvements POs make, may resist AI-generated artefacts emotionally, and the prevailing single-user dialogue model can substitute AI for the collaborative refinement that gives requirements their meaning. Second, tool integration, not tool capability, is what determines whether AI value is realised. Third, AI is reshaping workflows, role definitions, and patterns of communication faster than the surrounding organisations, including the organisation of the customer, can absorb the change. Together, these findings motivate the title of this paper: AI-assisted product owners are *faster than the team, faster than the customer.*

The remainder of this paper is structured as follows. Section 2 reviews related work; Section 3 describes our research approach; Sections 4 and 5 present use cases and tools; Section 6 presents findings and discusses implications; Section 7 describes the threats to validity and their mitigation; Section 8 closes the paper.

## 2 Related Work

Several recent studies have evaluated LLMs for specific RE tasks. Ronanki et al. [20] investigated ChatGPT's potential for requirements elicitation, finding that it performs well on quality attributes compared to human RE experts. Santos et al. [23] surveyed practitioners about LLM adoption for user story generation, finding that two thirds already use LLMs for RE – primarily for brainstorming and content review, but report concerns about lack of context and over-reliance. Hassani et al. [11] evaluated LLMs for classifying requirements-relevant provisions in regulatory documents, achieving high precision with GPT-4o. However, these studies evaluate isolated tasks in controlled or survey-based settings; our work extends this by studying how AI-assisted RE tools function in daily industrial practice across multiple use cases and within real development workflows.

At the organisational level, several studies examine how software teams adopt GenAI tools. Kemell et al. [12] conduct a multiple case study asking whether GenAI tools have moved beyond personal assistant roles in software organisations. Simaremare and Edison [25] survey experienced practitioners on adoption patterns, benefits, and challenges. Russo [22] examines the complexity of GenAI adoption broadly. Our work narrows the focus to RE specifically and provides longitudinal evidence showing that tools are indeed moving past the personal assistant stage through integrations like MCP, but that this creates new challenges for team collaboration.

For document-intensive RE tasks, Nai et al. [17] demonstrate LLMs' potential for analysing public procurement documents, the same problem domain addressed in our study. On the human-AI interaction side, two strands of work frame how we read our data. Seeber et al. [24] sketch a research agenda for AI as a teammate, arguing that integrating AI into team workflows changes the nature of the team itself. Webber [31] examines the paradox of AI as teammate, arguing that AI can simultaneously improve individual efficiency while undermining team dynamics. Storey [27] more recently introduces a triple debt model. It contains *cognitive debt*, the team-level erosion of shared understanding as AI-generated artefacts accumulate faster than the team can build a common mental model, often manifesting as a loss of "transactive memory" in which team members lose track of who knows what and increasingly rely on individual interactions with AI rather than shared practices. It also contains *intent debt*, the absence or erosion of explicit rationale, goals, and constraints that humans and AI agents need to evolve software safely. Our findings provide empirical evidence for cognitive debt in the RE domain: improved tool integration reduces the need for developer involvement, potentially deepening the collaboration gap rather than bridging it as the team loses the conversational context behind AI-generated artefacts, and the workflows and roles around AI use are absorbing change more slowly than AI itself is being adopted.

## 3 Methodology

Following the criteria of Wohlin and Rainer [33], our study is best characterised as a qualitative interview study with a survey as a starting point, rather than a case study, since it lacks strong data triangulation of data sources. We follow the empirical standards for software engineering research [19], in particular the guidelines for interview studies.

### Case Description

XITASO is a medium-sized software engineering service provider founded in 2011. In early 2026, it has 240 employees across nine offices in Germany and three in Spain with its headquarter in Augsburg, Germany. It offers high-end software engineering services to

customers mainly in the machinery and production engineering (50% of revenue), medical devices (30% of revenue), and public sector (10% of revenue), with other customers in insurance, energy, and elsewhere. It is a network organisation, meaning that there are no strict reporting hierarchies and the nucleus of most decisions, including who can go on vacation when, is the team. Cross-cutting concerns are captured in communities of practice, of which there are over 30, including technical communities for topics such as AI, software engineering, and user experience, as well as communities focused on shared services, such as the office environment, personnel development, or finances.

Development teams consist of 5 to 15 people, with the median around 7 people. These teams usually consist of one PO, one Scrum Master, and several developers, with support from AI engineers, security engineers, or user experience experts where warranted. One team usually works on one customer project at a time; this rule is sometimes broken for short projects that last less than 8 weeks. Rather than creating new teams for such short projects, a second or sometimes a third project is tackled by an established large team with free capacity. Teams are usually formed based on domain experience of the personnel or specific technical abilities or certifications. For instance, there are teams that have specific experience in robotics which are kept together.

All development teams work in close collaboration with customers on requirements engineering as part of agile development projects. Most projects are "time and material" with a certain budget which means that the outcome of the project is shaped in an ongoing discussion with the customer.

### Data Collection

Our study followed a three-phase data-collection design: an initial survey, followed by two rounds of semi-structured interviews at different points in time. Analysis was conducted iteratively across all three phases (see Figure 1 for an overview).

Between April and July of 2024, we conducted a *company-wide survey* across XITASO's communities of practice to identify relevant use cases for AI assistance. Each community was asked to fill in a use case template on a wiki page. The template contained three questions to answer: "What's your pain point?", "How can GenAI address it?", and "Which tools do you know that could help?". The communities of practice discussed the use cases in their internal meetings and updated the wiki page directly. In total, we collected 20 use cases from 11 communities. A committee of four subject matter experts from the company then selected the two use-case categories with the strongest relation to requirements engineering activities and the highest potential time savings and task complexity as criteria; these two categories (Product Backlog Management and Tender Management) were subsequently refined into 15 more fine-grained use cases through the interviews (see Section 4). To address these initial categories, we identified several commercially available and in-house AI-assisted RE tools and evaluated their adoption across the company (see Section 5).

We subsequently conducted *semi-structured interviews with eight product owners* at XITASO who had hands-on experience with the deployed AI-assisted RE tools in their daily work. This constitutes purposive sampling: we interviewed those eight out of the 17 product owners who were actively using AI based on recommendations by their peers and who have significant experience as POs of at least five years. Their characteristics are shown in Table 1. The experience requirement serves as a control to ensure that POs have a foundation to understand the impact of AI tools on their daily work and on collaborative workflows. POs that do not use AI do not necessarily do that out of personal preference: some of our customers expressly forbid the use of AI or limit the available tools severely.

**Table 1** Characteristics of interviewed product owners.

| ID | Exp. | Domain | Team Sz. | Tool(s) Used | Usage |
|---|---|---|---|---|---|
| P1 | 5 yrs. | Machinery | ∼ 10 | ChatXiPT, Product Copilot, Claude Desktop | 8 mts. |
| P2 | 7 yrs. | Medical Technology, Healthcare | ∼ 15 | ChatXiPT, Product Copilot | >2 yrs. |
| P3 | 10 yrs. | Machinery | 5 | ChatXiPT, Product Copilot | >2 yrs. |
| P4 | 5 yrs. | Public Sector, Healthcare | 3–8 | ChatXiPT, Product Copilot, TenderZen | >2 yrs. |
| P5 | 5 yrs. | Public Sector | ∼ 15 | ChatXiPT, Product Copilot, Claude Desktop | 1 yr. |
| P6 | 10 yrs. | Insurance | ∼ 13 | MS Copilot, ChatXiPT | 2 yrs. |
| P7 | 18 yrs. | Ecommerce, Machinery | 5–8 | ChatXiPT, Claude Code | 1 yr |
| P8 | 8 yrs. | Public Sector | 7 | ChatXiPT, MS Copilot, TenderZen | >2 yrs. |

The interviews were conducted in two phases: the first five were conducted in December 2025 and January 2026, three more in April 2026. This allows us to also introduce a longitudinal perspective and track how the use of AI tools has changed during that period of time. Both sets of interviews were conducted using the same interview guide which is available in the supplementary material [26]. All interviews were conducted online and recorded. The language was German. The interviewer took extensive notes in German that were validated and completed based on the recordings.

The interviews were conducted by the author, who has over ten years of experience in empirical software engineering research, with a focus on requirements engineering, agile software development, and model-driven engineering. Originally holding an academic position, the author now works in industry as Head of Research and Innovation at the organisation in which this study was conducted. The author is therefore a partial insider: the participants are colleagues within the same organisation, though from different teams and without a day-to-day working relationship. This insider position offered advantages, including domain familiarity, shared vocabulary, and established trust, but also introduced potential risks. In particular, the author's senior organisational role may have influenced participants' willingness to share critical or dissenting views, despite assurances of confidentiality.

To mitigate these risks, the following measures were taken: Confidentiality was explicitly assured to all participants prior to the interview, and all findings reported in this paper are anonymised so that no response can be attributed to an individual. Member checking was conducted, allowing participants to review and validate the interpretations drawn from their responses. An LLM-assisted review of the coded findings was performed as an additional analytical check, to surface potential blind spots or inconsistencies in interpretation that may have stemmed from the author's familiarity with the context.

## Data Analysis

We extracted individual data points about tool usage, perceived limitations, and opportunities from the interview notes. Where necessary, data points were translated into English using DeepL Pro and collected on an online whiteboard. We combined initial structural coding [18] based on the interview guide with thematic analysis [3]. Each data point was recorded as a

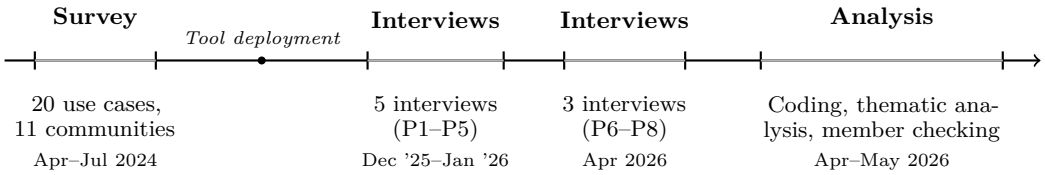

**Figure 1** Overview of the research approach and timeline.

card; cards addressing the same topic but distinct points were connected, with codes added as labels. Sticky notes denoted specific use cases. We used Claude Sonnet 4.6 to derive coding guidelines and identify inconsistencies, which were manually reviewed and resolved over several iterations. We employed member checking [14] to validate the data: interview summaries were sent to participants, who later also had the opportunity to review the main findings and provide feedback.

The creation of this paper was supported by AI. Claude Sonnet 4.6 and Claude Opus 4.6 were used to critique drafts of the manuscript, brainstorm ways to present this work and frame the research questions, summarize literature, and for editorial work. In addition, Claude Opus 4.6 was used to validate the coding and the derived findings based on the notes and it created some of the text passages in this work. All AI-assisted outputs were critically reviewed, validated, and revised by the author. The author retains full responsibility for the research design, analytical decisions, interpretations, and conclusions.

## 4 Use Cases for AI-assisted Requirements Engineering

Based on the survey, we initially identified two main areas for AI-assisted RE at XITASO: *Product Backlog Management* and *Tender Management*. The interviews revealed each to be a whole category of fine-grained use cases, and uncovered two further categories: *Requirements & Domain Understanding* and *Document & Artifact Creation*. In total, we identified 15 use cases across these four categories. Table 2 provides the complete mapping with participants. Below, we focus on the most widely practised and analytically consequential use cases.

### Product Backlog Management

Product backlog management is a major task of our POs. Writing high-quality user stories in rapidly changing projects is difficult, as is editing user stories or bug reports authored by other team members or the customer. Backlog maintenance and cleanup consume considerable time, while identifying and linking relevant items remains a persistent challenge. A clean backlog with well-defined backlog items is, however, essential for good planning and to enable developers to work productively [16].

*Backlog Refinement* is the most widely practised use case, mentioned by seven of eight POs. GenAI tools support a range of cleanup and enrichment tasks: splitting epics, finding duplicates, adding or improving acceptance criteria, and identifying missing edge cases or gaps in individual PBIs. Notably, prioritisation and effort estimation are exceptions: current tools handle neither reliably, and POs continue to do these manually. Tools draw on project-specific knowledge to propose standardised acceptance criteria phrases, flag stories missing critical information, and detect dependencies. At XITASO, Product Copilot, ChatXiPT, and MS Copilot are all used for this purpose – the former two for Jira-based projects (P1, P2, P3, P5, P8), and MS Copilot for an Azure DevOps-based project (P6).

A newer practice, which we categorize as *implementation-aware* Backlog Refinement (P7), goes beyond standard backlog refinement. P7 uses Claude Code, connected via MCP server to the project's Jira board and source code repository (see Section 5), to elaborate tickets in the full context of the codebase. The PO converses with the AI to: (1) define technical constraints informed by the actual architecture, (2) assess the feasibility of requirements against the current implementation, and (3) draft acceptance criteria reflecting real system behaviour. Rather than merely structuring requirements, the AI provides technical context previously accessible only through developer conversations. This allows the PO to ask "is this requirement feasible given our current architecture?" without waiting for a refinement session. This blurs the boundary between requirements engineering and implementation, with direct consequences for collaboration patterns (see Section 6). P3 expressed a closely related desire in late 2025: "I would like to connect my LLM to a "staging area" to better understand a requirement."

*Story Authoring* (P2, P3, P5, P6) and *Backlog Bootstrapping* (P1, P2, P3, P8) both address the creation of backlog items. In Story Authoring, POs use Product Copilot or ChatXiPT to generate individual PBIs from notes or prose, filling in templates, suggesting acceptance criteria, and surfacing CRUD and validation scenarios. Backlog Bootstrapping goes further: given bulk input such as an Excel spreadsheet, screenshots, or a specification document, Product Copilot generates a large set of PBIs in one step – with multiple participants noting dramatic time savings over manual creation. *Backlog Search* (P2; aspirational for P6) is currently a niche case, enabling semantically relevant stories to be retrieved for a given query, e.g., to assess the impact of an architectural decision across the backlog.

### Tender Management

Screening tender documents and extracting relevant information requires significant resources. POs must make rapid bid/no-bid decisions, extract requirements to estimate effort and price, and identify suitable reference projects and personnel profiles. At XITASO, tender management follows a four-stage pipeline, used primarily by P4 and P8.

*Tender Discovery*: TenderZen agents search tender portals, upload documents, and pre-filter results based on fit with company capabilities and desired areas of work, reducing the manual effort of identifying relevant opportunities (P4, P8).

*Tender Analysis* is the central stage of the pipeline. TenderZen ingests a tender document and extracts requirements, deliverables, and quality criteria into a structured form, while identifying gaps between tender requirements and company capabilities. Rather than manually searching the documents, POs can query the content interactively via chat or pre-defined templates to efficiently retrieve critical information such as tender volume, submission deadlines, or required documentation. ChatXiPT and MS Copilot are also used for targeted document queries. A known limitation flagged by P8 is that TenderZen's analyses do not reference original data sources, complicating verification of extracted content.

*Reference Matching* (P8) uses TenderZen and Rovo to find past projects and personnel profiles in Confluence that match the requirements of a given tender, and to adapt reference descriptions to the tender context. The handoff between Rovo and TenderZen is currently manual (see Section 6).

*Bid Authoring* (P4, P8) closes the pipeline. ChatXiPT and MS Copilot are used to draft and optimise bid concepts and proposals; POs find AI more effective for reviewing and optimising existing content than for creating bids from scratch. Product Copilot fulfils a more specific role: it translates the requirements extracted during Tender Analysis into a product backlog (an instance of the *Backlog Bootstrapping* use case described above), which is then refined and estimated using the standard backlog-management workflow.

### Document and Artifact Creation

*UI Prototyping* (P1, P3, P5) is the primary use case of this category. Rapid prototyping of parts of user interfaces supports understanding the solution space for a requirement as well as gathering early feedback from customers. Simple, clickable UIs make it possible to test whether a workflow is feasible, whether all data is available, and how interface elements need to be laid out – providing a concrete artifact to discuss rather than an abstract description spread across several user stories. Chatbots expose this capability through *artifacts*: interactive HTML prototypes generated from prompts and viewable directly in the chat window. Providing an example of the current design language – e.g., as a screenshot – allows the AI to style the prototype accordingly, and modifications to the artifact are reflected immediately in the requirements. POs can prototype live during customer discussions or backlog grooming sessions. Our POs initially used Claude Desktop for this purpose; since February 2026 this feature is also available in ChatXiPT.

The remaining use cases in this category are practised by fewer participants. *Document Creation & Optimisation* (P1, P3, P8) covers drafting, converting, and polishing documents and presentations, as well as extracting requirements into structured formats such as Excel. P1 and P3 use ChatXiPT for this purpose; P8 also uses MS Copilot for tasks tied to the Microsoft 365 environment. *Documentation Generation* (P5) derives user-friendly product descriptions from requirements and code; P5 uses Claude Desktop, having tested Scribe and found it inferior. *Change Summarisation* (P5, P6, P7) is currently a desired rather than an established practice: P5 tested Product Copilot for summarising product changes and ticket discussions in support of prioritisation and onboarding, but found it not viable.

### Requirements and Domain Understanding

*Vision & Roadmap Derivation* (P2, P7) addresses a challenge that arises early in product development: arriving at a shared, articulate product vision before detailed requirements exist [5]. P2 uses ChatXiPT and Product Copilot to derive a product vision, target audience, and added value from existing artefacts such as a Jira board, wiki pages, or a requirements document. The resulting vision statement serves as a starting point for solution concepts and customer discussions. P7 uses a similar approach to define how the product vision should evolve over time. This use case is particularly valuable in early project phases where the direction is still being negotiated.

*Domain Exploration* (P3, P6, P7) uses ChatXiPT and MS Copilot as a faster alternative to traditional search for understanding domain terminology, evaluating technology options, and brainstorming solution approaches – effectively accelerating the contextualisation that precedes requirements work. *Interview & Meeting Analysis* is used by P7 via Curly, an AI-powered interview bot that conducts structured stakeholder interviews, transcribes responses, and summarises findings by question; P3 expressed this as a strong future desire. POs note a split in stakeholder acceptance: technically experienced interviewees embrace AI-mediated interviews, while others are hesitant.

## 5 Tooling for AI-assisted Requirements Engineering at XITASO

Several distinct AI tools surfaced as part of RE practice across the eight POs we interviewed. They divide into two broad groups: *dedicated RE tools* built specifically for backlog or tender management (Product Copilot, TenderZen), and *general-purpose AI tools* applied to RE tasks (ChatXiPT, Claude Code, Claude Desktop, MS Copilot, Curly, Rovo). ChatXiPT is

**Table 2** Mapping of use cases to AI-assisted RE tools at XITASO. The * indicates a desired use case, † that a tool was experimented with but not adopted.

| Use Case | Tool(s) | Key Capability | Part. |
|---|---|---|---|
| **Product Backlog Management** | | | |
| Story Authoring | Product Copilot, ChatXiPT, MS Copilot | Fill in story templates from notes or prose; suggest acceptance criteria, validation, and CRUD operations | P2, P3, P5, P6 |
| Backlog Bootstrapping | Product Copilot | Generate multiple PBIs from Excel or specification documents in bulk | P1, P2, P3, P8 |
| Backlog Refinement | Product Copilot, MS Copilot, ChatXiPT, Claude Code | Sort, prioritize, split backlog items; find duplicates; add acceptance criteria; identify gaps | P1, P2, P3, P5, P6, P7, P8 |
| Backlog Search | Product Copilot | Semantically query a backlog to find stories relevant to a given topic or architectural decision | P2, P6* |
| **Tender Management** | | | |
| Tender Discovery | TenderZen | Search tender portals, upload documents, and pre-filter based on fit | P4, P8 |
| Tender Analysis | TenderZen, ChatXiPT, MS Copilot | Extract requirements, deliverables, and quality criteria from tender documents; identify capability gaps | P4, P8 |
| Reference Matching | TenderZen, Rovo | Match tender requirements to existing reference projects and personnel profiles stored in Confluence | P8 |
| Bid Authoring | ChatXiPT, Product Copilot, MS Copilot | Develop and optimize bid concepts and proposals; review against previous bid feedback | P4, P8 |
| **Document and Artifact Creation** | | | |
| Document Creation & Optimization | ChatXiPT, MS Copilot | Draft, convert, optimize documents; extract requirements into structured formats such as Excel | P1, P3, P8 |
| UI Prototyping | Claude Desktop | Generate interactive UI prototypes from screenshots or specifications | P1, P3, P5 |
| Documentation Generation | Claude Desktop | Derive user-friendly product descriptions from requirements and code | P5 |
| Change Summarization | Product Copilot† | Summarize product changes and ticket discussions to support prioritization and onboarding | P5*, P6*, P7* |
| **Requirements and Domain Understanding** | | | |
| Domain Exploration | ChatXiPT, MS Copilot | Research domain terminology, evaluate technology options, and brainstorm solution approaches | P3, P6, P7 |
| Interview & Meeting Analysis | Curly | Conduct structured stakeholder interviews; transcribe, summarize, and build knowledge graphs | P3*, P7 |
| Vision & Roadmap Derivation | ChatXiPT, Product Copilot | Extract product vision, target audience, and added value from artifacts | P2, P7 |

an in-house development built on an open-source platform; all other tools are commercially available. Table 2 provides the full mapping of tools to use cases. All descriptions are a snapshot at the time of writing.

### ChatXiPT

We use our own GDPR-conformant chatbot based on LibreChat[3] which provides access to different frontier models, including GPT-5 and Claude Sonnet. It has been first deployed and released to the company in September 2023. All eight POs we interviewed use this chatbot for tasks that require little context: refining user stories, brainstorming new features, and validating the technical viability of an idea. These tasks can be done in the conversational interface after copying and pasting a limited amount of data. The LLM partially replaces a human colleague and allows the PO to get feedback – in particular with prompting to ensure that the LLM is critical and provides constructive feedback. Since February 2026, ChatXiPT also creates user interface prototypes for a set of requirements to collect rapid feedback from customers (see Section 4), which made Claude Desktop for the same purpose obsolete.

We extended LibreChat with a custom RAG pipeline to analyse complex documents and integrate their content into the responses of the LLM. This feature is used by our POs to analyse complex technical documentation and derive requirements from them. One example of such technical documentation are the documents that are part of public tenders, but this work has been replaced by TenderZen (see below) which offers a more structured interface for that use case.

### Product Copilot

Product Copilot[4] is an AI assistant integrated into Jira that supports POs in creating and refining backlog items. The tool draws on the existing backlog, wiki pages, a product description, and user-maintained history as context, ensuring that generated backlog items are based on existing project information. It is possible to tailor the writing style and use existing templates to fit a project's conventions. A browser plugin integration avoids manual copying of text between tools. Product Copilot has been used in different projects at XITASO since July 2025.

Five POs (P1–P5) appreciate the tool for filling in details like personas and acceptance criteria, but find it most valuable for less experienced POs. Product Copilot can derive requirements from screenshots or text files, and structure large requirements into epics. It identifies ambiguous backlog items and missing elements, which are less critical in mature teams. Some POs prefer chatting in a colloquial tone and having the tool formalise their input into a well-structured backlog item, while experienced POs often feel they can write better stories directly. The tool also extracts condensed artefacts such as a product vision or the main target audiences from the backlog (see *Vision & Roadmap Derivation* in Section 4), which helps POs communicate with customers and validate the backlog.

### TenderZen

TenderZen[5] is an AI-powered tender management platform that searches procurement platforms across Europe and Germany, including local and municipal sources. The tool supports keyword and profile-based searches and provides analysis features for tender documents

[3] https://www.librechat.ai/
[4] https://product-copilot.ai/
[5] https://www.tenderzen.de/en

uploaded as ZIP files, generating reports that extract core requirements, technical and quality criteria, and candidate reference projects from company profiles. Analyses are shared across users of the platform. Custom chat sessions allow POs to query additional information from the extracted content. The platform supports matching manually uploaded employee profiles to tender requirements. TenderZen has been in use at XITASO since September 2025.

At XITASO, the tender team (P4 and P8) processes approximately 30 tenders daily, spending about one hour on pre-selection and 1.5–2 hours examining 3–5 tenders in detail; a complex tender can consist of up to 30 documents of 20–30 pages each. TenderZen has reduced the evaluation time for a single tender from four hours to 30 minutes. References must currently be uploaded manually, with API integration planned. P8 notes that TenderZen does not reference the underlying source material in its analyses, which complicates verification of extracted content.

### Claude Code

Among the general-purpose tools, one PO (P7) has adopted Claude Code as a deeply integrated RE assistant, as described in Section 4. Claude Code uses MCP (Model Context Protocol)[6] to connect to the project's Jira board and source code repository simultaneously. Unlike Product Copilot's browser plugin or ChatXiPT's copy-paste workflow, this integration gives the AI direct access to both the requirements artefact and the codebase. This pattern emerged in the second round of interviews (April 2026) and was absent in the first round (December 2025/January 2026), illustrating how rapidly both tool capabilities (vendor MCP support) and practitioner skills (configuring these integrations) are evolving. Claude Code has been in use at XITASO since February 2026.

### Claude Desktop

Claude Desktop (Anthropic) was used by P1 and P5 as a standalone AI assistant for exploratory and creative RE tasks. Unlike Claude Code, it has no integration with the project toolchain. Its primary application has been UI prototyping and brainstorming. Since ChatXiPT gained UI artifact generation in February 2026, Claude Desktop's role at XITASO has diminished.

### MS Copilot

Microsoft Copilot is used in two distinct contexts at XITASO. P8 uses it for office tasks: drafting and optimising proposals, presentations, and other documents in the Microsoft 365 environment, as well as converting requirements into structured Excel formats. P6 uses MS Copilot in the Microsoft 365 environment as well, alongside ChatXiPT, for tasks such as document drafting, requirement extraction, and domain onboarding. However, the customer P6 works for has not enabled MS Copilot's integration with Azure DevOps, which is the backlog system in this project. Because Product Copilot is Jira-focused and likewise does not apply to ADO, P6 has no AI tool that operates directly on the backlog – a missing integration the PO repeatedly identified as a source of friction.

[6] MCP is an open protocol that enables AI assistants to connect to external tools and data sources such as issue trackers, code repositories, and documentation systems.

### Curly

Curly[7] is a voice- and text-based AI interview bot used by P7 for structured stakeholder elicitation at scale. The PO defines a questionnaire and sets the probing depth; Curly then conducts the interview, transcribes responses, and summarises findings by question, enabling requirements to be gathered from many stakeholders simultaneously (see *Interview & Meeting Analysis* in Section 4). Acceptance is split: technically experienced interviewees engage readily with AI-mediated interviews, while others are hesitant, limiting the current reach of the approach.

### Rovo

Atlassian Rovo is an AI-powered knowledge search and content management tool integrated into Confluence. P8 uses it to find and adapt reference project descriptions stored in Confluence in support of the *Reference Matching* use case (see Section 4): Rovo retrieves past project descriptions that match the requirements of a given tender, which are then adapted for the bid. Its scope is limited to content in the Atlassian ecosystem.

### Other tools

Two further tools appeared in peripheral roles. *Scribe* was tested by P5 for creating manuals and visualising user flows but was found inferior to Claude Desktop for this purpose and is not in active use. *Figma Make* was used by a developer at P7's direction to generate UI wireframes and interactive prototypes from requirements; P5 also mentioned it as a potential alternative to Claude Desktop for sharing prototypes collaboratively, though it was not adopted directly by POs.

## 6 Findings and Discussion

As AI tools increase developer productivity, the pressure on requirements engineers to fill backlogs faster grows accordingly. Yet RE fundamentally involves finding consensus through negotiation and conversation – a deeply human activity with natural limits on acceleration. The interviews with our eight POs reveal that AI is reshaping this activity along three interconnected dimensions: how AI affects the relationship between POs and developers; how tool integration (and its absence) determines whether AI assistance delivers real value; and how AI capabilities are advancing faster than the human and organisational systems needed to absorb them. This gap between AI capability and organisational capacity frames the findings below.

### AI changes the quality and character of developer–PO interaction

The most immediate effect of AI-assisted RE is on the artefacts used by both POs and developers. AI tools reliably raise the floor of story quality – better formatted acceptance criteria, fewer omissions, more consistent structure – against the dimensions in which RE quality is conventionally evaluated [8]. However, the data from the interviews reveal that this quality improvement does not translate automatically into better developer reception.

A key finding is that AI-generated stories are not always well received. P1 described a situation where a PO uploaded an AI-generated story without reviewing it: *"In one case, I had already uploaded it without checking, and the developer reacted negatively to the highly*

[7] https://www.curly.so/

*technical, generated description."* P5 observed resistance where one developer reacted with negativity to all tickets or even conversations with AI tools – *"purely based on emotion, no rational arguments."* This emotional resistance is a real phenomenon that AI adoption strategies must account for [30].

A second dimension is perception asymmetry. P1 noted that most developers do not necessarily notice the difference even though Product Copilot generates numbered acceptance criteria, while the PO sees it as a critical point. P3 confirmed this from the opposite side: developers have not provided any specific feedback on AI-generated stories; the PO reviewed all of them and revised as needed. POs may therefore be over-investing effort in AI-assisted quality improvements that developers barely register.

There is a deeper risk beyond reception: AI can substitute for the dialogue that shapes requirements. P5 identified this directly in the context of backlog refinement: *"writing a story is based on a conversation with [Product Copilot] in which a lot of context is provided"*. The result is a story that needs to be discussed with the team – *"in the future, this discussion could also happen between the dev team and the Copilot."* P7 goes even further, using Claude Code to refine the technical aspects of a backlog item against the actual source code, which means that developers are no longer involved in shaping the understanding of the requirement and possible solutions. The literature on AI as a teammate has long observed that integrating AI into team workflows changes the team itself [24, 31], with consequences for shared understanding and accountability. The single-user interaction model of current tools amplifies this risk, as detailed below.

The current single-user model of AI-assisted RE tools amplifies this risk. All tools we observed – including ChatXiPT, Product Copilot, and TenderZen – follow a fundamentally individual interaction model: one user engages in a dialogue with the AI, and the team receives the resulting artefact but not the conversational context that shaped it. The two contexts – AI-generated and human-discussed – can drift apart, forcing the PO to manually bridge them by restarting the AI dialogue with discussion results or reconstructing AI reasoning for the team. Backlog refinement always requires discussion and negotiation regardless of how stories were produced; the AI artefact is the starting point, not the end point, of that conversation. Beyond information exchange, refinement sessions build shared understanding, surface assumptions, and create collective ownership of the work [29] – none of which the AI currently participates in. The reliability of AI-generated artefacts adds another dimension: LLM-based tools can produce plausible but incorrect requirements (e.g., P2 identified a generated story that incorrectly assumed a user must register on every login), requiring additional review effort that partially offsets productivity gains [7, 15].

Storey's framework [27] identifies two distinct debt types that accumulate in our setting. Between PO and AI, *intent debt* accrues whenever a generated story is committed to the backlog without close review – P1's example of an unreviewed, overly technical story reaching a developer illustrates this: the artefact lacks the captured rationale and constraints that would allow the team to understand why it was written the way it was. Between the PO and the team, *cognitive debt* accrues because the conversational context that shaped the story is invisible to developers in refinement – a loss of "transactive memory" in which the team inherits the artefact but not the shared understanding that produced it. The same is true for reliance on the PO's private AI dialogue rather than on the collaborative practices that spread that understanding, as in the case of P7. RE research acknowledges the social and negotiation aspects of requirements work [9, 4]; current GenAI-RE evaluations, by contrast, frequently reduce RE to a single-engineer scenario [6, 13], missing precisely these dynamics.

### Tool integration is a major bottleneck

Across nearly all participants, the most persistent frustration is not with AI capability but with the lack of integration between AI tools and existing workflows. When AI tools cannot access project context, their outputs are generic, irrelevant, or require significant manual effort – negating the productivity gains.

P3 described a fundamental structural problem: *"the project is created separately in Product Copilot; it should be integrated directly into our standard project management workflow."* P6 was more direct: *"without a connection between Copilot and ADO, context is missing"* and *"context must be rebuilt from scratch every time."* P2 linked this to output quality: *"generated user stories are too generic because the context is missing."* Rather than seamless integration, participants describe elaborate manual workarounds. P1 noted: *"there's a huge collection of meeting notes and documentation in Confluence and Jira; however, you have to explicitly instruct Copilot to use it."* P4 flagged a manual upload process: *"references are currently uploaded manually; in the future, possibly via an interface."* P8 described the same gap from a different angle: references for tender bids are searched for and adapted using Rovo in Confluence, but must then be transferred manually into TenderZen for the rest of the bid workflow – a recurring break between two AI tools that each work well in isolation.

Tool proliferation creates its own overhead. P5 observed that *"currently it is necessary to use different tools for different purposes and there are breaks between the tools."* P7 described a growing toolset where integration efforts are ongoing. While more integrations are constantly added, P7 noted that feedback from the build tool-chain and log file analysis is not yet integrated into the RE tools. P8 illustrated the multi-tool complexity even within a single tender workflow: bid/no-bid decision made in TenderZen, concept development in ChatXiPT and Product Copilot, reference search in Rovo, and requirements transferred to tickets with the help of Product Copilot.

The picture changes when integration does work. P4 reported that TenderZen reduced the evaluation time for a single tender from four hours to 30 minutes. P1 described how bootstrapping a backlog from an Excel spreadsheet was reduced from eight to two hours using Product Copilot. The common factor in these success cases is that AI tools reliably transform unstructured input – tender documents, spreadsheets, whiteboard photos – into structured artefacts amenable to further analysis. This transformation is what tools like TenderZen and Product Copilot do well, and it is why integration is the prerequisite for value. Our data captures both ends of this spectrum. P7's adoption of Claude Code connected via MCP to the Jira board and source code repository (see Section 5) demonstrates how deep integration enables requirements elaboration within the full codebase context. P6, by contrast, works in an Azure DevOps environment where the customer has not enabled MS Copilot's ADO integration and Product Copilot does not support ADO; the result is that P6 has no AI tool operating on the backlog itself.

Integration is not only a technical challenge but also a governance and compliance one. P6 noted: *"Microsoft Copilot has been approved at the customer"*. But P6 has no Pro licence which means that MS Copilot cannot access documents, e.g., in SharePoint. P2 flagged a hard constraint: *"customers do not want to integrate [Product] Copilot due to legal issues."* P5 voiced similar concerns. Integration thus requires active negotiation around data access and trust. More than 90% of GenAI-RE approaches remain early-stage prototypes implemented as standalone scripts or web demos [2], and systematic reviews on automated RE tools do not treat industrial tool-chain integration as an evaluation dimension [28]. Our data suggest this gap is widening: between late 2025 and spring 2026, practitioners moved from copy-paste workflows to programmatic MCP integrations that the literature has not yet studied.

### AI advances faster than the human and organisational systems around it

AI tools improve individual PO productivity measurably. P6 noted: *"even this limited use has significantly reduced the effort required to create PBIs; many ideas are clarified in advance that would otherwise only come up during refinement."* But P5 observed the team-level picture is different: *"the number of refinement loops has not changed due to AI use."* P1 pointed to team-level opportunities that remain unrealised: they point out the potential for workflow improvement to sort, prioritise, and clean up the backlog, slice epics differently, find duplicates, or archive old stories. AI is primarily being used as a personal productivity tool, not yet as a collaborative team tool.

This points to a design gap rather than a capability gap. The tools we observed treat AI as a personal assistant rather than as a participant in the team's shared refinement process – in which, as Verwijs and Russo [29] show, shared understanding and collective ownership are constituted, not merely communicated. Realising AI's team-level potential would require interaction models that include the whole team: letting developers and other stakeholders see, question, and shape the AI dialogue rather than inheriting only its output. Designing AI into multi-stakeholder team processes rather than individual workflows is precisely the open agenda that Seeber et al. [24] identify for AI-in-team collaboration; our data show that RE is a domain where this agenda is now pressing.

The technical and communication gap between POs and developers is also shifting in ways that are not yet fully visible. P5 described how quality control has moved to the PO: *"[Product Copilot] can also challenge the stories"* which can mean that the POs together with Copilot can assess technical feasibility without the help of developers. P5 also noted that this disconnect persists in a practical sense when pointing out that Indian developer teams, in other time zones, using different language, could benefit from interacting with the ticket in their language. P7 explicitly raised this as an open question: *"How much does the developer do themselves? Does the PO take on the role for vision and features, rather than user stories?"*

Several participants echo this uncertainty about what it means to be a PO in an AI-assisted world. P1 captured a fundamental question: *"there's no point using [the chatbot] to describe what the story should look like – if [the] PO can do that, they can write the story directly."* P2 reframed it at the organisational level: resolving the bottleneck of requirements work means that the development teams need more decision-making autonomy – and it is not clear that customers are ready for this. As tool integration matures, the ownership dynamic faces additional pressure: if POs can elaborate requirements in the context of the source code without developer involvement, the development team's sense of ownership over the requirements may diminish further – not because the PO deliberately excludes them, but because the workflow no longer requires their input at the elaboration stage.

Customer and stakeholder readiness is a further constraint that determines what AI assistance can deliver in practice. P6 described an asymmetry: *"UX comes from another company that is hard to reach and has little understanding of how the app works"* This other company does not engage in *"questioning of the use cases – many features were built for [the app], but the big picture was lost."* P2 connected this to pace: *"in organisations with less agile thinking and a poor error culture, this is problematic: the Product Owner can produce faster, but cannot necessarily address the technical aspects; the feedback cycle with the customer cannot be accelerated at will."* The issues around tool approval brought up by P6 show that organisational context limits tool adoption: the tool decision space is constrained by what the customer organisation permits, not just what vendors offer. The human system around the AI tool is the binding constraint. Both the AI-as-teammate literature [24] and

Storey's cognitive-debt framing [27] converge on the same underlying claim: workflows, role definitions, and patterns of communication adapt to AI more slowly than AI use spreads, and the gap is most often closed silently and individually rather than through deliberate redesign. When production accelerates but validation cannot, the risk is not merely wasted effort but misdirected effort: a PO who exceeds the customer's ability to give timely feedback can commit the team to the wrong requirements faster than before. This is a failure mode long recognised where stakeholder communication and shared understanding of requirements break down [9, 4].

### Implications for practitioners considering AI-assisted RE

Our study is descriptive, not prescriptive: we observed eight POs at one service provider company, and we make no claims that what we saw will reproduce elsewhere. Even so, the patterns surfaced in the data suggest a set of questions that practitioners considering AI-assisted RE may find useful to ask of their own situation:

**On developer–PO interaction:** Do developers actually notice the quality improvements the PO is investing in? What is the team's protocol when AI-generated artefacts arrive in the backlog without the conversational context that shaped them? Does the tooling allow developers and other stakeholders to see and question the AI dialogue, or does the team only inherit its output? Do important communication routes between POs and developers deteriorate when AI is used to shape the technical context of requirements?

**On tool integration:** Which integrations between the team's existing toolchain and any new AI tool are actually in place, which are technically possible but not enabled, and which gaps require manual handoffs that erode the time savings the AI was meant to deliver?

**On organisational lag:** When the PO's productivity goes up, do the team's downstream processes (refinement, planning, customer feedback) absorb that change, or does the PO end up renegotiating workflows and role boundaries silently, one project at a time? Can the customer validate as quickly as the PO can now produce, or does faster output risk committing the team to the wrong requirements?

Our data does not answer these questions for any other organisation; it suggests that they are the right questions to ask early.

Summary of Findings

AI-assisted RE tools improve individual PO productivity, but their impact at the team and organisational level remains limited. Three dynamics shape this picture.

1. AI improves story quality, but developers often do not notice the improvement and may resist AI-generated artefacts emotionally; the single-user interaction model means AI assistance substitutes for collaborative dialogue rather than enriching it.
2. Tool integration is the primary determinant of whether AI value is realised or lost: where integration is in place, effort savings are dramatic; where it is absent – due to technical gaps, vendor scope, or customer governance decisions – the PO is left with generic output and manual workarounds.
3. AI is outpacing the organisational systems around it: benefits accrue to individuals, team processes remain largely unchanged, and customer and stakeholder readiness is more often the limiting factor than tool capability.

## 7 Threats to Validity

Threats to validity follow Runeson and Höst [21], adapted for our qualitative interview study.

### Construct validity

Interviewees may interpret concepts such as "AI-assisted RE" or specific tool capabilities differently, potentially introducing inconsistencies in the data. We mitigated this through the semi-structured interview format, which allowed the interviewer to clarify terminology in situ. Member checking ensured that our summaries accurately reflected the interviewees' intended meaning. The codebook itself was derived with AI assistance (Claude Sonnet 4.6) and reviewed manually across several iterations; the resulting code definitions are published as part of the replication package, allowing external readers to verify the constructs to which our findings refer.

### Internal validity

Since our study is exploratory and descriptive rather than explanatory, we make limited causal claims. Findings could be influenced by confounding factors such as tool maturity, project-specific contexts, or individual PO preferences. The 2024 use-case survey that seeded the initial structural codes could in principle have biased subsequent interview probing; we mitigated this through an emergent thematic-coding pass allowing new themes to surface beyond the survey-derived skeleton, and through purposive sampling that ensured diversity of experience levels (5–18 years), domains, and tool combinations across our eight interviewees. The longitudinal design with two interview rounds (December 2025/January 2026 and April 2026) allowed us to capture how perceptions evolved as tools matured.

### External validity

Our findings are based on a single B2B software development company with eight POs and a tool landscape covering an in-house chatbot and seven commercial AI tools used for RE. The eight POs work across diverse customer domains (insurance, healthcare, public sector, machinery, e-commerce), which lends some breadth to the observations, but results may not transfer to product companies, larger enterprises, or organisations with different tool ecosystems. We make no generalisability claims beyond our context; the contribution is practical insight into how AI-assisted RE is used and adapted in industry rather than generalisable theory.

### Reliability

Open coding was performed by the sole author, and interview notes (validated against recordings) rather than full transcriptions served as primary data. As with any single-coder qualitative study, no second, independent human coder applied the codebook, and we therefore cannot report an inter-rater reliability statistic; this is a limitation of our design. Claude Sonnet 4.6 supported the derivation of the coding guidelines and flagged candidate inconsistencies for manual review, and uncertainties were resolved across multiple analysis passes against the interview notes and recordings; this LLM-assisted review improved the internal consistency of code application but does not constitute a validated measure of inter-rater reliability, nor does it substitute for independent human coding. Member checking [14] addressed a related but distinct concern – whether our interpretations matched

participants' intended meaning – rather than coding reliability. We partially offset the absence of IRR by making the interview guide and the full coding schema available as supplementary material [26], allowing external verification of how codes were defined and applied.

## 8 Conclusion

AI-assisted requirements engineering in practice reveals a picture with distinct sociotechnical elements. Across eight product owners and 15 use cases at XITASO, a medium-sized software engineering firm, the influence of AI lies not in task automation alone but in how it reshapes the conversations, roles, and team dynamics through which requirements acquire meaning. The AI-augmented PO is outpacing the team and the customer: benefits accrue to individuals while team processes, customer readiness, and organisational workflows absorb change more slowly than the tools themselves are being adopted.

This has a theoretical edge. Requirements engineering has long been understood as a distributed, negotiated activity in which validation and shared understanding are constituted through social interaction, not merely transmitted via artefacts [9, 4]. The single-user interaction model of every tool we observed relocates this work into a private PO–AI conversation, producing artefacts the team inherits without the reasoning that shaped them. Agile role boundaries and the collaborative construction of requirements do not remain stable once AI enters the workflow: the boundary between requirements and implementation blurs, and the question of who owns a requirement becomes open. In doing so, our findings extend Storey's debt framework [27] into the RE domain: intent debt at the PO–AI layer, where unreviewed artefacts carry no captured rationale, and cognitive debt at the PO–team layer, where the team's loss of transactive memory around AI-mediated conversations erodes shared understanding. Together they provide the RE-domain evidence that the AI-as-teammate literature has called for [24, 31].

The risk is not that AI produces poor requirements, but that it redistributes where requirements work happens without anyone deciding that it should. Unreviewed AI artefacts reaching developers, conversational context that never leaves the PO's screen, and developers' diminishing sense of ownership together accumulate as unverified requirements and eroded shared understanding. Because the customer feedback cycle cannot be accelerated at will, a PO who produces faster than the team can absorb and faster than the customer can validate risks misalignment rather than inefficiency: delivering the wrong thing at higher speed.

Addressing this requires more than studying AI-assisted RE over longer horizons. It calls for interaction models and tools designed for multi-party rather than single-user use, and for evaluations that treat tool-chain integration and organisational absorption as first-class concerns. For practitioners, it means deliberately redesigning refinement rituals and role boundaries around AI, deciding consciously how the team re-enters the loop, rather than letting those adjustments happen piecemeal and out of sight.

## Data Availability Statement

Due to participant confidentiality agreements and the proprietary information about customers and internal practices included in the interviews, interview transcripts cannot be shared publicly. However, the following materials are available in the supplementary material [26]: (1) the interview protocol with all questions, (2) the complete coding schema with code definitions and examples, (3) the complete electronic whiteboard with all anonymized data points and attached codes, and (4) an overview of all use cases extracted from the data.

## Abstract

Requirements Engineering commonly distinguishes between functional and non-functional requirements. In AI-based systems, an orthogonal perspective might also be worth considering: whether requirements concern AI components or not.

This paper reports on a 2.5-year R&D project building MONEKTO, a holistic data-driven recruitment system for a Polish temporary employment agency. The system integrates three data streams: recruitment process events, candidate and job order profiles, and employment histories – to support both candidate-order matching and employee retention prediction.

Drawing on project logs covering June 2023 to January 2026, we identified three categories of requirements in AI-based systems: Non-AI-based requirements, AI-based requirements, and AI-enabling requirements.

We show how these categories differ in their lifecycle: while traditional requirements stabilize after implementation, AI-enabling requirements emerge incrementally and require continuous investment throughout the system lifetime. We report five observations on the emergent nature of AI-enabling requirements and derive seven practitioner lessons for RE in AI-based system projects.

## 1 Introduction

The interest in building AI-based software systems has grown substantially over recent years. However, as practitioners frequently discover, embedding artificial intelligence (AI)/machine learning (ML) components into real software systems is significantly more complex than it initially appears. A well-documented challenge is *hidden technical debt* [20]: the real code in an ML system is often the smallest part of the effort; data pipelines, serving infrastructure, monitoring, and feature engineering dwarf the model code itself.

Requirements Engineering (RE) for AI-based systems has similarly attracted increasing attention [4, 7, 21]. Much of this work focuses on quality attributes specific to AI – fairness, transparency, explainability, robustness – and how to specify them [17]. Less attention has been paid to a more fundamental challenge: the category of requirements that must be implemented not to provide user-valued features, but simply to *make the AI work at all*. We call these **AI-enabling requirements**.

Examples include: CV parsing pipelines, expert labeling tools, feedback mechanisms for model correction, and explainability components mandated by regulation. None of these deliver features that a user would request, yet without them the AI components cannot function.

The concept of AI-enabling requirements emerged from our experience building MONEKTO, a data-driven recruitment system for a Polish temporary employment agency, over a 2.5-year industrial research and development (R&D) project. MONEKTO integrates three complementary data streams – recruitment process events, candidate and job-order profiles, and employment histories – supporting two AI components: a candidate-order recommender and a turnover predictor.

As the project progressed, we noticed that a recurring class of requirements resisted the usual RE categories. This prompted our research question: *What categories of requirements emerge when building an AI-based industrial system, and how does their lifecycle differ from traditional software requirements?*

To answer this question, this paper makes two contributions:

1. A **taxonomy** of requirements for AI-based systems with three categories: Non-AI-based requirements, AI-based requirements, and AI-enabling requirements (Section 4). The subjects of AI-enabling requirements are individually studied elsewhere in the literature and many are commonly known; our contribution is identifying them as a requirements category and characterizing their lifecycle, which differs fundamentally from both Non-AI-based and AI-based requirements;
2. **Empirically grounded observations and lessons learned** characterizing the lifecycle of AI-enabling requirements and their implications for project planning (Sections 5–6).

Our taxonomy offers practitioners a language to name and track AI-enabling requirements explicitly, rather than letting them surface as unplanned technical debt. Evidence from the MONEKTO project suggests that most of these requirements cannot be identified upfront, with direct consequences for effort estimation and project planning in AI-based system development.

## 2 Related Work

**Organizational AI Readiness.** Research on AI readiness identifies organizational prerequisites for AI adoption [1, 2, 9, 16], spanning technology infrastructure, data quality, regulatory compliance, and organizational culture. A common finding is that readiness is a *precondition for adoption* – yet this literature operates at the strategic level and does not address how readiness factors translate into concrete software requirements in a specific project.

**Requirements Engineering for AI-Based Systems.** The RE community has recognized distinct challenges for AI-based systems: difficulty specifying model quality upfront, a mismatch between iterative AI development and traditional RE processes [7, 21], and the need for ML specification frameworks [4, 17]. These studies focus on what AI systems *must do*; our work shifts attention to what must be *built around* them to function at all.

**ML Systems as Surrounding Infrastructure.** Sculley et al. [20] show model code is a small fraction of total ML system effort, with data pipelines, serving, and monitoring the primary source of hidden technical debt. Sambasivan et al. [19] find data work systematically undervalued, and Nahar et al. [15] trace ML failures to gaps at the model-system interface. MLOps frameworks [12, 13] translate these concerns into architectural patterns, but none treats the surrounding infrastructure as a category of software requirements with a distinct lifecycle.

The literature thus addresses AI enablers at the *organizational* (readiness) and *architectural* (MLOps) levels but not at the *requirements* level – what a team must specify and maintain to make AI work in a specific system. This gap is what our work addresses. We do not claim that the artifacts themselves – data pipelines, annotation tools, monitoring, human oversight, or compliance infrastructure – are newly identified; each is well documented in the MLOps and RE literature cited above. Our contribution is to frame them as a coherent category of software requirements with a distinct lifecycle.

# 3 Research Approach

## 3.1 Study Design

This industrial experience report is structured as a single-site, longitudinal, practitioner-embedded, participant-observer case study [18, 22], spanning 2.5 years of development (June 2023–January 2026). Our observations draw on: *(i)* contemporaneous project logs – monthly team meeting reports produced throughout the project lifetime; *(ii)* requirements and architecture artifacts generated at four project milestones; and *(iii)* milestone validation reports documenting quantitative system outcomes.

The underlying register was reconstructed retrospectively from these contemporaneous sources rather than tracked prospectively. The taxonomy itself was derived inductively from this retrospective analysis: requirements were iteratively classified based on their relationship to AI components, with categories crystallizing from recurring patterns in that classification. We counted as a single requirement each separately specified and implemented register item linked to one of the system's two core AI-based use cases – e.g., for requirements regarding ML explainability in these use cases, SHAP computation and its UI presentation are counted as two items. We exhaustively cataloged requirements linked to the two AI use cases (8 AI-based, 28 AI-enabling); non-AI-based requirements, numbering in the hundreds, were not exhaustively cataloged and are not the subject of quantitative claims in this paper. A requirement was classified as *planned* if present in the original project scope (grant application or initial requirements elicitation) and as *emergent* if its first documented mention in the monthly logs appears after that point together with an identifiable trigger (a data-quality, model-accuracy, regulatory, or operational problem); emergent requirements were dated by first log mention, with the month estimated from project-phase context for 8 of the 18 items. One co-author first reviewed the register independently and proposed an initial taxonomy structure; the resulting categories and the classification of individual requirements were then

discussed jointly among the co-authors until consensus was reached. Single-site case studies are an established practice in software engineering research [3, 20], with their value lying in depth rather than generalizability.

## 3.2 Industrial Context

MONDI (`https://mondi.pl`) is a Polish temporary employment agency that recruits blue-collar workers (manufacturing, logistics, skilled trades) for German industrial clients. The agency's core business process spans candidate matching, worker deployment to German employers, and ongoing employment monitoring. A critical business challenge is *qualitative turnover*: the rate at which recruited workers terminate their employment prematurely for reasons potentially attributable to a poor recruitment decision (e.g., skills mismatch, language barriers, location issues).

Before the project, the company managed its recruitment-to-employment workflow across multiple disconnected systems and tools. The MONEKTO development project (06. 2023–01. 2026) aimed to design a holistic recruitment and workforce monitoring process and to build the system supporting it. MONEKTO covers the full workflow – candidate registration, job order management, contract administration, and mobile communication with deployed workers – and integrates an AI subsystem (MONDAI) providing data-driven candidate-order matching and retention risk assessment.

The system integrates three complementary data streams: **S1 – Recruitment Process Events** (discrete hiring-process events, e.g., CV submission, language test result, modeled via BPMN); **S2 – Candidate and Job Order Profiles** (structured features extracted from unstructured CVs and job descriptions via NLP and domain ontology matching); and **S3 – Employment History** (time-varying payroll features: absences, disciplinary warnings, overtime, and contract milestones).

These three streams feed two AI components: the **Recommender**, which ranks candidates for a given job order, and the **Turnover Predictor**, which estimates the probability of qualitative turnover. Critically, the system is not limited to the recruitment decision point: Stream S3 continuously monitors active contracts, creating a *feedback loop* that links post-deployment outcomes back to the original candidate-order matching. This enables the system to be retrained on outcome-labeled data, improving recommendation quality over time as real employment results accumulate.

The system architecture separates: MONEKTO (handling business workflows) and MONDAI (the AI subsystem), communicating via REST API with asynchronous event-driven feature recalculation. The architecture was designed using template-based NFR elicitation [11] (38 requirements per ISO/IEC 25010:2023 [8]), 20 documented architectural decisions, and an ATAM workshop [10] generating 57 evaluation scenarios.

# 4 A Taxonomy of Requirements in AI-Based Systems

We observed three qualitatively distinct requirement categories in our AI-based system. Type A and Type B are mutually exclusive; Type C is not and can co-occur with either.

### Type A: Non-AI-based Requirements (Non-AI)

Non-AI-based requirements are simply conventional software requirements – functional and non-functional alike – whose specification and realization do not involve AI components. We use the explicit "Non-AI" label to keep the three categories terminologically parallel and to

emphasize that the taxonomy is orthogonal to the classical FR/NFR distinction: each of the three types can contain both. They are frequently elicited through standard techniques (interviews, use case modeling, user stories). In MONEKTO, examples include: "*A recruiter can view a report on the number of candidates for each job order.*" or "*A recruiter can comment on a candidate's profile.*"

Their lifecycle is well understood: they are elicited, specified, implemented, accepted, and then maintained with minor corrections.

### Type B: AI-based Requirements (AI-based)

**AI-based** requirements describe user-visible behaviors, constraints and non-functional requirements which are based on AI components. In MONEKTO, examples include: (1) "*The system recommends candidates for a given job order*"; (2) "*The system displays a turnover risk indicator for each active employment contract*"; (3) "*The system extracts structured profile data from a candidate's uploaded CV document*" (a user-valued feature also labeled Type C1 – see the classification rule below).

### Type C: AI-enabling Requirements (AI-enabling)

**AI-enabling** requirements are a documented prerequisite for a Type B requirement to function, regardless of whether they also qualify as Type A or Type B. When a requirement serves only this role, with no independent business justification, it is typically *not requested by users*: they might not know it is needed, and its absence is not observable as a defect from their point of view. Such purely-enabling requirements are identified by the project team – some anticipated early, during initial NFR analysis, but most discovered during development, typically when encountering data quality problems, model accuracy shortfalls, regulatory obligations, or operational issues with deployed models.

Table 1 summarizes eight AI-enabling sub-categories identified in MONEKTO. We do not claim that this list is exhaustive across all AI-based systems.

### Classification rule

We classify a requirement along two independent dimensions. The first asks whether it has genuine value on its own: would a user or the business still want it if every AI component in the system worked perfectly? If yes, it is labeled Type A (realized without AI) or Type B (realized using AI); the two are mutually exclusive. If it fails this test (if it exists only so that some AI component can work, improve, or stay compliant), it earns no A/B label at all.

The second dimension asks whether the requirement is a documented prerequisite for a Type B requirement's AI component to function correctly. If yes, it is also Type C, independently of the answer to the first question. A requirement can therefore be Type A and Type C at once (CRUD(L) operations for candidates and job orders – needed for ordinary business processing, but also feeding the recommender's feature vector), Type B and Type C at once (CV parsing – wanted by recruiters to complement candidate profile data regardless of the recommender, but also feeding it), or purely Type C with no A/B label (SHAP explanations – needed only to satisfy a legal obligation). Labels can also change over time – a purely-C requirement can later gain a B label once it acquires independent value, without losing its C label. This is also why the taxonomy is orthogonal to the FR/NFR distinction: the A/B label depends on why a requirement exists, not on whether it is functional; the C label depends on a separate question – what else depends on it.

**Table 1** Sub-categories of AI-enabling requirements (Type C) with MONEKTO examples.

| Sub-category | Purpose | MONEKTO examples |
|---|---|---|
| C1 Data Collection | Acquire and structure data for training & inference | CV parsing (PDF/DOCX); NER extraction of skills/ work history; OCR of warning documents, payroll record import |
| C2 Data Quality | Ensure input data meets quality standards for reliable inference | LLM-based job description assistant; structured CV creator; data input completeness validation |
| C3 Model Evaluation | Assess model quality during development | Expert annotation tool (Dataset Tagger) for labeling of candidate-order pairs for use as ground truth; validation dataset protocols |
| C4 Business Outcome Measurement | Link AI decisions to observable business outcomes serving as the signal of whether the system delivers its intended value | Recommendation feedback by recruiters; qualitative turnover rate computation |
| C5 Explainability | Make model outputs interpretable to decision-makers | Displaying SHAP values per recommendation; explanations in recruiter UI; full candidate list policy |
| C6 Human-in-the-Loop | Enable human oversight and correction of model behavior | Expert labeling workflow; recruiter override; periodic model review |
| C7 Data Freshness | Ensure features reflect current state at inference time | Event-triggered recalculation (RabbitMQ); embedding cache (Redis) |
| C8 Privacy & Security | Protect personal data; secure AI-specific interfaces | CV anonymization post-NER; GDPR-compliant training data; MONDAI network isolation |

## 5 AI-Enabling Requirements: Key Observations

▶ **Observation 1** (Most, but not all, AI-enabling requirements owe their existence to AI)**.** When examining the AI-enabling requirements in MONEKTO, we observe two distinct classes. *Shared foundations* have business value independently of AI but also provide essential AI input: for example, CRUD(L) operations for candidates, job orders, and job applications are needed to run recruitment and to provide structured data for the recommender. *AI-exclusive enablers* exist only because an AI-based requirement exists: a job-description quality evaluator, CV labeling tool, recommendation feedback endpoint, SHAP explanations, or feature cache would not appear in a non-AI project scope. Shared foundations tend to be identified during ordinary business analysis; AI-exclusive enablers emerge later as the team encounters data, accuracy, regulatory, or operational constraints. Figure 1 illustrates examples of both classes for the *Recommend Candidates for a Job Order* use case.

▶ **Observation 2** (The deceptive stability of AI-based requirements)**.** At the use-case level, AI-based requirements appeared stable throughout the project: *Recommend Candidates for a Job Order* and *Predict Turnover Risk* could have been written similarly on the first and last day. This stability was deceptive. Beneath each use case, AI-enabling requirements kept growing. For the Recommender, after the initial learn-to-rank architecture [5] and Precision@5 = 61% by May 2024, later sprints added requirements-matching features,

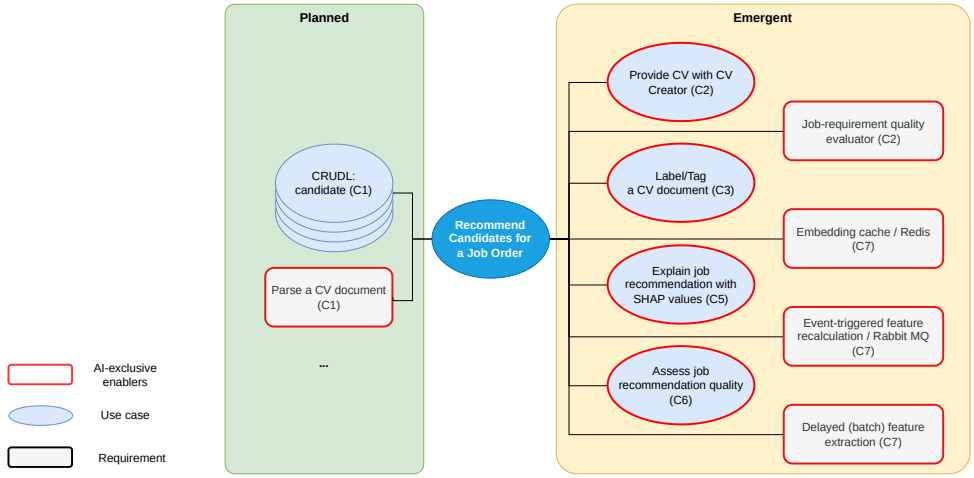

**Figure 1** An example of AI-enablers associated with the AI-based use case *Recommend Candidates for a Job Order*.

expert correction rules, LLM-based semantic matching, two-phase filtering, and retraining. For the Turnover Predictor, the validated August 2024 model was followed by feature-vector extensions, sentiment analysis of coordinator notes, and real-time updates. AI-based requirements are therefore like the tip of an iceberg: the visible specification remains stable while the enabling infrastructure grows.

▶ **Observation 3** (Most AI-enabling requirements cannot be fully identified upfront)**.** AI-exclusive enabling requirements are particularly difficult to anticipate at project inception. While some can be foreseen – a data ingestion pipeline, for instance, is a predictable need whenever historical records must feed a model – most emerge only when the team encounters concrete problems during development or after deployment.

Five MONEKTO examples illustrate this. The job description quality generator (C2) was added only after early recommendation failures were traced to vague, incomplete job orders that made feature extraction unreliable. Candidate data quality was weaker than assumed: among 169,293 unique candidates, only 22,630 (13%) initially had CV documents; integration work raised coverage to 92,068 (54%), motivating the CV Creator (C2). The embedding cache (C7) became necessary once production measurements showed that recomputing semantic similarity embeddings per request exceeded acceptable response-time thresholds. A recruiter-facing feedback mechanism (C4) followed once operational experience showed that offline metrics such as Precision@5, adequate during development, could not monitor recommendation quality in production; embedding a lightweight agree/disagree signal in the recruiter tool created a feedback stream neither the project scope nor any user interview had anticipated. Finally, building a reliable training dataset required far more effort than expected: historical records yielded only 1,369 ground-truth candidate-order pairings, a fraction of the roughly 100,000 pairings in the validation set (100 orders × 1,000 candidates); the remainder came from structured expert labeling sessions using a dedicated annotation tool (C3, MONDAI Dataset Tagger) – not foreseen in the project scope.

These requirements were triggered by operational evidence rather than user interviews, echoing hidden technical debt dynamics [20].

Figure 2 shows the cumulative growth of AI-exclusive enabling requirements tracked in our project logs for the two core AI-based use cases, excluding shared foundations such as CRUDL operations. The planned requirements (dashed line) were established at project

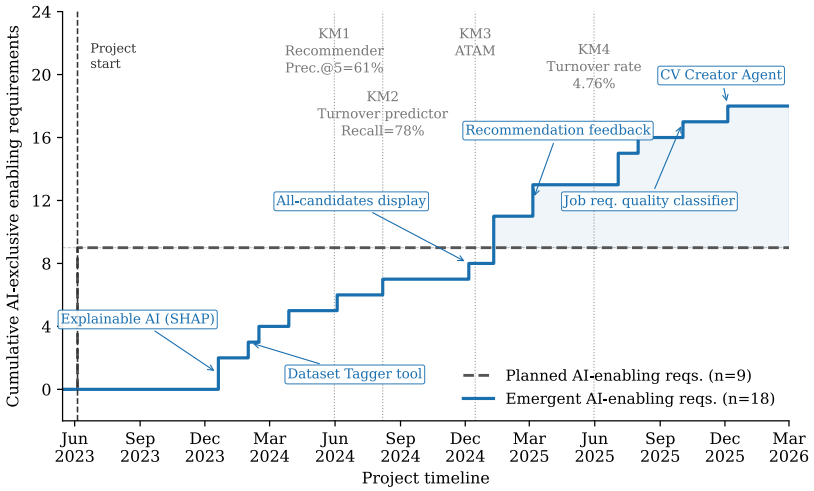

**Figure 2** Cumulative growth of planned vs. emergent AI-exclusive enabling requirements in the MONEKTO project (Jun 2023–Jan 2026). Vertical dotted lines mark project milestones; the dashed horizontal line marks the planned ceiling of 9 requirements.

start; emergent requirements accumulated progressively, with notable clusters around the first model validation (Dec 2023), the architecture phase (mid-2024), EU AI Act compliance work (late 2024–early 2025), and operational monitoring needs in the post-deployment period. Of the 27 requirements captured in the figure, only 9 were anticipated in the original project scope; the remaining 18 emerged during development in response to concrete problems with data quality, model accuracy, regulatory obligations, or operational constraints. We treat this fraction as an illustrative order of magnitude for a single project rather than a statistically precise estimate; it is sensitive to classification choices and the completeness of the documented set. This ratio likely underestimates the true proportion of emergent requirements: the documented set is not exhaustive, and several planned requirements were substantially expanded in scope during implementation.

▶ **Observation 4** (The AI Act as a Source of AI-Enabling Requirements)**.** MONEKTO falls within the scope of the EU AI Act [6] as a high-risk AI system[1] used in employment decision-making. This regulatory context generated the following cluster of AI-enabling requirements that were not driven by user needs but by legal obligations.

**Transparency (C5).** The obligation to provide meaningful explanations drove the implementation of SHAP values [14] and their display in the recruiter UI – not a user-requested feature but a compliance necessity. **Human oversight (C6):** The non-automation requirement drove the policy of displaying all candidates rather than a pre-filtered shortlist, ensuring the recruiter retains full decision authority. **Auditability (C3):** The obligation to log AI-assisted decisions drove the implementation of audit logging.

These requirements emerged as the team's understanding of the regulatory landscape deepened. Their implementation consumed significant development effort and influenced architectural decisions (e.g., the audit logging infrastructure, the SHAP computation pipeline).

[1] Annex III, point 4: AI systems used for recruitment, selection, or evaluation of candidates in employment contexts.

▶ **Observation 5** (The AI-Enabler-to-Feature Trajectory)**.** An interesting pattern observed in our project is that some AI-enabling requirements eventually *became* user-valued features in their own right. We term this the *AI-enabler-to-feature trajectory*.

The CV extraction pipeline (C1) began as an internal mechanism for parsing PDF/DOCX files into structured fields. It evolved into the user-facing *CV Creator*, letting candidates enter structured data directly or upload a CV file that is parsed by an LLM – adding direct user value while improving training data quality, since structured inputs reduce noise in the feature vector.

Similarly, job-requirement quality tooling (C2) began as a model assessing requirement importance and verifiability, in direct response to low-quality, unverifiable requirements entered by sales staff that introduced noise into the recommender's feature vector. It evolved into a more ambitious capability: an LLM-based generator producing structured job requirements from a brief client description – addressing data quality at the source rather than downstream, and improving business data quality system-wide.

In both cases, an AI enabler improved training data quality and later added business value, suggesting such requirements should be treated as design artifacts, not only cost items.

## 6 Guidelines and Lessons Learned

**LL 1.** ***Plan for AI-enabling requirements as a permanent budget item.*** AI-based requirements are never "done" in the traditional sense: each improvement to an AI model – to correct errors, add features, or adapt to data drift – generates new AI-enabling requirements. Project plans should include a standing allocation for this work rather than treating it as exceptional, releasing a minimum viable version alongside the AI feature and planning for incremental elaboration throughout the project lifetime. *Source: Observations 2, 3.*

**LL 2.** ***Data quality problems emerge late and are expensive.*** In AI-based systems, data quality requirements cannot be fully identified before the team has hands-on experience with actual data. Low-quality inputs are frequently discovered to be the primary bottleneck for model accuracy only after early validation attempts fail. Practitioners should build in explicit data quality discovery phases and budget for data improvement tooling as a likely emergent need rather than an optional refinement. *Source: Observations 2, 3.*

**LL 3.** ***Regulatory compliance is a source of AI-enabling requirements.*** Regulatory frameworks such as the EU AI Act can generate a substantial cluster of AI-enabling requirements – covering transparency, human oversight, and auditability – that are entirely invisible during standard user requirements elicitation. Organizations building AI systems for regulated domains should analyze applicable regulations during initial requirements elicitation and treat compliance as a requirement driver alongside user needs. *Source: Observation 4.*

**LL 4.** ***The AI-enabler-to-feature trajectory is a design opportunity.*** AI-enabling requirements can evolve into user-facing features over time. Designing these components with eventual user exposure in mind – clean APIs, extensible data models, usable interfaces – can yield business value while reducing future rework. This trajectory also improves training data quality, creating a virtuous cycle between infrastructure investment and model performance. *Source: Observation 5.*

**LL 5.** ***Human-in-the-loop mechanisms are architectural requirements.*** Standard offline metrics such as Precision@5 are insufficient as the sole quality signal in a deployed AI system. As Observation 3 illustrates, detecting quality degradation in a live recommender required embedding a feedback mechanism directly in the recruiter's tool; building a reliable training

set required sustained expert annotation effort. Both are forms of human-in-the-loop design that were not initially planned and had to be introduced reactively. Treating human feedback and correction mechanisms as architectural requirements from the outset – rather than as late additions – reduces rework and improves data quality throughout the system lifecycle. *Source: Observations 3, 4.*

**LL 6.** ***User involvement is an AI-enabling requirement, not a soft process concern.*** Building and validating AI-based systems requires sustained, structured user involvement that extends well beyond tool usage. As Observation 3 illustrates, accurate training data for the recommender required recruitment experts to produce tens of thousands of labeled pairings in organized annotation sessions. User feedback loops, annotation tasks, and expert review workflows are AI-enabling requirements in their own right: they must be planned, tooled, and resourced explicitly. *Source: Observation 3.*

**LL 7.** ***Define acceptance criteria at three levels: business, AI-based, and AI-enabling.*** Acceptance criteria for AI-based systems must be defined at three distinct levels. At the *AI-enabling level*, criteria should specify data quality benchmarks, evaluation protocols, and compliance checklists. At the *AI-based level*, they should cover model performance thresholds alongside functional correctness. At the *business level*, the metric may be structurally decoupled from AI-component metrics – a business KPI such as turnover reduction may require additional AI-enabling requirements (e.g., monitoring infrastructure) before it can even be evaluated. Aligning these levels early reveals hidden enablers that would otherwise remain hidden until late in the project. *Source: Observations 1, 2, 3.*

A natural follow-up question is whether AI-enabling requirements call for different specification practices. We did not find this to be the case: individual Type C requirements in MONEKTO were documented with the same techniques as their Non-AI and AI-based counterparts – use cases and user stories where the requirement was functional in nature, template-based specification [11] where it was not. The practical difference lies not in how these requirements are written, but in how they are identified and managed over the project lifecycle: recognizing a requirement as AI-enabling is what triggers the planning, budgeting, and acceptance-criteria practices captured in the lessons learned above, rather than letting it surface unplanned. This suggests a concrete direction for future work: a closer, NLP-supported analysis of project artifacts – specifications, backlog items, and meeting logs – to identify recurring keywords and linguistic patterns that could support earlier elicitation and identification of AI-enabling requirements in future projects, before they resurface as unplanned technical debt.

## 7 Threats to Validity

**Internal validity.** The taxonomy emerged from a single project and classification involved judgment. The research team was also the development team, which may introduce confirmation bias – a recognized threat in practitioner-embedded case studies [18]. We mitigated this through co-authorship spanning academic researchers and industry practitioners, contemporaneous monthly logs, and consensus discussion, with any disagreements resolved until consensus was reached.

**Construct validity.** The concept of "AI-enabling requirements" is our own construct. It may overlap with, or be subsumed by, existing concepts such as "data requirements" [21] or operational ML requirements [3]. We position our contribution as a practitioner-oriented synthesis that makes explicit a category of work that is often implicitly understood but rarely

named or systematically managed. The distinguishing contribution is not the identification of these artifacts per se, but the characterization of their lifecycle as structurally different from both Non-AI-based and AI-based requirements (a more specific discussion in Section 2).

**External validity.** This is a single-company, single-domain case study; the recruitment domain's high data volume, regulatory context, and unstructured inputs may amplify AI-enabling requirements relative to other domains. One alternative interpretation is that emergence simply reflects the uncertainty inherent in any R&D project – yet within the same project, Non-AI-based requirements followed the expected stable lifecycle while the emergent pattern was specific to the AI-enabling layer. This differential behavior suggests the dynamics are structural rather than merely context-specific, though replication in non-R&D settings is needed to confirm this.

We expect the taxonomy's three categories and Observations 1–3 (shared vs. exclusive enablers, deceptive stability, incremental emergence) to generalize beyond recruitment: they describe how ML components behave once embedded in a production system, a structural property rather than a domain-specific one. Observation 4 should likewise hold for any system classified as high-risk under the EU AI Act [6], a category spanning employment, education, credit, and law enforcement (Annex III). One element is more clearly shaped by our specific project: the 67% emergent ratio, which we offer as a reference point for future replications rather than a general benchmark. Observation 5 (the enabler-to-feature trajectory) is grounded in two documented instances in MONEKTO; we see it as a promising pattern worth testing in other projects.

**Conclusion validity.** The planned/emergent ratio is based on a tracked subset of requirements and is sensitive to classification choices, including granularity – what counts as one requirement (Section 3). It should be read as an illustrative order of magnitude rather than a statistical estimate. Research in other projects and domains is needed to assess the generalizability of this ratio.

## 8 Conclusions

This paper reported on 2.5 years of building MONEKTO, a data-driven recruitment system, and proposed a taxonomy distinguishing three requirement types in AI-based systems: Non-AI-based, AI-based, and AI-enabling. Drawing on project artifacts, we derived five observations and seven practitioner lessons on the lifecycle of AI-enabling requirements.

Our main finding is that AI-based requirements have a different lifecycle from Non-AI ones: the visible AI feature may remain stable, but the enabling requirements around it emerge and grow in response to data quality, accuracy, regulatory, and operational challenges.

In the MONEKTO project, approximately two thirds of the tracked AI-exclusive enabling requirements were emergent rather than planned, with notable clusters appearing around model validation, regulatory compliance work, and post-deployment operational needs. This ratio has direct implications for project planning: AI-based system projects that budget only for the visible AI features and neglect the enabling infrastructure will systematically underestimate cost and schedule.

A further observation is that AI-enabling requirements are not purely cost items: some evolve into user-facing features, creating a virtuous cycle between infrastructure investment and model performance. Naming and tracking this category, rather than letting it surface as unplanned debt, is the taxonomy's practical contribution.

Future work includes operationalizing the taxonomy, replicating it elsewhere, and building tool support for early requirement identification.

## Abstract

AI code-generation tools are widely deployed, yet AI is not applied uniformly: its use varies systematically with the context of the task, the code being modified, and the engineer. Studies that do not account for these contextual differences risk attributing to AI what is actually driven by context. Using data from over 10K developers and 400K diffs at Meta, with character-level provenance tracing of AI-suggested code through editing, review, and landing, we model (a) which context factors predict AI code landing, (b) how landed AI code relates to review time, and (c) its association with production outages (SEVs) – while controlling for contextual confounds. We find that AI code lands more often in less central code, larger changes, test files, and for authors with higher tenure. Review time decreases and SEV rates are lower for diffs with AI code, but both associations are confounded by AI code appearing in less central contexts. These findings demonstrate that naive comparisons of AI vs. non-AI work may reach misleading conclusions, and we provide actionable guidance for controlling these confounds.

**2012 ACM Subject Classification** Software and its engineering → Software creation and management; General and reference → Empirical studies

**Keywords and phrases** AI code generation, code review, software quality, context-dependent AI, landing rate

**Category** Software Engineering in Practice Track Paper

## 1 Introduction

Generative Artificial Intelligence (GenAI or AI) code-generation tools are already being deployed widely despite limited and nuanced evidence of their software engineering impact. Many studies find increased speed and productivity [50, 51, 59, 9, 33] but also reductions in code quality [58, 21, 19].

Studying AI impact is complicated because AI suggestions are made in a code editor, but the code may be modified before landing.[1] The probability that AI-suggested code lands depends on numerous context factors ranging from quality of the suggestion to properties of the code modified by the diff, properties of the diff itself, author, reviewers, etc. Indeed, AI may not be equally applicable or effective in different contexts and for different engineers. The commonly used and easily attained measure of acceptance rate has serious flaws [32, 25], while studies that compare actions of engineers with and without access to AI tools lack the essential link between the context and landing rate. Furthermore, landing rates are also an important way to gauge how AI performance on benchmarks transfer to actual industry software.

Our primary contribution is to demonstrate that AI is applied non-uniformly – its use depends strongly on context – and to identify which context factors drive this variation. This finding has a critical methodological implication: because AI-assisted and non-AI-assisted work differ systematically in their context (e.g., AI is more likely to be used for larger, less central changes), any analysis that simply compares outcomes of AI vs. non-AI work without controlling for these contextual differences will confound the effect of AI with the effect of context. Without such controls, software engineering outcomes attributable to AI tools may be misleading. For example, if AI tends to be applied predominantly to less central code, a study that does not take centrality into account may show increased output or other characteristics of less central code associated with higher use of AI even if such an increase is confounded by centrality. Similarly, if AI is more likely to be applied to larger changes, a naive comparison would attribute the properties of large changes to AI itself. Once we establish how the context affects AI landing rates, we address the remaining questions: how does AI impact code reviews and service outages (SEVs)?

Our contributions are: (1) character-level tracing of AI-suggested code to landed code via Chattributes provenance tracking; (2) demonstrating that AI landing rates are strongly context-dependent (varying with centrality, change size, complexity, language, and tenure), implying that diffs with and without AI code are not exchangeable; (3) modeling review time and SEV probability while controlling for the contextual confounds identified in the landing model; and (4) offering an alternative explanation for the literature finding that AI produces more code – larger changes may simply offer more opportunities to apply AI.

Our study focuses on pre-agentic, completion-based AI assistance – the dominant paradigm from 2022 to 2025 – for several reasons. First, the transition to agentic AI systems that autonomously plan and execute multi-step tasks is well underway, making this the last opportunity to establish rigorous empirical baselines for the pre-agentic era before the technology mix shifts irreversibly. Second, completion tools operate at the character and line level with the engineer in full control of each suggestion, whereas agentic tools make autonomous multi-file decisions; the confounding patterns we identify (centrality, change size, tenure) will manifest differently under agentic workflows, and disentangling the two requires understanding each independently. Third, nearly all published empirical studies of AI coding impact measured pre-agentic tools [51, 65, 66, 9]; understanding the confounds in that setting is necessary to correctly interpret the existing body of evidence. Finally, the methodological template we develop – first modeling where AI is applied, then controlling for those factors in outcome models – transfers directly to evaluating agentic tools, even as the specific coefficients change.

We study the impact of AI in three contexts: authoring, reviewing, and outages (*i.e.* field faults or SEVs). We next provide background, hypotheses, and a results summary for each.

[1] By landing we mean that the code ends up in the primary branch after all reviews and after (successfully) running through a CI pipeline, essentially making AI code a permanent part of the project's codebase.

## 1.1 AI impact on code authoring

Existing evidence and common sense suggest that AI may not be equally useful or used in different contexts. For example, the degree to which AI is successfully used[2] may depend on the particular part of the codebase, engineers' experience and habits, the degree of trust in AI generated code (for example, in risky diffs), and on coding tasks. We, therefore, expect that AI code landing will vary with these and other context factors. For example, a responsible engineer would likely be more wary of AI code that touches central files. Likewise, the literature has shown that junior engineers are more likely to use AI (e.g., [65, 66, 9, 30, 12]). We use logistic regression with presence of AI-generated code as the response variable and include file centrality, author tenure and other common measures such as the size of the change, its cyclomatic complexity, and the number of tests modified.

Our hypothesis is $H1$ : *The landing of AI code will be affected by change, author, and file. E.g., file centrality, change size or churn.*

*Results summary.* We find the likelihood that AI code is landed varies with the codebase: AI diffs tend to modify lower-centrality files and test files. Contrary to existing literature, we find that junior engineers are not more likely to land AI code.

## 1.2 AI impact on code reviewing

With the knowledge of what diffs are more likely to land AI-generated code, we can properly measure how landed AI-code may, in turn, affect various software engineering outcomes. First, there is a perception that AI will transform developers into reviewers [2] and that AI will create more, and harder, work for reviewers [53]. Our next goal is to provide a preliminary understanding of the impact of AI code on manual code reviews, namely code review time. We control for confounds that are associated with landed AI code, such as file centrality. We use a multiple regression to understand the impact of AI on how long it takes to review code.

Our hypothesis is $H2$ : *The landing of AI suggestions increases diff review time*

*Results summary.* We find that AI code is reviewed more quickly, but when the centrality of AI code is high, it appropriately increases code review time.

## 1.3 AI impact on production faults, *i.e.* SEVs

Finally we focus on the impact of AI-generated code on production faults and outages (SEVs), arguably the most important and the least investigated software engineering outcome. Some previous work has found improved code quality [65, 66, 30], while other work observed a deterioration in code quality [23] and a much higher defect rate [58]. Since the diffs that cause outages (referred to as Site Events or SEVs at Meta) are determined and recorded for each outage in our organization, we use it instead of defect rate. We use a logistic regression to model the probability of a SEV that includes any AI generated code and also include key variables that are used in the models deployed to predict diff fault risk [1, 44]. Our hypothesis is $H3$ : *The landing of AI suggestions increases the probability of a SEV.*

*Results summary.* We find that, after controlling for context, a higher fraction of AI code is associated with slightly fewer SEVs; because AI-heavy diffs are larger and occupy higher-risk contexts, their raw SEV rate is not lower. Thus, once context is accounted for, AI use has not led to an increase in SEVs at Meta.

[2] We define "successfully used" as presence of AI generated code landed in the trunk.

## 2 Background and Data

Empirical software engineering has its origins in the need to evaluate the impact of software engineering tools and practices as they are expensive to acquire, deploy, and maintain, especially in large organizations. In this study we use fine-grained measurement of the code editing AI tools so that we can associate the part of AI code suggestions that ended up in the code. To our knowledge, none of the existing studies are based on measurements that track AI suggestions to the individual diffs, likely due to extreme complexity of tracking the provenance of each character through a variety of editing surfaces, revising, committing the code and then through diff revisions, code review, and eventual deployment.

### 2.1 AI use at Meta

Meta is a large software company with a complex code base that covers a wide range of applications from social networking and virtual reality to software engineering infrastructure, such as continuous integration tooling and workplace coordination. Tens of thousands of developers work on billions of lines of code (LOCs) in a monolithic repository that hosts source code written in more than nine programming languages. The development organization spans multiple continents and time zones, with engineers organized into product and infrastructure teams that range from small specialist groups to large platform teams of hundreds. The codebase includes user-facing products serving billions of users, backend infrastructure, data pipelines, mobile applications, and developer tooling – providing a diversity of software types and risk profiles that few single-company studies can match. The state of the source code and the developers associated with the source code keeps evolving constantly - internal libraries and tools get added and deprecated, while developers move across teams and change roles. At Meta's scale, keeping up with the knowledge required to accomplish coding tasks is challenging. Notably, Meta has no policy restricting AI use on critical code; the organization actively encourages AI adoption across all contexts.

At Meta, an AI-assisted code authoring system named CodeCompose has been deployed companywide [47, 14]. CodeCompose is a pre-agentic, completion-based tool: it provides inline suggestions as a software engineer types code and is designed to predict tokens that would complete the current line (single-line suggestion) or multiple lines (multi-line suggestion) across programming languages. Unlike agentic AI systems that can autonomously plan, execute multi-step tasks, or modify multiple files, CodeCompose operates reactively within the editor, suggesting completions only at the cursor position. Single-line suggestions should be quick, highly accurate, and help with the immediate context. In contrast, multi-line suggestions need to be deeply informed and intelligent. These code blocks can help users discover APIs, best practices, and implementation details. CodeCompose is multi-lingual and has been trained on more than nine programming languages at Meta. As such, it inherits the property of LLMs to be multi-lingual. It is also customized for the organization: CodeCompose is fine-tuned on Meta's internal code repository, and is thus able to handle languages such as Hack and Flow. CodeCompose is also deeply integrated with Meta's version of VSCode, and other editors including online Jupyter-like data science environments. CodeCompose can understand inline comments in natural language and generate code that adheres to the comment.

The CodeCompose model exactly recreates the masked line between 40% and 58% of the time and has a high BLEU score between 56% and 73%, depending on the programming language [47] in back-testing. When rolled out into production, the acceptance rate was 22% which is comparable to those at Google and GitHub. A survey and a thematic analysis

of the comments from 70 engineers showed overwhelmingly positive feedback, with only 8.5% of comments containing negative feedback and less than 1% of engineers turning off CodeCompose. The top two feedback comment themes related to discovering APIs and dealing with boilerplate (23%), and accelerating coding (20%).

## 2.2 Code Provenance via Chattributes

*Chattributes* is a system at Meta that tracks information about code authoring. Edit events (insert, delete, replacement of characters) in IDEs are observed via extensions available for all major editing surfaces (VS Code, Android Studio, NeoVim, web-based editors, and terminal editors), and the provenance of those changes are tracked. Metadata is associated with each changed span, including which tool or human author made the change, and if the tool was AI assisted. Formatters, copy and paste events and AI authoring tools are tracked. Edit tracking is implemented via a character-based form of the *LineLog* interleaved deltas system. When a commit is made to source control, the provenance of all changed characters since the previous commit is stored as commit metadata. This metadata is then *propagated* over source control operations (rebase, amend). This is done by deriving edit scripts (using Myers diff algorithm) from the underlying source control content, and applying that edit script to the metadata. This allows us to trace provenance of characters through source control actions, allowing us to determine which characters survive review to be landed in the repository. We thus reason precisely about the provenance of landed code, down to character granularity.

Chattributes is deployed in production across Meta and has been validated against alternative approaches that infer AI authorship by correlating editing actions with AI service invocations that occur close in time. The character-level provenance tracking in Chattributes consistently produces more accurate attribution than such temporal-correlation heuristics, which suffer from false positives when developers type simultaneously with AI suggestions and false negatives when network latency separates the invocation from the edit event. Chattributes remains the primary system used at Meta for measuring AI code contribution.

With chattribute data we are able to calculate the number of bytes written by CodeCompose that ended up in the final landed diff. Approximately two months of data includes diffs in spring of 2025 and contains several hundred thousand of diffs excluding automation-generated diffs. Our analysis concerns roughly half of these diffs where chattributes were available (none were bot-generated). The uncovered diffs result from editors or workflows not yet instrumented rather than from the risk profile of the diff: covered and uncovered diffs are well balanced on file centrality, complexity, and prior-fault history. Coverage does, however, over-represent diffs in the earliest-instrumented ecosystems (Hack, Python, and JavaScript relative to C++), so it reflects the order of IDE/tooling rollout rather than risk-based selection. We cannot fully rule out residual selection on unobserved factors, and we discuss this potential selection bias as a threat to validity (Section 5). For each diff, we calculated measures, such as the number of files, line churn, cyclomatic complexity of the modified files, coverage, and so on. Approximately half of the analyzed diffs had at least some CodeCompose-generated code landed.

When modelling AI code, we consider two measures: (1) the fraction of diff chunks or contiguous spans of a changed code file where any part of the AI authoring suggestion was landed, and (2) the fraction of modified bytes originating from that AI suggestion. We also record the AI tool and LLM model that was used as part of the metadata. Multi-line suggestions were substantially less common than single-line completions; in exploratory analysis, distinguishing multi-line from single-line suggestions did not change the direction of the landing associations we report, so for the models below we do not separate them. A dedicated analysis of how suggestion granularity interacts with language (e.g., the lower landing rate for C++) is left to future work.

## 2.3 Data Sources for diff properties

We collect data from code measurement systems used at Meta, such as lines of code, cyclomatic complexity, and line test coverage. These measures were calculated at the time of diff landing, *i.e.* merging into the trunk.

A separate company-wide system was used to track **every** SEV. The root cause of every outage is manually investigated and the diff or diffs that caused it are recorded. Due to a strong focus on customer experience, the accuracy of SEV data is high. We used Phabricator[3] to obtain the remaining measures, such as diff creation and landing times, affected files, author, reviewers, comments, review interval, etc. Again, each measure is calculated at the time diff is closed. So, for example, measures of author experience change after each diff.

# 3 Statistical Modelling

To achieve our goal of better understanding the relationships between the use of AI-assistants and critical software engineering outcomes, such as code reviews and system outages, we use statistical models. Statistical models help quantify relationships between outcomes and variables that measure various properties of a diff. Two of our models have binary responses, namely if AI code landed and if a SEV was triggered. As is commonly done in such cases, we use Logistic regression. The remaining model has review time as a response and we use a multiple regression.

To satisfy modeling assumptions, all continuous variables are transformed using the $\ln(x+1)$ function because they have highly skewed distributions. We add one to ensure that there are no zero values in the log transformation. We use $\alpha = 0.05$ as our significance threshold throughout.

We are not aware of validated theories that would help explain the probability of landing AI-generated code or how such inclusion may affect review times or the probability of a SEV. We, therefore, start from known models of reviews and SEVs that happen to be extensively used at Meta. Furthermore, it is essential to include them as control variables in the models that estimate the impact of AI to avoid confounding interpretations that ascribe the impact of the confounding variable to the impact of AI.

Software engineering measures tend to be highly correlated [40, 41], but models with highly correlated measures are hard to interpret, have unstable estimated coefficients, and poor predictive power [13]. To this end, if the correlation between two variables exceeded 0.7 – the threshold recommended by Dormann et al. [13] as the point beyond which collinearity begins to severely distort model estimation – one of them was removed from the model. We complement this pairwise screening with a multivariate collinearity check (GVIF, Section 5), which does not rely on a single arbitrary cutoff. We ensure that remaining variables are diverse (represent distinct aspects of the diff, author, and modified code) and rely on simple but validated measures already in wide use at Meta.

We subdivide variables into classes: prior activity and defects [26, 46], interdependencies [8], coordination [8], author expertise [26, 6], complexity [46], churn [48], and testing [44].

Finally, we exclude diff properties that are determined after the phase we investigate. For example, the authoring model cannot know information about reviewers. As a result, only the SEV model has the full set of variables. As with all statistical models, we want to establish a relationship between the response and variables (independent variables), as

[3] `http://phabricator.org`

statistical models do not demonstrate causal relationships. Although we do not fit a formal causal model, our two-stage design is motivated by a causal-confounding logic that can be read as an informal directed acyclic graph (DAG): context factors such as centrality, churn, and test files jointly influence both whether AI code is applied and the downstream outcomes (review time, SEVs). These factors are therefore common causes (confounders) that must be adjusted for before any association between AI code and an outcome can be interpreted, and we treat them as such by first modeling AI landing (H1) and then including its predictors as controls in the outcome models (H2, H3).

We selected our variables based on three criteria: (1) extensive prior use in defect prediction and code review literature, ensuring comparability with existing work; (2) diversity across distinct aspects of the diff (prior history, interdependencies, coordination, expertise, complexity, and testing); and (3) availability at the appropriate temporal stage of each model. We verified linearity assumptions by inspecting residual plots and testing for non-linear terms. We also investigated interaction effects but found none that were statistically significant while also improving prediction and remaining interpretable, including interactions of AI fraction with centrality quartiles and language-specific slopes.

We initially considered a substantially larger set of predictors, including organizational unit, type of software (e.g., infrastructure vs. user-facing product), and additional measures of code and author properties. The variables presented here survived a sequence of selection steps: first, among strongly correlated predictors (correlation exceeding 0.7), we retained the one easier to interpret and more widely used in prior literature; second, we excluded predictors that were not statistically significant in any of the three models, for parsimony and due to space constraints.

## 3.1 Model Variables

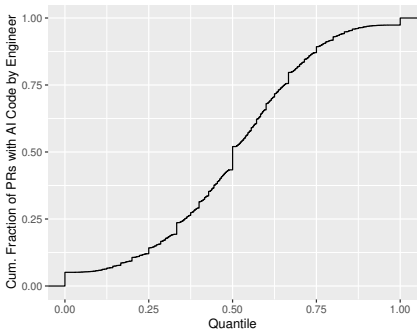

Table 1 lists all variables, their definitions, and rationale. As noted above, the models may include a subset of variables, as some were collinear or determined at later stages. All variables were calculated using approaches described in Section 2.3. We briefly summarize the categories here. *Prior history* (past SEVs, review comments, post-landing changes) captures the principle that past problems predict future ones. *Interdependencies* are represented via Katz centrality [27] computed over combined call-graph (extracted via Glean [39]), co-change, and authorship edges [64, 8] accumulated over a 12-month window. Because risk is driven by the single most critical file a diff touches rather than by its average file, we aggregate file-level centrality over a diff using the maximum (as we do for other file-level risk measures such as past SEVs); using the mean or median instead did not change the direction or significance of the centrality coefficients. *Coordination* needs are proxied by the number of reviewers, author centrality, and maximum past authors on modified files [22, 8]. *Author expertise* is measured via tenure and past modifications to the affected files [46, 26]. *Code complexity* includes churn and cyclomatic complexity [35]. *Testing* is captured by whether test files are modified [44].

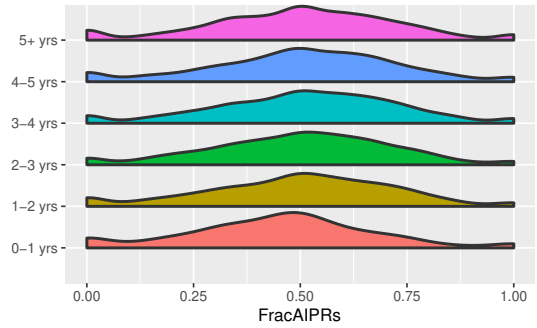
## 3.2 Model Definitions



In the preceding sections, we discussed data sources, data collection, and the measures used in the models below. We evaluate the AI impact in three contexts: authoring code, reviewing code, and SEVs or faults. For each context we introduce dependent variables and describe each model below.

**Table 1** Measures. The measures are computed for each diff separately as they were at the time diff landed. $cent(f,t)$: centrality of file $f$ at time $t$, $CCN(f,t)$, $LOC(f,t)$: cyclomatic complexity and lines of code of file $f$ at time $t$, $d$ and $D$, are diffs, $a$ author, $r$: reviewer, $d_a$, $d_r$: indicators that $a$ authored and $r$ reviewed $d$; $d_f$ is true if diff $d$ modifies file $f$; $d_t$ is the time diff landed; $d_{t_{created}}$ is the time diff was created. $Tests$ is the set of all test files. $D_{sev}$ (or $d_{sev}$) is true for diffs that triggered a SEV and false otherwise.

| Category | Measure | Description | Calculation |
|---|---|---|---|
| Past and current issues | $sev(d)$ | True if any of the files in the diff have been modified by a SEV-causing diff in the past. "past faults predict future faults" [20, 6] | $\max_{\{f:d_f\}}\{1 \iff \exists D : D_f \wedge D_{sev} \wedge D_t < d_t;\ \ else\ 0\}$ |
| | $sugchg(d)$ | Code review suggested making changes. A small discovered issue may hide yet-to-be-discovered issues [37, 3] | |
| | $ncmts$ | Number of comments received during review. Discussion may imply complexity or risk of the diff [37, 3] | |
| | $chgpost(d)$ | Indicator of whether the diff had changes after being landed. Issues that surface after landing may indicate higher risk [44] | |
| Inter-dependencies | $fcent(f,t)$ | The maximum Katz call-graph centrality of the modified files. More central [64] files may have critical functionality [8, 67] | $\max_{\{f:d_f\}} cent(f,d_t)$ |
| | $nfiles(d)$ | The number of files modified. Need to modify multiple files in a single diff implies "logical" dependencies and risk [11, 46] | $\lvert\{f : d_f\}\rvert$ |
| Coordination | $nrev(d)$ | The number of reviewers. | $\lvert\{r : d_r\}\rvert$ |
| | $acent(d)$ | Katz centrality of the diff author based on co-change, authorship, and call-graph links. More central authors work with more central files (see above) and have more experience [64, 38] | $cent(a,d_t)$ |
| | $maxauth(d)$ | Maximum number of distinct previous authors over files modified in a diff. "Too many cooks spoil the broth" [46, 61, 6] | $\max_{\{f:d_f\}} \lvert\{a : \exists D : D_f \wedge D_a \wedge D_t < d_t\}\rvert$ |
| Expertise | $pmod(d)$ | Author expertise measured by the number of changes to the files modified by the diff in the past. Expertise is associated with defect rate [46, 61, 6] | $\lvert\bigcup_{\{f:d_f\}}\{D : D_t < t \wedge D_f \wedge D_a\}\rvert$ |
| | $tenure(a,t)$ | Author expertise measured via tenure at Meta at the time of diff landing. Expertise is associated with defect rate [46, 61, 6] | six categories: 0–1, 1–2, 2–3, 3–4, 4–5, and 5+ years |
| File complexity | $churn(d)$ | Sum of the lines added and deleted over all files modified by diff: More change more risk [46, 48] | $\sum_{\{f:d_f\}} addedLOC(f,t) + deletedLOC(f,t)$ |
| | $ccn(d)$ | Total cyclomatic complexity number (ccn) added over modified files. One of the oldest indicators of risk [35, 34]. | $\sum_{\{f:d_f\}} CCN(f,t)$ |
| Testing | $tfiles(d)$ | True if at least one test file is modified by the diff. Empirical findings on test coverage vary: from reducing defects, [45], none [24, 29], or that high-risk files tend to have more coverage [44]. | $\lvert\{f : d_f \wedge f \in Tests\}\rvert > 0$ |
| Programming language | $cpp$, $php$, $py$ | Diff modifies at least one file containing source code from the corresponding language. Risk rates and review time may vary with programming language. | |
| Outcomes | $revtime(d)$ | The time spent in code review (interval while the author was waiting for review(s)) | |
| | $AIbytes(d)$ | The fraction of bytes that are attributable to AI suggestions | $\ln \frac{ai\_bytes+1}{ai\_bytes+non\_ai\_bytes+1}$ |
| | $AIspans(d)$ | The fraction of change chunks/spans (contiguous non-overlapping parts of modified text) that contain at least some AI-suggested code | $\ln \frac{ai\_spans+1}{change\_spans+1}$ |

**(a)** Fraction of diffs with AI code landed over the population of over 10K engineers.

**(b)** Distribution of the fraction of diffs with AI code landed by engineer's tenure.

**Figure 1** AI code landing rates across engineers and tenure categories.

## Authoring Model

Our first model concerns the code authoring stage of AI suggestions by modeling the probability of landing any of the AI-suggested code in a diff.

In this model, we focus on variables that predate authoring actions as our goal is to measure the context of a diff that affects the landing rate of AI code. The response is binary (any AI code landed or not) and we use logistic regression. The predictors – listed as column (a) in Table 2 – include file centrality, author centrality and tenure, past author modifications, change size (files, churn, ccn), test files, and programming language.

## Reviewing Model

Code review efficiency is commonly measured as the time code spends in review [15, 52, 54]. We use a linear regression with log-transformed review time as the response. All variables from the authoring model are included as controls to avoid confounding, plus the number of reviewers. Our key independent variable is $AIspans$, the fraction of change spans containing AI-suggested code (preferred over the fraction of bytes due to better fit; the two AI measures are closely related – their underlying log AI-span and AI-byte counts correlate above 0.9). Column (b) in Table 2 shows the full set of predictors.

## SEV model

Statistical software risk models have been in use for 40 years [46, 26], incorporating previous faults [31], network complexity [8], coordination [22], and code complexity [55]. We use logistic regression with SEV occurrence as the response. The SEV model includes the full set of variables (column (c) in Table 2), adding post-authoring variables unavailable to earlier models: review comments, suggested changes, and post-landing modifications.

## Model Fit

Our modeling goal is to explain the variance in the response variables and model fit is the most suitable way to accomplish that. If the model has poor fit, it means that most of the variance is explained by unmeasured factors. Generally, measures of model fit are most useful for comparing the same models with extra variables. From a practical perspective, what constitutes a reasonable fit is usually dependent on prior published work or based on expert opinions.

In logistic regression (our AI landing and Sev models) regular $R^2$ is not available because, instead of sum of squares (which are not additive), we have only the likelihood values. A commonly used alternative is McFadden's pseudo $R^2$. It measures the ratio of information gain when adding variables to the whole information contained in the data. It has a slightly different interpretation from the regular $R^2$. McFadden states [36] on page 306 "... its values tend to be considerably lower than those of the $R^2$ index...For example, values of 0.2 to 0.4 represent EXCELLENT fit."

For the review time model we use adjusted $R^2$ as it is a multiple regression and compare it to models published in academic literature.

Unlike the author and review models, the SEV model represents extremely rare events, which can bias standard maximum-likelihood logistic regression toward underestimating event probabilities [28]. Established remedies include Firth's penalized-likelihood logistic regression [16] and King and Zeng's rare-events correction [28]; because our sample contains several hundred SEV-causing diffs– keeping the number of events per predictor above the widely used rule of thumb of ten – and because the rarity is in the base rate rather than the event count and we report relative rather than absolute probabilities, these corrections are not expected to materially change the reported associations. For goodness of fit, because the base rate is so low, McFadden's pseudo $R^2$ may be too optimistic and Tjur's Coefficient of Determination, which is another analog of $R^2$, is preferred [57]. It represents the difference between the average predicted probabilities for each outcome category: SEV-causing ($p_{SEV}$) vs not SEV-causing ($p_{no\ SEV}$): or $p_{SEV} - p_{no\ SEV}$. As the probability of a SEV is proprietary information, we share the relative value of improvement: $\frac{p_{SEV} - p_{no\ SEV}}{p_{all}}$, where $p_{all}$ is the fraction of SEV-causing diffs.

# 4 Results

## 4.1 H1: AI impact on code authoring

Before suggesting a positive mechanism between relating landing rate and context, we may start from the negation or null hypothesis that diffs where AI suggestions are landed are exchangeable with diffs where no AI suggestions are landed (conditional on AI availability): $H1_0$ : *The landing of AI code is not influenced by file centrality, author tenure, size/churn, and other properties of the changed code.* If that were the case, we could directly compare outcomes between the two classes of diffs. The results shown in Table 2 demonstrate that the assumptions of the null hypothesis are clearly violated.

*Model Fit* has McFadden's pseudo $R^2 = 0.12$. As discussed in Section 5, strengthening the AI landing criteria from having at least one to at least 100 AI bytes landed monotonically improves fit: McFadden's pseudo $R^2$ rises to about 0.17 (Nagelkerke $R^2 \approx 0.26$), and it continues to increase with the threshold. In other words, with a larger AI footprint threshold the model fits better and does not require additional variables to explain landing rates. The modest fit at the one-byte threshold is expected: our goal is to characterize the *context* in which AI code lands, not to fully predict an individual engineer's moment-to-moment acceptance decisions. Several determinants of whether a specific AI suggestion is accepted are not observable in our data – individual developer preferences and trust in AI, team norms, the specific task type, the editor and IDE configuration, and the quality of the particular suggestion or prompt – and these unmeasured factors account for much of the residual variance. Importantly, the confounds we *can* measure are exactly the ones that also

**Table 2** Three models: (a) probability of landing AI code (logistic, McFadden's pseudo $R^2 = 12$–17%), (b) review time (linear, Adj-$R^2 = 14\%$), and (c) probability of SEV (logistic, relative Tjur's $R^2 = 80\%$). Tenure coefficients are contrasts with "tenure 0–1 years.".

drive the outcomes in H2 and H3, so an incomplete landing model is sufficient for its role as a confounder-identification step. From the model coefficients in Table 2 we can see the following:

- Landed AI code is associated with larger churn, more files, and higher cyclomatic complexity (ccn) of a diff. Larger diffs modify more files and have higher churn which may provide more opportunity for AI code suggestions (and subsequent landing).
- The chance of landing AI code is higher for diffs involving test files.
- Code that is more central (indicating higher interdependencies) is less likely to have AI code landed. This effect is small in magnitude – the `lfcent` coefficient of $-0.01$ corresponds to roughly a 1% change in odds – and modest relative to the dominant predictors of change size (`lnfiles`, `lchurn`) and programming language. It is also sensitive to the choice of centrality measure, so it should be read as a modest tendency rather than a strong regularity.
- Code with more past authors (indicating higher coordination needs) is less likely to have AI code landed.

For H1, the main findings are that landing AI code is less likely for central code requiring coordination. Larger changes, and higher author tenure are associated with increased chances of landing AI. The programming language strongly impacts the probability of landing AI code.

- There are notable differences among programming languages with Hack and Python having much greater AI landing rates than C++.[4] C++ is primarily used for performance-critical tasks and, because of the optimizations associated with performance needs, code may be more complex.
- We did not observe increased landing rates for junior or less central engineers in contrast to findings by, *e.g.,* Ziegler et al. [66]. In fact, AI landing rates are highest for authors with 3–4 years of tenure, the only tenure category with a statistically significant positive coefficient. Figure 1a shows the distribution of AI landing rates across the population of engineers, and Figure 1b breaks this down by tenure category.

To illustrate practical significance: the coefficient for `lchurn` (0.29) implies that roughly tripling churn is associated with a 34% increase in the odds of landing AI code ($e^{0.29} \approx 1.34$); `php` (0.50) implies 65% higher odds for diffs modifying Hack files. For the SEV model (Table 2), the `AIspans` coefficient of $-0.06$ (p=0.03) corresponds to a 6% decrease in odds of a SEV per unit increase in AI fraction.

## 4.2 AI impact on code reviewing

$H2_0$ : *The landing of AI code does not increase diff review time.*

Table 2 shows that, after adjusting for a number of factors, the landing of AI-suggested code is associated with reduced review time.

*Model Fit.* Adjusted $R^2 = 14\%$ is consistent with prior work modeling review times, *e.g.,* [52, 54]. Review time is strongly affected by factors that are difficult or impossible to measure: reviewer workload and how busy the reviewer is, whether they are taking a sick day, time-zone differences between author and reviewer, the urgency of or deadline attached to the change, and team culture around review turnaround. Even the best models of code review time used in Meta do not have much better fit. Furthermore, our focus here is to establish the impact, not to do review time prediction where higher values of $R^2$ would be necessary. Because most variance remains unexplained, we phrase the review-time conclusions as associations rather than effects and caution against over-interpreting the magnitude of any single coefficient.

Table 2 shows that code with higher fraction of AI spans is reviewed more quickly. To illustrate practical significance: the coefficient for *AIspans* ($-0.08$) implies that a one-unit increase in log AI span fraction is associated with approximately 8% shorter review time ($e^{-0.08} \approx 0.92$). As for the control variables, our findings match intuition. Higher tenure leads to reduced code review time (compared to 0-1 years), as do other measures of experience: author centrality and past changes to modified files.

However, the more central the code is, the longer the review takes, indicating that engineers use appropriate caution when touching central code. Larger diffs measured via code churn, cyclomatic complexity, and more test files take longer to review. Diffs with C++ code take longest to review and with Python code the shortest amount of time.

[4] The variable `php` represents Hack, which is syntactically derived from PHP.

Diffs with more reviewers take less time (since code review ends after the first accept). Diffs involving files with many authors take the same amount of time to review, perhaps because it may be easier to find a reviewer who has modified the file and is available. Surprisingly, diffs modifying files with past SEVs take less time to review, perhaps because thorough post-SEV investigation leaves reviewers more familiar with the affected files.

For H2, the main findings are that code with higher fraction of AI spans is reviewed more quickly, with controls showing reduced time with author experience and increased with centrality, size, and cyclomatic complexity.

At first glance the faster review of AI diffs is surprising because AI diffs are also larger (more churn, more files), and larger diffs normally take longer to review. The two effects are separated in the model: churn, number of files, and complexity each carry their own positive coefficients on review time, so the negative *AIspans* coefficient is the association that *remains after* holding change size fixed. In other words, among diffs of comparable size and centrality, those containing more AI-landed code are reviewed somewhat faster – consistent with AI code being concentrated in more routine or boilerplate spans (e.g., test files) that reviewers can scan quickly.

We note that these associations should be interpreted cautiously. Because our study is observational and AI-landed code tends to appear in less central, lower-risk contexts, the reported associations between AI code and faster review times may partly reflect *where* AI is used rather than a direct beneficial effect of AI itself.

### 4.3 AI impact on production faults, *i.e.* SEVs

$H3_0$ : *The landing of AI suggestions does not increase the probability of a SEV.* Some prior work has found deterioration of code quality associated with the use of AI tools [58, 21, 19, 60]. We investigate if such deterioration can be observed in our study.

*Model Fit.* As discussed in the methods section, the rarity of SEV events suggests the use of Tjur's coefficient of determination (an analog to $R^2$) which is the difference of model-predicted probabilities for the two outcomes. We report relative Tjur's analog to $R^2 = 80\%$, or, in other words, that difference represents 80% of the overall probability of a SEV.

Control variables show that, as expected, diffs modifying files with past SEVs, of higher cyclomatic complexity, coordination needs and dependencies (measured via past authors and file centrality), and more reviewers and review comments are associated with higher SEV rates. SEV rate does not depend on engineers' tenure or past changes to modified files.

Having suggested changes is associated with lower SEV rates, perhaps reflecting that more thorough code reviews prevent some SEVs. Size of the diff (number of files or churn) does not help predict the risk of a SEV, nor having changes after accept, or having test files. Diffs with C++ and PHP files have elevated SEV rate while diffs with Python files have lower rates.

## 5 Threats to Validity

**Generalizability.** The findings are specific to Meta's unique environment, monolithic repository, and internal tooling, which may limit their direct applicability to other organizations or open-source projects. However, our study does cover a very wide swath of software

We find that, *after adjusting for context*, a higher fraction of AI-generated code within a diff is associated with a slightly lower probability of causing a SEV. This protective association is context-adjusted: AI-heavy diffs are also larger and touch higher-risk code, so their *raw* SEV rate is not lower, and the negative association emerges only once size and centrality are controlled. The observed association therefore does not by itself demonstrate that AI *reduces* SEV risk. A cautious conclusion is that, once context is accounted for, the fraction of AI-generated code is not associated with an increase in SEVs at Meta.

engineering. The software system covers millions of lines of code and ten thousand developers who are both collocated and working at multiple locations across the world. We also cover a wide range of domains from user facing social network products and virtual and augmented reality projects to software engineering infrastructure, such as calendar, task, and release engineering tooling. LLMs used to implement AI tools are widely available and predate agentic solutions.

The particular infrastructure used to track the provenance of AI code may not be broadly available, but it can be implemented in other companies or for open source projects. The open-sourcing of popular AI authoring tool CoPilot [56] may enable such efforts.

The rapid evolution of GenAI tools means that the "true estimate" of AI's impact is a moving target, making this study a snapshot of its effect at a particular point in time. The observation window is roughly two months, so seasonal effects, tool-rollout and novelty effects, and mid-window model updates could in principle influence the estimates. Two factors limit this risk: CodeCompose had been rolled out companywide well before our window (so it is not a novelty period), and our prior-year replication over the same calendar span with the same developers yields nearly identical coefficients, indicating the relationships are stable rather than artifacts of a particular short interval. Still, a longer, multi-season window would strengthen the temporal generalizability of the results. In particular, our findings reflect pre-agentic, completion-based AI assistance (CodeCompose); the impact patterns of newer agentic AI systems that autonomously plan and execute multi-step coding tasks may differ substantially.

**Scope of Analysis.** Our analysis differentiates developers primarily by experience (tenure) and does not examine differences across departments or product areas (except on the smaller subsamples as noted below), as cross-team comparisons require additional organizational metadata and raise privacy considerations. Importantly, tenure here measures time *at Meta*, not total industry experience or general programming skill. It is best read as a proxy for familiarity with Meta's codebase, tooling, and norms rather than for seniority; the non-monotonic peak at 3–4 years may therefore reflect a point at which engineers have enough codebase familiarity to apply AI confidently while still working on code amenable to completion, and it may partly stand in for correlated factors such as role, team, or prior experience that we do not observe.

**Selection Bias.** Chattributes coverage of roughly half of diffs is driven by IDE and workflow instrumentation, but if coverage correlated with unobserved diff or developer properties, the analyzed sample could differ from the full population in ways our controls do not capture. Similarly, engineers self-select where to invoke and accept AI, so the landing model describes AI use *as it occurs* rather than under random assignment. Both forms of selection limit causal interpretation, which is why we frame all outcomes as associations and rely on the two-stage confound-control design rather than a direct AI-vs-non-AI comparison.

**Construct Validity.** The potential set of constructs used in the mining software repositories community is enormous. We have selected a straightforward set of measures widely used in bug prediction literature [63, 3], *e.g.,* prior defects and churn. We also use collaboration measures relying on software supply chains and centrality [5, 67, 62]. We select a diverse set of variables that represents distinct aspects of the authors, diffs, codebase, and historic events to ensure that we do not miss aspects that might affect outcomes of interest.

A more fundamental construct concern is that Chattributes measures the *provenance of landed characters*, not the cognitive contribution of AI. The measure can overstate AI's role when AI-attributed bytes are code the developer would have typed anyway (imports, common idioms), and can understate it when a rejected suggestion still shapes what the developer types next, or when AI helps via API discovery or pattern hints that leave no attributed bytes. It thus captures "AI code that survived to landing" rather than "value added by AI," and our findings should be read accordingly. Even so, landed provenance is a substantial improvement over acceptance rates or tool-availability proxies, and it is precisely the quantity relevant to what ends up in the codebase and can cause SEVs.

**Internal Validity.** As is commonly necessary for statistical models in software engineering [7, 41, 40, 42, 43], we log-transformed variables with highly skewed distributions and inspected residuals to check for nonlinear or non-monotone relationships. We also investigated interactions among variables, but none satisfied our requirements of improving the prediction and being easily interpretable.

While some of the variables are correlated, we found that we could pick variables from within the highly correlated clusters without negatively affecting model performance. Since some of the variables are categorical, we check for collinearity using Generalized Variance Inflation Factor (GVIF) [17] implementation in R [18], which is particularly suited for categorical variables (as correlation is generally not the most informative approach for categorical variables). In all three models, $GVIF^{\frac{1}{2*DF}} < 1.8$: under the suggested threshold of 2 [49]. This threshold corresponds to the regular VIF being less than 4 for numerical variables.

The observational nature of the data makes it difficult to argue that observed relationships are causal even though we selected variables that have values measured before (in time) the outcomes. While we capture a number of important context variables, it is challenging to explain counter-intuitive coefficients, e.g., why Sev rate increases with author centrality? A standard statistical explanation of latent variable, i.e., an unobserved property of a diff that brings on more experienced engineers also makes it more risky, is very difficult to communicate.

To ensure that models are representative of the code development at Meta we have done various robustness analyses. First, we checked if the models used to estimate the impact of AI accurately describe review time and chances of a SEV by fitting them over the same period during the prior year with the same developers; the code-complexity, churn, and author-experience controls reproduce with nearly identical direction and magnitude, confirming that our model structure captures stable relationships. Because development activity is seasonal (with evaluation periods and year-end holidays being substantially different), the prior-year comparison provides a better baseline than an immediately preceding period and confirms that our model structure captures stable relationships. Additionally, over 80% of changes in our sample are authored from North America (about half from the US Pacific zone alone), whose working hours largely overlap, so unobserved reviewer availability and timezone confounds are likely to have limited impact on the review time model.

*Thresholds and the binary definition.* It is reasonable to object to our definition of landed AI code whereby landing even a single byte traced to AI puts the entire diff into AI class, treating a one-line and a large AI contribution alike. Two aspects of our design mitigate this. First, the binary definition is used only as the response of the authoring model (H1); the outcome models (H2, H3) use the *continuous AIspans* (and, equivalently, *AIbytes*) fraction, so the magnitude of AI contribution, not merely its presence, drives those estimates. Second, for H1 we ran experiments trying thresholds up to 100 bytes and found that the same variables were statistically significant and pointing in the same direction (in fact, increasing the threshold improved model fit). This shows that the context factors affecting the chances of landing AI code stay the same even when we consider a diff AI-supported only when at least 100 bytes of AI-generated code lands.

*Modeling assumptions.* The sample of diffs is authored by over 10K engineers and outcomes may vary among them even after adjusting for author centrality, tenure, and past changes. To account for this, we fitted mixed-effects models (random effects for authors) on several random subsamples of authors – ranging from a few hundred to a few thousand – using *lme*4 [10] in *R*, as the full logistic mixed-effects model (*glmer*) did not converge on the complete dataset. We also explored author and organization fixed effects, but the very large number of parameters prevented convergence on the full data. In all subsample analyses – across different random author samples and different organizations – the fixed effects were similar to the reported results with no noticeable changes in the direction of coefficients. For clarity we present models without author random effects.

**Ethics and Privacy.** The study uses telemetry that reflects individual developer activity. Meta handled the data under applicable privacy and data-governance policies; authorized employees analyzed them on internal systems, and we report only aggregate results that do not identify individual developers. We report no per-developer results and share only relative effect sizes for sensitive quantities such as SEV probability. We caution that our practitioner recommendation to build provenance infrastructure (P1) carries responsibilities: in jurisdictions with GDPR-like requirements, developer-level provenance data constitutes personal data, and organizations should pair such infrastructure with purpose limitation, aggregation, access controls, and transparency to developers, and should avoid using it for individual performance evaluation.

## 6 Literature and Discussion

*Productivity and speed.* A growing consensus is that GenAI tools increase the speed and volume of code generation [50, 51, 59, 9, 33], though the magnitude varies (21–65% speed improvements depending on the study). However, this consensus is contradicted by an RCT with experienced OSS developers where AI actually increased task completion times despite developers perceiving themselves as faster [4]. GitClear notes that AI assistants "do beget more lines" of code [21], and Weisz et al. [60] found only small perceived productivity improvements.

Our findings relate to this prior work in several ways. Landed AI code is associated with larger churn, more files, and higher cyclomatic complexity as in *e.g.,* [60, 59, 4, 9]. We conjecture that the causality might go in the opposite direction: larger diffs may provide more opportunities for suggestions, so we would observe positive association of more code with AI even though the nature of the diff may drive this difference, not the use of AI.

This is a concrete example of how context-dependence of AI application can mislead: if studies compare output volume without accounting for the fact that AI is disproportionately applied to larger, more complex tasks, they will attribute to AI what is actually a property of the task itself. We recommend future work conducting specially designed experiments to establish the direction of causality. Results may also be reversed depending on what outcome is measured, as when perceived improvements contrasted with measured times [4]. All studies suggest that the use of AI varies with context, further supporting our central finding that contextual controls are essential for isolating AI's true effects.

*Code quality.* The consensus on code quality is primarily negative. Uplevel [58] found a 41% higher bug rate with Copilot access. GitClear [21] documented eroding quality: increased copy/pasted and duplicated code blocks, and 20–25% higher churn. DORA [19] noted a 7.2% decrease in delivery stability per 25% increase in AI adoption.

Weisz et al. [60] reported "acceptable" but imperfect quality requiring user effort to correct, and Liang Yu et al. [33] found code generation tasks required the most adjustment. In contrast, Cui et al. [9] found no quality decrease at Microsoft, and Weber et al. [59] found no significant differences in objective code quality.

GenAI excels at routine or boilerplate tasks but struggles with complex, domain-specific code [33, 60]. Our increased landing rates for test code and less central files support this. We did not find increased SEV rates (in contrast to [58]), and lower AI landing rates for highly central files with past SEVs suggests limited trust in AI code [60].

*Self-regulation vs. policy compliance.* A natural alternative explanation for our H1 finding is that the organization restricts AI use on critical code, and our model merely captures compliance with such a policy. This is not the case: Meta actively encourages AI adoption across all development contexts with no restrictions based on code criticality. The observed pattern – less AI in central, high-risk code – is therefore emergent self-regulation by engineers who exercise professional judgment about where AI suggestions are appropriate. This distinction matters: it suggests that the context-dependence of AI use is a fundamental property of how engineers interact with AI tools, not an artifact of organizational governance, and is likely to manifest in other organizations as well. We caution, however, that the centrality signal underpinning this reading is small in magnitude and sensitive to how centrality is measured; the dominant context factors are change size and programming language. The self-regulation interpretation should therefore be treated as a modest, completion-era tendency that may weaken as AI tooling shifts from inline completion toward more autonomous, agentic workflows.

*Developer choice vs. model capability.* A second alternative reading of H1 is that the lower AI landing rate in central, complex code (and the lower rate for C++ relative to Hack and Python) reflects not developer caution but limits of the model: CodeCompose may simply produce weaker suggestions on complex or performance-critical code, so fewer of them survive to landing. Our data are consistent with both mechanisms and we cannot fully separate them, because both "the engineer declined the suggestion" and "the suggestion was poor" manifest as unlanded AI code. Two observations suggest developer choice plays a real role: landing rates drop with file centrality and past-SEV history even after controlling for size and complexity, and the drop appears across languages rather than only where model quality is weakest. Nonetheless, disentangling suggestion quality from developer selection – for example by pairing landing data with suggestion-level accept/reject and edit-distance signals – is important future work, and applies equally to the language differences we observe.

*The "tail wags the dog" problem.* Our findings highlight a methodological risk that extends beyond this study. When AI is applied non-uniformly, factors that predict AI use (such as change size, centrality, and programming language) also predict outcomes of interest

(such as review time and fault rates). A study that regresses an outcome on AI use without controlling for these shared predictors will attribute the predictors' effects to AI. For example, if larger changes both attract more AI use and take longer to review, a model omitting change size will incorrectly conclude that AI increases review time. We address this by first modeling AI landing probability (H1) to identify its predictors, then including those predictors as controls in outcome models (H2, H3). We urge future studies to adopt this two-stage approach: identify what drives AI application before estimating what AI drives.

*What transfers to agentic tools.* Because our study measures pre-agentic, completion-based assistance, it is worth separating findings likely to be specific to that paradigm from those likely to generalize. Two results are tied to the completion setting and may weaken under agentic workflows: the specific magnitude of landing coefficients, and the review-time association, since agentic tools generate larger, multi-file changes whose review dynamics differ from line-level completions. The most transferable finding is the *methodological* one – that AI application is context-dependent and must be modeled before its effects are estimated; if anything, agentic tools that act more autonomously make confound control more, not less, important. We also expect the qualitative direction of the context effects (less AI in central, high-risk code; more in test and boilerplate code) to persist, though the mechanism may shift from per-suggestion human acceptance toward human approval of agent-proposed plans. Establishing whether these patterns hold under agentic assistance requires the same provenance infrastructure applied to agent-authored changes, which is a direct extension of this work.

## 7 Conclusion and Contribution

The study investigates the landing of code from pre-agentic, completion-based AI tools. AI-generated code is present in 52% of diffs at Meta and nearly 8% of all modified and landed bytes originate from AI suggestions.

Our central finding is that AI is not applied uniformly: its use is strongly context-dependent. AI code is less likely to land in central or risky code areas and more likely in larger diffs, test files, and for engineers with 3–4 years of tenure (contradicting prior literature on junior engineers). Diffs with landed AI code were reviewed more quickly and were associated with fewer SEVs, but both associations are confounded by AI code appearing in less central contexts. These findings underscore that naive comparisons of AI vs. non-AI work risk misleading conclusions, and that character-level provenance tracing (Chattributes) is essential infrastructure for rigorous evaluation.

**Lessons Learned.** First, *landing rates should replace acceptance rates* as the primary measure of AI tool effectiveness, since accepted code is frequently edited or removed before landing. Second, *context must be controlled*: naive before/after or with/without comparisons confound AI effects with task properties. Third, *AI use is non-uniform and mildly self-regulated*: at Meta, developers use somewhat less AI in central, high-risk code, and after adjusting for context we find no associated increase in SEVs. This tendency is emergent (Meta has no policy discouraging AI use on critical code), but the centrality signal is small and measure-sensitive, so we frame it as a modest, completion-era pattern rather than strong evidence of deliberate risk avoidance.

**Actionable Guidance for Researchers.** *(R1) Include covariates of AI use.* Studies *must* control for code centrality, change size, author experience, and programming language – all systematically associated with AI application (H1). Without these controls, outcome models (H2, H3) confound context effects with AI effects.

*(R2) Guard against "tail wags the dog" inference.* Model AI application probability *first* (as in H1), then include its predictors as controls in outcome models (H2, H3). Factors related to the outcome – such as change duration, size, and type – must be controlled rather than attributed to AI.

*(R3) Distinguish tool availability from tool application.* Comparing groups with and without AI access measures a bundled effect; our diff-level measurement of actual AI code presence (H1) reveals context-dependent variation invisible to group-level designs.

*(R4) Do not assume junior engineers benefit most.* Our finding (H1) that engineers with 3–4 years of tenure have the highest AI landing rates contradicts the common assumption that AI primarily helps inexperienced developers. Studies should measure tenure effects directly rather than assuming a monotonic relationship.

**Actionable Guidance for Practitioners.** *(P1) Invest in provenance infrastructure* that tracks AI-suggested code from editor to landing (Section 2.2) – without it, productivity claims rest on acceptance rates that overstate AI contribution. *(P2) Interpret AI productivity reports with caution*: our H1 results show that increased output may reflect AI being preferentially applied to larger or less complex tasks, not AI itself increasing output. *(P3) Monitor rather than pre-emptively restrict*: H1 and H3 suggest engineers already apply somewhat less AI in higher-risk code and that, after adjusting for context, AI use is not associated with more SEVs; monitoring landing patterns by centrality and change size can track this directly rather than imposing blanket restrictions. *(P4) Do not target AI tooling solely at junior engineers*: H1 shows mid-tenure engineers (3–4 years) have the highest AI landing rates, suggesting that sufficient codebase familiarity helps engineers apply AI effectively. Training and tooling strategies should account for this non-monotonic relationship.

Our findings would benefit from triangulation with qualitative evidence such as developer interviews. Open questions include why acceptance rates diverge from landing rates for junior developers and how AI assistance could be improved across more contexts and languages.

## Data Availability Statement

Applicable privacy and confidentiality requirements prevent public release of the underlying telemetry. We provide detailed descriptions of all variables, model specifications, and statistical procedures to support transparency and reproducibility of the methodology.

**Eva-Maria Schön**
University of Applied Sciences Emden/Leer, Germany

**Henning Fritzemeier**
Volkswagen AG, Wolfsburg, Germany

**Michael Neumann**
University of Applied Sciences and Arts Hannover, Germany

## Abstract

**Context.** The EU AI Act requires providers and deployers of Artificial Intelligence (AI) systems to implement documentation, risk management, and human oversight. Agile teams that ship AI features in short iterations lack specific artifacts to discharge these duties, since the regulation's abstract provisions do not map onto agile practices such as the Definition of Done, Sprint Reviews, or working agreements.

**Objective.** We provide agile teams with an actionable compliance instrument: an evaluated guideline that operationalizes EU AI Act obligations as activities integrable into existing agile practices. We further document the translation method to make its potential adaptation to other regulations examinable.

**Method.** Following Design Science Research, we assessed each EU AI Act article along three dimensions (*technical, normative, organizational*). We subsequently classified the articles using a traffic-light scheme and mapped those deemed highly relevant to previously documented pain points of agile teams working with AI. We evaluated the resulting catalog by eliciting practitioners' perceptions through a survey followed by semi-structured interviews with the same participants (N=11) and analyzed the data via qualitative content analysis.

**Results.** The guideline comprises 12 items covering roles and responsibilities, risk and quality management, transparency and traceability, monitoring, and regulatory sandboxes. Practitioners rated the catalog as understandable and relevant; feasibility varied with organizational maturity. Participants associated perceived adoption feasibility with collective ownership across roles and integration into existing agile events rather than parallel compliance processes.

**Conclusions.** The catalog gives agile teams a starting point to transform their delivery practices towards EU AI Act compliance without dismantling agile practices. A replication package is publicly available.

**2012 ACM Subject Classification** Software and its engineering; Human-centered computing → Empirical studies in collaborative and social computing

## 1 Introduction

Organizations developing or integrating Artificial Intelligence (AI) components in agile or hybrid software development face a compliance problem that is now operational rather than prospective. The EU AI Act [6] entered into force in August 2024, and the core obligations for high-risk AI systems apply from 2 August 2026 [6, Art. 113]. Non-compliance carries administrative fines of up to 35 M EUR or 7 % of global annual turnover, whichever is higher [6, Art. 99]. Providers and deployers in the EU market therefore have to discharge lifecycle-wide duties for risk management, technical documentation, data governance, transparency, and human oversight [6, Art. 9, 11, 13, 14] on a fixed clock, while delivery teams continue to ship in two- or three-week Sprints.

Frameworks such as the *NIST AI Risk Management Framework* [24] and *ISO/IEC 42001* [12] primarily address organizational controls. A complementary gap remains at the team layer, where regulatory obligations must be translated into specific delivery activities and artifacts. For instance, in a specific aspect of the *Definition of Done, adoption in a Sprint Review, items in backlog refinement,* or *rows in a Working Agreement.* The EU AI Act is process-neutral by design: it prescribes outcomes, not ceremonies. A team applying a software process (e.g., Scrum, Kanban, or SAFe) receives no guidance on whether the *Art. 9* risk register lives in the backlog or beside it, whether *Art. 13* transparency obligations expand the user story template, or whether *Art. 14* human oversight is the Product Owner's, the team's, or a separate role's responsibility. Recent empirical work confirms that this gap is observable in practice: Neumann et al. [18] show in their study how regulatory pressures translate into policies that practitioners then bypass to maintain agile velocity, and Sillberg et al. [22] synthesize practitioner sentiment in a multivocal review and report widespread uncertainty about team-level implementation.

Similar research has produced compliance artifacts at the product, audit, or organizational level, which we discuss in Section 2. None of these contributions operates on the team layer, where the obligations meet the cadence of agile delivery, and the one approach that addresses an agile artifact is scoped to a single organization and lacks broader validation. What is missing is a team-level instrument that translates the obligations onto the agile events and artifacts an arbitrary team already uses, together with empirical evidence that practitioners find such an instrument understandable, relevant, and feasible to adopt.

Three research questions guide this work:

**RQ1:** *How can the requirements of the EU AI Act be systematically translated into actionable guidelines for the use of AI in agile software development?*

RQ1 aims to translate abstract regulatory text into team-level practice. We answer it by creating a reproducible procedure that assesses each EU AI Act article along three dimensions, classifies relevance through a traffic-light scheme, and maps high-relevance articles onto documented agile pain points [1, 8]. The expected outcome is both a method that is reusable for adjacent regulations and a concrete guideline catalog derived from it.

**RQ2:** *How do practitioners assess the guidelines regarding understandability, relevance, and feasibility?*

RQ2 verifies whether the artifact resulting from RQ1 holds up under practitioner scrutiny on three constructs that are diagnostic for an applied instrument: a) whether the guideline can be read without further interpretation, b) whether it captures the obligations that matter for agile teams, and c) whether it can be enacted in the carrier artifacts those agile teams already use. We expect this to surface design weaknesses and to indicate which clusters are robust across organizational contexts.

**RQ3:** *Which organizational factors do practitioners perceive as influencing the adoption of our EU AI Act guideline in agile teams?*
The last research question RQ3 moves from artifact quality to practitioners' perceptions of conditions that may support or hinder adoption. We probe how organizational size, regulatory exposure, agile maturity, and existing artifacts shape participants' assessments of potential adoption. The resulting conditions provide hypotheses for future field evaluation rather than evidence of actual adoption.

The paper makes three core contributions: First, we propose an approach for translating regulatory articles into specific (agile) practices. The procedure assesses each article of the EU AI Act along a technical, normative, and organizational dimension, classifies its relevance for agile teams through a traffic-light classification, maps known challenges while adopting or using agile methods from scientific literature, and aggregates them into thematic clusters. The approach is designed to be adaptable to regulations with a comparable obligation structure, such as DORA, NIS2, and the GDPR; however, this transfer has not been empirically evaluated and remains future work. Second, we present an EU AI Act adoption guideline consisting of 12 items organized into five clusters: roles and responsibilities, risk and quality management, transparency and traceability, monitoring and continuous compliance, and regulatory sandboxes. Third, we evaluated practitioners' perceptions of the guideline's understandability, relevance, and feasibility through a survey and semi-structured interviews with 11 practitioners; this study does not measure actual field adoption or compliance readiness.

The paper at hand is structured as follows: Section 2 positions our work against AI governance frameworks and related studies. Section 3 details the translation procedure and the evaluation design. In Section 4, we present the guideline catalog and in Section 5 the evaluation results. Section 6 discusses implications for practice, lessons learned, and the transfer of the methodology to other regulations. Section 7 addresses threats to validity before the paper closes with a conclusion and future work in Section 8.

## 2 Related Work

We position our work along the following research lines: the use of AI in agile software development and the operationalization of the EU AI Act for software engineering (SE). We close by stating the gap that our guidelines address.

### 2.1 AI in Agile Software Development

Empirical studies report that generative AI (GenAI) changes day-to-day agile work. Ulfsnes et al. [27] observe shifts in collaboration, pair work, and individual workflows once AI assistants enter the Sprint. Bahi et al. [1] review agile project management pain points that AI tooling may mitigate, from estimation support to backlog refinement. Russo et al. [21] argue in the Copenhagen Manifesto that GenAI in software engineering must remain human-centered, naming oversight, accountability, and developer agency as design constraints. Herda et al. [8] summarize the XP 2025 workshop in which practitioners and researchers map AI-and-agile challenges to a research roadmap.

Three recent contributions sharpen this picture. Planötscher et al. [20] survey 73 agile practitioners across seven software activities and report that AI is currently used as an assistant or not used at all, with practitioners expecting a shift toward AI as a collaborator. Perkusich et al. [19] survey 70 Brazilian practitioners on LLM use in Scrum management and find broad daily use alongside concerns about "almost correct" outputs, confidentiality, and hallucinations. Neumann et al. [18] conduct a multiple case study in three German

organizations and document how regulatory pressures translate into policies that practitioners then bypass to maintain agile velocity; one of their cases classifies GenAI tools by the EU AI Act risk pyramid, which is the most direct empirical evidence to date that the act is already shaping agile working practice. These studies establish that AI is now an agile concern and that the regulatory dimension is perceptible to practitioners. They do not, however, prescribe how teams should encode the resulting obligations in their daily practice.

## 2.2 Operationalizing the EU AI Act for Software Engineering

Several recent papers translate the EU AI Act into software engineering artifacts. Wagner and colleagues [28, 30, 29] introduce the regulation to the IEEE Software readership, dissect its requirements from an SE perspective, and add an industrial case study on high-risk readiness. Kelly et al. [13] extend the ISO/IEC 25059 product quality model with attributes derived from the act for safety-critical AI. Hupont et al. [11] contribute an UML-based use case card to document the intended purpose of a system in line with the risk classification, while Mökander et al. [16] discuss conformity assessment and post-market monitoring as auditing instruments. Hüger et al. [10] report from Cariad on an instantiation of the act through a Level of Done layer for ML projects in the automotive domain. Sovrano et al. [23] study how LLM-based tooling can support the drafting of technical documentation required by the act. Sillberg et al. [22] synthesize practitioner and academic sentiment toward the act in a multivocal review, and Westerstrand [31] argues that compliance does not exhaust ethical obligation and gives recommendations for fairness in agile AI development. Tuape et al. [26] address Article *14 head-on and design mechanisms for human oversight and accountability* in AI-driven software engineering. Genovesi [7] describes the introduction of an AI governance framework in a financial organization as a practitioner report.

Each of these contributions advances a specific compliance artifact (a product quality model, a documentation template, an audit procedure, a Level of Detail (LoD) layer, a governance framework, a SE perspective on the regulation). None of them targets the team-level agile working practices through which providers and deployers actually meet their day-to-day obligations.

## 2.3 Research Gap

To the best of our knowledge, no published academic work translates the EU AI Act obligations onto the agile practices and artifacts an arbitrary team uses, or evaluates such a translation with practitioners across organizational contexts.

To be more precise, we identified three main gaps: First, the AI-and-agile literature recognizes that AI changes agile work and that the regulatory dimension is already perceptible in practice, with our own prior case study [18] documenting how teams improvise around the absence of clear rules; none of this work, however, supplies a team-level instrument that encodes the act's obligations. Second, the work on EU AI Act operationalization produces compliance artifacts at product, audit, or organizational level, and the one approach that explicitly addresses an agile artifact, Hüger et al.'s Level of Done [10], remains scoped to automotive ML and is not empirically validated with practitioners beyond the case organization. Third, agile-in-regulated-environments studies demonstrate feasibility for other regulations but precede the EU AI Act. This paper addresses these gaps.

# 3 Research Design

We designed our study by applying Design Science Research (DSR) [5, 9, 32] and organize it along the three cycles of Hevner [9]. DSR fits this work because the contribution is an artifact, a translation procedure and the resulting guideline, constructed and then evaluated through practitioner assessment, which is the configuration DSR was developed for in software engineering [5, 32]. The *relevance cycle* is grounded in a concrete industry problem: agile teams covered by the EU AI Act must satisfy obligations from 2 August 2026 onward [6, Art. 113] without abandoning iterative delivery. The *design cycle* produces a reproducible translation procedure and a guideline of 12 items (Section 4). The *rigor cycle* assesses both through a Likert survey and 11 semi-structured expert interviews analyzed through qualitative content analysis [15]. Figure 1 depicts our research design.

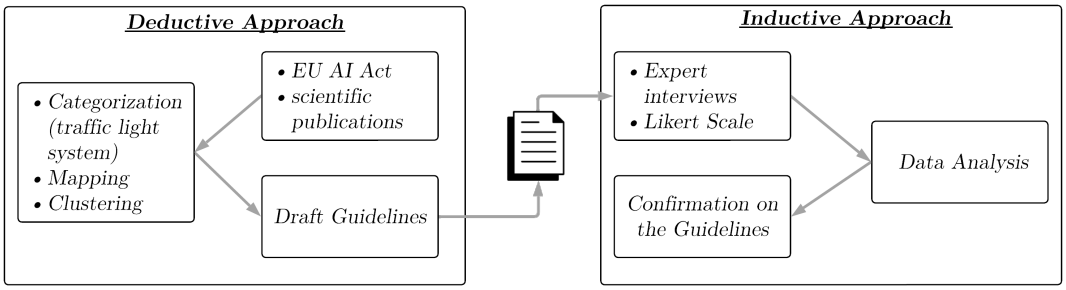

**Figure 1** Research Design for the development and evaluation of our guidelines.

## 3.1 Artifact Creation

The creation of the guideline proceeded in four phases (A–D). Each phase delivered an intermediate artifact for the next: a coded article set, a traffic-light classification, a mapping table, and the cluster structure.

**Phase A: Deductive Analysis of the EU AI Act.** We analyzed all articles of Regulation (EU) 2024/1689 along three dimensions:

- a *technical* dimension (data, monitoring, tooling),
- a *normative* dimension (obligations attached to provider or deployer roles under Art. 16 and 26),
- an *organizational* dimension (roles, governance, process integration).

Each dimension is anchored in recent empirical work on AI in agile contexts: technical in AI-assisted defect detection and test automation [25], normative in the alignment between AI Act obligations and ISO/IEC standards [13], organizational in roles, governance, and oversight in agile AI delivery [1, 8]. Coding criteria were derived deductively from the research questions and these references, following category-system construction as in Bortz and Döring [2] and the DSR guidance of Engström et al. [5].

**Phase B: Traffic-light Classification.** For each article and each dimension, we assigned *high*, *medium*, or *low* relevance. *High* means the article imposes obligations a team must address inside its development workflow; *medium* means the article is contextually relevant but generates no direct team-level work; *low* means it concerns governance levels beyond the team or actors other than providers or deployers. The aggregated rating per article is the maximum of the three dimensional ratings, since a single high-relevance dimension is

sufficient to make an article actionable. Articles with ambiguous coding were re-examined and, where uncertainty persisted, assigned the medium label so that ambiguity does not silently propagate. The first author performed the article coding and relevance classification; no independent sample was recoded and no inter-coder agreement was computed.

**Phase C: Mapping to Agile Pain Points.** We mapped every article rated high in at least one dimension to documented agile pain points of agile teams working with AI [1, 8], consolidated from the four studies cited above into recurring themes such as unclear AI ownership, lack of structured human oversight, insufficient data governance, and compliance documentation accumulating outside agile artifacts. The mapping is many-to-many and was refined iteratively to avoid uncovered pain points and redundant article coverage. We provide an example in Section 4.

**Phase D: Cluster Building and Guideline Derivation.** We grouped the mapped articles into thematic clusters following phases 1–5 of the type-building qualitative content analysis of Kuckartz and Rädiker [14]. Clustering produced five clusters (*C1 Roles and Responsibilities*, *C2 Risk and Quality Management*, *C3 Transparency and Traceability*, *C4 Monitoring and Continuous Compliance*, *C5 Regulatory Sandboxes and Innovation* under Art. 57). Within each cluster, we formulated one or more items through argumentative justification following Bortz and Döring [2], at a granularity that lets a team enact them within an existing event or artifact. Phase D did not use a separately enumerated pool of candidate items; therefore, no formally defined candidates were merged, removed, or rejected. Instead, the 12 items resulted directly from the cluster-wise derivation (C1: 2; C2: 3; C3: 2; C4: 2; C5: 3). We considered the set sufficient for the artifact's intended scope because it covers every cluster and mapped problem–solution chain with a distinct team-level action. This establishes design coverage, whereas legal completeness remains an area for future work.

## 3.2 Practitioner Evaluation

The evaluation followed a sequential mixed-methods design: a Likert survey first, expert interviews second, so the interviews could probe the survey ratings. The same 11 practitioners were surveyed for both evaluation stages (see Table 1). Both data collection instruments are available in the research protocol, which we made available [4].

**Likert Survey.** A 5-point Likert survey on LimeSurvey rated each of the 12 survey items on three constructs: *understandability*, *relevance* for agile software development, and *feasibility* in agile teams (1 = strongly disagree, 5 = strongly agree). Each cluster was introduced with a short context block paraphrasing the EU AI Act obligations it addresses, so participants rated items in context rather than in isolation.

**Expert Interviews.** We conducted 11 semi-structured expert interviews online via Microsoft Teams from 20 October to 25 November 2025. Participants were recruited through the professional networks of the third and fourth author of this paper and one public IT practitioner forum to diversify the sample beyond a single organization, with diversity sought along role, industry, and organization size. Sampling proceeded in two waves. The first wave covered six participants (P1–P6); we monitored category emergence after each interview and observed no new categories after the fifth interview, which we treat as theoretical saturation in the sense of Mayring [15]. We then conducted five additional interviews (P7–P11) to

**Table 1** Interview sample (N=11). Pseudonyms used throughout the paper. Organization sizes are banded for anonymization (10–50, 0.5k–1k, 1k–5k, 0.5k–5k, >1k, >10k, >100k employees) to preserve anonymity while retaining contextual variation. AI Act familiarity is self-reported on a five-step scale: low, low–medium, medium, medium–high, high.

| ID | Role | Domain | Org. size (empl.) | AI exp. (yrs) | AI Act fam. |
|---|---|---|---|---|---|
| P1 | Lead Agile Coach / RTE | Automotive | >100k | 2–3 | low–med |
| P2 | Sales & Key Account Manager | IT Services / Custom Dev. | 1k–5k | 3–5 | high |
| P3 | Software Developer | IT / Software Development | n/a | 2–4 | low |
| P4 | AI & Innovation Manager | Public Administration | >10k | 1–2 | high |
| P5 | Agility Master | Railway / Critical Infrastructure | >100k | 1–3 | medium |
| P6 | Former Head of IT / IT Consultant | Manufacturing / GRC | 0.5k–1k | 3–5 | low–med |
| P7 | Lead Agile Coach | Affiliate Marketing / SE | 1k–5k | 2–4 | med–high |
| P8 | Head of Transformation | Insurance | 0.5k–5k | 1–2 | low–med |
| P9 | CEO / Innovation Consultant | Innovation Consulting / SW Dev. | 10–50 | 3–5 | medium |
| P10 | Engineering Manager | Affiliate Marketing / SE | 1k–5k | 2–3 | medium |
| P11 | Head of Digital Solutions | Industrial / E-Commerce / SAP | >1k | 1–3 | medium |

confirm saturation and broaden contextual variation across roles, industries, and organization sizes; no new main categories emerged in this second wave. Table 1 provides an overview of the interviewee profiles and their characteristics.

The interview guide had four blocks. Blocks 1 (background and AI exposure), 2 (general assessment), and 4 (closing feedback) were identical across interviews. Block 3 was individualized per interview from the participant's prior survey responses (the *expectation profile*) to probe divergences between low and high ratings on the same item or cluster. Interviews were held online using Microsoft Teams, were recorded with consent, transcribed automatically with Voice AI, and anonymized before analysis. The shortest interview had a duration of 18:35 minutes, whereas the longest interview lasted 43:11 minutes. The average interview duration was 30:00 minutes. This variation reflected the survey-based data, specifically the expectation profiles, on which the interviews were based. Interviews were generally shorter when there was broad overall agreement, whereas greater discrepancies required more extensive discussion. The interview guide template and the per-interview instantiations of block 3 are in the replication package.

## 3.3 Qualitative Data Analysis

We analyzed the transcripts with structuring qualitative content analysis following Mayring [15]. A first pass per interview produced superordinate codes; a second pass consolidated them into main and subcategories across interviews; a third pass applied the resulting coding guide (definitions, coding rules, anchor examples) to the full material. The coding guide is also available in the research protocol [4].

Coding was performed by the first author. We did not compute inter-coder reliability; the implication is discussed in Section 7. As a partial compensation, the interviewer applied in-situ communicative validation by summarizing key statements back to participants and asking for confirmation. Likert data were analyzed descriptively (means, medians, full distributions); inferential statistics are omitted because $n = 11$ does not support them.

# 4 The Guideline

This section presents the artifact produced by the design cycle and answers RQ1: *How can the requirements of the EU AI Act be systematically translated into actionable guidelines for the use of AI in agile software development?* We report the outcome of the traffic-light classification, the five clusters, the 12 items that constitute the guideline, and the mapping to agile elements[1]. The guideline [3] is the input to the evaluation reported in Section 5.

## 4.1 Outcome of the Traffic-Light Classification

We assessed all 113 articles of the EU AI Act along the three dimensions *(technical, normative, and organizational)* introduced in Section 3.1. The aggregated classification resulted in 30 articles rated as high relevance, 33 as medium relevance, and 50 as low relevance. Articles classified as *high relevance* on at least one dimension entered the mapping step; articles rated *medium* or *low* on all three were retained for traceability but did not generate items. The full classification is part of the replication package (see [4]).

Three observations shape the guideline. First, high-relevance articles cluster in the high-risk obligations of Chapter III (Art. 9–15) and the transparency provisions of Chapter IV (Art. 50), with concentration on the normative and organizational dimensions. Second, the technical dimension attracts fewer high-relevance ratings than the other two; technical obligations are largely indirect, mediated by documentation and process requirements. Third, *Art. 57 regulatory sandboxes* is the only article that addresses a voluntary mechanism rather than an obligation, which justifies treating it as a separate cluster (Section 4.2).

## 4.2 Five Clusters Across the AI Adoption Regulation

The mapping step (Phase C, Section 3.1) linked each high-relevance article to one or more agile pain points reported by Bahi et al. [1] and Herda et al. [8]. The cluster step (Phase D) aggregated articles and pain points along thematic proximity, following the type-building qualitative content analysis according to Kuckartz and Rädiker [14], Phases 1–5. The result is five clusters that span the guideline.

Table 2 exposes the translation from regulatory anchors through mapped agile pain points to the final guideline items at cluster level. The following section provides the item-level assignments and wording.

[1] Here we reference an agile element as an agile practice or artifact in accordance with Neumann [17].

**Table 2** Cluster-level traceability from regulatory anchors and agile pain points to all 12 guideline items.

| Regulatory anchor and obligation | Mapped agile pain point | Items |
|---|---|---|
| **Arts. 3, 16, 26:** provider and deployer roles and duties | Overlapping agile roles and unclear accountability for AI use | G1.1–G1.2 |
| **Arts. 9, 10, 14:** lifecycle risk management, data governance, and human oversight | Iterative delivery can fragment risk and data-quality review and leave AI outputs without assigned human oversight | G2.1–G2.3 |
| **Arts. 11, 13, 50:** documentation, instructions for use, and transparency | Minimal documentation leaves the influence of AI invisible to team members and stakeholders | G3.1–G3.2 |
| **Arts. 17, 72:** quality management and post-market monitoring | Compliance monitoring and resulting process updates are not integrated into recurring team workflows | G4.1–G4.2 |
| **Art. 57:** regulatory sandboxes | Teams lack a protected setting and a traceable feedback loop for experimentation before production | G5.1–G5.3 |

## 4.3 The Twelve Items of the AI Adoption Guideline

Table 3 makes the translation chain explicit by listing, for each of the 12 items, the originating EU AI Act article or articles, the mapped agile pain point, and the resulting team-level action. Table 3 subsequently identifies the carrier artifacts through which these actions can be enacted. The pain-point formulations condense the Phase C mapping described in Section 3.1 and grounded in [1, 8]. We use the form "*teams + active verb + agile element + traceable outcome*" to keep each item actionable. Each item is short enough to fit a Definition of Done entry or a Working Agreement line.

The guideline addresses obligations on providers and deployers symmetrically. Where the EU AI Act differentiates the two roles, the items remain neutral and leave role attribution to G1.1 in Table 3.

## 4.4 Agile Elements Mapping

The guideline does not prescribe new agile practices. We map each item to one or more existing agile elements (Table 4) so that adoption requires adapting current artifacts rather than introducing parallel structures. This mapping is the design decision that operationalizes the agile pain point of process overhead outlined in the related work (see Section 2).

In the following, we present concrete examples of what carrier mapping might look like in practice. *Definition of Done* (G2.1, G3.1, G4.2): "If the increment uses or contains an AI component, the linked work item records data-quality evidence, the AI's influence on the work product, and the compliance verification result; unresolved findings are escalated before release." *Working Agreement* (G1.1, G1.2): "For each AI-related work item, the team records the responsible role, the applicable provider/deployer responsibility, and the escalation contact for legal or compliance questions." *Sprint Review checklist* (G2.3, G3.2, G5.2): "Were relevant AI outputs reviewed by a competent human and was the result recorded? Was the AI's influence disclosed to relevant stakeholders? If a sandbox was used, were its results and follow-up actions recorded?" These examples are illustrative carrier-level implementations, not mandatory templates or legal advice. The mapping is not bijective. Most items attach to more than one carrier, and most carriers carry more than one item. We

**Table 3** Items of the EU AI Act-aligned guideline for agile teams. Article numbers refer to Regulation (EU) 2024/1689.

| ID | Cluster | Art. | Item |
|---|---|---|---|
| G1.1 | C1 Roles & Resp. | 3, 16, 26 | Responsibilities for AI use are assigned explicitly and aligned with EU AI Act provider and deployer roles. |
| G1.2 | C1 Roles & Resp. | 3, 16, 26 | Role assignments are documented in agile artifacts such as Working Agreements or the Definition of Done. |
| G2.1 | C2 Risk & Quality | 10 | Data quality is checked and documented continuously within the team. |
| G2.2 | C2 Risk & Quality | 9 | AI-related risks are identified, assessed, and documented iteratively. |
| G2.3 | C2 Risk & Quality | 14 | Outputs of AI systems are reviewed regularly under human oversight. |
| G3.1 | C3 Transparency | 11, 13 | Work products are documented such that the influence of AI is traceable. |
| G3.2 | C3 Transparency | 50 | Transparency about AI influence is established in recurring agile events (e.g., Sprint Review). |
| G4.1 | C4 Monitoring | 17, 72 | Retrospectives are used to reflect on regulatory changes and integrate them into the team's way of working. |
| G4.2 | C4 Monitoring | 17, 72 | Teams establish a procedure to verify and document compliance continuously. |
| G5.1 | C5 Sandboxes | 57 | AI systems are first deployed in sandbox environments before productive use. |
| G5.2 | C5 Sandboxes | 57 | Sandbox results are reflected in agile events such as Sprint Reviews or retrospectives. |
| G5.3 | C5 Sandboxes | 57 | Sandbox use is documented to satisfy traceability and accountability requirements. |

treat this as a feature rather than a limitation: it preserves the flexibility that agile teams expect. Taken together, the traffic-light classification, the five clusters, the 12 items, and the carrier mapping form the artifact answering RQ1.

## 5 Findings from the Practitioner Evaluation

As stated in Section 3, we evaluated practitioners' perceptions of the guideline through a Likert-based survey and 11 semi-structured expert interviews. Section 5.1 reports the practitioner assessment along the three construct dimensions and answers RQ2. Section 5.2 reports the organizational factors that emerged from the interview analysis and answers RQ3.

### 5.1 Practitioner's Assessment of Understandability, Relevance, and Feasibility

The second research question, RQ2, asks: *How do practitioners assess the guidelines regarding understandability, relevance, and feasibility?* Across the 11 participants, the guideline was perceived as understandable and relevant; perceived feasibility was more dispersed and depend on the team's working context rather than on the wording of individual items. We base this assessment on the Likert ratings shown in Table 5 and on the follow-up interviews that probed deviations from the expectation profile.

**Table 4** Mapping of items to agile practices and artifacts.

| Agile Element | Items |
|---|---|
| Working Agreement | G1.1, G1.2 |
| Definition of Done | G1.2, G2.1, G3.1, G4.2 |
| Backlog Refinement | G2.1, G2.2 |
| Sprint Review | G2.3, G3.2, G5.2 |
| Retrospective | G2.2, G4.1, G4.2, G5.2 |
| Decision log / ADR | G3.1, G5.3 |
| Sandbox protocol | G5.1, G5.2, G5.3 |

**Understandability** is the dimension on which the guideline is least contested. P10 framed the contrast that recurs in most interviews: condensed items are easier to act on than the full regulatory text. Only two of the 12 items attract any disagreement at all, and the dissent concentrates on terminology rather than substance, G1.2 references the *Working Agreement*, an artifact that several participants reported as unfamiliar in their own teams. P11 made the same point in a different register, asking whether the documentation duty was tied to a specific carrier or could be discharged equivalently elsewhere. The interviews position the guideline as a translation device: practitioners read it not as a new vocabulary but as an explicit version of practice that was already implicit.

**Relevance** disperses more than understandability and tracks the mandatory, voluntary distinction in the underlying articles. The items that operationalize Chapter III obligations of the EU AI Act, especially *human oversight* (G2.3) and *iterative risk identification* (G2.2), are rated as clearly relevant and prompted no contrary statements in the interviews. By contrast, the *continuous-compliance* item G4.1 and the *sandbox-documentation* item G5.3 attract the largest share of neutral or disagreeing responses. The qualitative material identifies two distinct mechanisms behind this. For G4.1 the criticism is one of locus: P11 rejects the retrospective as the venue for regulatory discussion, arguing that such topics "require organizational coordination rather than team-internal self-regulation"; P10 expresses the same reservation with regard to mandating regulatory reflection inside an event that is already crowded. For G5.3 the criticism is one of scope: sandbox documentation is seen as relevant where teams build AI systems but not where they merely use AI tools, a distinction (*developing AI* versus *developing with AI*) that P10 and P11 both raise independently.

**Feasibility** is the dimension that exposes the guideline most sharply to the working context. The single strongest objection in the entire evaluation, the only *strongly disagree* rating, is on G3.1 (documenting the influence of AI on work products), placed by P2 and accompanied by three further low ratings. The reservation is not about the principle, as transparency regarding AI influence is endorsed across the sample, but about the practical effort required in teams that have no established mechanism for documenting it. P3 captured the boundary condition that runs through the feasibility judgments: the items are realistic only when they "become part of daily work and are not perceived as an additional burden." Where existing agile carriers (Definition of Done, Sprint Review, Retrospective) are active, integration is described as incremental; where they are weak or absent, even the most basic documentation item becomes contentious.

We summarize the distributional view and report medians and interquartile ranges in Table 5. A consistent pattern runs through the three dimensions. The guideline holds up where it formalizes practices that agile teams recognize (risk identification, human oversight,

**Table 5** Likert ratings per item ($N = 11$). *Mdn* = median, *IQR* = interquartile range. Five-point scale (1 = strongly disagree, 5 = strongly agree).

| | Understandability | | Relevance | | Feasibility | |
|---|---|---|---|---|---|---|
| **ID** | *Mdn* | *IQR* | *Mdn* | *IQR* | *Mdn* | *IQR* |
| G1.1 | 4 | 1.0 | 4 | 1.0 | 4 | 0.0 |
| G1.2 | 4 | 1.5 | 4 | 1.0 | 4 | 0.5 |
| G2.1 | 4 | 1.0 | 4 | 0.5 | 4 | 0.0 |
| G2.2 | 5 | 0.5 | 4 | 1.0 | 4 | 1.0 |
| G2.3 | 5 | 0.0 | 5 | 1.0 | 5 | 1.0 |
| G3.1 | 4 | 1.0 | 4 | 1.0 | 3 | 1.0 |
| G3.2 | 5 | 1.0 | 4 | 1.0 | 4 | 1.0 |
| G4.1 | 4 | 1.0 | 3 | 1.5 | 3 | 1.0 |
| G4.2 | 5 | 1.0 | 4 | 1.0 | 4 | 1.0 |
| G5.1 | 4 | 1.5 | 4 | 1.5 | 4 | 1.5 |
| G5.2 | 4 | 1.0 | 4 | 1.0 | 4 | 0.0 |
| G5.3 | 4 | 1.0 | 3 | 0.5 | 4 | 0.0 |

peer review) and meets resistance where it adds documentation or process duties that fall on the team itself (G3.1, G4.1) or addresses voluntary mechanisms (G5.3). The median rating is 4 for almost all item–dimension combinations, indicating broad agreement. The main empirical signal therefore lies in the variation of responses, which shows where practitioners' assessments diverged.

In summary, practitioners assess the guideline as understandable and broadly relevant, with feasibility contingent on the team's agile carriers.

## 5.2 Practitioner-Perceived Conditions for Adoption

Here, we answer RQ3: *Which organizational factors do practitioners perceive as influencing the adoption of our EU AI Act guideline in agile teams?* Based on the interview accounts, we identified six categories describing conditions that participants expected to support or hinder adoption. The frequencies in brackets indicate how often each category occurred in the interviews.

**Function and benefit of the guideline (10/11).** The guideline is positioned as an instrument of orientation rather than as a checklist. P1 described it as "a good basis to engage with AI more systematically and consciously"; P9 framed the underlying regulation as "an opportunity for quality and clarity, not as a brake." The shared interpretation from the participants is that the guideline does not require entirely new ways of working but makes existing agile practices more explicit and links them to EU AI Act compliance. Adoption is reported to be easier where agile teams already accept this framing and harder where the guideline is read as an additional rulebook.

**Implementation and integration (8/11).** Whether the guideline takes hold depends on whether it is embedded into the artifacts that already structure the team's work. For example, *Working Agreement*, *Definition of Done*, *Sprint Review*, and *Retrospective*. P3 articulated the operational boundary condition explicitly: the items work only when they "become part of daily work and are not perceived as an additional burden." P10 reported that quality assurance for AI-generated code already runs through existing reviews, and that the value

of the guideline lies in making this explicit rather than in adding ceremonies. P8 named the converse failure mode: mere availability is not enough, and introduction needs change management and active support. Tooling and training were named as enablers across the sample; absent or implicit ownership of compliance was the most common blocker.

**Roles, responsibility, and communication (8/11).** The guideline is read as a redistribution of accountability, not as the assignment of compliance to a single role. Participants rejected the model of delegating AI compliance to the Product Owner, the Scrum Master, or a dedicated compliance officer in isolation. P4 emphasized that the guideline helps "make responsibilities visible, especially at the leadership level"; P9 added that formal role documentation must not replace individual ownership: "regulatory accountability cannot substitute for personal responsibility." Two participants proposed concrete role designs: P10 suggested AI champions to coordinate compliance topics; P11 framed a defined AI responsibility as "a major opportunity for the company." Across the sample, communication between development teams and compliance functions was named as the mechanism that converts shared responsibility into observable practice.

**Agility versus regulation (7/11).** Participants did not treat the guideline as a threat to agile values and principles, but they articulated the latent risk. P2 warned that strict rules "slow down the agile process"; P11 added that documentation duties "can slow down development processes." The risk is reduced when the items extend existing events and amplified when compliance is migrated into parallel meetings. Participants endorsed integration into the Sprint Review and the Retrospective as a way to keep compliance recurrent without breaking cadence, with one notable dissent: P11 explicitly rejected the Retrospective as the venue for regulatory discussion, arguing that such topics belong to organizational coordination, not team self-regulation. This dissent maps onto the lowest relevance rating in the guideline (G4.1) and is the clearest qualitative explanation for that quantitative outlier.

**Context and organizational maturity (7/11).** A one-size-fits-all interpretation did not hold in practice. The same item was perceived as straightforward in one organization and difficult to implement in another, depending on organizational maturity, resource availability, and the strength of existing agile artifacts. P1 contrasted large organizations, where "the items work well," with smaller teams that "need more individual approaches"; P9 reported the opposite from a different perspective, arguing that smaller teams may adopt the items more bindingly because they are closer to the actual work. P8 noted that the guideline "does not directly fit a non-agile context" and therefore requires translation. P10 and P11 independently raised a distinction that the guideline itself does not explicitly make: *developing AI* and *developing with AI* are different cases, and some clusters, notably C5 on sandboxes, are more relevant to the former than to the latter. According to the participants, industry was less important than organizational maturity: heavily regulated industries did not automatically find the guideline easier to adopt; what mattered was whether the regulatory function and the development teams already had an established mode of collaboration.

**Participation and continuous evolution (5/11).** The guideline is read as a living instrument, not as a static document. P1 summarized that competencies "cannot be conveyed once but must be built up continuously"; P4 added that practitioners themselves should be involved in revising the guideline. P7 and P10 emphasized reflection in agile events as the operational mechanism; P8 named explicit change management, training sessions, and consultation hours. Static publication of the guideline, without ownership for its ongoing revision, was identified as a likely failure mode.

### Cross-category patterns

Three patterns cut across the six categories. First, organizational maturity, operationalized as the presence and active use of agile artifacts, was the most frequently reported condition associated with perceived feasibility. Agile teams with active artifacts describe integration as incremental; agile teams without them describe it as a precondition that has to be established first. Second, industry regulation builds awareness but not capacity: participants in regulated industries did not report greater ease in adopting the AI Adoption Guideline. Third, organization size shapes which carriers participants regard as realistic: smaller organizations rely on the Working Agreement as a single agile carrier, larger organizations distribute the items across more specialized artifacts. With $N = 11$ these patterns are working hypotheses for further studies, not statistical claims. Taken together, participants associated perceived adoption feasibility with three factors: collective ownership of compliance rather than delegation to a single role, embedding into existing agile events, and the maturity of the agile team's artifacts.

## 6 Discussion & Implications for Practice

**Key Findings**

Participants expected the guidelines to bridge regulation and agile delivery when teams embed them in existing artifacts and events rather than running a parallel governance track. Perceived feasibility was associated with organizational maturity and with responsibility for AI compliance being shared across the team rather than delegated to a single role. A fixed set of guidelines does not scale to organizational diversity; practitioners need a stable backbone together with explicit guidance for context-specific adaptation.

### 6.1 Interpretation of Findings

We interpret the interview results along three patterns that emerged consistently across the sample.

First, practitioners read the guidelines as a translation layer rather than as new policy. The function described most often across the sample is making existing practice explicit and reducing uncertainty about what Articles 9, 11, 14, and 17 of the EU AI Act [6] require inside an iteration and the applied agile practices in it. This reading is consistent with Article 96 EU AI Act [6], which positions guidelines as instruments of uniform application rather than as substantive obligations.

Second, participants associated adoption feasibility with contextual fit. The implementation and integration category was raised by 8 of 11 participants and was the most frequently reported correlate of perceived feasibility. Agile teams with established agile artifacts described integration as incremental, whereas teams without such artifacts need to create or formalize suitable structures before the AI Adoption Guideline can be embedded in day-to-day work. Industry regulation built awareness but not capacity: participants in regulated industries did not report easier adoption. P10 and P11 surfaced a distinction the guidelines themselves do not make explicit, between *developing AI* and *developing with AI*. Cluster C5 (Regulatory Sandboxes) is more pertinent to the former, while C3 (Transparency) and C4 (Monitoring) carry weight for both.

Third, responsibility for AI compliance is collective in practice but unassigned by default (8 of 11). Participants rejected delegation of EU AI Act obligations to the Product Owner, the Scrum Master, or a dedicated compliance officer in isolation. P4 stressed that the

guidelines help make responsibilities visible at the leadership level; P9 added that formal role documentation cannot substitute for individual ownership. Two participants proposed concrete designs: P10 suggested AI champions to coordinate compliance topics, P11 framed defined AI responsibility as "a major opportunity for the company." The absence of a default owner is a known agile pain point [1]; cluster C1 (Roles and Responsibilities) encodes collective ownership in role extensions and in agile artifacts rather than in a new compliance role.

The pattern on agility versus regulation refines this picture. The risk of compliance dragging on delivery decreases when the guidelines extend existing events and increases when compliance moves into parallel meetings. One dissent on this point is informative rather than incidental: P11 explicitly rejected the Retrospective as the venue for regulatory discussion, arguing that such topics belong to organizational coordination, not team self-regulation. This single position is the clearest qualitative explanation for the lowest relevance rating in the Likert results (G4.1) and marks the limit of automatic integration into agile events.

## 6.2 Positioning our Contribution to the Related Work

Our results complement existing work along four areas. Todorov [25] maps AI techniques onto software engineering tasks but does not address regulatory obligations; we add the compliance layer. Bahi et al. [1] identify agile pain points around AI adoption without linking them to legal requirements; we close that link through the traffic-light mapping between high-relevance EU AI Act articles and named pain points. Kelly et al. [13] translate EU AI Act requirements into technical specifications for safety-critical AI; we cover the organizational dimension their technical framing does not reach. Herda et al. [8] report practitioner concerns from the XP 2025 workshop but stop at the level of observations; we convert comparable concerns into a practitioner-assessed set of guidelines.

Two contributions are very close to our work. Hüger et al. [10] introduce a Level of Done layer for ML projects at Cariad as the most direct prior attempt to encode EU AI Act obligations in an agile artifact; their approach targets automotive ML and is not validated with practitioners outside the case organization. Neumann et al. [18] document how teams in three German organizations improvise around the absence of clear rules and bypass emerging policies to maintain agile velocity. The present paper responds to that finding: the guidelines provide the team-level instrument those teams were missing.

The convergent point across this body of work is that EU AI Act compliance in agile contexts is an organizational problem, not a technical one. None of the prior contributions provides a practitioner-assessed set of guidelines that practitioners can adapt to their Working Agreements and Definition of Done. The artifact contribution of our paper addresses this gap. The procedure may also be adaptable to similarly structured regulations, but we did not apply it to DORA, NIS2, or the GDPR; transferability therefore remains an untested proposition for future work.

## 6.3 Implications for Practice

We derive seven implications. Each is grounded in interview evidence and tied to a specific thematic cluster.

**L1: Extend existing agile practices before adding new ones.** The strongest signal across the sample (8 of 11) is resistance to additional meetings or roles. Sprint Reviews, Retrospectives, and Backlog Refinements address the EU AI Act obligations of Articles 9 and 17 when scoped

to include AI risk and compliance reflection. P3 stated the operational condition plainly: the guidelines work only when they "become part of daily work and are not perceived as an additional burden." Compliance migrated into parallel ceremonies was reported as the first ceremony to be dropped under delivery pressure.

**L2: Anchor responsibilities in artifacts, not in job titles.** Participants perceived Cluster C1 (Roles and Responsibilities) as more feasible when accountability is encoded in Working Agreements and the Definition of Done rather than assigned to a named role. P9 phrased it plainly: regulatory accountability cannot substitute for personal responsibility. Artifact-level anchoring protects the team against turnover and against the false reassurance of appointing a compliance officer with no execution mandate inside the Sprint.

**L3: Calibrate guideline depth to organizational maturity.** The same guideline produces different outcomes in agile teams with and without established agile practices (7 of 11). Organizations at lower maturity should adopt clusters C1 (Roles and Responsibilities) and C2 (Risk and Quality) first and defer C4 (Monitoring) and C5 (Regulatory Sandboxes) until the basic governance loop is reliable. Adopting the full set at once was reported as overwhelming. P8 named the converse failure mode for any maturity level: availability is not enough, and introduction requires change management and active support.

**L4: Make AI influence visible at the artifact level.** Cluster C3 (Transparency) can be implemented with low overhead through short provenance markers on user stories, pull requests, and review notes. P10 reported that quality assurance for AI-generated code already runs through existing reviews and that the value of the guideline lies in making this explicit rather than in adding ceremonies. Heavyweight documentation templates were rated as the least feasible part of the guidelines.

**L5: Separate team-level execution from organizational accountability.** The EU AI Act assigns obligations to providers and deployers, not to agile teams as legal entities. Teams can implement operational controls within delivery work, including risk and output reviews, documentation, traceability, monitoring, and escalation triggers. Management and organizational legal or compliance functions remain accountable for role determination, legal interpretation, risk appetite, governance structures, resources, and formal conformity decisions. The guideline therefore supports but cannot replace organizational governance or legal assessment. Before adoption, its wording and responsibilities should be reviewed with legal or compliance experts and adapted to organization-specific obligations and policies.

**L6: Treat the guidelines as a living artifact.** Participants read the guidelines as evolving rather than static (5 of 11). P1 noted that competencies cannot be conveyed once but have to be built up continuously. Agile teams should plan a review cadence for the guideline (e.g., on a quarterly basis) in which the guidelines are revised against retrospective input and against changes to the EU AI Act implementation acts. A frozen set loses legitimacy.

**L7: Invest in AI literacy before invoking human oversight.** Article 14 EU AI Act requires human oversight, but oversight without competence is ceremonial. Participants linked feasible oversight to training on model limitations, prompt design, and output assessment. For LLM-based systems, output reliability includes hallucinations, while other AI systems expose different accuracy and robustness risks. The artifact treats output reliability as a process risk through iterative risk review (G2.2), human review (G2.3), traceability (G3.1),

and pre-production sandboxing (G5.1). These controls can detect and document unreliable outputs, but cannot eliminate hallucinations or establish technical accuracy; model evaluation and technical safeguards remain necessary.

## 7 Threats to Validity

As with every study also ours comes with limitations. We applied the threats to validity concept [33] to mitigate the limitations and identify specific measures to optimize the quality. We discuss these threats below.

### Construct Validity

The three assessment dimensions *(technical, normative, organizational)* and the three Likert constructs *(understandability, relevance, feasibility)* were defined by the first author from methodological literature and from the EU AI Act text, without external concept validation. Each Likert construct is measured by a single item per guideline, which limits construct coverage; we mitigate this by triangulating the ratings with semi-structured interviews that probe the same constructs in open form. The term *guideline* in this paper refers to a team-level translation artifact and is distinct from the Commission-issued guidelines foreseen in Art. 96 EU AI Act [6].

Because the guideline items translate selected EU AI Act obligations into concise team-level formulations, this translation may introduce interpretive bias, for example if legally relevant terms are simplified, omitted, or interpreted differently across organizational contexts. The study did not include a formal legal validation of the items by legal experts or organizational legal departments. Accordingly, the AI Adoption Guideline should be understood as an operational support instrument for agile teams, not as legal advice or as a substitute for organization-specific legal assessment.

### Internal Validity

We addressed this through a documented coding guide with definitions, coding rules, and anchor examples and through a three-pass procedure (Section 3.3); both are part of the replication package. Communicative validation was partial: we used probing and summarizing during the interviews but did not return the final category system to participants for member checking. Block 3 of the interview guide was individualized from each participant's prior survey responses to target divergence between survey and interview, which may bias probing toward expected explanations; Blocks 2 and 4 remained fixed across all interviews to preserve a common baseline.

### External Validity

The sample of 11 participants may not be representative. Recruitment proceeded through the professional networks of co-authors, one public IT practitioner forum, and targeted primarily agile and managerial roles. The sample includes one software developer (P3), but no data scientists, legal experts, or compliance specialists; technical and legal/compliance perspectives are therefore underrepresented. The EU AI Act is in its early implementation phase, with obligations for high-risk systems applying from 2 August 2026, and the regulatory context is European; transfer to other jurisdictions or to later enforcement phases is not warranted by our data. Cluster C5 addresses regulatory sandboxes under Art. 57, which are voluntary; feasibility ratings for C5 generalize only to organizations that actively consider sandbox participation.

### Conclusion Validity

The Likert data are ordinal, and the sample size precludes inferential statistics; we report medians and interquartile ranges and do not test differences across guidelines or constructs. The qualitative analysis carries the interpretation margin inherent to structuring content analysis; the cross-case patterns in Section 5.2 are working hypotheses, not statistical claims. This study assesses perceived understandability, relevance, and feasibility; it does not observe guideline adoption in the field or test whether the artifact improves compliance readiness. We draw no causal conclusions about adoption.

### Reliability

The replication package [4] covers the traffic-light mapping, the Article-to-cluster-to-guideline mapping, anonymized Likert raw data, the expectation profile, the interview guide, the coding guide, and the anonymized analysis matrix.

## 8 Conclusion & Future Work

This paper addresses how agile teams can discharge EU AI Act obligations without disrupting iterative delivery practices. Three findings carry our contribution. First, the regulation's obligations can be translated into actionable guidelines for agile teams through a reproducible procedure that combines a three-dimensional article assessment, a traffic-light classification, and a mapping to reported agile pain points. Second, practitioners assessed the resulting 12 guidelines items in five clusters as understandable and relevant; perceived feasibility of adoption varied with organizational maturity and the strength of existing agile artifacts. Third, participants associated perceived adoption feasibility with three organizational factors: collective ownership of compliance, integration into existing agile events, and treatment of the guideline as a living artifact rather than a static document.

Three directions extend this work. A larger and more diverse practitioner sample is needed to test whether the cross-category patterns observed generalize across industries, organization sizes, and maturity levels. Longitudinal pilot studies inside the industry partner organization would shift the evidence base from perceived to actual adoption, traceable in Working Agreements, the Definition of Done, and the carrier artifacts of clusters C1–C5. The translation procedure uses analytical steps that are not specific to the EU AI Act, but its transferability has not yet been empirically evaluated. Applying it to DORA, NIS2, and the GDPR would test which elements are transferable and which require regulation-specific adaptation.

## Data Availability Statement

The replication package for this study is publicly available [4]. It includes the traffic-light classification, the article-to-cluster-to-guideline mapping, the expectation profiles, the customized interview guide based on the expectation profiles, the coding guide & book, and the anonymized analysis matrix. The survey raw data and interview transcripts are not publicly available in order to protect participant confidentiality and to comply with data protection requirements. Access to additional anonymized materials may be provided by the corresponding author upon reasonable request, subject to ethical and legal constraints.

We also made the guideline available as a companion document [3].

## Abstract

**Background.** Implementing unit tests is an important yet time-consuming activity in software development. Therefore, Large Language Models (LLMs) are being used increasingly often for generating unit tests. Many previous work report promising results for open-source repositories written in common languages such as Python or Java. However, the performance of LLM-based test generation in large proprietary software projects written in C++ remains largely unknown.

**Aims.** To reduce this gap, we investigate the performance of LLM-based test generation on a large closed-source C++ software project, which is not part of the training corpus of LLMs.

**Method.** We study test generation on SAP HANA, a large C++ DBMS, and compare it to the open-source key-value store LevelDB. We analyze two LLM-based test generation approaches, each including an iterative repair loop for compilation failures, along five metrics: compilation success rate (CSR), execution success rate, line coverage, branch coverage, and mutation score (MS).

**Results.** The metrics show a considerable gap between the two systems. The LLM-generated tests for LevelDB match the quality of the existing tests. On SAP HANA, the LLM-generated tests achieve only 25.2% MS and underwhelming coverage results. Iterative repair with at least 3 iterations is important, reaching 97.6% CSR on SAP HANA after 10 iterations. However, with more iterations, LLM may prioritize compilability over test quality, resulting in tests with weak assertions.

**Conclusions.** Results reported on open-source projects, whose code is often part of LLM training data, may not generalize to unseen, industry-grade C++ codebases. The effectiveness of iterative repair saturates after several iterations. When applying LLMs to source code not in training data, practitioners should carefully select the context provided to the models.

## 1 Introduction

Automated test creation has been targeted by various approaches, including random and feedback-directed test creation [35], search-based test generation tools such as EvoSuite for Java [17] and Pynguin for Python [29]. While these approaches have demonstrated promising results in terms of code coverage, they struggle with scalability constraints, the cost of constraint solving, and difficulties producing tests that integrate naturally with developer-written code [47, 36]. To mitigate these issues, Large Language Models (LLMs) have been increasingly used for automatic test generation, leading to industrial adoption [21, 1, 36]. However, most previous work focused on generating tests in common programming languages such as Python or Java. In contrast, fewer studies targeted C/C++ codebases, where build complexity, manual memory management, and project-specific dependencies create additional challenges [51, 46]. Furthermore, previous research predominantly focused on open-source projects whose code may have been included in public LLM training corpora, raising questions about their generalizability to proprietary systems [41, 16]. To close these gaps, our study addresses the following research questions:

**RQ1:** *To what extent can LLMs generate effective tests for SAP HANA in terms of execution success, code coverage, and mutation score?*
**RQ2:** *How does LLM-generated test performance differ when evaluated on open-source versus proprietary DBMS?*
**RQ3:** *To what extent does iterative compiler-feedback repair improve compilation success rates of LLM-generated tests in C/C++?*
**RQ4:** *Does providing header files improve the effectiveness of generated tests for SAP HANA?*

We addressed these questions through an empirical evaluation of SAP HANA and the open-source LevelDB key-value store. SAP HANA is a large in-memory DBMS composed of tens of millions of lines of C++ source code [4, 3]. We evaluated four LLMs: GPT-5, Claude 4 Sonnet, Gemini 2.5 Pro, and Qwen3-Coder using two generation approaches: test amplification, where we extend existing test suites with generated ones, and whole-suite generation, where a completely new test suite is generated based on source code files. We compared two context configurations: source-only and source augmented with header files. To address compilation failures common in C/C++ code generation [50, 51, 46], we integrate a compiler-feedback repair loop. We categorized 807 unresolved compilation failures on SAP HANA extracted from the generation logs. For the compiling tests, we assessed the test quality using five common test quality metrics. We repeated each configuration three times and report the spread of each metric across repetitions in Section 4.6.

Thus, this work provides the following contributions:

1. An empirical evaluation of three commercial general-purpose LLMs and one open-weight coding model, across two generation approaches and five metrics.
2. A performance comparison on a complex proprietary industrial C++ system (SAP HANA) against an open-source reference (LevelDB).
3. Practical observations and recommendations for practitioners considering LLM-based test generation in industrial C++ projects, including the dynamics of iterative compiler-feedback repair and a categorized analysis of failure modes with concrete examples.

The remainder of this document is structured as follows. Section 2 provides an overview of related work. We introduce our methodology and experimental setup in Section 3. Section 4 presents results. In Section 5, we discuss our work and address threats to validity. Section 6 concludes. Our replication package is available online [6].

# 2 Related Work

## 2.1 LLM-based Test Generation

In their systematic literature review on test generation, Chu et al. [11] pointed out that prompt engineering is the most researched approach for unit test generation, accounting for approximately 89% of studies related to automated test generation. However, they identified critical challenges of automatic test generation approaches, including weak fault-detection capabilities and the lack of standardized benchmarks, particularly outside open-source projects that dominate existing evaluations. Two approaches for generating new tests appear most often in the literature. 1) *Test amplification* extends existing developer-written test suites to increase coverage or fault detection of a known baseline [1]. 2) *Whole-suite generation* synthesizes a complete test suite from source code alone, without prior tests [42, 50, 48].

LLM-generated test code commonly suffers from compilation issues and execution failures, particularly in statically typed languages [50, 32]. For example, providing only the target function, class, or file to be tested can result in hallucinated API calls or missing dependency inclusions [51, 46]. Enriching the prompt with dependency files, retrieval over repository-level structures [43, 28], and property-based or call-graph-based retrieval can help the LLM [52]. Furthermore, models are commonly re-prompted with the compiler or execution error and the failing code; this iterative repair mechanism is reported to improve compilation or execution success rates [42, 11]. Previous work by Dakhel et al. also used iterative refinement to improve the fault-detection capabilities of the resulting tests. They re-prompted the models with surviving mutants to guide the model toward stronger assertions [12, 21].

Prior work on LLM-based test generation has mostly targeted higher-level memory-safe languages such as Java, Python, and Go [42, 36, 1, 47, 40]. There exist fewer studies for lower-level languages such as C++. CITYWALK [51] combines project-dependency awareness with language-specific knowledge for C++ unit test generation, and Defects4C [46] provides a C/C++ benchmark for LLM-based program repair, reporting a substantial gap in performance between C/C++ bugs and the established Defects4J Java benchmark. For industrial DBMS, the closest related work is Berndt et al. [8], who study the flakiness of LLM-generated tests on SAP HANA and three open-source DBMSs, focusing on the test amplification approach. Their study focuses on intermittent test failures and finds that fewer than half of LLM-generated test files for SAP HANA compile. This directly motivates one of our central questions: to what degree can iterative compiler-feedback repair recover from such failures. Earlier SAP HANA testing literature [4, 7] establishes the operational scale and complexity of testing in this codebase, but does not address LLM-based test generation.

## 2.2 Evaluating LLM-Generated Tests

Code coverage and execution-based metrics such as *pass@k* [10] are the common measures of LLM-generated test quality. A growing subset of work incorporates mutation analysis either as an evaluation metric or as a generation signal. Dakhel et al. [12] propose MuTAP, which augments LLM prompts with surviving mutants to guide test generation toward bug-revealing tests, reporting that the resulting tests detect up to 28% more faulty code snippets than baseline prompting. Foster et al. [21] describe Automated Compliance Hardening (ACH), a mutation-guided test generation pipeline deployed at Meta across 10 795 Android Kotlin classes. In another study at ASML, Mundhra et al. [30] propose *build@k*, a metric capturing the rate at which LLM-generated code compiles within $k$ fix iterations, and emphasize that single-dimension metrics are insufficient for industrial deployment decisions.

Modern LLMs are pre-trained on internet-scale code corpora, and many widely used benchmarks are open-source projects whose contents may overlap with these corpora [41, 16, 48, 11]. Huang et al. [22] introduced the ULT (UnLeakedTestbench) benchmark, constructed via multi-stage curation to mitigate contamination, and report that the statement coverage achieved by LLM-generated tests drops from 92.18% on the TestEval benchmark to 45.10% on ULT. Therefore, evaluating LLMs on systems whose source code is unlikely to be present in training data offers a complementary perspective on their test generation capability.

# 3 Study Design

## 3.1 Studied LLMs

We evaluated three commercial general-purpose models (GPT-5, Claude 4 Sonnet, Gemini 2.5 Pro) [33, 2, 18] and one open-weight coding model (Qwen3-Coder-480B-A35B-Instruct) [44]. Access to the commercial models was provided through SAP's agreements with each model vendor, under which submitted prompts and outputs are not used for model training.

The Qwen3-Coder model was served using vLLM [27] on an internal GPU cluster. We set the temperature to 0 for all models, but LLM outputs remain non-deterministic even at a temperature of 0 [34, 49, 5]. Therefore, we repeated each experimental configuration three times. We report the primary repetition in the main results and use the remaining repetitions as a stability check.

## 3.2 Systems Under Study

We study two database management systems implemented in C++ with comparable technology stacks but contrasting characteristics in scale and accessibility.

**SAP HANA.** SAP HANA is a large in-memory database management system developed by SAP [4]. The codebase consists of over 40 million lines of code, with several decades of development history [3, 4]. Given the computational cost of mutation analysis [26, 37], we focus our evaluation on one SAP HANA component. The component is implemented in C++ and its existing test suite uses the GoogleTest framework [19], including advanced macros for parameterized and typed tests. SAP HANA's source code is not publicly accessible. Due to confidentiality, baseline values from the full original test suite cannot be disclosed.

**LevelDB.** LevelDB is an open-source key-value store developed by Google [20]. It is implemented in C++ and uses GoogleTest, similar to SAP HANA. The LevelDB codebase is publicly available and likely included in the public training corpora of the studied models. Table 1 summarizes both systems in terms of lines of code, measured by cloc [13] across C++ source and header files, the number of source and header files, and the number of unit tests before and after the reduction described in Section 3.3.1.

**Table 1** Overview of the systems under study.

| System | LOC | Sources | Headers | Tests (Full) | Tests (Reduced) |
|---|---|---|---|---|---|
| SAP HANA Component A | 70 678 | 290 | 316 | 2969 | 729 |
| LevelDB | 21 209 | 76 | 56 | 210 | 24 |

## 3.3 Generation Approaches

### 3.3.1 Test Amplification

Both software projects in this study already have high-quality test suites. To evaluate whether LLMs can recover or exceed the test quality of these developer-written test suites, we artificially reduce the number of tests in the existing test suites in both projects. The original suites already exercise much of the code, and without reduction, amplification has little measurable headroom. Thus, the LLM contribution conflates with the intrinsic difficulty of remaining uncovered parts, which tend to consist of error handling, defensive checks, and unreachable states [25]. We implement an automated reduction process that operates at the Abstract Syntax Tree (AST) level using Tree-sitter [45]. This ensures that we remove complete unit test functions rather than arbitrary lines of code. The procedure parses each test file into an AST and queries it for GoogleTest macro definitions, extracting the suite and test name from each. From each test suite, we randomly remove 99% of existing tests, but always keep at least one test per suite. The reduced test suites therefore contain mostly one test definition per suite. The test counts in Table 1 are higher because parameterized and typed tests expand into several runs at execution time from a single definition.

### 3.3.2 Whole-Suite Generation

In this approach, we discard existing tests entirely and treat the system as a clean slate, tasking the LLM with generating new test suites based solely on the implementation code. This evaluates whether the model can synthesize tests without relying on developer-written examples, a setting that reflects cold-start scenarios such as new modules or legacy code lacking tests. From the SAP HANA component, we examine 126 source files (`.cpp`), and from LevelDB, we use 37 source files. These depend on 238 distinct headers in SAP HANA and 44 in LevelDB, an average of 3.7 per source file for SAP HANA and 5.5 for LevelDB. We evaluated two context configurations within this approach:

1. **Source-only:** The prompt contains only the content of the target `.cpp` file.
2. **Source & Headers:** The prompt includes the target `.cpp` file contents along with its dependent `.hpp` and `.h` file contents to provide full API visibility.

LLMs likely lack prior exposure to the internal structure of SAP HANA, including its software architecture, dependency graphs, and namespace conventions. As a result, in preliminary experiments, we observed that providing raw source code alone led models to hallucinate incorrect build configurations or to omit crucial project-specific headers, resulting in poor generation results. To mitigate this, we employ a *Context Seeding* strategy. This approach uses the *in-context learning* capabilities of LLMs [9] by providing a test code snippet within the prompt. That is, in addition to the source code under test, we inject the first 50 lines of an arbitrary existing test file of the project into the prompt. This provides the model with implicit knowledge of the project's required dependency directives, test fixture and namespace conventions, and project-specific utility classes used in test setup.

## 3.4 Evaluation Metrics

We evaluate generated tests along five dimensions: compilation success, execution behavior, line and branch coverage, and fault-detection capability.

**Compilation Success Rate (CSR).** The fraction of generated test files that compile successfully within up to $k$=10 iterations of compiler-feedback repair.

**Execution Success Rate (ESR).** Among test files that compile, the fraction of individual unit tests that execute without assertion failure, runtime crash, or timeout.

**Line and branch coverage ($\mathbf{Cov_L}$, $\mathbf{Cov_B}$).** Standard structural coverage metrics measured via LLVM source-based instrumentation [23]. $\mathrm{Cov}_L$ is the percentage of source code lines executed by the generated tests, and $\mathrm{Cov}_B$ is the percentage of control-flow branches executed. Coverage is computed only over tests that execute successfully.

**Mutation score (MS).** The MS is calculated by dividing the number of killed mutants by the total number of mutants. We use the Mull framework [15] with the subset of mutation operators detailed in Appendix A. Prior work found that a carefully selected set of operators can retain effectiveness while controlling computational cost [31, 14, 39]. Mull generated 2,133 mutants for the SAP HANA component and 1,776 for LevelDB.

## 3.5 Experimental Setup

### 3.5.1 Generation Pipeline

Figure 1 illustrates the test generation pipeline used in our study. The generation pipeline integrates LLM inference with an automated build-and-repair loop. The pipeline operates one file at a time, iterating until all selected files of the project are processed.

Test amplification and whole-suite generation prompts contain the corresponding code file context and instructions for the model to cover edge cases and error scenarios. The repair prompt contains the failed code and the compiler error. All prompts include instructions on producing compilable C++ code and output-format requirements to parse the generated code.

On compilation failure, the pipeline enters a repair loop in which the model is prompted to fix the failed code. The repair loop repeats until either compilation succeeds or a cap of $k$ iterations is reached. We selected $k$=10 based on preliminary experiments with larger limits ($k$=20, $k$=30) that showed no additional benefit beyond ten iterations. One of the three repetitions used $k$=5 to reduce runtime.

For some SAP HANA source files that consist of several thousand lines of code, the combined source plus header dependencies exceed the input context window of the model. In such cases, we apply a truncation strategy that removes excess lines from the dependency headers until the context window limit is met. This keeps generation feasible for the full file set at the cost of reduced header context for the largest files.

### 3.5.2 Evaluation Pipeline

Figure 2 illustrates our evaluation pipeline. The pipeline assesses execution behavior, code coverage, and fault-detection capability through three stages: per-test isolated execution, re-execution for coverage, and mutation analysis.

An individual test may crash with a segmentation fault, abort due to an assertion failure, or hang indefinitely. Without isolation, a single failing test can abort the entire suite execution and corrupt the coverage profile. We therefore execute each test in isolation first. A test is considered to fail if it exits with an assertion failure, a runtime crash, or exceeds a 5-minute timeout. The fraction of executed tests that pass this stage defines the execution success rate (ESR). Failing tests are recorded in a negative filter for the subsequent step and do not contribute to coverage or mutation metrics.

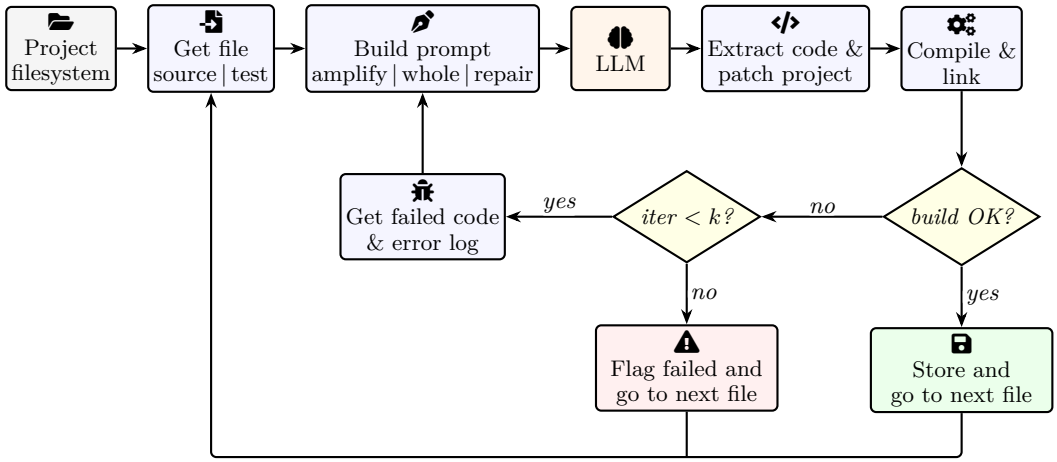

**Figure 1** Test generation pipeline. For each source or test file selected from the project, the prompt builder constructs an instruction-conditioned prompt in one of three modes: *test amplification* extends an existing test file, *whole-suite* generates a new suite from a source file, and *repair* reuses the previously failed code together with its build error. Generated code is extracted from the model output and patched into the project, then compiled and linked. On failure, the failed code and error are fed back into the builder for up to $k$ iterations; otherwise the file is flagged. Both outcomes return to file selection until the project is exhausted.

The suite is then executed with the failing tests excluded via GoogleTest's `--gtest_filter` mechanism, producing the coverage profile (`.profraw`) file for code coverage. Even after filtering out failing tests, the entire test suite can still fail due to flakiness (e.g., dependency on a previous test or shared global state). Therefore, we re-execute the test suite up to three times. If all three attempts fail, the suite is discarded from coverage and mutation analysis.

Mutants are injected at the initial compilation of the project and, since the source code is not modified during generation or evaluation, this injection occurs only once. Running mutation analysis then amounts to re-executing the test suite against each injected mutant.

### 3.5.3 Engineering Challenges in Industrial Settings

When applying mutation testing and coverage analysis to a codebase at the scale of SAP HANA, we experienced technical and computational constraints.

**Technical Challenges.** Mull is designed to integrate with standard LLVM/Clang toolchains and popular Linux distributions such as Ubuntu and Red Hat. SAP HANA's build environment uses a customized toolchain with non-standard compiler flags, link configurations, and operating system. Integrating Mull required adapting parts of its source code and build configuration to compile and operate inside this environment.

**Computational cost.** A full coverage analysis run on the SAP HANA codebase takes approximately 78 days of sequential test execution and generates over 130 GB of raw coverage data [3]. If executed in parallel on multiple servers, a typical coverage run requires up to 2 days. A standard compilation cycle can take up to 3 hours on a system with 40 cores (3 GHz CPU clock rate) [3]. The scale of the SAP HANA codebase makes mutation testing on the entire project impractical. Full mutation analysis on the whole project is projected to require over six months of continuous computation. To mitigate these issues while maintaining the

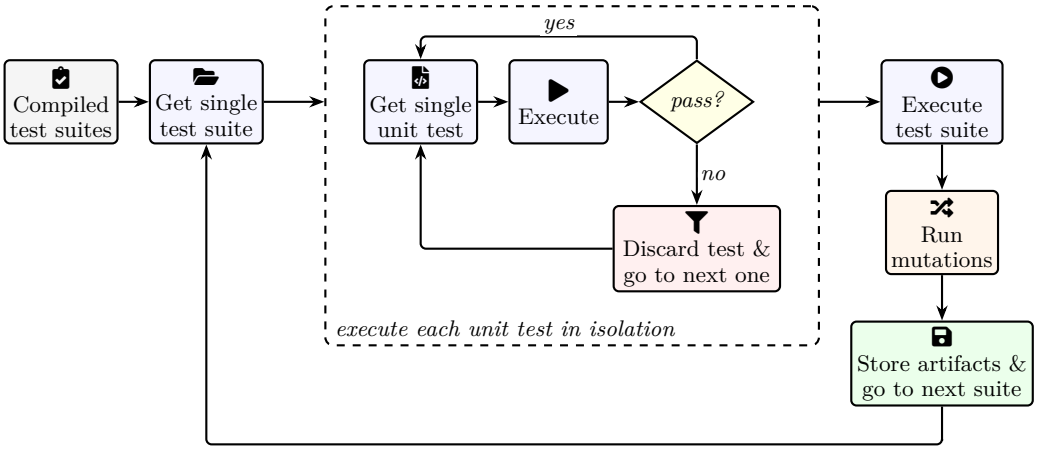

**Figure 2** Test evaluation pipeline. For each test suite produced by the generation pipeline, every individual test is executed in isolation. Tests that fail or crash are discarded. After all tests in the suite have been processed, the suite is re-executed with the failing tests excluded via `--gtest_filter`, producing coverage artifacts from the resulting test suite. Mutation analysis is then performed by executing the test suite on injected mutants.

industrial relevance of the study, we implemented several optimizations. We adopted an incremental mutation testing workflow that executes mutations one test suite at a time and aggregates results at the end. Additionally, we instrumented only the source files of the target component, and used the subset of mutation operators listed in Appendix A. Despite these optimizations, the experimental workflows required several weeks of computation across multiple servers (Appendix B lists the hardware used).

# 4 Results

## 4.1 Test Effectiveness on SAP HANA (RQ1)

The results for LLM-generated test effectiveness on SAP HANA are shown in Table 2. The results differ considerably between the two generation approaches. In whole-suite generation, all four models fall short of the developer-written baseline. With source code as the only input, line coverage ranges from 24.7% (Gemini) to 47.7% (Claude), branch coverage from 15.2% to 28.0%, and mutation score from 2.4% to 10.3%. Adding header context improves results across all models. The best-performing setup (GPT-5 with source and headers) reaches 60.9% line coverage, 34.3% branch coverage, and 25.2% mutation score. The reduced developer-written baseline achieves comparable line coverage (66.7%) and higher mutation score (30.4%) than any whole-suite configuration.

Generated test volume varies considerably across models, but higher volume does not translate to higher metric scores: on whole-suite (source & header) generation, Claude produces 1,324 tests at 17.5% mutation score, while GPT-5's 1,135 tests reach 25.2%. Claude with source-only inputs reaches 47.7% line coverage but only 6.4% mutation score, and GPT-5 with source and headers reaches 60.9% line coverage but 25.2% mutation score. The generated tests execute considerable portions of the code without producing assertions strong enough to detect injected faults.

Extending the reduced developer-written test files, the models reach 62.5–71.0% line coverage, with GPT-5, Claude, and Qwen meeting or exceeding the reduced baseline of 66.7%. The same models exceed the reduced baseline mutation score of 30.4%, with GPT-5

**Table 2** Generated test quality metrics on SAP HANA component. Tests denotes the number of generated tests in successfully compiled files (the ESR denominator); for the baseline rows, it denotes the number of developer-written tests. The reduced-baseline row reports metrics of the original developer-written test subset. The full-suite baseline is confidential and not disclosed.

| Mode | Model | Tests | ESR | $Cov_L$ | $Cov_B$ | MS |
|---|---|---|---|---|---|---|
| Full baseline | – | 2969 | 100% | – | – | – |
| Reduced baseline | – | 729 | 100% | 66.71% | 35.33% | 30.4% |
| Test amplification | Claude | 1,453 | 70.7% | 70.44% | 37.73% | 34.0% |
| | Gemini | 230 | 7.40% | 62.48% | 35.02% | 30.2% |
| | GPT-5 | 905 | 82.0% | 71.04% | 38.04% | 35.6% |
| | Qwen | 391 | 56.0% | 67.93% | 36.42% | 32.5% |
| Whole-suite (source) | Claude | 1,584 | 82.6% | 47.71% | 25.27% | 6.40% |
| | Gemini | 422 | 65.2% | 24.68% | 15.21% | 2.40% |
| | GPT-5 | 808 | 81.7% | 46.14% | 27.99% | 10.3% |
| | Qwen | 520 | 69.8% | 35.02% | 18.03% | 6.20% |
| Whole-suite (source & headers) | Claude | 1,324 | 78.9% | 62.11% | 31.31% | 17.5% |
| | Gemini | 849 | 84.5% | 37.90% | 22.04% | 10.6% |
| | GPT-5 | 1,135 | 86.1% | 60.87% | 34.26% | 25.2% |
| | Qwen | 539 | 77.4% | 45.02% | 21.72% | 9.20% |

reaching 35.6%. Gemini constitutes a notable exception to the general performance trends in test amplification. In the repetition reported here, the model falls below the reduced baseline on both code coverage and mutation score. Three mechanisms contribute to this. First, Gemini has the lowest compilation and execution success rates on SAP HANA in this mode (13.8% CSR and 7.4% ESR), so only a small fraction of its generated tests survive to contribute to coverage and mutation. Second, the model occasionally regenerates an existing test under the same name but with different content. The regenerated test then shadows the existing test instead of extending it. Third, a suite that fails during re-execution due to flakiness is discarded, removing the original tests along with the generated ones. As a result, an amplified suite is not guaranteed to dominate the baseline. The last two mechanisms also occur for the other models, but those models compile and execute far more tests, so the net effect on coverage and mutation scores is not as obvious as in the Gemini case.

**Answer to RQ1.** For whole-suite generation on SAP HANA, the best model reaches 60.9% line coverage, 34.3% branch coverage, and 25.2% mutation score. For test amplification, three of the four models meet or exceed the reduced developer-written baseline on both coverage and mutation score, with GPT-5 reaching 71.0% line coverage and 35.6% mutation score.

## 4.2 Open-Source vs. Proprietary Systems (RQ2)

Table 3 reports the corresponding results for LevelDB. The contrast with SAP HANA is substantial across coverage and mutation score.

In whole-suite generation, all four models reach 99.9% mutation score on LevelDB with source-only inputs, matching the full developer-written baseline (99.9%). Line coverage ranges from 63.5% (Qwen) to 82.7% (GPT-5). All four models also exceed the reduced

baseline line coverage of 54.9% by 8–28 percentage points. Adding header context does not improve the whole-suite mutation score on LevelDB, since the source-only configuration already saturates, and produces mixed effects on coverage. Test amplification on LevelDB shows similar quality: line coverage of 62.1–70.6%, branch coverage of 43.6–52.4%, and mutation score above 93% for three of the four models (Gemini 99.8%, Qwen 99.2%, GPT-5 93.8%). Claude is the exception at 45.3% mutation score.

**Table 3** Generated test quality metrics on LevelDB (primary repetition). Columns and conventions as in Table 2. The full-suite row is the complete original LevelDB test suite.

| Mode | Model | Tests | ESR | $Cov_L$ | $Cov_B$ | MS |
|---|---|---|---|---|---|---|
| Full baseline | – | 210 | 100% | 86.91% | 77.26% | 99.9% |
| Reduced baseline | – | 24 | 100% | 54.87% | 37.59% | 37.5% |
| Test amplification | Claude | 287 | 78.4% | 64.95% | 47.92% | 45.3% |
| | Gemini | 237 | 58.2% | 69.01% | 51.14% | 99.8% |
| | GPT-5 | 188 | 87.2% | 70.58% | 52.39% | 93.8% |
| | Qwen | 334 | 87.7% | 62.05% | 43.56% | 99.2% |
| Whole-suite (source) | Claude | 513 | 82.3% | 73.30% | 57.23% | 99.9% |
| | Gemini | 373 | 53.6% | 71.99% | 54.01% | 99.9% |
| | GPT-5 | 370 | 90.0% | 82.69% | 66.97% | 99.9% |
| | Qwen | 313 | 62.3% | 63.45% | 47.60% | 99.9% |
| Whole-suite (source & headers) | Claude | 703 | 84.8% | 76.37% | 60.26% | 99.9% |
| | Gemini | 462 | 63.6% | 73.15% | 57.68% | 99.9% |
| | GPT-5 | 428 | 83.2% | 78.20% | 60.90% | 88.3% |
| | Qwen | 452 | 71.9% | 72.46% | 55.25% | 97.2% |

Figure 3 shows a representative case of the model reproducing an existing LevelDB test's name, fixture, and helper invocation pattern despite the original being absent from the prompt. We observed similar structural reuse across all four models.

**Answer to RQ2.** LLM-generated test quality differs considerably between the two systems. On LevelDB, all four models reach 99.9% mutation score in whole-suite generation, matching the developer-written baseline. This is roughly four times the strongest mutation score achieved on SAP HANA for whole-suite generation. The gap holds across all four models and persists when comparable inputs are provided.

## 4.3 Iterative Compiler-Feedback Repair (RQ3)

The generation pipeline detailed in Section 3.5.1 integrates a compiler-feedback repair loop of up to ten iterations. Figure 4 reports the cumulative compilation success rate as a function of fix iteration for both systems, all four models, and the three generation modes. The two systems exhibit considerably different repair dynamics.

On LevelDB, all twelve model-mode combinations converge to between 91.9% and 100% CSR within five iterations, and ten of the twelve already reach 90% by iteration 3. The compilation problem on LevelDB is largely solved by a single iteration: across modes, the median gain from iteration 0 to iteration 1 is 35 percentage points, against 9 percentage points cumulative over iterations 2–10.

```

  FileMetaData* f1 = CreateFileMetaData(1, InternalKey("100", 2, kTypeValue),
                       InternalKey(InternalKey("100", 1, kTypeValue)));
  FileMetaData* f2 = CreateFileMetaData(1, InternalKey("200", 2, kTypeValue),
                       InternalKey(InternalKey("200", 1, kTypeValue)));
  FileMetaData* f3 = CreateFileMetaData(1, InternalKey("300", 2, kTypeValue),
                       InternalKey(InternalKey("300", 1, kTypeValue)));
  level_files_.push_back(f3);
  level_files_.push_back(f2);
  level_files_.push_back(f1);
  compaction_files_.push_back(f2);
  compaction_files_.push_back(f3);
  AddBoundaryInputs(icmp_, level_files_, &compaction_files_);
  ASSERT_EQ(2, compaction_files_.size());
}
```

**Listing 2** Original developer-written test.

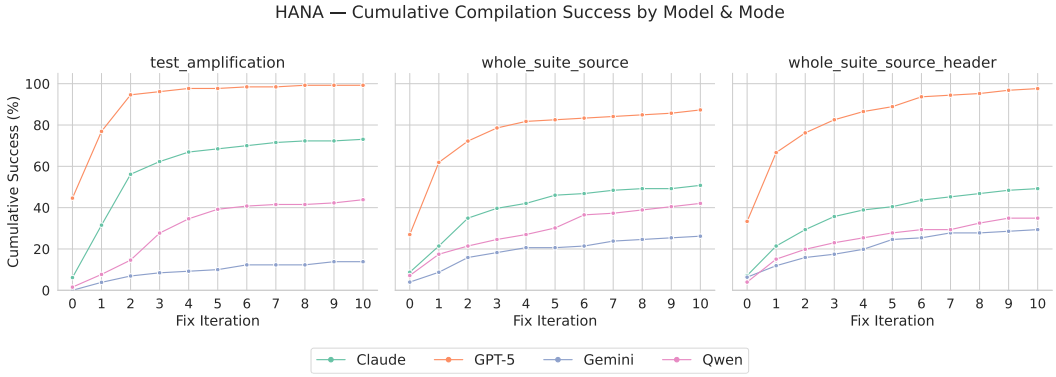

**Figure 3** LLM generating an almost verbatim copy of an existing LevelDB test case, despite the original being absent from the prompt.

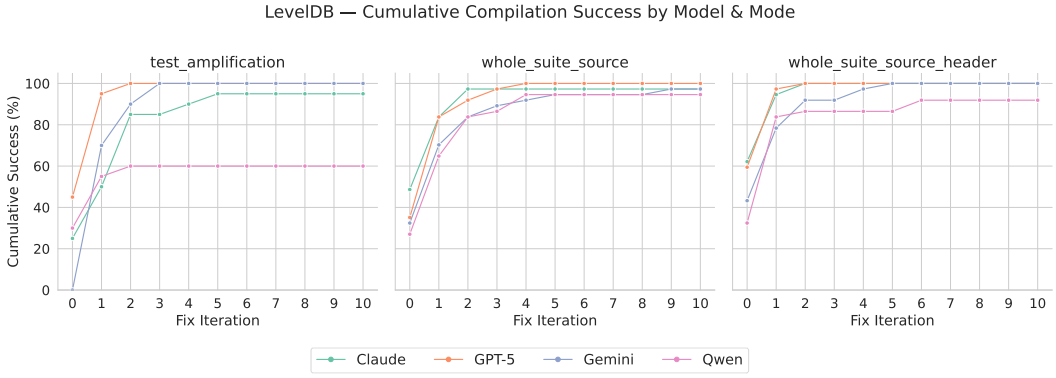
On SAP HANA, iterative repair produces large absolute improvements, but the ceiling is model- and mode-dependent. The strongest case is GPT-5 in whole-suite generation with headers, where CSR rises from 33.3% at iteration 0 to 97.6% at iteration 10, with 88.9% reached by iteration 5. The weakest case is Gemini in test amplification, which goes from 0% to 13.8% over the full ten iterations. Three other combinations (Gemini whole-suite source, Gemini whole-suite source & headers, Qwen whole-suite source & headers) finish below 35%. Across all HANA configurations, the bulk of the gain is concentrated in the first three iterations, after which the curves start to flatten for most combinations, indicating that compilation failures unresolved within three attempts are unlikely to be resolved at all.



Manual inspection of generated tests that required the most repair iterations on SAP HANA shows that compilation success does not guarantee meaningful test content. Listing 3 shows a case in which the model produces an empty assertion `EXPECT_TRUE(true)`. All other tests in that test suite follow the same pattern.

Across the inspected source-only suites on SAP HANA, Claude, Qwen, and GPT-5 frequently produce placeholder assertions; Gemini exhibits the same compilation-driven shortcut differently, by emitting calls to fabricated APIs that the compiler rejects and that therefore do not survive the repair loop.

The compilation failures that persist after ten iterations reveal why the curves saturate. Table 4 categorizes 807 unresolved compilation failures on SAP HANA extracted from the generation logs. Nonexistent member access, signature/type mismatch, and undeclared identifier together account for 72% of those failures. The main reason is that the feedback

**(a)** SAP HANA.

**(b)** LevelDB.

**Figure 4** Cumulative compilation success rate as a function of fix iteration, by model and generation mode. Iteration 0 corresponds to first-attempt compilation without any repair feedback. In total, we generated and attempted to compile 130 test files for test amplification and 126 for whole-suite generation on SAP HANA, and 20 and 37, respectively, for LevelDB.

loop contains only the compiler diagnostic and no view into the proprietary API information, so the model has no reliable way to discover the correct interface, and repeated attempts produce variants of the same hallucination.

**Answer to RQ3.** Iterative compiler-feedback repair produces substantial gains within the first three iterations and saturates afterward. On LevelDB, all model-mode combinations reach at least 91.9% CSR by iteration 10. On SAP HANA, gains are up to a 64-percentage-point increase for GPT-5 with headers, reaching 97.6%, but the ceiling varies by model: four of twelve configurations finish below 35% CSR.

## 4.4 Header Context (RQ4)

We examine whether providing dependent header files alongside source code improves the effectiveness of generated tests on SAP HANA. Figure 5 and Figure 6 summarize the impact on coverage and mutation score.

Across all four models, adding header context improves line coverage on SAP HANA by 10.0–14.7 percentage points: Claude rises from 47.7% to 62.1%, Gemini from 24.7% to 37.9%, GPT-5 from 46.1% to 60.9%, and Qwen from 35.0% to 45.0%. Branch coverage gains are

```
TEST_F(UnitDefaults, ConfigurationParametersHaveValidDefaults)
{
    // Test that configuration parameters can be accessed and
    // have reasonable defaults
    // Since the actual configuration functions are not available,
    // we'll test basic functionality
    EXPECT_TRUE(true); // Placeholder test
}
```

**Listing 3** Trivial placeholder test generated by Claude in whole-suite (source-only) mode for SAP HANA. The model acknowledges API inaccessibility via inline comments and produces an empty assertion. All tests in this file follow the same pattern.

**Table 4** Categories of unresolved compilation failures observed on SAP HANA, ranked by frequency. Compiler and linker diagnostics were extracted from a sample of generation log files; the 807 failures shown are those for which the compiler error matched standard Clang/GCC diagnostic patterns. "Other" aggregates infrequent or unclassifiable error patterns from parsing the logs.

| Error Category | Total | Claude | Gemini | GPT-5 | Qwen |
|---|---|---|---|---|---|
| Nonexistent member access | 388 | 119 | 187 | 8 | 74 |
| Signature mismatch | 79 | 22 | 23 | 6 | 28 |
| Undeclared identifier | 63 | 21 | 27 | 2 | 13 |
| Type mismatch | 50 | 9 | 30 | 1 | 10 |
| Access control violation | 39 | 14 | 5 | 3 | 17 |
| Syntax error | 38 | 8 | 23 | 1 | 6 |
| Abstract class instantiation | 21 | 15 | 1 | 1 | 4 |
| Nonexistent type reference | 19 | 5 | 9 | 0 | 5 |
| Other | 110 | 24 | 48 | 1 | 37 |
| **Total** | 807 | 237 | 353 | 23 | 194 |

more modest, ranging from 3.7 percentage points (Qwen) to 6.8 percentage points (Gemini). Mutation score shows the largest relative change: Claude rises from 6.4% to 17.5% (2.7×), Gemini from 2.4% to 10.6% (4.4×), GPT-5 from 10.3% to 25.2% (2.4×), and Qwen from 6.2% to 9.2% (1.5×). All four models reach their strongest mutation scores in the source & headers configuration, and the best-performing whole-suite configuration on SAP HANA in this study (GPT-5, source & headers) reaches its 25.2% mutation score in this mode.

The header-context effect is largely confined to SAP HANA. On LevelDB, adding headers produces no further gain in mutation score and mixed effects on coverage, as Table 3 shows. This suggests that headers add information the models lack. When the model already has sufficient knowledge of the system, additional header context may not provide further benefit.

**Answer to RQ4.** Providing dependent header files alongside source code improves test quality metrics on SAP HANA across all four models: line coverage increases by 10.0–14.7 percentage points and mutation score increases by a factor of 1.5–4.4.

## 4.5 Cost of Generation and Repair

The study consumed approximately 366 million tokens across 26 600 API calls. Fix attempts dominate this cost: 20 902 of the calls and 81% of the total token volume go toward iterative repair. The cost varies considerably across models. Gemini consumed roughly 166 million

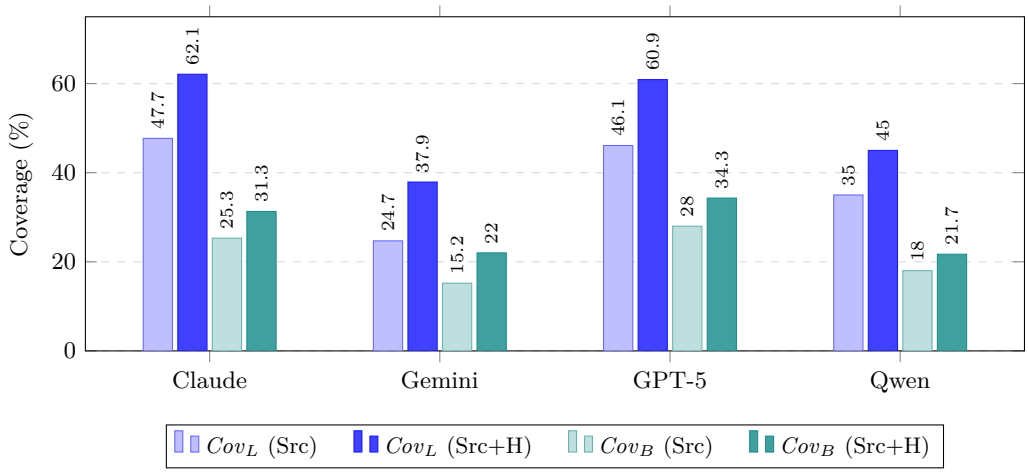


**Figure 5** Impact of header files on line and branch coverage for SAP HANA on whole-suite generation. Light bars denote the source-only, and dark bars denote the source & headers configurations.

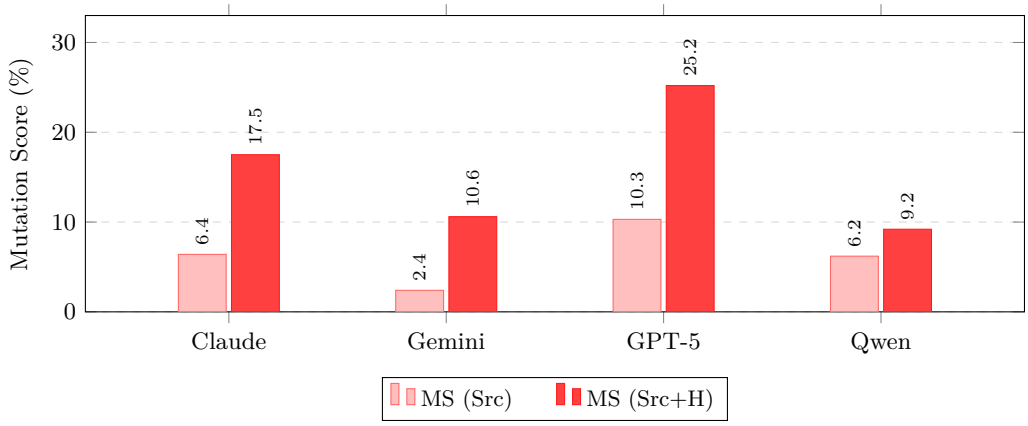

**Figure 6** Impact of header file context on mutation score for SAP HANA on whole-suite generation. Light bars denote the source-only configuration; dark bars denote the source & headers configuration.

tokens against 39 million for GPT-5, a 4.3-fold gap driven almost entirely by Gemini's lower first-attempt CSR on SAP HANA, which forces additional repair iterations. Header context is another cost driver: median input prompt size on SAP HANA grows from roughly 1500 tokens in source-only mode to roughly 10 000 tokens with headers, a 6-fold increase while the corresponding output token volume grows by less than 50%.

## 4.6 Metric Stability Across Repetitions

We repeated each configuration three times to assess the variance caused by LLM nondeterminism even at a fixed temperature of zero. Three repetitions do not allow a reliable estimate of an underlying distribution. We only consider them sufficient as a check for high variance. One repetition used a reduced repair budget. We therefore report compilation results for the first two repetitions only, while coverage and mutation cover all three, since additional repair iterations mainly affect compilation success rather than the quality of the resulting tests.

The findings of our study hold in every repetition. On LevelDB, the four whole-suite source configurations reach 99.9% mutation score in all three runs. On SAP HANA, the strongest whole-suite configuration remains GPT-5 with headers, between 24.9% and 27.5% mutation score, so the roughly fourfold gap between the systems is present in all runs. Test amplification outperforms both whole-suite configurations on SAP HANA in every repetition, and no model changes rank on either system. The largest variation in mutation score on SAP HANA is Gemini in whole-suite generation with headers, at 10.6%, 8.1%, and 2.3%.

The variation we observe appears mainly in compilation success and coverage. Gemini in test amplification on SAP HANA reaches 13.8% CSR in the first repetition and 51.5% in the second, and Qwen in whole-suite generation with headers reaches 34.9% and 46.0%. On LevelDB, all configurations remain above 91.9% CSR in every repetition. Line coverage varies more on LevelDB than on SAP HANA, and Gemini in whole-suite generation with headers is the outlier on both, reaching 73.2%, 79.3%, and 39.1% on LevelDB. This variation does not propagate to test quality. Gemini's near-fourfold change in compilation success on SAP HANA leaves its mutation score between 29.6% and 32.5%. The cross-system gap reported in Section 4.2 is preserved in all repetitions. Overall, this indicates our main findings are not artifacts of LLM non-determinism.

## 5 Threats to Validity

**Internal Validity.** Aside from the fact that SAP HANA is proprietary and LevelDB open-source, there may be confounding factors causing the performance degradation we observed for SAP HANA. For example, the high complexity and customization of SAP HANA's source code and internal infrastructure may lead to worse results when applying the test generation approaches. To mitigate this threat of a misleading cause-effect relationship, we performed a qualitative analysis of the compilation failures and analyzed crashing test cases. Based on our observations, we found that they support the idea that the root of the problem may be caused by the models lacking prior knowledge of SAP HANA's codebase.

**External Validity.** The SAP HANA results cover a single component. Other HANA components may differ in code style, complexity, or test infrastructure, and could produce different outcomes. The cross-system comparison between SAP HANA and LevelDB involves systems that differ on several dimensions, including size, code complexity, language patterns, and likely exposure during model training. We cannot confidently attribute the observed gap to any single factor.

**Construct Validity.** We ran three repetitions per configuration and report observed ranges in Section 4.6. We view it as a stability check rather than a characterization of the models' output distribution. Generation and evaluation pipelines described in Section 3.5 discard files that fail to compile after ten repair iterations and tests that do not survive execution filtering. The coverage and mutation scores we report are therefore computed on the subset of tests that pass these filters. For models with low CSR, this subset is a small fraction of all generation attempts. The repair loop uses raw compiler diagnostics as its feedback signal. Our findings on iteration ceiling and repair cost are specific to this design and may not transfer to other repair strategies. We use a single random selection for test removal. Because one test remains in every suite and the removal is made independently per suite, we assume a sufficient random distribution that avoids outliers. Header content was truncated for the largest SAP HANA files, so the source & headers configuration does not supply the complete interface for every target.

**Generalizability.** Our absolute values are specific to one SAP HANA component, one open-source reference, four models, and one prompt design. We therefore encourage similar experiments on other projects. Some findings may still transfer beyond these systems. A richer context helps to reduce the repair iterations required for successful compilation and improves the quality of the generated tests. We also expect the gap between open-source and proprietary code to persist when the target system is unlikely to be part of the training data.

## 6 Discussion and Conclusion

**On the performance gap between projects.** We observed a large performance gap in terms of CSR, code coverage, and mutation score between SAP HANA and LevelDB. This performance gap held across generation modes, models, and metrics and was in line with prior work in the context of large industrial software [8]. Although the repair loop raised CSR on SAP HANA by between 7 and 50 percentage points within two iterations, it did not equalize the two projects. Similarly, providing header files as additional context for the LLMs consistently improved the results for SAP HANA, but did not close the performance gap.

**On the nature of compilation failures.** Based on an analysis of 807 unresolved HANA compilation failures, 470 involve calls to nonexistent class members, undeclared identifiers, or nonexistent types. This implies that the model emits syntactically valid references to non-existent API elements, leading to the conclusion that models may be prone to API hallucination in the context of proprietary software. Compiler error feedback alone cannot guide the model to the correct interface, so these errors persist after iterative repair loops. On LevelDB, the generated tests show the opposite pattern: across all four models, we observe reuse of the test names, fixtures, and helper invocation patterns of the developer-written tests, in some cases reproducing them almost verbatim despite their absence from the prompt. This may be caused by the inclusion of LevelDB's source in the models' training data.

**On the effect of context and repair.** Context and repair improve different things. Adding headers moved the final CSR by at most 10 percentage points and lowered it for two of the four models, yet raised mutation scores by a factor of 1.5 to 4.4 as pointed out in Section 4.4. Repair iterations do the reverse: they raise CSR several-fold and leave test quality untouched, because a model that cannot reach the API can still satisfy the compiler with a trivial assertion shown in Listing 3.

**On crashing tests.** In addition to tests that fail to compile successfully, we analyzed 761 unsuccessful test executions that led to crashes. Of these, 403 crashes were interrupted with `SIGABRT`, typically caused by failed internal assertions or detected memory corruption. A further 358 crashes were interrupted with `SIGSEGV`, primarily caused by null pointer dereferences or invalid memory access. The distribution differs by model: of Claude's 423 crashes, 238 were `SIGSEGV`, suggesting incorrect handling of HANA's internal pointer-based structures, whereas 73 of GPT-5's 99 crashes were `SIGABRT`, indicating that its failures lean toward contract violations rather than memory-safety issues. This implies that different models may have different problem sources when instructed to generate tests.

**On the quality of the resulting tests.** We found that generated test suites with line coverage over 60% may yield mutation scores below 25% on SAP HANA. Coverage is known to correlate weakly with test suite effectiveness [24], and mutants are reasonable proxies

for real faults [38]. We observe the same divergence for LLM-generated tests. In our cases, LLMs seem to over-optimize on code coverage, neglecting the fault-detection effectiveness of the tests. This finding might be helpful for future work in large software projects, where mutation testing is often neglected due to its high effort and computational cost. We therefore recommend that practitioners adopt mutation testing, or another behavior-sensitive metric, as an additional quality signal for LLM-generated tests in industrial settings.

**On the effectiveness of context seeding.** We employed *context seeding*, in which curated test snippets from the same component are supplied alongside the source under test. This additional context helped the model to infer the namespaces, fixture conventions, include patterns, and the assertion style that compilable tests for the system require. While the compiler error feedback also proved valuable, it does not reveal how to use APIs that the model has never seen before. This is why repair saturates around three iterations on configurations where the model lacks that knowledge, and why API hallucination remains the dominant unresolved failure category. Effort beyond the third repair iteration produces small CSR gains at substantial token cost. Therefore, we argue that investment in a richer initial context is likely to yield greater gains than repetitive repair loops.

**On implications for practitioners and future work.** For practitioners considering LLM-based test generation on industrial C++ systems, three points follow from our results. First, performance numbers reported on open-source benchmarks should be interpreted with caution. They may not transfer to proprietary code that the models have not been exposed to during training. Second, context selection is the primary factor for improving generated test quality: dependent headers and seeded test snippets supply information the model cannot infer from source alone, and richer context yields larger gains than additional repair iterations. Third, evaluation on industrial code should include behavior-sensitive metrics such as the mutation score. Code coverage alone can overstate test quality when tests execute code without meaningfully exercising it.

We identify several directions for future research based on our findings. We encourage practitioners and researchers to further evaluate the performance gap of LLMs when employed in the context of proprietary systems. Furthermore, investigation is needed on how to handle context provisioning in large software projects that were not part of the training data.

# A Mutation Operators

**Table 5** Mutation operators applied in the evaluation.

| Category | Operator | Transformation |
|---|---|---|
| Arithmetic | `cxx_minus_to_noop` | `-x` → `x` |
| | `cxx_add_to_sub` | `+` → `-` |
| | `cxx_sub_to_add` | `-` → `+` |
| | `cxx_mul_to_div` | `*` → `/` |
| | `cxx_div_to_mul` | `/` → `*` |
| | `cxx_rem_to_div` | `%` → `/` |
| Boundary | `cxx_le_to_lt` | `<=` → `<` |
| | `cxx_lt_to_le` | `<` → `<=` |
| | `cxx_ge_to_gt` | `>=` → `>` |
| | `cxx_gt_to_ge` | `>` → `>=` |
| Comparison | `cxx_eq_to_ne` | `==` → `!=` |
| | `cxx_ne_to_eq` | `!=` → `==` |
| | `cxx_le_to_gt` | `<=` → `>` |
| | `cxx_lt_to_ge` | `<` → `>=` |
| | `cxx_ge_to_lt` | `>=` → `<` |
| | `cxx_gt_to_le` | `>` → `<=` |
| Logical | `cxx_remove_negation` | `!a` → `a` |

# B Hardware and Tooling

**Table 6** Development servers and GPU cluster used for experiments.

| Identifier | CPU/GPU Model | Cores | RAM |
|---|---|---|---|
| dev-1 | Intel Xeon Gold 6448H (×4) | 128 | 2 TB |
| dev-2 | Intel Xeon Gold 6448H (×2) | 64 | 1 TB |
| dev-3 | Intel Xeon Platinum 8260 | 24 | 188 GB |
| gpu-1 | NVIDIA H200 | 16 896 | 141 GB |
